BE excretion is detectable for 1 to 3 days following cocaine use. However, for chronic heavy cocaine users, the detection time may extend to 10 to 22 days following the last dose,[831] apparently because of tissue storage of cocaine. Ordinarily, cocaine may be detected in urine by chromatographic methods for only about 8 to 12 hours after use, but in heavy chronic users, this detection period may last 4 to 5 days.[169] These facts should be considered when the results of urine drug testing for individuals in drug treatment programs are interpreted. A positive urine drug test for benzoylecgonine beyond 3 days after the last dose does not necessarily indicate continued use. For such purposes, it is better to monitor quantitatively the urinary excretion of benzoylecgonine, normalized to creatinine, over time.[768] Drug abstinence would be indicated by decreasing urinary excretion of cocaine metabolites. However, creatinine normalization may not always reliably indicate reuse.[656]

The initial screening test for cocaine (BE) is typically immunoassay. For confirmation of a presumptive positive, BE is quantified by GC-MS.

Screening. The half-life of cocaine is 0.5 to 1.5 hours, of ecgonine methyl ester 3 to 4 hours, and of BE 4 to 7 hours.[376] Thus, BE is the analyte of choice in screening for cocaine use.[362] The initial screening test for BE is typically immunoassay, and screening immunoassays frequently apply a 300-ng/mL cutoff.

Confirmation. Most confirmation assays offer quantification of both parent drug and metabolite. Numerous methods have been described for the measurement of COC and various metabolites. GC techniques for analysis of COC and its metabolites require derivatization, especially of polar metabolites. Early detection techniques have included flame ion detection (FID), EC, and nitrogen-phosphorous detector (NPD).* GC-MS is the method of choice for many laboratories.† Some methods have included not only COC and BE, but also clinically and forensically relevant secondary metabolites such as m-HOBE, CE, NC, AEME, and AEEE.[164,399,435,622] The use of LC-based separation techniques that detect COC, BE, and CE has been described previously, including LC-UV detection,[517,543,760] as well as LC-DAD.[147] LC-MS/MS methods have also been described, including COC, BE, and m-HOBE,‡ along with other relevant secondary metabolites such as CE, NC, AEME, and AEEE.[460] Reports have suggested that AEME is not a truly unique indicator of smoked cocaine use, because it has been reported to be produced in the injector port of a GC[370,495,776] at high temperatures. However, less than 1% generation of AEME occurs if the injector port of the GC is maintained at 250 °C.[164] In an LC method, high temperatures are not present in the injector or in any other part of the LC; therefore, AEME is not generated, and its presence identifies a smoked route of COC use.

Lysergic Acid Diethylamide (LSD)

LSD shares structural features with serotonin (5-hydroxytryptamine; Figure 35-15), a major CNS neurotransmitter and neuromodulator.[32,857] LSD is synthesized from D-lysergic acid, a naturally occurring ergot alkaloid found in the fungus *Claviceps purpurea,* which grows on wheat and other grains. During synthesis, some LSD epimerizes to iso-LSD, which is inactive.[649]

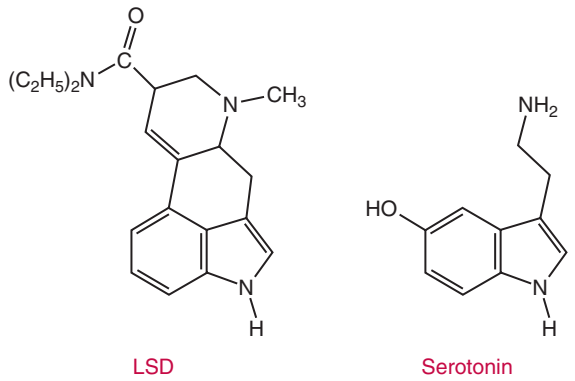

Figure 35-15 Chemical structure of lysergic acid diethylamide (LSD) and serotonin.

Pharmacologic Response

LSD is an extremely potent psychedelic ergot alkaloid derived from the fungus, *Claviceps purpurea*.[32] The drug LSD binds to serotonin receptors in the CNS and acts as a serotonin agonist. The principal psychological effects of LSD are perceptual distortions of color, sound, distance, and shape; depersonalization and loss of body image; and rapidly changing emotions from ecstasy to depression or paranoia. These hallucinogenic actions of LSD are stereoselective, elicited only by the D-isomer. A resurgence has occurred in the use of LSD, previously popular as a drug of abuse during the 1960s. The Department of Defense includes LSD among the drugs for which urine testing is required (see Table 35-7).

The physiologic effects of LSD are related to its sympathomimetic actions and include mydriasis (most frequent and consistent), tachycardia, increased body temperature, diaphoresis, and hypertension; at higher doses, parasympathomimetic actions may be observed [e.g., salivation, lacrimation, nausea, vomiting (muscarinic actions)]. Neuromuscular effects may include paresthesia, muscle twitches, and incoordination (nicotinic actions).[32,857]

The most common adverse effects of LSD are panic attacks. In addition, unpredictable recurrence of hallucinations (flashbacks) may occur weeks or months after last drug use, and LSD may elicit psychotic reactions (thought disorders, hallucinations, depression, and depersonalization). LSD is used illicitly because of its hallucinogenic effects. No evidence suggests that repeated LSD use results in dependence or withdrawal symptoms.[32,857]

Popular dosage forms include powder, gelatin capsule, tablet, and LSD-impregnated sugar cubes, filter paper, or postage stamps. The drug is rapidly absorbed from the GI tract; the effects begin within 40 to 60 minutes, peak at about 2 to 4 hours, and subside by 6 to 8 hours. The elimination $t_{1/2}$ is about 3 hours. The metabolism of LSD in humans is incompletely understood, but 2-oxo-3-hydroxy-LSD is present in urine at concentrations 10- to 43-fold greater than LSD.[642,643,649,672] *N*-demethyl-LSD is also present in urine specimens, but at concentrations approximately equivalent to those of LSD. The other metabolites are among those identified in animals, but as yet not conclusively identified in man.[649] Iso-LSD is not a metabolite but is formed by nonenzymatic epimerization of LSD during synthesis or storage of urine at alkaline pH and elevated temperature.[700]

The clinical effects of LSD ingestion are usually benign and require no medical intervention. However, panic attacks may be severe and require treatment with diazepam; LSD-induced psychosis has been treated with haloperidol. Rare cases of massive overdose have resulted in life-threatening hyperthermia, rhabdomyolysis, acute renal failure, hepatic failure, disseminated intravascular coagulation (DIC), respiratory arrest, and coma. Few if any well-documented deaths directly related to LSD ingestion have been reported.

Analytical Methods

Because of the very high potency of LSD, and therefore a low typical dose (20 to 80 μg) and rapid and extensive metabolism, only about 1 to 2% of the drug is excreted unchanged in urine.[672] Thus, detection of LSD presents an especially difficult analytical challenge. Even with sensitive assays, the detection window for LSD is generally only 12 to 24 hours.[672]

Immunoassays are targeted to detect LSD at the usual cutoff concentration of 500 pg/mL. Confirmation is typically performed by GC-MS[256,624] at the U.S. Department of Defense established cutoff concentration of 200 pg/mL. Although the metabolites 2-oxo-3-hydroxy-LSD and *N*-demethyl LSD generally cross-react only when present at about 100 to 200 times the amount in LSD,[841] other metabolites may potentially account for some instances of nonconfirmed positive immunoassay response.[152,859] However, true false-positive results due to various therapeutic drugs may occur.[152,675,841] The detection window may be extended, perhaps twofold to threefold, by including 2-oxo-3-hydroxy-LSD in the confirmatory test, using sensitive techniques such as GC-MS-MS,[672] LC-MS-MS,[643] or LC-MS.[434,642] Likewise, detection of iso-LSD in addition to LSD may extend the detection interval.[146] Urine specimens should be protected from sunlight, bright fluorescent light, or elevated temperature at alkaline pH to avoid degradation of LSD[478] and 2-oxo-3-hydroxy-LSD or epimerization of LSD to iso-LSD.[478,700]

Drugs Used in Sexual Assault

Drug-facilitated sexual assault (DFSA) is defined as voluntary or surreptitious use of alcohol, drugs, and/or chemical agents to incapacitate an individual and facilitate sexual assault.[315] In addition to alcohol, the drugs most often implicated in drug-facilitated sexual assault include (1) choral hydrate, (2) flunitrazepam, (3) nonbenzodiazepine sedative-hypnotics, (4) gamma-hydroxybutyric acid (GHB), (5) dextramethorphan, (6) ketamine, (7) phencyclidine, and (8) benzodiazepines, and nonprescription medications such as (9) antihistamines and (10) anticholinergics (Box 35-3). These drugs share similar characteristics that are desired by an assailant such as fast onset, colorlessness, tastelessness, and easy access. Similar clinical effects permit the victim to be easily incapacitated. They include impaired judgment, confusion, reduced inhibitions, sedation, hypnosis, loss of muscle coordination, and sometimes anterograde amnesia. These

BOX 35-3 Examples of Agents Used in Drug-Facilitated Sexual Assault

Anticholinergics
Antihistamines
Barbiturates
Benzodiazepines
Chloral hydrate
Dextromethorphan
Ethanol
γ-Hydroxybutyrate (GHB)
Ketamine
Opioids
Sedative-hypnotics

effects are intensified when they are coadministered willingly or involuntarily with other psychotropic medications that produce CNS depression. This is a common occurrence in reported cases of sexual assault or rape.[232,336]

Choral Hydrate

Anecdotal reports concerning assailants dosing beverages with incapacitating compounds to assault their victims date back to the early nineteenth century. An infamous example is the saloon proprietor Mickey Finn. He was alleged to have drugged his customers with the addition of chloral hydrate to their ethanol-based beverages and to have subsequently robbed them.

Chloral hydrate is classified as a nonbarbiturate hypnotic. It is an inexpensive transparent crystalline compound that easily dissolves in beverages. It was first synthesized in 1832 and was one of the original "depressants" developed for the specific purpose of inducing sleep. This drug is still used today in pediatric medicine for sedating children before diagnostic procedures. Abuse and misuse of this drug and subsequent introduction of newer sedatives (barbiturates and benzodiazepines) led to its decline for medicinal purposes.

Pharmacologic Effects

The clinical diagnosis of chloral hydrate intoxication is difficult to differentiate from alcohol, benzodiazepine, and barbiturate intoxication, as all share similar clinical effects. Although the exact mechanism of action of chloral hydrate has not been determined, it is a general CNS depressant that has sedative effects with minimal analgesic effects when administered independently. At low doses (<20 mg/kg), symptoms may include relaxation, dizziness, slurred speech, confusion, disorientation, euphoria, irritability, and hypersensitivity rash. At higher doses (>50 mg/kg), chloral hydrate causes hypotension, hypothermia, hypoventilation, tachydysrhythmias, nausea, vomiting, diarrhea, headache, and amnesia.[690] Onset of action is rapid (10 to 20 minutes). The elimination half-life of choral hydrate is 4 to 12 hours.[93,690] If coingested with alcohol, the metabolism of chloral hydrate may be seriously impaired. Because both ethanol and chloral hydrate are metabolized by CYP2E1 and alcohol dehydrogenase, coingestion may not only exacerbate their clinical effects, but may also prolong their duration of action.[93,587]

Analytical Methods

Chloral hydrate is not detected on routine, commercially available drug screens. Quantification of chloral hydrate and its metabolites trichloroethanol (TCE), TCE-glucuronide, and trichloroacetic acid is detected in plasma using HPLC-MS and capillary gas chromatography with electron-capture detection (GC-ECD),[352,546,710] or GC-flame ion detection (GC-FID).[393] Typical therapeutic concentrations are 2 to 12 μg/mL. Chloral hydrate metabolites have been detected as low as 10 ng/mL using GC-ECD.[352]

Flunitrazepam

It is estimated that 8% of sexual assault cases are positive for benzodiazepines.[232,336,582,581] Flunitrazepam (Rohypnol) is the most frequently reported benzodiazepine used in DFSA, partially because of the development and implementation of specific toxicologic tests in response to increased public awareness, resulting in a testing bias.[219,232,600,705,729] Other benzodiazepines that have been reported in sexual assault victims are diazepam, triazolam, temazepam, tetrazepam, and clonazepam.[4,134,398,507,581]

Flunitrazepam is a fast-acting sedative-hypnotic categorized as a Schedule I drug in the United States. Because it is still licensed for use in Europe, Asia, and Latin America for sedation and treatment of insomnia, sexual predators can acquire this drug through illegal trafficking.[822] Sexual assault predators use flunitrazepam because it can be easily dissolved into a beverage, it is relatively tasteless and odorless, it will quickly incapacitate their victims, and routine drug screens do not detect its presence.

Pharmacologic Effects

Flunitrazepam is more potent than diazepam because of its slower dissociation from the GABA receptor.[137,520,521] It is rapidly absorbed and distributed into tissues upon oral administration. Onset of its sedative, amnesic, hypnotic, and disinhibitory effects can occur within 20 to 30 minutes.[520] Flunitrazepam has a long half-life (≈26 hours), permitting an extended window of detection in blood and urine.

Although the effects of flunitrazepam occur rapidly when used alone, it is often coingested with alcohol, which amplifies its effects.[209,720] Initial symptoms may consist of dizziness, disorientation, lack of coordination, and slurred speech, all of which mimic alcohol intoxication. Another unique effect is anterograde amnesia as early as 15 minutes after oral administration.[294] Rapid alternation of hot and cold flashes may be followed precipitously by loss of consciousness. Large doses (>2 g) have produced aspiration, muscular hypotonia, hypotension, bradycardia, coma, and death.[134,507,716]

Analytical Methods

The detection of flunitrazepam is especially challenging because of the low therapeutic and illicit doses and the low degree of cross-reactivity of most immunoassays with the

principal urinary metabolite, 7-aminoflunitrazepam.[518,699,743] As for other benzodiazepines, prior glucuronidase hydrolysis may improve immunoassay detection. Enzyme-linked immunosorbent assay (ELISA) methods with high selectivity for 7-aminoflunitrazepam and low limits of detection have been developed.[821,824] Direct analysis or confirmation of 7-aminoflunitrazepam by GC-MS or LC-MS/MS is indicated in suspected cases of flunitrazepam ingestion.[230,824,863] Flunitrazepam metabolites are detectable as early as 7 days in hair samples (HPLC-MS/MS).[134] Deposition and stability of a drug in hair samples are variable, depending on the route of exposure and the chemical characteristics.

Nonbenzodiazepine Sedative-Hypnotics

Zopiclone, eszopiclone (Lunesta), zolpidem (Ambien), and zaleplon (Sonata) belong to a new generation of sedative-hypnotics that are structurally different from benzodiazepines (Figure 35-16). Similar to benzodiazepines, these drugs modulate the $GABA_A$ receptor chloride channel by binding to the benzodiazepine (BZ) receptors, otherwise known as the omega$_1$ (ω_1) receptors, in the brain[812] without binding to peripheral BZ receptors.[703,721] Therefore, these drugs have fewer muscle relaxant properties.[721]

Most of the nonbenzodiazepine sleep aids are available through a prescription as a Schedule IV drug and are readily prescribed, shared, and sold illegally. The rapid-onset and amnesic properties of this class of drugs can result in disinhibition, passivity, and retrograde amnesia, making it a favored DFSA drug. These drugs require only a low dosage to cause an effect and are rapidly metabolized. Because of the amnesic properties of these drugs, victims are often confused following the event and may be delayed in reporting their sexual assault. Commonly utilized drug screens do not test for these substances.

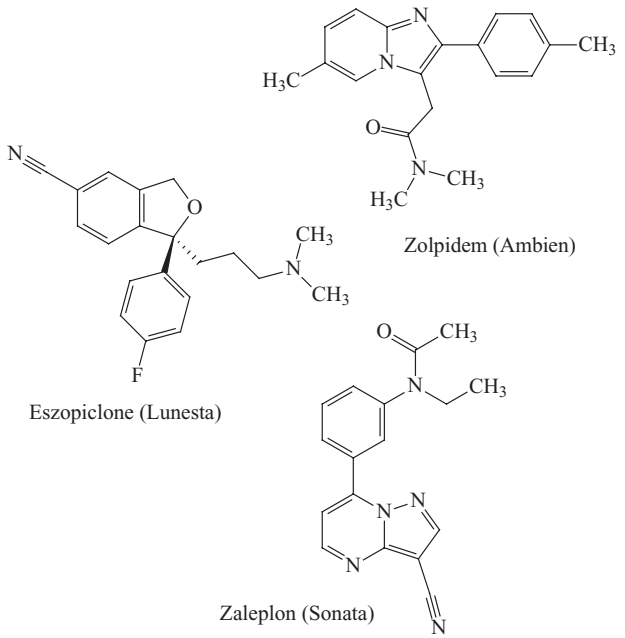

Figure 35-16 Chemical structures of the nonbenzodiazepine sedative-hypnotics (zolpidem, eszopiclone, zaleplon).

Recognition of these new-generation sleep aids as agents potentially used in facilitating sexual assault has been reported in the United States, the United Kingdom, and France for over a decade.[17,232,295,336,716] Yet only two published reports in the United States tested sexual assault victims for the presence of zolpidem.[429,805]

All may produce additive CNS-depressant effects when coadministered with other psychotropic medications such as anticonvulsants, antihistamines, ethanol, and other drugs that produce CNS depression.

Pharmacologic Effects

Examples of nonbenzodiazepine sedative-hypnotics include (1) zolpidem, (2) zaleplon, (3) eszopiclone, and (4) zopiclone.

Zolpidem. The pharmacologic effects of Zolpidem (Ambien) are believed to result from its interaction with a specific subtype of $GABA_A$ receptor complex consisting of α_1-subunits.[319] It is available as an immediate- or extended-release tablet. After an average oral dose of 10 to 15 mg, onset of effects occurs in 10 and 30 minutes. Clinical effects peak at approximately 1.5 hours for immediate release, duration is about 6 to 8 hours for both immediate- and extended-release preparations, and the $t_{1/2}$ is approximately 2.5 hours.[23] Evidence of minimal respiratory depression is noted when used as a single agent, but it may produce additive CNS-depressive effects and death when coadministered with other sedatives.[289]

Zaleplon. Zaleplon (Sonata) is available as an immediate-release tablet or capsule. After an average oral dose of 10 to 15 mg onset of effects occurs in approximately 10 to 30 minutes. Although the $t_{1/2}$ for zaleplon is about 1 hour, the duration of clinical effects may persist for longer than 6 hours. This may be due to the higher affinity of zaleplon for specific α_2- and α_3-subunits of the GABA receptor, in contrast to zolpidem or zopiclone.[277] At higher doses (>40 to 60 mg), its use may cause increased central nervous system effects and impaired motor skills.[690]

Eszopiclone. The exact mechanism of action of eszopiclone (Lunesta) is unknown, but its effect is believed to result from interaction with $GABA_A$ receptor complexes containing α_1- to α_5-subunits.[319] After an average dose of 2 to 3 mg onset of effects occurs in approximately 30 minutes. Both immediate- and extended-release forms are available. The clinical effects of eszopiclone are longer in duration compared with those of zopiclone or zolpidem, with a $t_{1/2}$ of 6 hours.[703]

Zopiclone. Zopiclone is not currently available in the United States. It is the racemic mixture of two stereoisomers; the active stereoisomer is eszopiclone. Therefore, clinical effects are similar to those of eszopiclone.

Analytical Methods

Because of the amnesic properties of these drugs, victims often may not report their sexual assault for several days. Therefore, sensitive analytical techniques are necessary to

detect these drugs and their metabolites in urine or hair samples after a single dose. Although these drugs do not cross-react with most benzodiazepine immunoassays, specific reagent systems (ELISA) directed against the non-benzodiazepine hypnotics are available.[668] Screening and confirmation are performed by GC-MS or LC-MS/MS.

γ-Hydroxybutyrate, 1,4-butanediol, and γ-butyrolactone

γ-Hydroxybutyrate (GHB) and its synthetic precursor compounds, 1,4-butanediol (1,4-BD) and γ-butyrolactone (GBL), are Schedule I agents in the United States, and availability is restricted in numerous other countries. GHB is illegally purchased as an odorless and colorless liquid form, or as an off-white powder that easily dissolves in liquids. When ingested, GHB stimulates dopamine release, leading to pleasurable effects such as euphoria, muscle relaxation, and heightened sexual desire.[74,180] It also has CNS depressant effects, resulting in sedation and hypnosis. Because GHB was reported to enhance growth hormone release, it has been used by body builders and athletes as a steroid alternative. Athletes have used GHB as a sleep aid because they believe it promotes rapid recovery from vigorous repetitive competition. These properties and the availability of GHB in dietary supplements have led to growing recreational abuse of the drug. GHB has become popular as a euphorigenic club drug, most often used in combination with alcohol, and also with MDMA or cocaine, to "mellow" their adverse stimulant properties. Its rapid onset and hypnotic and short-term amnestic properties have resulted in the use of GHB for drug-facilitated sexual assault (date rape drug).[201,295,716,737] Publications estimate that 4% of alleged sexual assault cases in the United States are positive for GHB.[225,232,716,729]

GHB is a naturally occurring substance produced in the brain. GHB is reversibly metabolized to GABA through multiple endogenous enzymes (Figure 35-17).[202,503,797] Illicit consumption of GHB, or the synthetic GHB precursor compound 1,4-BD or GBL, will promote GABA activity.[202] In addition to increased metabolism to GABA, GHB has direct effects on the CNS by binding GHB-specific receptors and $GABA_B$ receptors.[74,410,439,862] The latter are G-protein–coupled receptors distinct from the $GABA_A$ receptors for depressant drugs, such as benzodiazepines and barbiturates. Of note, patients with GHB overdose do not respond to the opioid antagonist naloxone or to the benzodiazepine antagonist flumazenil.

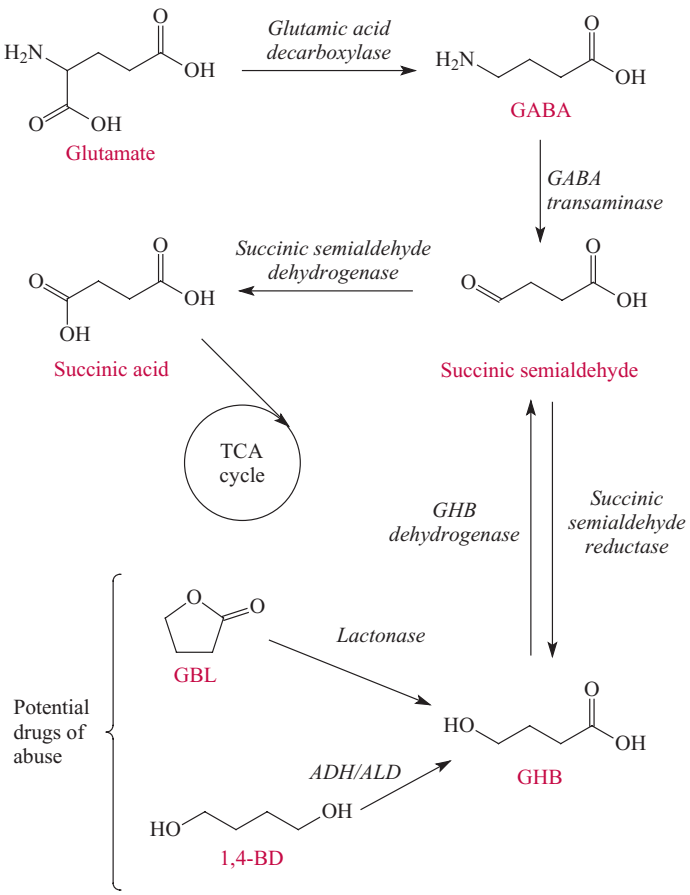

Figure 35-17 Metabolism of γ-hydroxybutyrate. γ-Hydroxybutyrate (GHB) and its synthetic precursor compounds, 1,4-butanediol (1,4-BD) and γ-butyrolactone (GBL), are often used illicitly. These drugs are endogenously metabolized to γ-aminobutyric acid (GABA). GHB and GABA mediate GABA receptors.

Fomepizole, an inhibitor of alcohol dehydrogenase, is likely beneficial for patients who ingest 1,4-butanediol.[878] GHB is suggested to increase dopamine concentrations in the substantia nigra, to potentiate the endogenous opioid system, and to mediate GABA transmission.[202]

Pharmacologic Effects

Onset of GHB effects occurs in approximately 15 to 30 minutes, depending on the dose (average, 1 to 5 g) and the chemical purity. The duration of response is short, typically 1 to 3 hours for normal dose and 2 to 4 hours with excessive doses. The clinical effects are dose dependent and typically last 3 to 6 hours. A low dose (<1 g) produces mild symptoms such as CNS depression, amnesia, hypotonia, and reduced inhibitions (similar to alcohol). Larger doses (1 to 2 g) cause increased somnolence, drowsiness, dizziness, bradycardia, and bradypnea. High doses (>2 g) often interfere with motor coordination and balance and may induce significant respiratory depression and bradypnea, Cheyne-Stokes respiration, nausea, and vomiting, diminished cardiac output, seizures, coma, and death.[289,514,804] Periods of agitation may be interspersed between times of apnea and unresponsiveness. It is uncertain whether this agitation is a direct GHB effect or a consequence of coingested stimulant drugs. Deaths have been reported but are almost always associated with coingestion of alcohol or other drugs.

Analytical Methods

GHB is metabolized rapidly ($t_{1/2}$ ≈30 minutes) and currently is not detected on immunoscreens. GHB is identified on urine and serum specimens using GC-FID or GC-MS.[225,430,531] Because GBH is metabolized rapidly, timely sample collection is an important facet of GBH assay; plasma samples should be collected within 6 to 8 hours after ingestion, and urine samples within 10 to 12 hours. Urine and plasma concentrations may exhibit endogenous concentrations of GHB within 8 to 12 hours after ingestion (<1 mg/dL in urine; <4 mg/L in blood/plasma).[868] Samples approaching endogenous concentrations make it difficult to legally associate GHB doping in sexual assault cases. Exogenous concentrations of GHB have been detected in hair samples at 7 days post intoxication.[295] Timely presentation of the patient for medical attention and physician recognition of GHB symptoms presented by sexually assaulted victims are essential for prosecution of sexual offenders.

Dextromethorphan

Dextromethorphan (DXM) is structurally related to the opioids, but it does not bind to opioid receptors at normal dose and thus is devoid of analgesic activity.[585] The (–) isomer of dextromethorphan, levorphan (not available in the United States), is a potent opioid analgesic and is an example of the stereoselective nature of opioid receptor binding. DXM lacks analgesic activity but does have antitussive activity comparable with that of codeine. At high doses, DXM binds opioid receptors to produce miosis, respiratory depression, and CNS depression. High doses may also cause lethargy, agitation, ataxia, nystagmus, diaphoresis, and hypertension.[594,851,870]

DXM is present in various over-the-counter (OTC) cough medications, often in combination with antihistamines, nasal decongestants, guaifenesin, aspirin, and acetaminophen. Potential toxicity from OTC combination medications must be considered when DXM is consumed in large doses to achieve euphoric effects.[41,432] Abuse of DXM, especially by adolescents and teenagers, who refer to it as "Dex, Robos, Skittles," has become widespread. Abusers describe feelings of euphoria, dissociative effects such as a sense of floating, and hallucinations. Discontinuation of the drug is frequently followed by dysphoria and depression.

Pharmacologic Effects

Dextromethorphan is metabolized to dextrophan[649] by the cytochrome P450 isozyme 2D6 (CYP2D6), which exhibits genetic polymorphisms. Dextrophan may be responsible for the more pleasant psychotropic effects of high-dose dextromethorphan, whereas the parent drug may cause dysphoria, sedation, and ataxia.[870] Thus, poor metabolizers (deficient in CYP2D6 activity) may be less prone and extensive metabolizers more prone to continue the abuse of dextromethorphan. Dextrophan and to a lesser degree DXM bind to the PCP- and ketamine-binding site on the NMDA receptor, causing sedation; this may account for their similar dissociative psychotropic actions[585] (see phencyclidine and ketamine sections).

Analytical Methods

Clinically approved doses of DXM are not detected by most clinical opiate immunoassays,[755] but larger doses may cross-react.[740] However, ELISA assays are now available to detect DXM and its major metabolite, dextrorphan.[678] Some toxicologic laboratories have used the cross-reactivity of DXM with phencyclidine antibodies to screen for the presence of DXM.[709] Because most preparations contain dextromethorphan as the bromide salt, excessive ingestion of dextromethorphan may result in bromide poisoning and in a negative serum anion gap consequent to the disproportionate response to bromide with common methods of chloride analysis.[586] The presence of DXM or dextrophan in a sample is confirmed by GC-MS or LC-MS/MS.

Dextrophan is the enantiomer of levorphanol, a potent opioid agonist available in the United States (Levo-Dromoran). Unless chiral analytical techniques are used, these enantiomers are not resolved. Drug testing laboratories that use conventional chromatographic techniques should not report a finding of levorphanol only, but should instead report dextrophan/levorphanol, with a comment on their isomeric relationship and on the origin of dextrophan. This is especially important for pain management drug screening, in which a false report of levorphanol may result in dismissal from the program. This report duality is advisable even when parent dextromethorphan is also detected. Savvy abusers of levorphanol conceivably may coingest dextromethorphan to conceal use of levorphanol. If such is suspected, chiral

resolution of dextrophan and levorphanol would then be necessary.

Ketamine and Phencyclidine

Ketamine and phencyclidine (PCP) are potent analgesics and general anesthetics used in veterinary medicine. PCP is listed as a Schedule II drug in the U.S. Federal Controlled Substance Act and is not approved for human use. Ketamine is a Schedule III drug, commonly used as an anesthetic in pediatric medicine for short surgical procedures. Both drugs have been used illicitly in human cases of drug abuse, as well as in cases of drug-facilitated sexual assault.

On the street, ketamine and PCP are sold under a variety of names. They are available as a colorless, odorless liquid, or as a white powder. Either form can be easily disguised in a victim's beverage. More commonly, these powdered agents are sprinkled onto marijuana or tobacco and smoked.

Pharmacologic Effects

Ketamine and PCP share similar structural features[649] and pharmacologic actions. They are classified as dissociative anesthetics because they produce rapid-acting dissociation of perception, consciousness, movement, and memory.[171,342,601] The effects are dose dependent and vary between individuals. Some individuals experience effects similar to the psychosis observed in schizophrenia.[11,664] An anesthetic dose produces profound analgesia, but the individual is awake yet incapacitated, with limited voluntary limb movement. Ketamine has about one tenth the potency of PCP, a shorter duration of action, and less prominent emergentce reactions, especially in children. Both PCP and ketamine have been associated with psychologic disturbances.

The mechanism of action for these compounds consists of complex integration of neurologic pathways. They bind and antagonize the excitatory glutaminergic system by binding to NMDA receptors. They also decrease GABA transmission, disrupt cortical activity, and increase dopamine and norepinephrine synaptic reuptake. These actions can produce clinical effects such as euphoria, elevated blood pressure, tachycardia, and bronchodilation, all of which are consequences of inhibition of dopamine and norepinephrine synaptic reuptake.[461,601] At a higher dose, GABA-ergic and central nicotinic actions may produce sedation, lethargy, coma, and respiratory depression. Additionally, central and peripheral muscarinic and nicotinic responses may cause miosis or mydriasis, diaphoresis, increased salivation, bronchorrhea, blurred vision, and urinary retention.

Phencyclidine. PCP [1-(1-**p**henyl**c**yclohexyl)-**p**iperidine] was synthesized in 1926 and was clinically utilized as a general anesthetic. Because of adverse side effects experienced by some individuals, such as acute psychosis and dysphoria during emergence from PCP-induced anesthesia, clinical use was discontinued. PCP is used recreationally for its mind-altering "out of body" experience. Recreational use of PCP declined in the 1980s but has re-emerged in recent years. Presentation of adverse effects such as (1) dysphoria, (2) ataxia, (3) nystagmus, (4) agitation, (5) anxiety, (6) paranoia, (7) amnesia, (8) seizures, (9) muscle rigidity, (10) hostility, (11) delirium, (12) delusions, and (13) hallucinations is unpredictable. LSD users can experience "flashbacks of the drug experience." Flashbacks occur suddenly, often without warning, and may occur within a few days or more than a year after LSD use.

The onset of action for PCP is fast for intravenous and inhalation routes (2 to 5 minutes) and slower following oral administration (30 to 60 minutes).[172,173] Clinical effects typically last 4 to 6 hours, yet psychotic episodes have been reported to last a month.[11,664] The relationship between dosage, clinical effects, and serum concentrations is not a reliable predictor of the degree of PCP intoxication.[601] PCP has a pK_a between 8.5 and 9.4, is highly lipophilic, and distributes to the brain and fat tissues. An ion-trapping phenomenon occurs after oral, IV, or inhalation dosing. PCP enters acidic gastric fluid after oral administration, where concentrations may be 20 to 50 times greater than in serum, then undergoes gastroenterohepatic recirculation.[857] Ion trapping also occurs in cerebrospinal fluid (CSF), causing it to cross back into the blood; CSF may accumulate to concentrations six to nine times greater than those observed in serum.[544] These properties may contribute to the waxing and waning of clinical effects and prolonged excretion. PCP has a large V_d of 5 to 7 L/kg, a long elimination $t_{1/2}$ (20 to 50 hours), a long duration of action (24 to 48 hours), and prolonged urinary excretion after the last dose (1 to 2 weeks; longer with long-term use).[857]

With repeated use of PCP, psychologic dependence may develop, but tolerance or withdrawal syndrome is not profound. A sense of superhuman strength coupled with lack of pain perception may lead to excessive physical exertion and accidental or intentionally induced trauma. Thus PCP-related deaths most often are secondary to these adverse behavioral drug effects. Treatment of PCP toxicity is supportive. Severe agitation or seizures may respond to diazepam; severe psychoses may require a neuroleptic drug, such as haloperidol. For the most serious cases, continuous nasogastric suction to help remove PCP may be beneficial; urine acidification to hasten elimination has been advocated by some but is controversial.[601]

Ketamine. Ketamine was discovered during subsequent studies characterizing PCP analogs. Liquid ketamine is rapidly injected intramuscularly. The liquid or powder form can be easily disguised in a victim's beverage; this has resulted in its use in DFSA.[716,737] Ketamine powder can even be sprinkled onto marijuana or tobacco and smoked.

Ketamine produces effects similar to those of phencyclidine. Onset of clinical effects is rapid and is dependent on dose and route of administration. Anesthesia effects via intramuscular injection take as little as 20 to 30 seconds, oral ingestion about 30 minutes,[301] and nasal insufflation approximately 10 minutes.[332,493,690] Its hallucinatory effects may be short-acting (<1 hour) but so intense that the victim may have trouble discerning reality.[737]

Ketamine has a $t_{1/2}$ of 2 to 3 hours.[148] Ketamine is metabolized to norketamine, which has about one third the activity of ketamine, and to dehydronorketamine, which also may be active.[649] Duration of anesthetic effects is dose dependent (usually <1 hour), and effects on the senses, judgment, and coordination can have a longer duration (≈6 to 24 hours). At higher doses, ketamine causes delirium, amnesia, dissociative anesthesia, hallucinations, delirium, hypersalivation, nystagmus, impaired motor function, hypertension, and potentially fatal respiratory problems. Effects on blood pressure and respiratory depression are significantly enhanced when coingested with alcohol.

Analytical Methods

Initial screening for PCP is typically done by immunoassay. Confirmation of a presumptive positive test is performed by GC-MS.[253] No immunoassays are available to detect ketamine at this time. Ketamine and its active metabolites are detected in urine samples using GC-MS or LC-MS analyses.[557]

Immunoassay. Quantification of PCP in serum is not helpful in the diagnosis or management of PCP toxicity because the correlation between drug concentration and drug effects is low.[601] However, qualitative identification of PCP in urine is useful to help diagnose PCP toxicity. For this purpose, PCP-specific immunoassays are rapid and generally are more sensitive than thin-layer chromatography. Whether or not PCP is included in a general urine drug screen depends on applicable regulations and on the prevalence of PCP use in the local community. In some locations, the prevalence of PCP use may be too low to warrant routine screening for PCP. Immunoassays for PCP are generally reliable; false positives have been reported because of high concentrations of dextromethorphan,[104,709] diphenhydramine,[476] and thioridazine.[490,814] Immunoassay-positive specimens should be confirmed using GC-MS.[253]

Gas Chromatography–Mass Spectrometry. PCP is required to be included in U.S. Government–regulated drug abuse screening programs (see Table 35-7); nongovernmental screening programs may elect to include PCP in drug abuse screens, depending on the local probability of PCP use. Initial screening by immunoassay, if positive, is followed by confirmation using GC-MS. Ketamine and its active metabolites norketamine and dehydronorketamine are detected in urine samples using GC-MS[132,420] or LC-MS analyses.[557]

Detection of Drugs of Abuse Using Other Types of Specimens

The collection of biological samples for the purpose of determining exposure to various agents is dominated by blood and urine. Blood is considered invasive, and the collection of urine may require some invasion of privacy and loss of dignity; urine specimens are subject to adulteration or manipulation to evade detection. For these reasons, alternate biological specimens have been investigated.[116,197A] Cutoff values had been proposed by SAMHSA[110] for some of the matrices and are listed in Table 35-8. However, current guidelines for Federal Workplace Drug Testing have determined that urine will continue to be the only biological fluid approved for testing.[239] An additional review conducted by DHHS is expected.

Meconium, oral fluid, hair, and sweat have been investigated as alternative types of samples for drug analysis.

Meconium

Illicit drug use during pregnancy is a major social and medical issue. Drug abuse during pregnancy is associated with significant perinatal complications, including a high incidence of (1) stillbirth, (2) meconium-stained fluid, (3) premature rupture of the membranes, (4) maternal hemorrhage (abruptio placentae or placenta previa), and (5) fetal distress.[607] In the neonate, the mortality rate and morbidity (e.g., asphyxia, prematurity, low birth weight, hyaline membrane disease, infection, aspiration pneumonia, cerebral infarction, abnormal heart rate and breathing patterns, drug withdrawal) are increased.[607]

Unfortunately, identification of the drug-exposed mother or her neonate is not easy. Maternal admission of the use of drugs is often inaccurate principally because of denial about addiction or fear of the consequences stemming from such admission. Likewise, many infants who have been exposed to drugs in utero may appear normal at birth and show no overt manifestations of drug effects. Thus, identification of the drug-exposed mother or her infant requires a high index of suspicion. Drug testing, on the other hand, is an objective means of determining drug exposure in both mother and infant. In infants, drug testing is necessary to document proof of the infant's exposure to illicit drugs. Urine testing of the mother or newborn can detect only recent drug use (within a few days before birth), and urine collection from newborns may be problematic.

The first intestinal discharge from newborns is meconium, which is a viscous, dark green substance composed of intestinal secretions, desquamated squamous cells, lanugo hair, bile pigments, and blood. Meconium also contains pancreatic enzymes, free fatty acids, porphyrins, interleukin-8, and phospholipase A_2 primary bile acids with a small quantity of secondary bile acids. Water is the major liquid constituent, making up 85 to 95% of meconium.[7] Meconium is derived from the Greek word "mekonion," meaning poppy juice or opium. Aristotle is credited with noting the relationship between the presence of meconium in amniotic fluid and a sleepy fetal state in utero.[7] Meconium begins to form during the second trimester and continues to accumulate until birth; drugs taken by the mother can be detected in the meconium of the newborn.[608]

The disposition of drug in meconium is not well understood. The proposed mechanism is that the fetus excretes drug into bile and amniotic fluid. Drug accumulates in meconium by direct deposition from bile or through swallowing of amniotic fluid.[229,608] The first evidence of meconium in the fetal intestine appears at approximately the 10th to 12th week of gestation; meconium slowly moves into the colon by the 16th week of gestation.[7] Therefore, the presence of drugs in meconium has been proposed to be indicative of in utero

drug exposure up to 5 months before birth—a longer historical measure than is possible by urinalysis.[608]

Meconium has been used for detection of prenatal drug use, showing an improved drug detection rate compared with urine.[114,477,572,608] The collection of meconium is noninvasive, making sample collection easy,[693] and is more successful than urine collection.[527] The amount collected is usually sufficient for complete analysis, including confirmation. Meconium testing does have some limitations. Meconium is usually passed by full-term newborns within 24 to 48 hours, after which transition from a blackish-green color to a yellow color indicates the beginning of passage of neonatal stool. Infants with low birth weight (<1000 g) have been shown to pass their first meconium at a median age of 3 days. Thus, meconium collection is missed because of delayed passage, and meconium may not be available soon after birth for early detection of intrauterine drug exposure.

In the clinical laboratory, meconium is an unfamiliar matrix; it is a sticky material that is more difficult to work with than urine. Meconium drug screening has been adapted to various analytical techniques, including radioimmunoassay, enzyme immunoassay, and fluorescence polarization immunoassay. Urine drugs-of-abuse screening assays frequently use meconium extracts and therefore must be investigated for possible effects of matrix on accuracy, precision, and assay linearity. However, some other immunoassays screening methods have been used.

Radioimmunoassay (RIA), fluorescence polarization immunoassay (FPIA), enzyme multiplied immunoassay technique (EMIT), and enzyme-linked immunosorbent assay (ELISA) have been used for detection of drugs in meconium, but ELISA is rapidly becoming the method of choice for screening.[272] The sample preparation for the ELISA screen is usually a simple buffer extraction versus a lengthy and more laborious sample preparation procedure for the other immunoassay methods.

As with any immunoassay-based drug screen, confirmation by MS is critical. Confirmation assays for meconium are more difficult than those for urine. Recovery of drugs from meconium is sometimes low (30 to 50%). A variety of GC-MS, LC-MS, and LC-MS/MS methods and their advantages and disadvantages have been described elsewhere[272,477,555] and will not be discussed here.

Many questions remain to be answered about the disposition of drugs in meconium. Some debate continues as to which are the most appropriate drug analytes to measure in meconium; Table 35-12 attempts to summarize the current knowledge. Meconium drug testing is growing but is far less standardized than urine drug testing. Assay cutoff limits and units (ng/g meconium or ng/mL of extract) may vary; suitable reference or control materials are not yet available.

Meconium should be sent to the laboratory for processing as soon as it is collected to prevent possible loss of drugs. Meconium, allowed to stand at room temperature for 24 hours, showed a decrease in cocaine and cannabinoid concentrations.[607] However, suspending meconium in an organic solvent, such as buffered methanol, may prevent decreases for as long as 72 hours.[607] For prolonged storage, meconium should be frozen. Drugs are stable in meconium, frozen at −15 °C, for as long as 9 months.[607]

TABLE 35-12 Drugs and Metabolites of Significance in Meconium

Drug Class	Confirmation Compound[69,229,474,555]
Cocaine	cocaine
	benzoylecgonine
	cocaethylene
	m-hydroxybenzoylecgonine
Opiates	morphine
	codeine
	6-monoacetylmorphine (6-MAM)
	hydromorphone
	hydrocodone
	oxycodone
Cannabinoids	9-carboxy-11-nor-delta-9-THC
	11-hydroxy-delta-9-tetrahydrocannabinol
	8,11-dihydroxy-delta-9-tetrahydrocannabinol
Amphetamines	amphetamine
	methamphetamine
	MDMA
	MDA
	MDEA
Ethanol	fatty acid ethyl esters
PCP	PCP

Overinterpretation of meconium data is a dangerous practice. It is clear that matrix effects are associated with the analysis of meconium, as they are with each biological fluid or tissue.[474] Another important confounding factor is possible contamination of the meconium specimen by urine. Numerous reports have described the specificity and sensitivity of different analytes with the use of different testing methods.[454,455,527,607,609] A tremendous, and potentially inappropriate, value has been placed on a meconium result. On occasion, decisions about treatment or custody of the infant have been based solely on meconium drug screen results. It is critical to remember that a positive test could indicate intrauterine drug exposure. However, a negative result does not rule it out. It is clear that additional work is necessary to address these important issues and to improve our understanding of the disposition of drugs in meconium.[474]

Oral Fluid

Reports concerning the appearance of organic solutes in saliva have been included in the scientific literature for longer than 70 years.[726] Analysis of saliva for drugs was first used almost 30 years ago for the purpose of therapeutic drug monitoring.[344] It has since been evaluated for use in forensic

toxicology, with recognition of its advantages over other biological matrices.[638A] Most studies on saliva in humans use whole saliva. The term "oral fluid" is preferred for the specimen collected from the mouth. Oral fluid is a complex fluid consisting not only of secretions from the three major pairs of salivary glands (parotid, submandibular, and sublingual), but also secretions from the minor glands (labial, buccal, and palatal), bacteria, sloughed epithelial cells, gingival fluid, food debris, and other particulate matter.[338] The concentration of drug from each secretion and the relative contributions of the various glands to the final fluid may vary.[726]

Biologically, before any drug circulating in plasma can enter the oral fluid, it must pass through the capillary wall, the basement membrane, and the membrane of the salivary gland epithelial cells. However, this fluid is not a simple ultrafiltrate of plasma, as has sometimes been suggested, but rather a complex fluid formed by different mechanisms, including ultrafiltration through pores in the membrane, active transport against a concentration gradient, and passive diffusion.*

Ethanol was the first drug of abuse to be investigated in oral fluid[261]; since then, many additional studies have expanded on our knowledge of this drug in it. Ethanol appears to reach a higher peak concentration in oral fluid than in peripheral blood. Because distribution of ethanol in the body is considered to occur by passive diffusion, under equilibrium conditions, ethanol content will be dependent upon the water content of the fluid or tissue being measured. The content in saliva therefore will be higher than that found in blood or serum. On a theoretical basis, the saliva-to-blood (S/B) ethanol ratio should be 1.17; however, lower ratios have been found in the postabsorption phase.[159,388]

In recent years, great interest has been expressed in the use of oral fluid testing for roadside drug screening, for monitoring the compliance of individuals on drug maintenance programs, and for workplace drug testing (see Table 35-8). Low concentrations of drugs and metabolites necessitate sensitive screening methods, which typically are immunoassays.[431] Again, the low concentrations of drugs have necessitated that confirmatory methods be equally as sensitive. Many confirmatory methods have been developed for oral fluid testing of abused drugs, including GC-MS, LC-MS and LC-MS/MS.† Specimens can be monitored for cannabinoids, cocaine, opiates, amphetamines, phencyclidine, methadone, barbiturates, and benzodiazepines. Interpretation of the presence and concentrations of these drugs in saliva and information on their use have been extensively reviewed elsewhere.[159,208,400,417,708]

Several advantages are associated with monitoring oral fluid as contrasted with monitoring plasma or serum concentrations.[749] Collection of oral fluid is considered to be a noninvasive procedure, and some of the risks associated with the drawing of blood are avoided. Furthermore, for the patient, fear, anxiety, and discomfort that may accompany the drawing of blood are diminished. Although some training and explanation are necessary to ensure proper gathering of oral fluid samples, the level of training needed for blood sampling is not required. In principle, oral fluid drug concentration is related to plasma free drug concentration, except when buccal contamination may have occurred because of oral ingestion, smoking, or snorting of the drug. Therefore oral fluid has the potential to show a relation between behavior/impairment and drug concentration, making it a possible medium for monitoring drug intoxication or for conducting therapeutic drug management.[431,459] On a related note, one significant disadvantage of oral fluid is that the window of detection is about equivalent to that of blood or serum and is short compared with that in urine.[712,713,749] Another disadvantage is the small volume of sample collected. The problem of small sample size can be overcome by using methods that simultaneously extract multiple drug groups.[431,865]

Hair

For more than 30 years, hair has been analyzed for trace metals, including lead, arsenic, and mercury. This was achieved using atomic absorption spectroscopy (see Chapters 10 and 36). At first, the examination of hair for organic substances, specifically drugs, was not possible because the analytical methods were not sensitive enough.[424] Baumgartner and associates in 1979[66] published the first report on the detection of morphine in the hair of heroin abusers using RIA. Since that time, interest in analysis of hair for the purpose of detecting drug use has increased.[67,356,416,422]

It is generally accepted that drugs enter hair by at least three mechanisms: (1) from blood that supplies the growing hair follicle, (2) through sweat and sebum, and (3) via the external environment.[396,424] The exact mechanism by which chemicals are incorporated into hair is not known. It has been suggested that passive diffusion may be augmented by binding of the drug to intracellular components of hair cells such as the hair pigment melanin. Specific binding of basic drugs to hair components is likely to involve both electrostatic attraction and weaker forces, such as van der Waals attraction. Neutral and acidic drugs presumably bind through weaker forces and possibly by other mechanisms.[160]

Factors that may affect how efficiently drugs are incorporated into hair are not well established but may include rate of hair growth, anatomic location of hair, hair color (melanin content), and hair texture (thick or fine, porous or not); these are determined by genetic factors and by the effects of various hair treatments.[424] For example, in vitro substantially higher binding was found with hair from black men than with hair from blond white men, suggesting that melanin pigment plays an important role in drug binding.[397] Studies have demonstrated that after the same dosage is given, black hair incorporates much more of the drug than is incorporated

by blond hair.[329,339,449] This may lead to bias in hair testing for drugs of abuse and discussions about possible genetic variability of drug deposition in hair and is still under evaluation.

Drugs, when deposited in hair, are generally present in relatively low concentrations (pg/ng/μg/mg); thus sensitive analytical techniques are required for detection. Immunoassay procedures have been modified for use with hair.[424] Although GC-MS is generally the method of choice,[696] various GC-MS/MS or LC-MS/MS methods may be used for targeted analysis of low-dose compounds such as fentanyl, buprenorphine, and flunitrazepam.[450,451,697,787,829] These methods are also useful in the detection of some drugs or metabolites typically present in hair at trace concentrations such as THC-COOH[135,788] or in retrospective detection of drugs administered as single doses.[430,580,581,583]

As mentioned, external exposure to drugs causes them to be detected in hair, and because it is unlikely that anyone would intentionally or accidentally apply drugs of abuse to his or her own hair, the most crucial issue facing hair analysts today is technical and evidentiary false positives.[424] False positives may be caused during collection or after collection. Externally deposited substances easily contaminate the hair because of its high surface-to-volume ratio. Substances deposited in hair from the environment are loosely bound to the surface of the hair, and thus are removed by appropriate decontamination procedures. These usually involve a washing step.[67,424] It is fundamental to be able to distinguish between passive exposure (environmental contamination) and active consumption; consequently, decontamination procedures for hair are compulsory.[88] Needless to say, hair analysis is a complex scientific undertaking, and a comprehensive review on this topic has been published.[655]

Hair is advantageous as a biological specimen because it is easily obtained, with less embarrassment; it is not easily altered or manipulated to avoid drug detection. Hair also differs from other human materials used for toxicological analysis such as blood or urine in that it has a substantially longer detection window. Once deposited in hair, drugs are very stable, and analysis can be performed even after centuries.[653]

Hair also differs from other human materials used for toxicological analysis such as blood or urine because of its substantially longer detection window (months to years). Hair grows at a relatively constant rate. The average rate of hair growth is usually stated to be 0.44 mm per day (range, 0.38 to 0.48 mm/d) for men and 0.45 mm per day (range, 0.40 to 0.55/d) for women in the vertex region of the scalp.[573] The rate of hair growth depends on anatomic location, race, gender, and age. Scalp hair grows faster than pubic or axillary hair (≈0.3 mm/d), which in turn grows faster than beard hair (≈0.27 mm/d).[88] It is generally accepted that sectional hair analysis can be used to prove drug history.[88] Numerous forensic applications in which hair analysis was used to document the case have been described in the literature; these include (1) differentiation between a drug dealer and a drug consumer, (2) chronic poisoning, (3) crime under the influence of a drug, (4) child sedation and abuse, (5) suspicious death, (6) child custody, (7) abuse of drugs in jail, (8) body identification, (9) survey of drug addicts, (10) chemical submission, (11) obtaining a driver's license, and (12) doping control.[423,431,549,834]

Sweat

Drugs may be excreted in sweat, with the parent drug generally present in a greater amount than metabolites.[356,417] Moreover, sweat excretion may be an important mechanism by which drugs enter hair.[165]

Sweat patch collection devices that resemble an adhesive bandage may be worn for several days to several weeks; during this time, drug, if present, accumulates in the absorbent pad in the patch, while water vapor escapes through the semipermeable covering.[428] Thus sweat drug testing offers the possibility of monitoring drug use over extended periods of time without the need for frequent collection of urine.[108] Sweat drug testing would be particularly advantageous for monitoring drug use in correctional institutions or in drug rehabilitation programs.[425]

Athletes and Drug Testing

"Doping" in athletic competitions has a history of abuse in a variety of sports for centuries. Regulation of performance-enhancing substances was initiated in 1967 in response to the death of Danish cyclist, Knud Jensen, at the 1960 Olympic Games in Rome. After decades of reform between universal governments and sporting agencies, the World Anti-Doping Agency (WDA) was established in 1999. Currently, 36 facilities around the world are accredited by the International Organization for Standardization (ISO) for detecting drug use among competitive athletes.[122] Prohibited drugs are substances or methods that conform to two of three criteria: (1) performance enhancing, (2) may endanger the athlete's health, (3) go against the spirit of the sport. "In-competition" testing was established to detect drugs (stimulants, narcotics, cannabinoids, glucocorticosteroids) taken at the time of a competition to temporarily enhance performance. "Out-of-competition" testing is performed to detect substances and methods such as anabolic-androgenic steroids (AAS), hormones, hormone modulators, oxygen transfer enhancement, and gene transfer, whose performance-enhancing effects have a gradual onset to allow for more intense and efficient training; they can be abruptly discontinued before competition.[5,122]

Most testing for prohibited substance abuse is performed by GC-MS. Specialized testing such as isoelectric focusing ("double blotting") was implemented at the 2002 Salt Lake City Olympics to discriminate between endogenous and recombinant forms of erythropoietin.[121] Erythrocyte phenotyping by flow cytometry is used to detect homologous blood transfusions.[30,285,484] Limited windows of detection and individual biological variability for specific substances (especially hormones) are challenges faced when novel analytical methods are developed and validated. Tracking of specific clinical biomonitors (such as hormone or hormone-responsive

protein concentrations) over an athlete's performance career, termed *biological passport* and *longitudinal profiling,* is currently under investigation.[584,660]

CHAPTER 36

Toxic Metals

Thomas P. Moyer, Ph.D.

Metals have been recognized as toxins for centuries. For example, arsenic (As) poisoning was a favored way to dethrone royalty in the Renaissance era, and mercury (Hg) poisoning was common in eighteenth century Europe, where it was associated with the generation of felt from beaver pelts to make the popular top hat. This resulted in behavioral changes and common use of the phrase "mad as a hatter."

This chapter explores these and other toxic metals and the role of the clinical laboratory in diagnosing and monitoring toxicity associated with exposure to them.

ASSESSMENT OF METAL POISONING

Important questions to address when considering metal toxicity today are listed in Box 36-1. These questions are addressed generally in the first section of this chapter. In the second section, the unique characteristics of the more common metals known to be associated with toxicity are discussed. Readers are referred to *The Handbook on the Toxicology of Metals*[101] for details on rare metal toxicities.

Prevalence of Metal-Based Toxicity

As the twenty-first century begins, one would expect that metal toxicities would be thoroughly known and avoidable. However, humans frequently still encounter elemental toxins, and chronic, low-concentration exposure occurs more frequently in individuals than in large population groups. Concern continues regarding low-concentration exposure to lead and the effect such exposure has on mental development in the young. As is common in our environment, individuals are occasionally exposed because of lack of knowledge of the household products they are using. Many insecticides contain As as an active ingredient; careless use of these products has led to significant exposure. As is frequently identified as the cause of peripheral neuropathy among patients who have been unwittingly exposed. Ground water contaminated with As in the Bengal basin of Bangladesh, exceeding World Health Organization (WHO) safety limits because of leaching from bedrock, presents a serious health risk to the large population living in that region. Cadmium (Cd) is used to manufacture brightly colored paint pigments; painters who fail to use adequate respiratory protection while using abrasive materials to remove paint, or while spray painting with cadmium-containing products, can experience significant exposure. Cd is also significantly present in tobacco products.[61] Studies indicate that apoptotic pathways are initiated by metals such as As, Cd, chromium (Cr) , nickel (Ni), and beryllium (Be); and possibly lead (Pb), antimony (Sb), and cobalt (Co).[108]

Although rare, manufacturing errors have caused the production of products that contain toxic metals. For example, in the early 1960s, a Canadian beer brewery accidentally contaminated a large lot of its product with Co. The product was sold to and consumed by the public, resulting in an outbreak of renal disease and cardiomyopathy. In this type of situation, the Public Health Service is often called in to identify the cause of an outbreak of unusual symptoms. The clinical laboratory should be prepared to support these types of investigations.

The incidence of metal poisoning in a large population attributable to As, Cd, Pb, or mercury (Hg) poisoning appears to be of the same scale as the more common inborn errors of metabolism, such as neonatal hypothyroidism and phenylketonuria, and is the same order of magnitude as the incidence of adult-onset hemochromatosis, a disease for which mandatory screening has been suggested. Screening for these diseases is indicated because they are treatable, and treatment significantly reduces long-term morbidity.[92] The same is true for metal toxicities. When identified early, disease caused by metal exposure is readily treatable with good outcomes. Conversely, if exposure is not identified and reduced, serious and sometimes irreparable damage to the nervous, renal, and cardiovascular systems can occur.

Diagnosing Toxicity

Confirming the diagnosis of metal toxicity is difficult because signs and symptoms are similar to those of a number of non–element-dependent diseases. Diagnosis of metal toxicity requires demonstration of *all* of the following factors: (1) a source of metal exposure must be evident, (2) the patient must demonstrate signs and symptoms typical of the metal, and (3) abnormal metal concentration in the appropriate tissue must be evident. If one of these features is absent, one cannot make a conclusive diagnosis of metal toxicity. The laboratory plays a key role in this process, and appropriate specimen collection coupled with accurate analysis can make a major difference in correct diagnosis.

In clinical practice, analysis of toxic elements should always be considered in the clinical work-up of the patient with (1) renal disease of unexplained origin, (2) bilateral peripheral neuropathy, (3) acute changes in mental function, (4) acute inflammation of the nasal or laryngeal epithelium, or (5) a history of exposure. Certain elements should be considered as the active, causative, or deficient agent in specific circumstances (Table 36-1).

Classification of Metals

Some metals are essential for life (see Chapter 31), but if an individual's exposure exceeds a certain threshold, toxicity may develop. Some nonessential metals are toxic even at low concentrations. Review of the periodic table provides some insight into the determination of a metal's potential toxicity (Figure 36-1).

BOX 36-1 Pertinent Questions Relative to Metal Toxicity

1. Is the metal of concern toxic?
2. What is the prevalence associated with the metal of concern?
3. What are the signs and symptoms of exposure to that metal?
4. Is the degree of exposure known?
5. Are adequate analytical techniques available to measure the metal?
6. Are appropriate body fluids and tissues and analytical techniques available to identify and quantify the metal?

TABLE 36-1 Conditions That Involve Metal Toxicity

Metal	Condition
Aluminum	Dialysis, encephalopathy, or dementia
Arsenic	Bilateral pain radiating from feet to legs or peripheral neuropathy, or unexplained impaired renal function
Cadmium	Impaired renal function in aerosol painters
Copper-zinc deficiency	Impaired wound healing
Gadolinium	Nephrogenic systemic fibrosis
Lead	Children younger than 2 years living in older homes, or unexplained gastric upset, anemia, or impaired renal function at any age
Mercury	Acute changes in behavior, impaired speech, visual field constriction, hearing loss, and somatosensory disorders
Manganese	Onset of parkinsonism younger than age 50
Selenium (deficiency)	Patients undergoing total parenteral nutrition
Thallium	Acute hair loss
Zinc (deficiency)	Burn patients exhibiting erythema

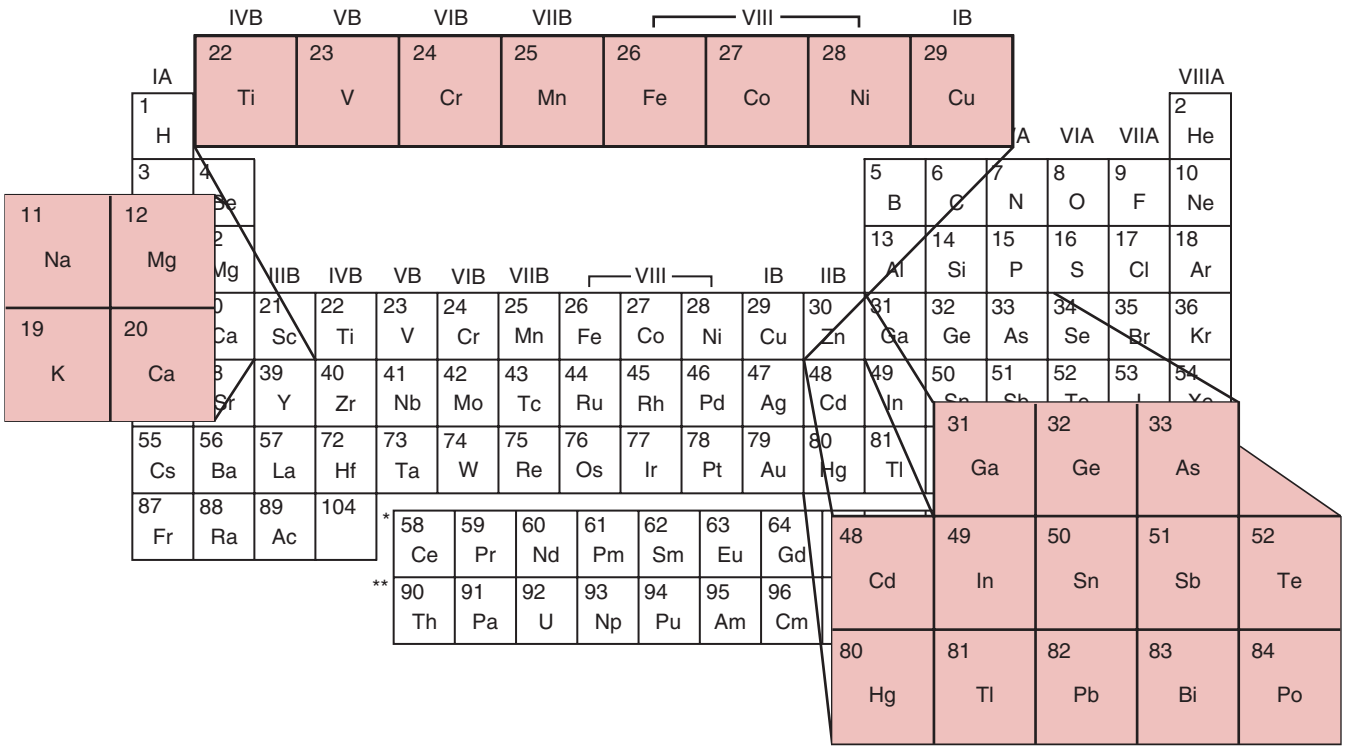

Figure 36-1 Periodic table, with emphasis on toxic elements.

Elements in rows 3 and 4 of groups 1 and 2 of the periodic table are essential elements. The gastrointestinal tract and the dermis are very effective at regulating the body burden of these compounds—patients rarely experience toxicity from one of these elements unless the element is injected directly into the vascular system. Elements in groups 6 through 12 in row 4 of the periodic table are essential for life but are required at low concentrations; many are protein cofactors required for enzymatic activity. The gastrointestinal tract and the dermis regulate intake to some degree, but overload will induce passive diffusion that can lead to excessive concentrations and toxicity. Elements in rows 5 and below are classified as nonessential (or if essential, are required at picomolar concentrations or less). As one moves from right to left across the periodic table, the elements become more prevalent and therefore have greater potential to induce toxicity. Elements in groups 13 through 16 in rows 4 through 6 are of particular interest as toxins, because they have electron configuration that allows them to bond covalently with sulfur. Later in this chapter, this characteristic is identified as a significant factor in the mechanism of action of this group of metals. These include As, Cd, Pb, Hg, and thallium (Tl)—all toxins of considerable concern. Elements in group 17 (halides) are essential for life but are toxic when present in excess. The inert elements that constitute group 18 are toxic in the gas phase because they can cause anoxia; their inert characteristic is the very cause of their toxicity.

Occupational Monitoring

Employees are frequently monitored when working in an environment where exposure to toxic metals is a possibility.[101] The most common form of monitoring involves quantification of airborne concentrations of metals in the production process. Threshold limit values (TLVs) for airborne concentrations and time interval exposure concentrations are defined by the U.S. National Institute for Occupational Safety and Health (NIOSH) to ensure worker safety. Workers may also be monitored by quantification of biological samples. The most common sample used is a random urine sample, and results are expressed in concentration units for the metal of interest per gram of creatinine to normalize for excretion volume variances. Cd, Cr, and Pb have defined urine excretion concentrations set by a U.S. federal agency to ensure worker safety.[15,26,80] Additional technical and regulatory information about toxic metals is available at the Occupational Safety and Health Administration (OSHA) Website at http://www.osha.gov/SLTC/metalsheavy/index.html/ accessed June 2, 2011.

The WHO and OSHA have defined blood concentrations for Pb that are designed to warn employers when workers are overexposed.[113] Safety limits for other metals have been set by professional organizations, such as the American Conference of Governmental Hygienists.[36]

Analytical Methods

Analytical techniques used to measure metals in biological fluid includes (1) atomic absorption spectrometry with flame (AA-F) or electrothermal atomization furnace (AA-ETA), (2) inductively coupled plasma emission spectroscopy (ICP-ES), (3) inductively coupled plasma mass spectrometry (ICP-MS), and (4) high-performance liquid chromatography–inductively coupled plasma mass spectrometry (LC-ICP/MS). These tecniques are specific, sensitive, and provide the clinical laboratory with the capability to measure a broad array of metals at clinically significant concentrations. For example, ICP-MS is used to measure several metals simultaneously.[13,88,100] Photometric assays have been used in the past but require large volumes of sample and have limited specificity. Spot tests are also available but should be considered obsolete because they are error prone, often yielding false-positive results.

SPECIFIC METALS

Certain metals are known to be toxic when humans are exposed to elevated concentrations; five metals are listed in the top 20 of the 2007 CERCLA (Comprehensive Environmental Response, Compensation, and Liability Act) Priority List of Hazardous Substances.[21] They include As (No. 1), Pb (No. 2), Hg (No. 3), Cd (No. 7), and Cr (No. 18). Other metals of concern include aluminum (Al), Be, Co, copper (Cu), gadolinium (Gd), iron (Fe), manganese (Mn), Ni, platinum (Pt), selenium (Se), silicon (Si), silver (Ag), and Ti. The Agency for Toxic Substances and Disease Registry (ATSDR) provides toxicologic profiles for many of these metals on its Website.[2] These hazardous substances are ranked on the basis of their frequency of occurrence, toxicity, and potential for human exposure.

Several of these metals are also considered essential trace elements and are discussed in Chapter 31. Risk assessments for essentiality versus toxicity for Cr, Cu, iodine (I), Fe, Mn, molybdenum (Mo), Se, and zinc (Zn) have been performed by several U.S. governmental and private organizations.[52,98]

Aluminum

In 1972, Alfrey and colleagues first described an encephalopathy that was observed in patients undergoing prolonged hemodialysis for renal failure.[1] The disease was characterized by abnormal speech, myoclonic jerks, and convulsions. Patients with these signs also showed a predominance of osteomalacic fractures. Subsequently, it was found that exposure of patients in renal failure to Al (1) laden dialysis water, (2) containing oral phosphate binders, and (3) laden albumin administered during dialysis is the primary cause of these signs of Al toxicity. Aluminum is also a developmental toxicant if administered parenterally.[37]

Under normal physiologic conditions, the usual daily dietary intake of Al is 5 to 10 mg, which is completely excreted. This excretion is accomplished by avid filtration of Al from the blood by the glomerulus of the kidney. Patients in renal failure lose this ability and are candidates for Al toxicity. The dialysis process is not highly effective at eliminating Al and can be a significant source of exposure. Furthermore, it is a common practice to administer Al-based gels orally to

patients in renal failure to reduce the amount of phosphate absorbed from their diet to avoid excessive phosphate accumulation.[104] A small fraction of this Al may be absorbed and patients in renal failure accumulate this Al. Following dialysis, albumin may be administered to replace that which is removed during dialysis. Some albumin products have high Al content resulting from the pharmaceutical purification process of passing the product through Al silicate filters.

Aluminum (1) accumulates in blood if not filtered by the kidney; (2) avidly binds to proteins, such as transferrin; and (3) rapidly distributes throughout the body. Deposition of it in bone interrupts physiologic calcium exchange; the calcium in bone becomes unavailable for resorption into blood, a process under the physiologic control of parathyroid hormone (PTH) and 1,25-dihydroxy vitamin D (see Chapter 52). The normal physiologic action of PTH on bone is blunted in patients with renal failure because their renal cells are not synthesizing the 1,25-dihydroxy vitamin D required for normal PTH action. It is typical for patients in renal failure to have high serum PTH values and low serum calcium; this represents secondary hyperparathyroidism, the normal physiologic response to vitamin D deficit. Deposition of Al at the bone mineralization front and binding to parathyroid calcium receptors interfere with this physiologic process. The usual parathyroid response to these conditions decreases secretion of PTH. The result is lower-than-expected serum PTH concentration for the degree of renal disease present.

In addition, a biochemical profile that characterizes Al overload disease has been defined.[87] In human subjects with normal renal function, serum Al concentration is typically lower than 6 µg/L, but patients in renal failure invariably have serum Al concentrations significantly higher. Clinical guidelines published in 2006[91] suggest that patients with no signs or symptoms of osteomalacia or encephalopathy are likely to have serum Al concentrations <20 µg/L and PTH whole molecule concentrations 150 to 300 ng/L, typical for secondary hyperparathyroidism associated with renal failure.[119] Patients with signs and symptoms of osteomalacia or encephalopathy typically have serum Al concentrations >60 µg/L, and PTH concentrations <65 ng/L indicate Al-related bone disease. Patients with serum Al concentrations >20 and <60 µg/L were identified as candidates for likely onset of Al-related bone disease; these patients required aggressive efforts to reduce their daily Al exposure. Efforts to reduce Al intake include (1) switching from Al-containing phosphate binders to calcium-containing phosphate binders, (2) ensuring that dialysis water contains less than 10 µg/L of Al, and (3) ensuring that albumin used during postdialysis therapy is Al-free.

Interest in the role of Al in Alzheimer's disease (AD) was raised when Perl observed that Al accumulates in the neurofibrillary tangle of patients with AD.[107] He concluded that the focal accumulation of Al had an association with neurofibrillary degeneration in the hippocampal neurons that might play a role in the development of AD. Although a cause-and-effect relationship between accumulation of Al in brain and AD has yet to be conclusively demonstrated,[11A,112] studies have clearly shown an increased concentration of Al in the brain.[90] It is possible that accumulation of Al in the neurofibrillary tangle of AD patients is a secondary finding associated with the disease but not directly related to the cause. Also, the neurofibrillary tangle has a higher than normal affinity for Al that may explain increased accumulation of Al in brain tissue of Alzheimer's patients.

Aluminum-related bone disease has been diagnosed and treated with deferoxamine, an avid chelator of both iron and Al.[31] The deferoxamine infusion test is useful for the ultimate diagnosis of Al overload disease, and the drug has demonstrated utility for treating acute Al overload.[31,40]

Preanalytical considerations related to collection of specimen for Al analysis are significant. Most of the common evacuated blood collection devices used in phlebotomy today have rubber stoppers that are made of Al silicate. Puncture of the rubber stopper for blood collection is sufficient to contaminate the sample with Al and produce an abnormal concentration of Al. Typically, blood collected in standard evacuated blood tubes will be contaminated by 20 to 60 µg/L of Al; this is readily demonstrated by collecting blood from a healthy volunteer into a standard evacuated phlebotomy tube. Special evacuated blood collection tubes are required for Al testing.[94] These tubes are readily available from commercial suppliers and should always be used. Failure to pay attention to this issue can result in the generation of abnormal results because of sample contamination, which leads to misinterpretation and misdiagnosis.

Analysis of Al is routinely performed by inductively coupled plasma (ICP) mass spectrometry (ICP-MS). Alternatively, atomic absorption spectrometry with electrothermal atomization may be employed, but considerable attention must be paid to matrix interferences.

Antimony

Sb compounds have been known since ancient Egyptian times and were used as cosmetics by the women of that era. In the sixteenth century, Sb preparations were thought to be wonder drugs that in the nineteenth century were prescribed for a number of conditions. Today antimony compounds are used to treat parasitic diseases such as leishmaniasis, schistosomiasis, and bilharziasis.[18,126]

Pure metallic Sb is very brittle; however, alloys of Sb are used in various fields of technology. For example, addition of Sb to lead, tin, and copper increases the hardness of these metals when used as electrodes, bullets, type metal for printing, and ball bearings. Other uses include fire-resistant chemicals, pigments, and dyes.

Antimony is not an essential metal. Workplace exposure to Sb dust over a period of years leads to pneumoconiosis. The size of the dust particles of Sb trioxide significantly increases the occurrence of pneumoconiosis, with smaller particles being more dangerous.[126] The workers at greatest danger are those in underground facilities and metal production. Smoking may also contribute to respiratory problems. Symptoms of acute exposure include (1) a metallic taste,

(2) headache, (3) nausea, and (4) dizziness; and after a short interval, (5) vomiting, (6) diarrhea, and (7) intestinal spasms. In chronic intoxication, adverse health effects include (1) cardiac arrhythmias, (2) upper respiratory and ocular irritation, (3) spontaneous abortion, (4) premature birth, and (5) dermatitis.[35] Lymphocytosis, eosinophilia, and a reduction in leukocyte and platelet counts are also seen and indicate damage to the liver and spleen. Evidence supports increased risk for the development of lung cancer in Sb smelter workers, but the effect may be multifactorial and may be due, for example, to the presence of arsenic in the work environment.[30] It is important to remember that when intoxication occurs with metallic Sb, the effect is caused not only by Sb, but also by the lead, arsenic, and other metals that may accompany it.

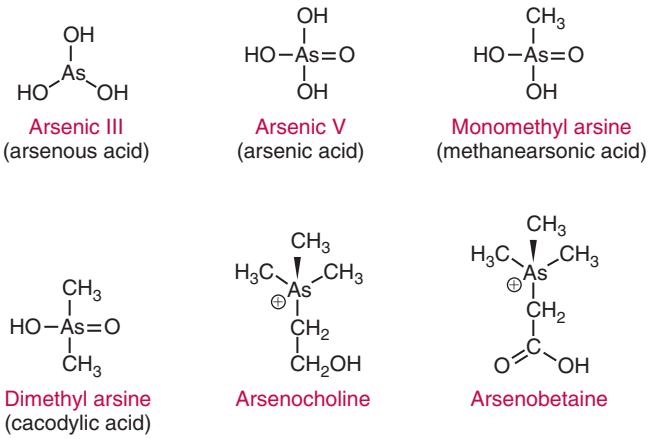

Figure 36-2 Structures of arsenic species.

Arsenic

As is perhaps the best known of the metal toxins, having gained notoriety from its extensive use by Renaissance nobility as an antisyphilitic agent and an antidote against acute arsenic poisoning; long-term administration of low arsenic doses protects against acute poisoning by massive doses—an historic example of hepatic enzyme induction. This agent was memorably used in the well-known tale "Arsenic and Old Lace"[73] as a means of terminating undesirable acquaintances. Currently, As is still a dangerous toxicant as evidenced by the Bangladesh incident wherein several hundred persons were poisoned by drinking ground water contaminated with As leaching from bedrock. As discussed earlier, As is listed as the No. 1 toxicant on the 2007 U.S. CERCLA Priority List of Hazardous Substances,[21] and it is still used extensively in insecticides.

Arsenic exists in numerous toxic and nontoxic forms.[93] The toxic forms include (1) the inorganic species As^{3+}, also denoted as As(III); (2) the more toxic As^{5+}, also known as As(V), and their partially detoxified metabolites; (3) monomethylarsine (MMA); and (4) dimethylarsine (DMA). Detoxification occurs in the liver as As^{5+} is reduced to As^{3+} and then is methylated to MMA and DMA. As a result of these detoxification steps, As^{3+} and As^{5+} are found in the urine shortly after ingestion, whereas MMA and DMA are the species that predominate longer than 24 hours after ingestion. Urinary As^{3+} and As^{5+} concentrations peak in urine at approximately 10 hours and return to normal 20 to 30 hours after ingestion. Urinary MMA and DMA concentrations normally peak at about 40 to 60 hours and return to baseline 6 to 20 days after ingestion.[93] In a large U.S. population study, for all participants aged >6 years, dimethylarsinic acid and arsenobetaine had the greatest contribution to the quantity of total urinary arsenic. Aarsenobetaine was the primary contributor to high total urinary arsenic concentrations.[16,33,45]

The half-life of inorganic As in blood is 4 to 6 hours, and the half-life of the methylated metabolites is 20 to 30 hours. Blood concentrations of As are elevated for only a short time after administration, after which As rapidly disappears into the large body phosphate pool. Abnormal blood As concentrations in the 5 to 50 ng/mL range are detected after exposure.[55] The structures of these and related As species are shown in Figure 36-2.

Nontoxic forms of As are present in many foods. Arsenobetaine and arsenocholine are the two most common forms of organic As that are found in food.[59] The foods that most commonly contain significant concentrations of organic As are shellfish and other predators in the seafood chain (e.g., cod, haddock). In the large U.S. population study, for all participants aged >6 years, dimethylarsinic acid and arsenobetaine had the greatest contribution to the total urinary arsenic. Arsenobetaine was the primary contributor to high total urinary arsenic concentrations.[16] Arsenic excretion in normal people who have ingested arsenobetaine-containing foods is >120 μg per 24-hour specimen. Following ingestion, arsenobetaine and arsenocholine undergo rapid renal clearance to become concentrated in the urine. Arsenobetaine and arsenocholine are completely excreted within 1 to 2 days after ingestion, and no residual toxic metabolites are present. The apparent half-life of organic As is 4 to 6 hours. Consumption of seafood before collection of a urine sample for As testing is likely to result in an elevated concentration of As in the urine; this can be clinically misleading.

The toxicity of As is due to three different mechanisms, two of which are related to energy transfer. Arsenic avidly binds to dihydrolipoic acid, a necessary cofactor for pyruvate dehydrogenase. Absence of the cofactor inhibits the conversion of pyruvate to acetyl coenzyme A—the first step in gluconeogenesis. Arsenic competes with phosphate for reaction with adenosine diphosphate (ADP), resulting in formation of the lower-energy adipic acids (ADPAs) rather than adenosine triphosphate (ATP). Arsenic also binds with any hydrated sulfhydryl group on protein, distorting the three-dimensional configuration of the protein, thus causing it to lose activity. British antilewisite (BAL) is an effective antidote for treating As intoxication; the active agent in BAL is dimercaprol, a sulfhydryl-reducing agent. This suggests that the primary mechanism of action of the toxicity of As is related to sulfhydryl binding. Arsenic also interferes with the activity of several enzymes of the heme biosynthetic pathway.[49] Arsenic is also a known carcinogen[24] as evidence suggests increased

risk of bladder, skin, and lung cancers, as well as lung cancer associated with smoking, following consumption of water with high As contamination.[11,115]

Of note, is the fact that As compounds are also used for therapeutic reasons. For example, arsenic compounds have been used for decades in the management of protozoal infections such as trypanosomiasis. A preparation of arsenic trioxide called Fowler's agent was used in the nineteenth century as a health tonic and for a variety of ailments ranging from skin disease to leukemia. Arsphenamine was used intravenously to treat syphilis, yaws, and some protozoal infections. Arsenic is still a key ingredient of certain herbal remedies, and arsenic trioxide is currently used in the management of refractory promyelocytic leukemia.

To distinguish among toxic inorganic species and nontoxic organic species of As of seafood origin, high-performance liquid chromatography (HPLC) techniques that separate the various species of As in biological fluids and tissues have been developed.[16] A typical finding in a urine specimen with total 24-hour excretion of As of 350 µg/24 hours is that more than 95% is present as the organic nontoxic seafood species, and less than 5% is present as the inorganic toxic species. Such a finding indicates that the elevated total As concentration was likely due to ingestion of seafood.

Hair analysis is frequently used to document time of As exposure.[76] Arsenic circulating in the blood will bind to protein by formation of a covalent complex with sulfhydryl groups of the amino acid cysteine. Because As has a high affinity for keratin, which has high cysteine content, the As concentration in hair or nails is greater than in other tissue. Several weeks after exposure, transverse white striae, called *Mees' lines*, may appear in the fingernails; this event is caused by denaturation of keratin by metals such as As, Cd, Pb, and Hg. Because hair grows at a rate of approximately 0.5 cm/mo, hair collected from the nape of the neck can be used to document recent exposure. Axillary or pubic hair is used to document long-term (6 months to 1 year) exposure. Hair As >1 µg/g dry weight indicates excessive exposure. In one study, the highest hair As observed was 210 µg/g dry weight in a case of chronic exposure that was the cause of death.[63]

Blood is the least useful specimen for identifying As exposure. Blood As concentrations are elevated for only a short time after administration[55] and rapidly disappear into the large body phosphate pool, because the body treats As like phosphate, incorporating it wherever phosphate would be incorporated. Absorbed As is rapidly circulated and distributed into tissue storage sites. Abnormal blood As concentrations are detected for only a few hours (<4 hours) after ingestion. This test is useful only to document an acute exposure when the As is likely to be >20 ng/mL for a short period of time. Typically, serum As is <40 ng/mL.

Arsenic has been accurately analyzed by ICP-MS. The specimen is prepared in dilute acid containing gallium as an internal standard and is aspirated directly into the argon plasma. Mass response from the argon plasma is monitored for As (75 m/z), gallium (70 m/z), and $^{16}O^{35}Cl$ (51 m/z) to allow for correction for $^{40}Ar^{35}Cl$ (75 m/z) interference. The operator must be aware of the potential for interference from argon chloride. A correction is made by accounting for chloride by measuring 51 m/z and subtracting that residual from 75 m/z.[100] Urine is the sample of choice for As analysis because As is excreted predominantly by the kidney, where it becomes concentrated.

Beryllium

Be is an alkaline earth metal found in the earth's crust at an approximate concentration of 3 to 5 mg/kg; it is poisonous and is not necessary for human health. Beryllium alloys are lightweight, stiff, and highly electrically conductive. Beryllium metal and alloys and Be ceramics are used in a wide range of applications, including dental appliances, golf clubs, nonsparking tools, wheelchairs, satellite and spacecraft manufacture, circuit board production, and nuclear power, and in weapons as a neutron modulator.

The general population is exposed to low concentrations of Be through food and drinking water; these exposures are of no clinical consequence. The major route by which Be enters the body is via the respiratory tract, and industrial exposure usually occurs from inhalation and ingestion of Be dust. Inhaled Be compounds are cleared very slowly from the lungs. Soluble compounds are absorbed to a much greater degree than other such as Be oxide, which are much less soluble. Beryllium salts are strongly acidic when dissolved in water, and this is thought to have a major toxic effect on human tissue. Absorbed Be accumulates in the skeleton. Renal clearance is very slow. Beryllium inhibits a variety of enzyme systems, including alkaline phosphatase, acid phosphatase, phosphoglycerate mutase, hexokinase, and lactate dehydrogenase.[114]

Acute exposure to Be is rare, is usually caused by an industrial accident or explosion, and typically results in chemical pneumonitis. Chronic Be exposure in the workplace has led to occupational health concerns because of its potential to cause a progressive and potentially fatal respiratory condition called *chronic Be disease (CBD)*. This disease, also known as berylliosis, is characterized by the formation of granulomas resulting from an immune reaction to Be particles in the lung.[34,67] To reduce the number of workers currently exposed to beryllium in the course of their work at the U.S. Department of Energy (DOE) facilities or among its contractors, the DOE has established a chronic beryllium disease prevention program (CBDPP) to minimize the concentrations of, and the potential for exposure to, beryllium, and has put forth medical surveillance requirements to ensure early detection of the disease (http://www.hss.energy.gov/healthsafety/wshp/be/ accessed June 2, 2011).

Studies have suggested that the size of the Be particles affects not only the site of deposition but also the amount deposited. This in turn may influence the clearance rate and thus the time of contact between the immune cells and Be.[74] Several years ago, researchers noted that blood and lung cells from CBD patients proliferated when exposed to Be in culture. This assay has been refined and is offered as the Be lymphocyte proliferation test (BeLPT). Unfortunately,

because of the nature of the test and the variability from lab to lab, the BeLPT has been known to produce false-negative and problematic results.[34,86] Efforts are under way by several groups to standardize the assay. Despite these issues, the BeLPT in bronchoalveolar cells is part of the current "gold standard" diagnosis for CBD.[114] Quantification of Be in serum or urine is not useful in making this diagnosis. Air analysis (TLV) is the preferred method of exposure evaluation.[75]

Cadmium

Cd is a byproduct of zinc and lead smelting. It is used (1) in industry in electroplating, (2) in the production of rechargeable batteries, (3) as a common pigment in organic-based paints, and (4) in tobacco products. Breathing the fumes of Cd vapors leads to nasal epithelial deterioration and pulmonary congestion resembling chronic emphysema. Spray painting of organic-based paints without the use of protective breathing apparatus is a common source of chronic exposure. Auto repair mechanics represent a work group that has significant opportunity for exposure to Cd.

The toxicity of Cd resembles that of As, Hg, and Pb in that it attacks the kidney; renal dysfunction with proteinuria of slow onset (over a period of years) is the typical presentation. Chronic exposure to Cd causes accumulated renal damage.[15,33,101] Breathing the fumes of Cd vapors leads to nasal epithelial deterioration and pulmonary congestion resembling chronic emphysema. Cadmium toxicity is expressed via formation of protein-Cd adducts that change the conformational structure of the protein, causing it to denature. This protein denaturation occurs at the site of highest concentration—in the alveoli if exposure is due to dust inhalation, and in the proximal tubule of the kidney because this is a major route of excretion.

NIOSH regulations mandate that employees exposed to Cd in the workplace must be monitored using quantification of urine Cd and creatinine, with the results in μg of Cd expressed per gram of creatinine.[95] This is based on the finding that renal damage caused by Cd exposure is detected by increased Cd excretion relative to creatinine. Cadmium excretion >3 μg Cd/g of creatinine indicates significant exposure to Cd. Results >15 μg Cd/g of creatinine are considered indicative of severe exposure. Urine Cd is a more specific measure of Cd exposure than are other markers of renal function, such as β_2-microglobulin, retinol-binding protein, and *N*-acetyl glucosaminidase.[33,95]

Normal blood Cd concentration is less than 5 ng/mL, with most concentrations in the interval of 0.5 to 2 ng/mL. Moderately increased blood Cd (3 to 7 ng/mL) may be associated with tobacco use.[61] Acute toxicity is observed when the blood concentration exceeds 50 ng/mL. Usual daily excretion of Cd is less than 3 μg/d. Collection of urine samples using a rubber catheter has been known to result in elevated results because rubber contains trace amounts of Cd that are extracted as urine passes through it. Brightly colored plastic urine collection containers should be avoided because the pigment in the plastic may be Cd-based. Cadmium concentrations also increase with age and may be involved with senescence.[9] Cadmium is usually quantified by atomic absorption spectrometry, but it has been accurately quantified by ICP-MS.[100]

Chromium

Occupational exposure to Cr represents a significant health hazard.[77,103] Chromium is used extensively (1) in the manufacture of stainless steel, (2) in chrome plating, (3) in the tanning of leather, (4) as a dye for printing and textile manufacture, (5) as a cleaning solution, and (6) as an anticorrosive in cooling systems. The toxic form of Cr is Cr^{6+} [Cr(VI)], which is rare; a strong oxidizing environment is required to convert the common form Cr^{3+} [Cr(III)] to Cr^{6+}, as might be found when Cr^{3+} is exposed to high temperatures in the presence of oxygen or during high-voltage electroplating. Inhalation of the vapors of Cr^{6+} causes erosion of the epithelium of the nasal passages and produces squamous cell carcinomas of the lung.[120] Cr^{6+} is highly lipid soluble and readily crosses cell membranes, whereas Cr^{3+} is rather insoluble and does not readily cross membranes. Clinically, monitoring biological specimens for Cr^{6+} is neither practical nor clinically useful to detect Cr toxicity, because the instant it enters a cell, it is reduced to nontoxic Cr^{3+}.[77] Instead, monitoring the air at the manufacturing site for Cr^{6+} is the usual way to test for Cr^{6+} exposure.

Quantification of total Cr in urine can be used to assess exposure to total Cr. NIOSH has proposed <30 μg chromium/g creatinine as the concentration of concern, but this concentration does not indicate that the specific exposure was to Cr^{6+}. The presence of chromium in erythrocytes is suggestive of exposure to Cr^{6+} within the past 120 days, because Cr^{6+} crosses biological membranes but Cr^{3+} does not.[25] Increased serum chromium concentrations are observed in association with orthopedic implants made from chromium alloys.[72,82] ICP-MS is the preferred technology for quantification of Cr in body fluids.

Cobalt

Co is widely distributed in the environment and is the essential cofactor in vitamin B_{12}. Quantification of active vitamin B_{12} (see Chapter 31) is the usual way to assess nutritional status; quantification of serum, blood, or urine Co concentration is not typical for assessing vitamin B_{12} status. Cobalt deficiency has not been reported in humans.

Cobalt is found in metal alloys that (1) are very hard, (2) have high melting points, and (3) are resistant to oxidation. Cobalt is not highly toxic, but large exposures will produce (1) pulmonary edema, (2) allergy, (3) nausea, (4) vomiting, (5) hemorrhage, and (6) renal failure. Occupational exposure occurs during production and machining of these metal alloys and has been known to result in interstitial lung disease. Cardiomyopathy and renal failure are symptomatic of acute Co exposure; this was exemplified by an incidence of mass population exposure to Co when beer contaminated with the metal was consumed.[124] Chronic exposure may cause (1) pulmonary syndrome, (2) skin irritation, (3) allergy, (4) gastrointestinal irritation, (5) nausea,

(6) cardiomyopathy, (7) hematologic disorders, and (8) thyroid abnormalities. Cobalt exposure alone may not lead to toxicity and must be considered within the context of exposure to multiple metals.[83] Quantification of urinary Co is an effective means of identifying individuals with excessive exposure; the National Health and Nutrition Examination Survey (NHANES/http://www.cdc.gov/nchs/nhanes.html/ accessed June 2, 2011) reported that the geometric mean of cobalt excretions in a large population was 0.54 µg/g creatinine in children and 0.34 µg/g creatinine in adults. Serum cobalt concentrations are increased above normal (>1 µg/L) in patients with orthopedic implants made from cobalt alloys.[72,82] Cobalt is quantified in biological tissues by atomic absorption spectrometry or by ICP-MS.

Copper

The homeostasis and analysis of Cu are discussed in Chapter 31. Copper ingestion has been known to cause serious toxicity,[46] and exposure may be caused by common pesticides. Copper arsenate is one of the active agents in marine antifouling paints and in the wood preservative used with green "treated" wood; copper arsenate wood products have been taken off the market in the United States because of this concern. Ingestion of copper produces severe gastrointestinal pain with erosion of the epithelial layer of the gastrointestinal tract, hemolytic anemia, centrilobular hepatitis with jaundice, and renal damage. The classical presentation of Cu toxicosis is represented by the genetic disease of Cu accumulation known as Wilson's disease.[85] This disease is typified by hepatocellular damage (increased transferases) and/or changes in mood and behavior caused by accumulation of Cu in central neurons. Evaluation of serum and urine copper concentration is useful in diagnosing Wilson's disease (see Chapter 21). Because most Cu circulating in blood is bound to ceruloplasmin, and ceruloplasmin formation is decreased in Wilson's disease, serum copper concentration is less than normal (reference interval for serum Cu, 0.7 to 1.4 µg/mL), while urinary Cu concentrations are increased to 15 to 60 µg/L in Wilson's disease. Increased hepatic Cu >2.0 (adjusted for age and reported as the hepatic iron index) is diagnostic for Wilson's disease.[85] Increased serum Cu is observed in patients prescribed estrogen. Excess Zn ingestion interferes with absorption of copper and leads to copper deficiency, which is characterized by myeloneuropathy.[123]

Gadolinium

Gd is a chemical element found in image contrast agents that are used during magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) procedures. These agents have come under scrutiny by the U.S. Food and Drug Administration (FDA) (http://www.fda.gov/ accessed June 2, 2011) because gadolinium-based contrast agent (GBCA) is thought to be involved in nephrogenic systemic fibrosis (NSF), a debilitating disorder characterized by edema, plaques, discoloration, and severe thickening of the skin, resulting in contractures and immobility. In addition to GBCA exposure, other proposed contributing factors and associations with NSF include (1) renal insufficiency, (2) pharmaceutical erythropoietin usage, (3) hypocalcemia acidosis, (4) low serum albumin concentrations, and (5) high serum ferritin concentrations.[125,130] Exposure to GBCA during a condition of low glomerular filtration rate (GFR) appears to be the most consistent risk factor.[8,29] Because GBCA is excreted by the kidney, exposure is prolonged in patients with renal insufficiency[68]; it is thought that extended exposure permits transmetallation to occur; this allows free gadolinium to come in contact with proteins and other cellular components. Although several different attempted therapies have been administered, some leading to moderate disease regression, no known cure is uniformly effective.[71] Gadolinium accumulates in tissues affected by NSF,[62] but it is not detectable in the skin of patients with normal renal function after exposure to GBCA.[12]

Iron

The homeostasis and analysis of iron (Fe) are reviewed in Chapter 32. Iron supplements are used frequently to maintain an adequate body burden of Fe. Occasionally, ingestion exceeds the needed daily requirement, resulting in Fe toxicity. For example, ingestion of more than 0.5 g of Fe has been known to produce severe irritation of the epithelial lining of the gastrointestinal tract, resulting in hemosiderosis, which may develop into hepatic cirrhosis. The presence of Fe >350 µg/dL or transferrin >125 micromole/L in serum corroborates this diagnosis.[132]

Lead

Lead (Pb) is a metal commonly found in the environment. It is an acute and a chronic toxin. Lead is present at high concentration (up to 35% w/w) in many paints manufactured before 1972. The Pb content of paints intended for household use was limited to <0.5% in 1978, but Pb is still found in paint products intended for nondomestic use and in artists' pigments. Ceramic products for use in homes available from noncommercial suppliers (e.g., local artists) have been known to contain significant amounts of Pb; lead is leached from the ceramic by weak acids such as vinegar and fruit juices. Leaded crystal contains up to 10% Pb, which is leached during long-term storage of acidic fluids such as fruit juice. Lead is also found (1) in dirt from areas adjacent to homes painted with Pb-based paints and (2) on highways, where it has accumulated from the use of leaded gasoline in automobiles. Use of leaded gasoline has diminished significantly since the introduction of unleaded gasoline, which has been required in personal automobiles in the United States since 1978. Lead is also found in soil near abandoned industrial sites where Pb may have been used. Water transported through Pb or Pb-soldered pipe contains some Pb, with higher concentrations found in water that is weakly acidic. Some foods (e.g., moonshine distilled in Pb pipes) and some traditional home medicines also contain Pb.[60] Exposure to Pb from any of these sources by ingestion, inhalation, or dermal contact has been known to cause significant toxicity.

A typical diet in the United States contributes approximately 3 µg of Pb per day, of which 1 to 10% is absorbed;

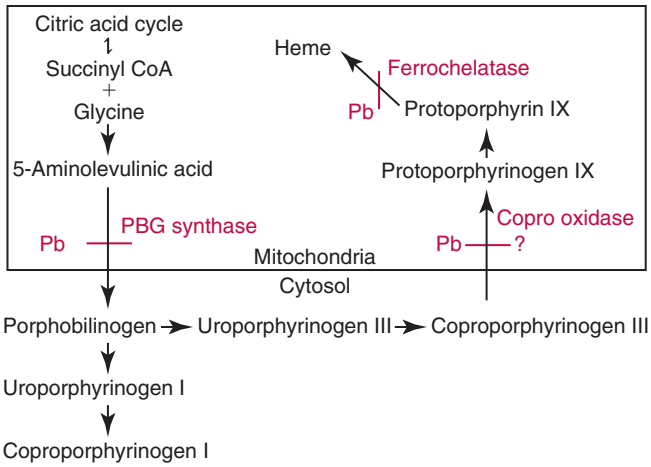

Figure 36-3 Erythropoietic effects of lead.

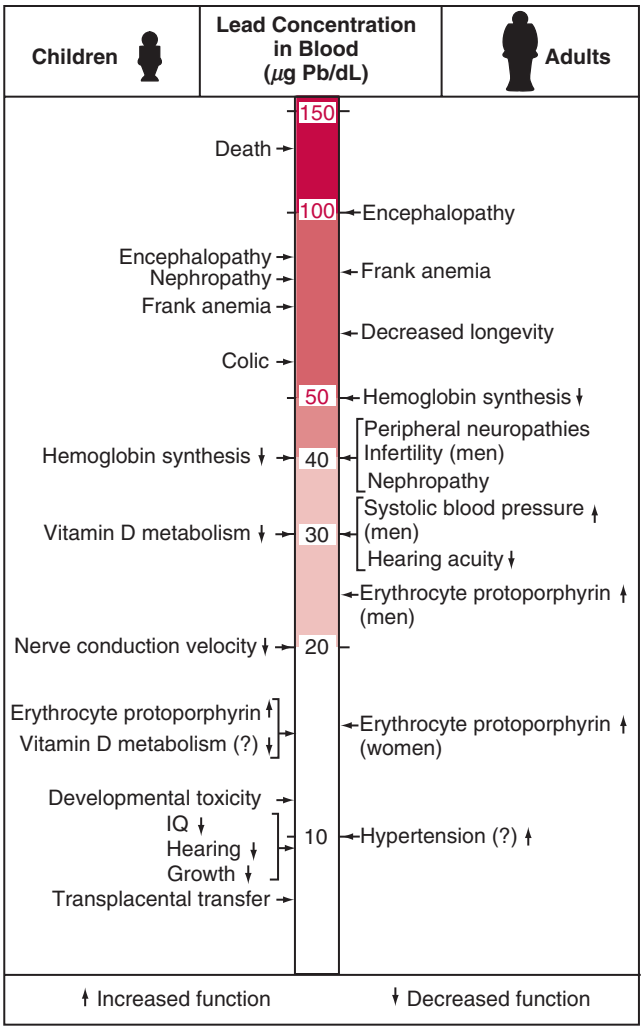

Figure 36-4 Effects of inorganic lead on children and adults (lowest observable adverse effect concentrations). *(From Royce SE, Needleman HL, eds. Case studies in environmental medicine: lead toxicity. Washington, DC: U.S. Public Health Service, ATSDR, 1990.)*

children may absorb as much as 50% of the dietary intake. The fraction of Pb absorbed is enhanced by nutritional deficiency. Most of the daily intake is excreted in the stool after direct passage through the gastrointestinal tract. Although a significant fraction of the absorbed Pb is rapidly incorporated into bone and erythrocytes, Pb is ultimately distributed among all tissues. Lipid-dense tissues, such as the central nervous system, are particularly sensitive to organic forms of Pb. Erythrocyte turnover of Pb occurs within approximately 120 days. Lead is ultimately excreted in bile or urine.

Lead expresses its toxicity by several mechanisms that are described graphically in Figure 36-3. It avidly inhibits amino levulinic acid dehydratase (ALAD), one of the enzymes that catalyze synthesis of heme from porphyrin. Inhibition of ALAD causes accumulation of protoporphyrin in erythrocytes (see Chapter 33), which is a significant marker for Pb exposure. Anemia caused by lack of heme is frequently observed in Pb toxicity. Lead also is an electrophile that avidly forms covalent bonds with the sulfhydryl group of cysteines in proteins. Thus proteins in all tissues exposed to Pb will have Pb bound to them. Keratin in hair contains a high fraction of cysteine relative to other amino acids and avidly binds Pb; hair analysis for Pb is a good marker for exposure. Some proteins become labile as Pb binds with them because Pb causes the tertiary structure of the protein to change; cells of the nervous system are particularly susceptible to this effect. Some Pb-bound proteins change their tertiary configuration sufficiently that they become antigenic; renal tubular cells are particularly susceptible to this effect because they are exposed to relatively high Pb concentrations during clearance.[33]

The development of Pb toxicity follows a progressive pattern. Figure 36-4 describes this progression through a series of symptoms.[19] The finding that Pb contributes significantly to decreased intellectual capability in the very young is of particular concern.[69,89] Young children are particularly prone to the effects of Pb because they have greater opportunity for exposure.[5] Children tend to spend a lot of time on the floor. In older homes that have been previously treated with Pb-based paints, Pb-laden paint chips and dust accumulate on the floor, which children are likely to ingest.

The definitive test for Pb toxicity is measurement of blood Pb.[113] Over the past 3 decades, studies have shown an inverse relationship between blood Pb concentrations and children's IQ at increasingly lower Pb concentrations. In response, the Centers for Disease Control and Prevention (CDC) has continued to lower the upper limit of normal for children, which is now stated at less than 10 μg/dL (http://www.cdc.gov/nceh/lead/ accessed June 2, 2011). It is important to note that the median blood Pb concentration in children fell from 15 μg/dL in 1978 to 2 μg/dL in 1999.[110] Consequently, renewed interest in determining safe blood Pb concentrations resulted in additional studies.[69,89] These studies assessed intellectual impairment in children with Pb concentrations below 10 μg/dL. Preliminary data have revealed an inverse relationship between Pb concentrations and children's IQ even at blood Pb concentrations <10 μg/dL.[17,69,89] Based

on these findings, in 2009 New York State redefined the preferred blood lead concentration for children to <5 μg/dL.[102]

The WHO has defined blood Pb concentrations >30 μg/dL in adults as indicative of significant exposure.[44] Lead concentrations >60 μg/dL require chelation therapy. In 2000, the CDC recommended that, as a preventive health measure, blood Pb concentrations in exposed workers should be reduced to <25 μg/dL by the year 2010.[58] Similar to the situation seen in children, adult blood Pb concentrations have dropped to a mean value of 1.4 μg/dL for ages 20 to 49 and a mean value of 1.9 μg/dL for ages 50 to 69.[99] Given the decreasing blood Pb concentrations in adults, it may be important to revisit the recommendations regarding Pb exposure. Studies have shown a number of adverse health effects in adults exposed to Pb at concentrations below existing regulatory exposure limits. These include hypertension, adverse reproductive outcomes, and subtle central nervous system problems.[53]

Although erythrocyte protoporphyrin concentrations are not a sensitive indicator of low-concentration Pb exposure, they are definitive markers for Pb overdose. For example, an erythrocyte protoporphyrin concentration greater than 60 μg/dL is a significant indicator of Pb exposure (see Chapter 33). Serum ALAD concentrations are also a useful indicator for medium to high concentrations of Pb exposure; however, they do not correlate with low concentrations of Pb exposure. Serum Pb analysis is of very limited utility because Pb concentrations are abnormal only for a short time after exposure.[22] The National Health and Nutrition Examination Survey (NHANES) reported a median urine excretion of 3 μg/L lead or 2.4 μg lead per g creatinine in a large population.[97] Quantification of urine excretion rates before or after chelation therapy has been used as an indicator of Pb exposure.[122] Normally, the hair Pb content is lower than 5 μg/g; hair Pb concentration >5 μg/g indicates significant Pb exposure. Blood Pb concentrations have the strongest correlation with toxicity.

Avoidance of continued exposure to Pb is paramount when blood Pb concentrations exceed acceptable limits. Oral dimercaprol has become a standard therapy and is being used in the outpatient setting for all except those with the most severe Pb poisoning.[10] Although chelation therapy is effective in reducing blood Pb concentrations, a 2003 study indicated that chelation therapy given to preschool children with Pb concentrations in the range of 20 to 44 μg/dL showed no beneficial effect on tests of cognition or behavior.[110] Thus, prevention is the best therapeutic option.

Analysis of Pb is routinely performed by ICP-MS,[13] electrothermal atomic absorption spectrometry,[14] or anodic stripping voltammetry.[134] Because Pb is concentrated in the erythrocytes, ethylenediaminetetraacetic acid (EDTA) anticoagulated blood is the specimen of choice for Pb analysis. Sodium heparin may also be used; however, samples that are not analyzed within 48 hours are frequently clotted and must be rejected. Care must be taken when obtaining capillary blood. Surface contamination, insufficient collection volume, or inadequate mixing with EDTA results in frequent sample rejection. Urinalysis can also be performed; urine quantification correlates with exposure.

If ICP-MS is used to measure Pb concentrations, care must be taken to sum the masses of 206, 207, and 208 m/z to account for the natural isotopic variation of Pb in the environment. Failure to sum masses will skew results above or below the actual concentration, as the isotopic abundance of a particular mass in the calibrator might not match the sample. However, this isotopic variation has been exploited to determine the source of Pb exposure. By determining the relative abundances of Pb in blood and of potential sources of exposure (e.g., paint chips, soil), it is possible to identify a matching pattern. The exposure source with the same ratio of major Pb isotopes as the blood should then be avoided or removed from the patient's environment.

Manganese

Mn is ubiquitous in the environment and is used as (1) a binding agent in red brick, (2) an anticorrosive in most steel alloys, (3) a cleaning agent for glassware, and (4) a common pigment in paints and glazes. Humans exhibit toxicity to Mn when exposed to large quantities of dust containing the metal, which occurs in mining, ore crushing, the machining of Mn alloys, and the construction and destruction of brick. Manganese exposure during metal welding has been suggested to cause neurologic disease, but this finding was not substantiated in a large study.[116] After chronic exposure, Mn accumulates in the substantia nigra of the brain, causing a Parkinson-like neurodegenerative disorder known as manganism.[117] Manganese toxicity is also a concern in newborns and children receiving long-term parenteral nutrition.[41]

Blood or urine Mn concentrations are good indicators of exposure.[117] Adult reference values for blood Mn are 0.4 to 1.1 ng/mL (7.0 to 20.0 nmol/L) for serum or plasma and 7.7 to 12.1 ng/mL (140 to 220 nmol/L) for whole blood. Typical daily excretion of Mn in urine varies from 0.2 to 0.5 μg/d. However, approximately 5% of healthy individuals excrete up to 2 μg of the metal per day, probably because of greater than average exposure.

Most of the Mn in daily diets is not absorbed. Because Mn-containing dust is common, contamination of urine with the metal occurs easily. Trace contamination of acid preservatives used for stabilizing the urine has also been observed. Manganese is quantified by electrothermal atomization atomic absorption spectrometry and ICP-MS.

Mercury

Metallic mercury is a liquid at room temperature; its elemental symbol, Hg, is derived from the Greek word *hydrargyrias*, meaning "water silver" (http://emedicine.medscape.com/article/819872-overview/ accessed June 2, 2011). As mentioned earlier, mercury is listed as No. 3 on the 2007 CERCLA Priority List of Hazardous Substances.

Hg is widely found in the environment[81] and occurs both naturally and as the result of industrial processes, with the single largest source of Hg being its natural out-gassing from granite rock.[6] Hg is also found in deposits throughout the

world, mostly as cinnabar (mercuric sulfide), which is the source of the red pigment vermilion.

In the past, Hg was extensively used in the manufacture of devices such as thermometers, barometers, manometers, and sphygmomanometers. However, concerns about its toxicity have resulted in the phasing out of Hg-based instruments, which have been replaced with alcohol-filled, digital, or thermistor-based ones. It is still used as a dental amalgam and in lighting as mercury vapor lamps, although these are being replaced by sodium vapor bulbs. Hg is used in the pulp and paper industry as a whitener, as a catalyst in the synthesis of plastics, and as a potent fungicide in antifouling and latex paints.

Mercury is essentially nontoxic in its elemental form (Hg^0). In the absence of any chemical or biological system that chemically alters Hg^0, it is possible to consume it orally with no significant side effects. However, once Hg^0 is chemically modified to the ionized, inorganic species, Hg^{2+}, it becomes toxic. Further bioconversion to an alkyl Hg, such as methyl Hg (CH_3Hg^+), yields a very toxic species of Hg that is highly selective for lipid-rich tissue, such as the neuron.[28] The relative order of toxicity is as follows:

$$Hg^0 <<<< Hg^{2+} << \text{Monomethyl-Hg } (CH_3Hg^+) \text{ or Dimethyl-Hg } [(CH_3)_2Hg]$$

Chemically, it is possible to convert Hg from its elemental state to its ionized state; in industry, this is frequently accomplished by exposing Hg^0 to a strong oxidant, such as chlorine. Elemental Hg is also bioconverted to both Hg^{2+} and alkyl Hg by microorganisms that exist both in the normal human gut and in the bottom sediment of lakes and rivers. When Hg^0 enters bottom sediment, it is absorbed by bacteria, fungi, and related microorganisms; these organisms metabolically convert it to Hg^{2+}, CH_3Hg^+, $(CH_3)_2Hg$, and similar species. Consequently, the methyl mercurials are accumulated in the aquatic food chain and reach their highest concentrations in predatory fish.[20,27]

As a consequence of accumulation of methylmercury in the aquatic food chain, most human exposure to mercury happens through the eating of contaminated fish, shellfish, and sea mammals. In adults, cases of methylmercury poisoning are characterized by the focal degeneration of neurons in regions of the brain such as the cerebral cortex and the cerebellum. Depending on the degree of in utero exposure, methylmercury may result in effects ranging from fetal death to subtle neurodevelopmental delays. Consequently, because pregnant women, women of childbearing age, and young children are particularly at risk, the FDA recommends that they avoid eating shark, swordfish, mackerel, and tilefish (http://www.fda.gov/food/foodsafety/product-specificinformation/seafood/foodbornepathogenscontaminants/methylmercury/ucm115662.html/ accessed June 2, 2011.[43] Mercury toxicity is expressed in three ways. First, Hg^{2+} avidly reacts with sulfhydryl groups of protein, causing a change in the tertiary structure of the protein with subsequent loss of the biological activity associated with that protein; because Hg^{2+} becomes concentrated in the kidney during regular clearance processes, this is the target organ that experiences the greatest toxicity. Second, with the tertiary change noted previously, some proteins become immunogenic, eliciting a proliferation of β-lymphocytes that generate immunoglobulins to bind the new antigen (collagen tissues are particularly sensitive to this). Third, alkyl Hg species, such as methylmercury, are particularly lipophilic and avidly bind to proteins in lipid-rich tissue, such as neurons; myelin is particularly susceptible to disruption by this mechanism.[27] Mercury has also been found to alter porphyrin excretion patterns.[131]

Experience with Hg poisoning has been gained from investigation of the 1951 to 1963 industrial dumping of Hg-laden waste sludge into Minamata Bay, Japan. Fish in Minamata Bay became heavily laden with Hg through the food chain. The local human population, whose diet was dependent on fish from the bay, exhibited symptoms of methylmercury poisoning, which include (1) ataxia, (2) impaired speech, (3) visual field constriction, (4) hearing loss, and (5) somatosensory change, characterized histologically by cerebral cortex necrosis. Collectively, these symptoms have become known as Minamata disease.[42]

In the late 1980s, the public became concerned about exposure to Hg from dental amalgams.[81,109] However, later studies have failed to confirm a causal relationship.[4,56] Basic to the initial concerns was the fact that restorative dentistry used an Hg-silver amalgam for approximately 90 years as a filling material. In 1989, Hahn showed that a small (2 to 20 μg/d) release of Hg^0 from amalgam occurs when it is mechanically manipulated, such as by chewing.[54] The normal bacterial flora present in the mouth converts a fraction of Hg^{2+} to CH_3Hg^+; the latter has been shown to be incorporated into body tissue. In addition, the habit of gum chewing can cause release of Hg from dental amalgams at concentrations greatly above normal. Hanson noted in 1991 the release of up to 100 μg/d of Hg in several human subjects who had the typical placement of dental amalgams (weighing approximately 800 mg each) after chewing gum for 8 hours.[57] In 2010, the FDA issued rules that classify dental amalgam, reclassify dental mercury, and specify special controls for dental amalgam, mercury, and amalgam alloy (21 CFR Part 872/http://www.fda.gov/ accessed June 2, 2011).

Concerns have been raised about the possible relationship between Hg exposure from vaccines and autistic disorders. In the United States, the prevalence of autism has risen from 1 in approximately 2500 in the mid-1980s to 1 in approximately 300 children in the mid-1990s.[50,108A] Some investigators believe that this rise occurs because of the Hg that is present in vaccines as the preservative thimerosal (sodium ethyl mercury thiosulfate).[7,32,50] However, this causality has been questioned by numerous other studies, which have not been able to confirm this relationship.[118] In 2001, the Committee on Immunization Safety Review of the Board on Health Promotion and Disease Prevention of the Institute of Medicine[127] initiated a study to review the connection between Hg-containing vaccines and neurodevelopmental disorders, including autism. The Committee has issued

several reports; in its eighth and final report, put forth in 2004, the Committee reported that the hypothesis was biologically plausible, but that evidence was insufficient to accept or reject a causal connection. At that time, the Committee recommended a comprehensive research program.[127] The findings of this report have been challenged,[51] and thimerosal has been removed from most vaccines in the United States.

The reader should note that the issue of linking Hg exposure from vaccines with autistic disorders became highly controversial and resulted in the Journal Lancet retracting the article linking autism to MMR (Measles, Mumps, and Rubella) vaccines.[38A,39A,104A] However, the senior author involved with this publication has challenged this retraction.[38B]

Dietary sources also contribute to Hg body burden, as many foods contain Hg. For example, commercially distributed fish considered safe for consumption contain less than 0.3 µg/g, but some game fish contain more than 2 µg/g and, if consumed on a regular basis, contribute to significant body Hg loads.

Of note is the fact that Hg compounds have been used for therapeutic reasons. For example, Hg has been used (1) in medications that were touted as cures for syphilis and dysentery, (2) to treat constipation, and (3) as diuretics.

Analysis of blood, urine, and hair for Hg concentrations is used to determine exposure. The quantity of Hg found in blood and urine correlates with the degree of toxicity, and hair analysis has been used historically to document the time of peak exposure. However, it should be noted that hair analysis for metals in general is difficult because of contamination. Normal whole blood Hg concentration is usually lower than 10 µg/L. Individuals who have mild occupational exposure (e.g., dentists) may routinely have whole blood Hg concentrations up to 15 µg/L.[39] Significant exposure is indicated when the whole blood Hg concentration is greater than 50 µg/L (if exposure is to methylmercury) or greater than 200 µg/L (if exposure is to Hg^{2+}). The WHO safety standard for daily exposure of Hg is 45 µg/d; daily urine excretion exceeding 50 µg/d indicates significant exposure. Normally, hair contains less than 1 µg/g of Hg; greater amounts indicate increased exposure. Treatment with BAL or penicillamine will mobilize Hg, allowing for its excretion in the urine. Therapy is usually monitored by following urinary excretion of Hg; therapy may be terminated after the daily urine excretion rate falls below 50 µg/L.

Nickel

Ni is frequently used (1) in the production of metal alloys (which are popular for their anticorrosive and hardness properties), (2) in Ni-based rechargeable batteries, and (3) as a catalyst in the hydrogenation of oils. Nickel alloyed with transition metals is considered nontoxic, except that it will induce inflammation at the point of contact. Nickel oxides and sulfides and aqueous solution of Ni in the oxidation state of 1^+, 2^+, or 3^+ are considered group I carcinogens.[47,129] If Ni is essential for life, it is only so at very low concentrations, below the detection limit of most analytical techniques (see Chapter 31). Nickel carbonyl [$Ni(CO)_4$], used in petroleum refining, is one of the most toxic chemicals known to humans[3] as it is absorbed after inhalation, readily crosses all biological membranes, and noncompetitively inhibits ATPase and RNA polymerase. Patients exposed to Ni carbonyl exhibit rapid onset of pulmonary congestion and inability to oxygenate hemoglobin, followed by development of lesions of the lung, liver, kidney, adrenal glands, and spleen.[70]

Patients undergoing dialysis are exposed to Ni and accumulate Ni in blood and other organs. No adverse health effects have been associated with this exposure. Nickel is quantified by AA-ETA or ICP-MS.

Platinum

A variety of Pt-containing antineoplastic agents are used in chemotherapy, typified by cisplatin (*cis*-dichlorodiammineplatinum dihydrate).[38,128] All of these compounds have some nephrotoxicity that is related to the concentration of Pt circulating in the blood.[79] Although it is not common to measure Pt concentrations in all patients receiving cisplatin therapy, quantification of Pt concentrations in patients with reduced renal function helps to identify whether Pt is the cause of the compromised renal function. Peak serum concentrations greater than 1 µg/mL but less than 1.5 µg/mL correlate with little nephrotoxicity and good therapeutic response.[48] Both AA-ETA and ICP-MS are used to measure Pt.

Selenium

Se is an essential element (see Chapter 31) and may play a role in mitigating biological damage caused by oxidative damage.[64,105] It is a cofactor required to maintain glutathione peroxidase activity, an enzyme that catalyzes the degradation of organic hydroperoxides. Absence of Se correlates with loss of glutathione peroxidase activity and is associated with damage to cell membranes caused by the accumulation of free radicals. In a situation of Se deficiency associated with loss of glutathione peroxidase activity, the serum concentration is less than 40 ng/mL.[121]

In humans, cardiac muscle is the tissue most susceptible to Se deficiency; with cell membrane damage, normal cells are replaced with fibroblasts.[23] This condition, known as *cardiomyopathy*, is characterized by an enlarged heart consisting of predominantly nonfunctioning fibrotic tissue.

The geographic source of plant and animal foodstuffs determines the amount of dietary intake. In the United States and Canada, wheat and other cereal products are a good source of selenium; average intakes in North America range from 80 to 220 µg Se/d, whereas in the United Kingdom, dietary intake is about 30 to 60 µg/d. Intakes in China are as low as 11 µg/d, and in New Zealand 28 µg/d (see Chapter 31). Symptoms of selenium toxicity vary among individuals and are dependent on a number of factors such as the dose, type, and form of selenium ingested, and the length of time the product was used. Symptoms of selenium poisoning include significant hair loss, muscle cramps, nausea, vomiting, diarrhea, joint pain, fatigue, fingernail changes, and blistering

skin. The tolerable upper limit has been set at 400 µg/d for adults and less for children.[133]

Selenium deficiency among people who consume food only from a particular region has been related to the low soil content of the metal in that region; the soil of the Keshan region of China is noted for this characteristic.[133] Children living in the Keshan region who receive no Se supplement develop cardiomyopathy. Deficiency is also related to use of total parenteral nutrition, which is administered to patients who have no functional bowel (e.g., those who have undergone surgical removal of the small and large intestines because of cancer) or who have acute inflammatory bowel disease, such as Crohn's disease (see Chapter 51). Selenium supplementation to raise serum concentration to above 90 ng/mL is the usual practice in these patients, and serum monitoring is performed on a semiannual basis to ensure the adequacy of supplementation.

Selenium toxicity has been observed in animals when daily intake exceeds 400 µg/d.[133] Teratogenic effects are frequently noted in the offspring of animals living in regions where Se soil content is high, such as in south central South Dakota and the northern coastal regions of California. Selenium toxicity in humans is not known to be a significant problem except in acute overdose cases, and Se is not classified as a human teratogen. Selenium is found in many over-the-counter vitamin preparations because its antioxidant activity is thought to be anticarcinogenic.

Selenium is quantified by ICP-MS or by atomic absorption spectrometry after the specimen has been mixed with matrix modifier.

Silicon

Si is the most abundant element in the earth's environment; it constitutes 26% of the earth's crust. From the toxicologic viewpoint, several forms of Si are of interest, including asbestos (amorphous oxides of Si) and methylated polymers of Si (e.g., silicone).

Inhalation of asbestos-containing dust leads to deposition of asbestos fibers in the pulmonary alveoli.[96,106] These fibers are needle-shaped spicules approximately 150 micrometer in length and up to 15 micrometer in diameter. When these fibers are inhaled, they deposit in the alveoli, where they are surrounded by macrophages and become coated with protein and mucopolysaccharide to form "asbestos bodies." The diagnosis of asbestosis is made by interpretation of a chest x-ray by a qualified radiologist, demonstration of asbestos in sputum, and documentation of asbestos bodies in a lung biopsy by electron microscopy.[111] Direct analysis of lung tissue for Si is not useful because all lung tissue is infiltrated with Si, most of which is not asbestos. Thus, direct analysis for Si cannot distinguish asbestosis from normal background Si.

Methylated polymers of Si (silicone) are used in breast implants. Concern as to the safety of such devices has been a subject of debate. A recent Medscape report states, "A great deal of recent safety research combined with more than 40 years of clinical experience has proven the value and relative safety of breast implants. To date, no convincing evidence exists of any systemic disorder that can be attributed to silicone" (http://emedicine.medscape.com/article/1275451-overview/ accessed June 2, 2011).[96A]

Silver

Clinical interest in Ag analysis is limited to two applications: (1) monitoring burn patients treated with Ag sulfadiazine, and (2) monitoring patients treated with Ag-containing nasal decongestants. In both cases, Ag deposits in many organs, including the subepithelium of the skin and mucous membranes, producing a syndrome called *argyria* (graying of the skin). Argyria is associated with (1) growth retardation, (2) hemopoiesis, (3) cardiac enlargement, (4) degeneration of the liver, and (5) destruction of renal tubules. The customary concentration of serum Ag is less than 2 ng/mL. Typical Ag concentrations observed in serum of unaffected patients during treatment range up to 300 ng/mL, and their urine output has been found to be as high as 550 µg/d.[78]

Thallium

Tl is a byproduct of lead smelting. Interest in Tl derives primarily from its former use as a rodenticide; accidental exposure represents the most likely source of exposure. Additionally, environmental concerns are growing because thallium is a waste product of coal combustion and the manufacturing of cement. Thallium is rapidly absorbed via ingestion, inhalation, and skin contact. It is considered to be as toxic as lead and mercury and has similar sites of action. The mechanism of Tl toxicity consists of (1) competition with potassium at cell receptors to affect ion pumps, (2) inhibition of DNA synthesis, (3) binding to sulfhydryl groups on proteins in neural axons, and (4) concentration in renal tubular cells to cause necrosis. Patients exposed to high doses of Tl (>1 g) demonstrate alopecia (hair loss), peripheral neuropathy and seizures, and renal failure. Typical serum concentrations are less than 10 ng/mL, and daily urine excretion is less than 10 µg/d. Exposed patients have been observed to have serum concentrations as high as 50 µg/mL, with urine output in excess of 500 µg/d.[65]

Titanium

Ti is the ninth most abundant element in the earth's crust. No evidence indicates that titanium is an essential element (see Chapter 31). In part because of the formation propensity of titanium oxide, the element is considered to be nontoxic. Average daily oral intake through food consumption is 0.1 to 1 mg/d, which accounts for more than 99% of exposure. Gastrointestinal absorption of titanium is low (approximately 3%), and most ingested titanium is rapidly excreted in the urine and stool. The total body burden of titanium is usually in the range of 9 to 15 mg, a significant portion of which is contained in the lung. Titanium dust entering the respiratory tract is nonirritating and is almost completely nonfibrogenic in humans.[66]

Titanium-containing alloys are used in artificial joints, prosthetic devices, and implants. Titanium dioxide allows osseointegration between an artificial medical implant and

bone. Despite their wide use, exposure to these materials has not been linked to toxicity. However, as implant wear occurs, a significant increase in detectable serum titanium becomes evident. Although titanium concentrations are not a measure of toxicity, they are useful in determining whether implant breakdown is occurring.[84] Serum titanium <1.0 ng/mL suggests that a prosthetic device is in good condition. Serum concentrations >3 ng/mL in a patient with a titanium-based implant suggest prosthesis wear. An increased serum titanium concentration in the absence of corroborating clinical information does not independently predict prosthesis wear or failure.

Vanadium

V is naturally found in minerals and rocks and is considered an essential element for mammals (see Chapter 31), although conclusive evidence for humans is lacking. V is recovered from minerals or is derived as a byproduct of iron, titanium, and uranium refining. Vanadium compounds are used in dyes, photography, and ceramics, and in the production of special glasses. V is also a component of many fiber mesh prosthetic devices.

The main source of V intake for the general population is food, with an estimated daily intake of 20 µg, of which most is not absorbed and excreted in the feces. Absorption through the inhalation route results in more effective uptake. The clearance half-life is not well documented, but it appears to be on the order of several days. V has been recognized as an occupational hazard for many years. Elevated atmospheric V concentration can result from burning fossil fuels with a high V content. Inhalation and ingestion are the primary exposure routes. V exposure can result in a metallic taste and so-called "green tongue." Sensitization has been known to result in asthma or eczema.

Because the kidney is primarily responsible for V elimination, increased serum concentrations are observed in dialysis patients and those with compromised renal function. Serum V values <1.0 ng/mL are typical; values >5.0 ng/mL indicate probable exposure. Elevated serum V concentrations have been observed in patients with joint replacement; concentrations are likely to be increased above the reference interval in patients with metallic joint prosthesis.[84] A modest increase (1 to 2 ng/mL) in serum V concentration is likely to be associated with a prosthetic device in good condition. Serum concentrations >5 ng/mL in a patient with a vanadium-based implant suggests significant prosthesis wear. Increased serum trace element concentrations in the absence of corroborating clinical information do not independently predict prosthesis wear.

Molecular diagnostics represents one of the most rapidly developing areas in clinical chemistry. Advances in the field have been made possible by our improved understanding of molecular biology and genetics and of their relationships with human diseases, and by the development of powerful technologies for analysis of nucleic acids.[21] The chapters in this section attempt to provide an overview of important advances in molecular diagnostics. Fundamental concepts in molecular biology are reviewed in this chapter. Molecular diagnostic techniques are discussed in Chapters 38 and 39. The subsequent chapters focus on key areas of molecular diagnostics, specifically, inherited diseases (see Chapter 40), identity assessment (see Chapter 41), infectious diseases (see Chapter 42), pharmacogenetics (see Chapter 43), and hematologic malignancies (see Chapter 44). Last, molecular diagnostic applications based on analysis of plasma nucleic acids are discussed in Chapter 45.

LANDMARK DEVELOPMENTS IN GENETICS AND MOLECULAR DIAGNOSTICS

Amazing developments in biotechnology have taken place in the late twentieth century. For example, we have witnessed dramatic progress in sequencing of the human genome, cloning of organisms, and progress in stem cell research and gene therapy. Many of these advances would not have been possible without the many earlier landmark discoveries that unveiled the mysteries of genetics and paved the way for modern molecular diagnostics.[32] Genetics began modestly when Mendel experimented with garden peas. His findings, published in 1866 and suggesting the concepts of alleles and genes as units of heredity, essentially captured the most fundamental concepts in inheritance. In 1910, Morgan revealed that the units of heredity are contained within chromosomes, but it was Avery in 1944 who confirmed through studies on bacteria that it was DNA that carried the genetic information. Franklin and Wilkins studied DNA by x-ray crystallography, which subsequently led to unraveling of the double-helical structure of DNA by Watson and Crick in 1953. In the 1960s, Smith demonstrated that DNA can be cleaved by restriction enzymes, which Arber had discovered earlier; this facilitated the subsequent development of recombinant DNA technologies. Nathans furthered the work on restriction enzymes and was the first to construct a genetic map. In 1975, the Southern blot was invented, which allowed the detection of specific DNA sequences. Soon after, in 1977, DNA-sequencing methods were developed, and the first complete DNA sequence of an organism, a bacteriophage, was published. Cloning of the first human gene mutation, a β-thalassemia mutation, was achieved by Orkin and associates in 1980. Prenatal genetic diagnosis of sickle cell disease was shown to be feasible by Chang and Kan in 1981. Mullis and coworkers developed the polymerase chain reaction in 1985. The existence of functional small noncoding RNAs (ncRNAs) in organisms was first realized in 1993. DNA microarrays, which allow the simultaneous interrogation of many DNA/cDNA loci by nucleic acid hybridization, became a reality in 1996. Remarkably, the draft human genome sequence was released in 2001 and completed in 2003.[33,60] Massively parallel genomic sequencing became an accessible laboratory tool from 2005[41] and vastly accelerated the pace of molecular biology research in a way that was not achievable before.

This brief account describes a fraction of the many great discoveries that shaped modern genetics and molecular diagnostics. Although the explosive accumulation of genetic knowledge has translated into escalating clinical demands for molecular diagnostics, improved molecular diagnostic techniques have reciprocally led to the discovery of new genetic knowledge. An understanding of the fundamental aspects of molecular biology as outlined in this chapter is required for the effective implementation and interpretation of molecular diagnostics. This chapter begins with an overview of the essential principles of molecular biology, which is followed by a more in-depth discussion of key aspects, starting with the Watson and Crick model of DNA, through to discussion of the greatest biotechnological achievement of

humankind of our time—the Human Genome Project—and beyond.

THE ESSENTIALS

On the simplest level, genes can be defined as segments of deoxyribonucleic acid (DNA) that encode for proteins or ribonucleic acid (RNA) products with biological functions. DNA is a biological substance that carries genetic information and is a polymer of nucleotides or bases. Genetic information is reproduced from parent to daughter cells during cell division through the process of DNA replication. When genes are expressed ("switched on"), the DNA sequence is transcribed into RNA. RNA molecules (RNAs) are polymers of ribonucleotides that exist in a number of functional forms. RNA molecules that act as intermediates for protein production are termed *messenger RNA (mRNA)*. RNA molecules that serve a direct biological function without coding for a protein are collectively termed *ncRNAs*.[58] mRNA is the product of a transcribed nucleotide sequence and is in turn translated into a protein, which is a polymer of amino acids. Each amino acid is encoded by a triplet nucleotide code, termed a *codon*. The human genetic code comprises 64 codons encoding for 21 amino acids and 3 stop codons. mRNA codons are read by the anticodon regions of transfer RNA (tRNA) molecules, which are small RNAs that bring the corresponding amino acid to the growing polypeptide chain. The polypeptide chain is synthesized by ribosomes, which are macromolecular complexes containing ribosomal RNA (rRNA) and a protein component with catalytic function.

Most human cells contain two full copies/versions of the haploid human genome, which is organized and packaged into 23 pairs of chromosomes (diploid genome). A chromosome is a highly ordered structure of a single DNA molecule with specialized structural features, namely, one centromere and two telomeres. Every individual inherits one copy/version of the human genome from his or her father and another from the mother. Thus, the human genome contains two copies, termed *alleles*, of each autosomal gene. Although a gene sequence may encode for a specific protein or RNA with defined functions, alleles of genes may demonstrate sequence variations that in turn contribute to variations in the functional characteristics of the gene product between individuals. The primary nucleotide sequences of the two gene alleles form the *genotype*, whereas the expressed function or biological effect of the gene product is termed the *phenotype*. Thus one could study a human disease or trait at the genetic level through determination of the allelic sequence of a gene (i.e., genotyping) or at the functional level (i.e., phenotyping). Examples of phenotyping include the investigation of enzyme concentrations or activities, ABO blood groups, electrophoretic mobility of hemoglobin variants, RNA expression levels, and others. The choice of genotyping or phenotyping for making a diagnosis depends on the specific diagnostic application and the strength of the association between a genotype and its consequential phenotype.

NUCLEIC ACID STRUCTURE AND ORGANIZATION

An intimate relationship has been observed between nucleic acid structure and function. The physiologic function of nucleic acid is facilitated by its "strategically designed" structure. Although an alteration in the structure of nucleic acids would lead to an altered function, an altered function, on the other hand, may be seen as an altered structure. Thus, a discussion of nucleic acid structure is pertinent to further discussion on nucleic acid function.

Molecular Compositions and Structures of DNA and RNA

DNA

The physicochemical properties and functions of nucleic acids are largely governed by the compositions and structures of DNA and RNA. A single molecule of DNA is a polymer consisting of a backbone of invariant composition and side groups arranged in a variable sequence (Figures 37-1 and 37-2). The polymer is synthesized from monomers (nucleotides) composed of the sugar deoxyribose, a phosphate residue, and a purine or pyrimidine base. The purines are adenine (A) and guanine (G), and the pyrimidines are cytosine (C) and thymine (T) (see Figure 37-1). The four nucleotide building blocks of DNA are abbreviated dATP (deoxyadenosine-triphosphate), dGTP (deoxyguanosine-triphosphate), dCTP (deoxycytidene-triphosphate), and dTTP (deoxythymidene-triphosphate), respectively. Nucleotides are joined by phosphodiester bonds that link the 5′-phosphate group of one to the 3′-hydroxyl group of the next (see Figure 37-2). No 3′-3′ or 5′-5′ linkages are present; thus the sugar and phosphate moieties compose the nonspecific portions of the molecule. The sequence of the bases varies from molecule to molecule and uniquely identifies each DNA polymer, which, as discussed later, determines the identity and function of the protein or RNA products that the DNA encodes.

Although the purines and pyrimidines are of different compositions and sizes, when in the proper orientation, adenine forms two hydrogen bonds with thymine, and guanine forms three hydrogen bonds with cytosine, to form planar structures of similar dimensions (see Figure 37-1). This combined with the fact that the base portion of each nucleotide is hydrophobic contributes to the energetically favorable secondary structure of DNA as it is found in its native form: a right-handed, double-stranded helix. The planar base pairs stack in the inside of the helix, 10 bases per turn, whereas the hydrophilic sugar-phosphate backbone forms noncovalent bonds with surrounding water molecules. For the two DNA polymers to form the proper hydrogen bonds between the bases, two requirements must be fulfilled: the polymers must run in opposite directions (antiparallel) as defined by the free hydroxyl groups at each end (3′-5′ vs. 5′-3′), and the sequences of each molecule must be such that A:T and G:C hydrogen bonds are always formed (base

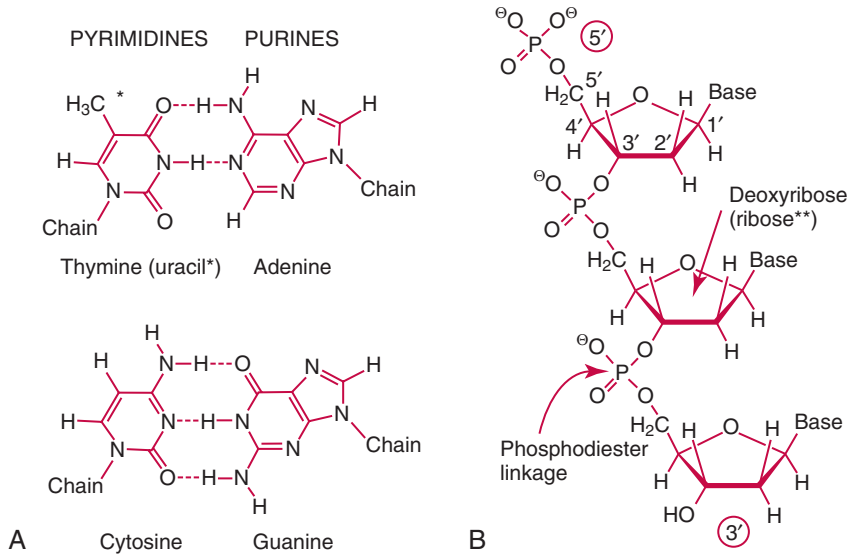

Figure 37-1 A, Purine and pyrimidine bases and the formation of complementary base pairs. *Dashed lines* indicate the formation of hydrogen bonds. (*In RNA, thymine is replaced by uracil, which differs from thymine only in its lack of the methyl group.) B, A single-stranded DNA chain. Repeating nucleotide units are linked by phosphodiester bonds that join the 5′ carbon of one sugar to the 3′ carbon of the next. Each nucleotide monomer consists of a sugar moiety, a phosphate residue, and a base. (In RNA, the sugar is ribose, which adds a 2′-hydroxyl to deoxyribose.)**
(Modified from Piper MA, Unger ER. Nucleic acid probes: a primer for pathologists. Chicago, Ill: ASCP Press, 1989.)

pairing). Two DNA strands that meet this requirement are called *complementary*.

Owing to base pairing and the double-helical conformation, double-stranded DNA (dsDNA) is an exceptionally stable molecule. Retention of base pairs in the inner portion of the helix prevents disruption by water molecules. The helical conformation places each monomer in an identical orientation within the molecule and forms the same secondary bonds as every other monomer. This secondary bonding contributes to the overall stability. Because the base pairs are of similar size, the helix retains a constant angle of rotation and avoids distortion. All of these features dictate that all dsDNA molecules, regardless of base sequence, retain the same shape and size within a pH range of approximately 4 to 9. Outside these limits, the base pair bonds are disrupted and the helix unwinds.

RNA

RNA is chemically very similar to DNA but differs in important ways. The sugar unit is ribose with an added hydroxyl group at the 2′ position, and the methylated pyrimidine uracil (U) replaces thymine. RNA exists in various functional forms but mostly as a single-stranded polymer that is much shorter than DNA and that has an irregular three-dimensional structure. Despite their irregular shape, RNA conformations are not random structures, and the folding mechanism of RNA molecules is complex.[1,53] The secondary structure adopted by an RNA molecule is to a large extent related to its nucleotide sequence. RNA molecules fold sequentially from 5′ to 3′ to form stable submotifs dictated by their primary sequence. One such example is the hairpin loop structure of precursor miRNAs (see below section on ncRNAs). RNA molecules may adopt further tertiary folding. An RNA molecule has the potential to be folded into a number of different conformations, but usually only one conformation is functional.[53] The folding process is influenced by ions, cofactors, and proteins.[1] Once an RNA molecule adopts a conformation most favored by its immediate cellular environment, it rarely switches to another conformation.[1] RNA molecules can further interact with other RNA or protein molecules to form complex quaternary structures, such as ribonucleoproteins, that are essential to certain cellular processes.

Chromosome Structure

DNA molecules are extremely long and in the eukaryotic cell are maintained in orderly and compact three-dimensional structures. Each diploid human cell contains two full sets of the human genome, with each copy consisting of approximately 3.2 billion nucleotides. This vast amount of genetic material is organized into 23 homologous chromosome pairs, with each pair contributed by a homolog of maternal origin and one of paternal origin. The two chromosomes of each

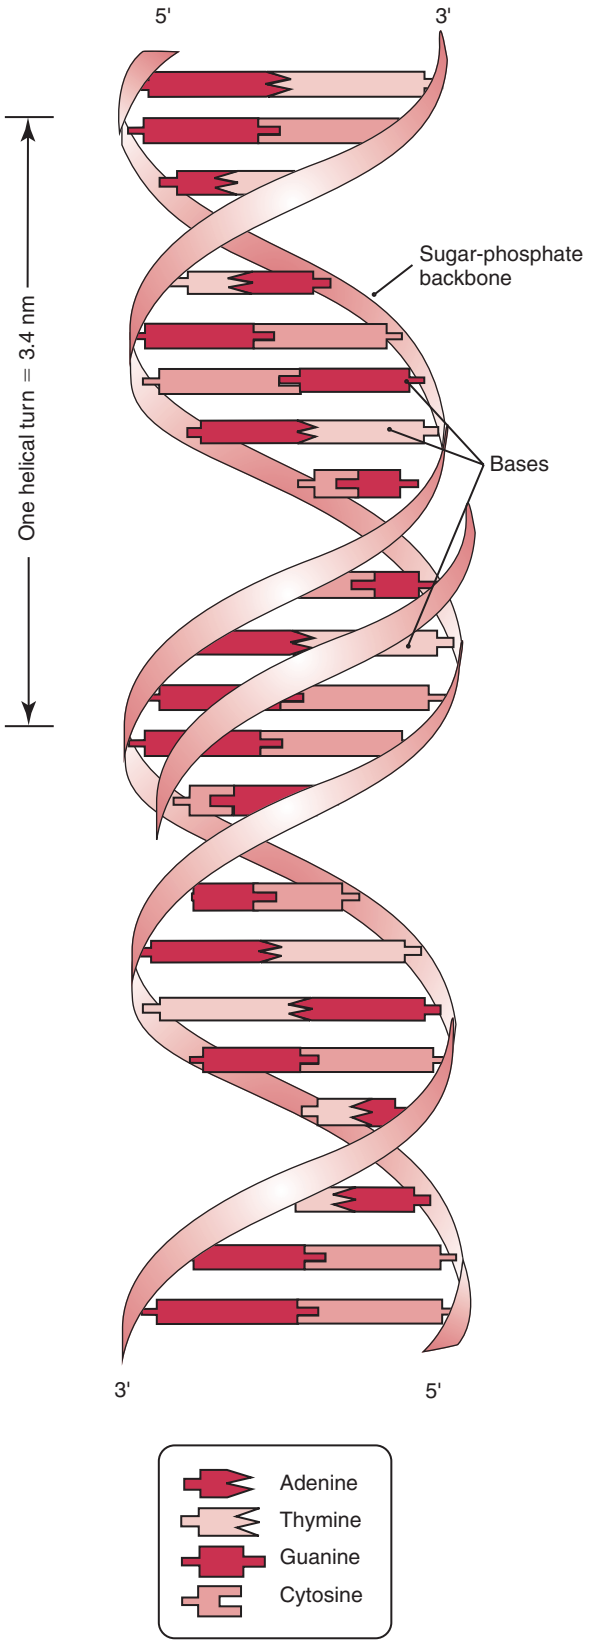

Figure 37-2 The DNA double helix, with sugar-phosphate backbone and pairing of the bases in the core-forming planar structures. *(From Jorde LB, Carey JC, Bamshad MJ, editors: Medical genetics, 4th edition, Philadelphia: Mosby, 2010.)*

pair are similar (homologous) and, except for the sex chromosomes (X and Y), contain the same genes arranged in the same sequence. Each chromosome is a highly ordered structure of a single dsDNA molecule, compacted many times with the aid of structural DNA-binding proteins, for example, histones (Figure 37-3). The chromosomes are in their most compact state and appear as finger-like structures during metaphase of the cell cycle. A primary constriction, the centromere, is also notable on each chromosome (see Figure 37-3). The ends of the chromosomes are termed the *telomeres* (see Figure 37-3). Both centromeres and telomeres have specialized functions, which are discussed later. The nonsex chromosomes, the *autosomes*, in the human genome are numbered in order of decreasing size (except chromosomes 21 and 22). Chromosome 1 is 250 Mbp long, and chromosome 21 is 48 Mbp long. The chromosomal arrangement of human DNA not only allows packaging of the vast human genome into the limited physical dimensions of the cell nucleus, but also governs one of the mendelian laws of inheritance on independent assortment whereby genes located on different chromosomes recombine at random from one generation to the next.

Chromatin Packing

Nuclear DNA in conjunction with its associated structural proteins, including histone and nonhistone proteins, is known as chromatin. Chromatin is arranged and organized in a hierarchical fashion whereby the degree of packing or condensation increases with higher levels of structural organization.[9,23,51] The nucleosome represents the most basic level of chromatin organization and is present as repeated units along the full length of each chromosome. Each nucleosome unit consists of a nucleosome core particle and 20 to 80 base pairs of linker DNA, which spans between adjacent nucleosomes, resembling what has been referred as "beads on a string" (Figure 37-4). A nucleosome core particle involves 147 base pairs of dsDNA tightly wound 1.65 times around an octamer of histone proteins, two each of four histone proteins, namely, H2A, H2B, H3, and H4.[9,23] Amino termini or "tails" of these histone molecules protrude from the nucleosomal core. The histone tails are subjected to covalent modifications, including acetylation, methylation, phosphorylation, and ubiquitination.[34] The linker DNA segments are associated with the linker histone H1. Nucleosomes are further packed in successive levels of complexity by up to a factor of 10,000[23]; in the most compact stage, chromatin appears as discrete mitotic chromosomes seen in the metaphase of a cell cycle, as described earlier. The orderly process of chromatin condensation involves DNA methylation, histone modifications, ncRNAs, and sequence-specific DNA binding proteins.

Chromatin packing serves the function of containing the genome within the nucleus, but this could potentially render the genetic code inaccessible to various cellular machineries.[23] However, this is not the case because chromatin condensation is not a static process but a dynamic one that changes in a coordinated fashion during the cell cycle. In general, chromatin is much less condensed during interphase,

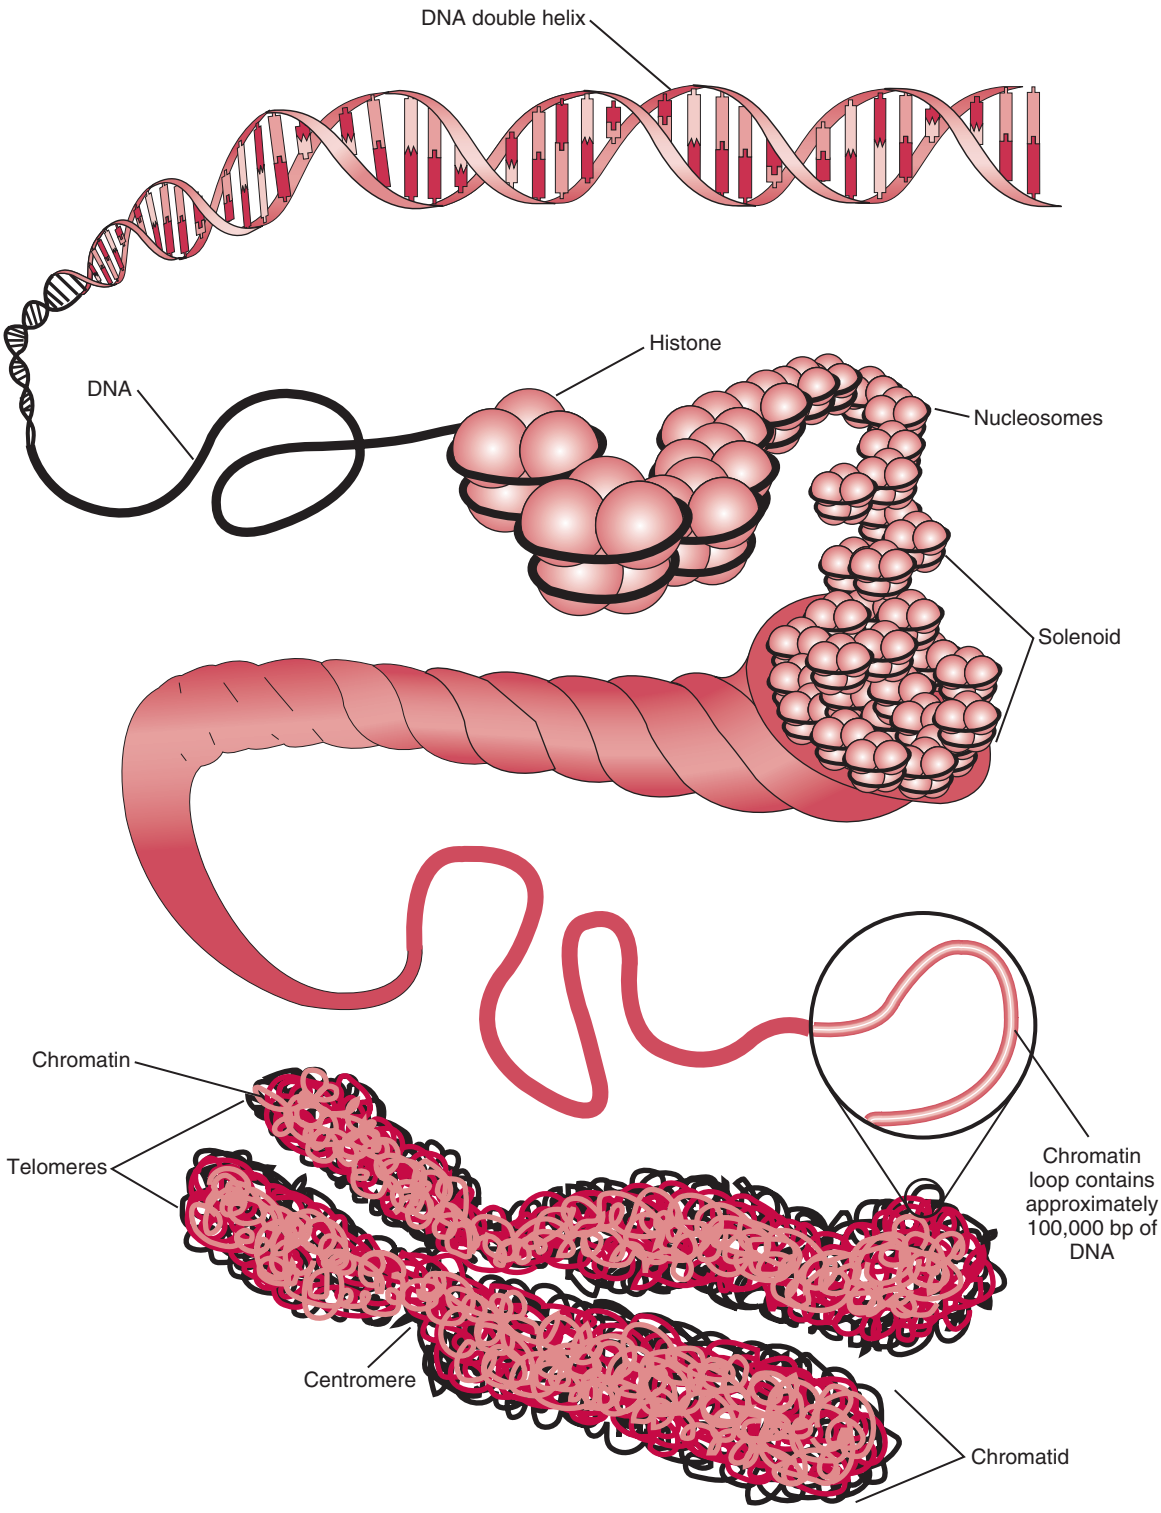

Figure 37-3 Structural organization of human chromosomal DNA. Double-stranded DNA is wound around histones to form nucleosomes. Nuclear DNA in conjunction with its associated structural proteins is known as *chromatin*. Chromatin in its most compact state forms chromosomes. The primary constriction of a chromosome is the centromere, and the chromosome's ends are the telomeres. *(From Jorde LB, Carey JC, Bamshad MJ, editors: Medical genetics, 4th edition, Philadelphia: Mosby, 2010.)*

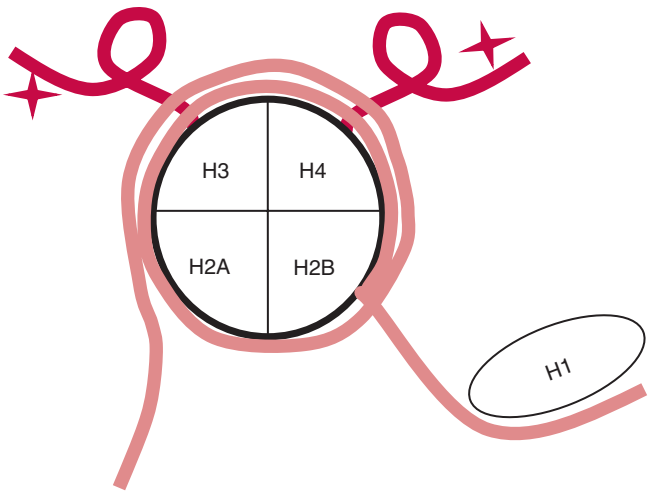

Figure 37-4 Schematic illustration of a nucleosome unit. A segment of DNA is wound around a nucleosome core particle consisting of an octamer of two each of the histone proteins H2A, H2B, H3, and H4. Tails with modifications *(indicated by a red star)* are shown to protrude from H3 and H4. Adjacent nucleosomes are separated by a segment of linker DNA and the linker histone, H1.

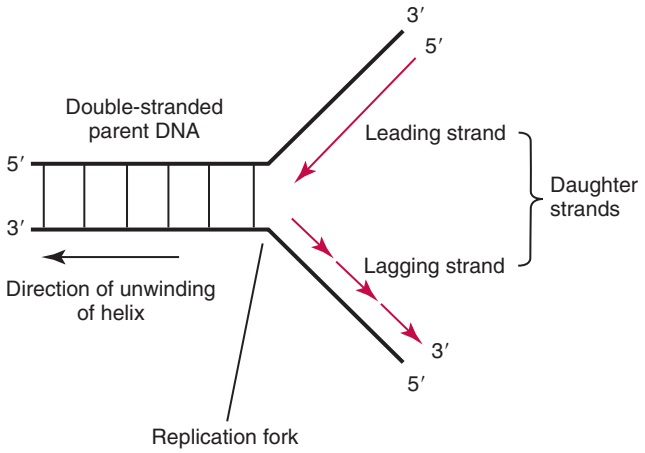

Figure 37-5 DNA replication. Double-stranded DNA is separated at the replication fork. The leading strand is synthesized continuously, while the lagging strand is synthesized discontinuously but is joined later by DNA ligase.

at which time DNA is replicated. The extent of chromatin condensation during interphase varies among regions of the genome. Genomic regions that are rich in genes generally open up to become less compactly organized during interphase and are termed *euchromatin*. Regions that are gene-poor or that span transcriptionally silent genes remain mostly densely packed and are called *heterochromatin*. Heterochromatin is important for maintenance of specialized chromatin structures, inactivation of the X chromosome in females, and maintenance of genome stability by stabilizing repetitive DNA sequences.[19,30] Eukaryote chromosomes contain two specialized regions of heterochromatin, namely, centromeres and telomeres. Centromeres play an important role in directing the movement of chromosomes between daughter cells during cell division.[2] Poor execution of this process could result in incorrect segregation of chromosomes, leading to chromosomal gains or losses in the daughter cells. Telomeres contain repetitive nucleotide sequences that are located on and protect the ends of chromosomes. Alterations in the lengths of telomeres contribute to aging and cancer development.[5] Genomic regions that remain condensed during the cell cycle, such as centromeres, telomeres, and the inactivated X chromosome in female cells, are termed *constitutive heterochromatin*. On the contrary, some other heterochromatin domains are scattered throughout the genome and are able to respond dynamically in various cellular states. Those regions are termed *facultative heterochromatin* and are associated with regulation of gene expression.[19,30] Functional implications of the structural organization of chromatin will be discussed further in the following sections.

NUCLEIC ACID PHYSIOLOGY AND FUNCTIONAL REGULATION

Nucleic acids form the repository for hereditary information and provide the means of translating that information into the cellular machinery of life. *Gene expression* refers to the process of transforming the genetic blueprint into functional products that participate in various biological processes of a cell. Faithful reproduction of the DNA content from parent to daughter cells during cell division is termed *replication*. A gene is expressed through transcription of its DNA sequence into RNA. mRNAs encode for proteins, and a polypeptide is synthesized through translation of the mRNA base sequence into the corresponding amino acid sequence.

Replication

Each time a cell divides, the entire DNA content of that cell must be faithfully duplicated, so that the total complement of hereditary information (the human genome) is retained in each daughter cell. This process is called replication. Owing to the laws of base pairing (i.e., adenine pairs only with thymine, and guanine only with cytosine), the sequence of a single strand of DNA dictates the sequence of its complementary strand. In replication, each of the two parent strands of a dsDNA molecule serves as the template for the synthesis of a daughter strand (Figure 37-5). The process is called *semiconservative* because each of the duplicated dsDNA molecules produced in this manner is composed of one parent (conserved) strand and one daughter strand. For replication to occur, the original double-stranded helix must be separated. This is an energetically unfavorable event that is accomplished with a combination of DNA-specific proteins and enzymes, and synthesis of both daughter strands proceeds as the parent strands separate. Replication is initiated at multiple sites (origins of replication) during this process, but each origin of replication is used only once during a single cell cycle.

Daughter strands are synthesized by DNA polymerase III, an enzyme that reads the parent template and attaches nucleotides to the growing daughter strand according to the base pairing rules of dsDNA. DNA polymerase III begins synthesis at the replication fork (see Figure 37-5), the point of strand separation, with a short RNA primer that base pairs to the parent template. Later, this primer is excised and replaced with DNA by the DNA repair enzyme, DNA polymerase I. Because DNA polymerase III synthesizes DNA only in the 5′-3′ direction, one daughter strand, the leading strand, is synthesized continuously, whereas the other, the lagging strand, must be synthesized discontinuously in short segments (see Figure 37-5). Fragments on the discontinuous strand are then joined by the DNA ligase enzyme. Many other proteins are involved in unwinding and stabilizing the parent strands for synthesis, in protecting single-stranded regions, in recognizing initiation sites, and in synthesizing the RNA primer. In addition to synthetic capabilities, the DNA polymerases possess an exonuclease or "proofreading" function: when an incorrect nucleotide is added to the growing polymer, a conformational change brings the chain in contact with the exonuclease portion of the enzyme, which cuts out ("excises") the incorrect nucleotide. This helps maintain the integrity of the original DNA sequence. In fact, it has been estimated that one nucleotide error could occur for every 10^5 nucleotides incorporated into the growing strand. However, the proofreading function of DNA polymerase works in concert with a set of DNA repair mechanisms that detect and correct DNA replication errors in such a way that the resultant error rate of DNA replication is reduced to one error per 10^9 to 10^{10} nucleotides replicated.[39] Given that 3 billion base pairs are present in the human genome, about 0.3 to 3 errors occur per cell division.

Transcription

DNA carries information that specifies the production of RNA molecules and proteins that can execute biological functions. The segment of the genome that specifies the production of a functional product, that is, a protein or ncRNA, is termed a *gene*. In short, a gene is a functional unit of the genome. On the most basic level, the span of a gene encompasses the nucleotide sequence that specifies its ncRNA product or the amino acid sequence of its protein product. However, a series of processes determines the timing and rate of expression of each gene. Those processes that control gene expression act via regulatory regions of the genome. Thus, it is customary to define a gene to be inclusive of such associated regulatory elements.[17,49] An important regulatory region is the promoter of a gene, which, as will be discussed later, is the genomic region where regulatory factors act in concert to activate expression of said gene. Previously, it was generally thought that the promoter region laid immediately 5′ to the start of the protein-coding portion of a gene. Yet, recent evidence demonstrates that regions showing properties of a promoter could be found within the protein-coding portion of genes, toward the 3′ end, or lying at a substantial distance between coding sequences.[28] In addition, the same promoter region could trigger the expression of different DNA segments both 5′ or 3′ to it.[28] Hence, it has become increasingly difficult to precisely define the physical boundaries of individual genes.[17,49]

When a gene is expressed, the DNA sequence is first transcribed into RNA. The process of transferring the sequence information from DNA to RNA is called *transcription*. Regulation of transcription is the primary mechanism that cells use to control gene expression.[59] Similar to replication, transcription requires separation of duplex DNA strands and uses a polymerase to copy the template DNA strand. For transcription, the polymerase is RNA polymerase II, which first binds to specific sequences in the promoter, called the *core promoter*, upon initiation of gene expression. Core promoters that have been identified to date generally occur within a hundred bases around the initiation site of transcription, known as the *transcription start site*, where the first ribonucleotide unit is paired with the template DNA (uracil pairs with adenine). Several nucleotide sequence motifs or patterns have now been recognized among core promoters.[26] For example, one of the best studied core promoter motifs, the TATA box, refers to a short stretch of nucleotides rich in thymine and adenine in repeating patterns. It is typically located between 24 to 31 nucleotides "upstream" (i.e., at the 5′ end) of the transcription start site.[59] Some other core promoter elements are located just downstream to the transcription start site. Research has suggested that the various core promoter elements may have different strength and efficiency in activating gene expression.[59]

To initiate transcription, a series of protein cofactors, known as *general transcription factors*, is required to bind to RNA polymerase II to form an assembly known as the *preinitiation complex*, which, in turn, acts on the gene by interacting with the core promoter.[59] Other regions of DNA known as *activators* or *coactivators* may interact with the preinitiation complex to stimulate or repress transcription.

Once transcription is activated, RNA polymerase II moves along and unwinds the DNA double helix. The growing RNA transcript pairs with one of the DNA strands, called the *template*, where RNA polymerase II adds complementary ribonucleotide triphosphates in a 5′ to 3′ direction. It is now known that both DNA strands of the double helix can act as the template for RNA transcription.[4] For example, when the growing RNA transcript pairs with the antisense (–) DNA strand, the resultant RNA molecule is a copy of the sense (+) strand of DNA, and vice versa. Natural antisense transcripts (i.e., RNA transcripts that are copies of the antisense DNA strand) have been better known only in recent years.[45] Both protein-coding and non–protein-coding RNAs have been reported to be natural antisense RNAs.[14]

RNA elongation continues until chain termination occurs. The precise signaling mechanism for chain termination still is not well understood. The RNA transcript quickly detaches from the template DNA because restoration of the DNA-DNA duplex is energetically more favorable than is retention of the DNA-RNA hybrid or a segment of single-stranded DNA. The newly synthesized RNA molecule then undergoes further

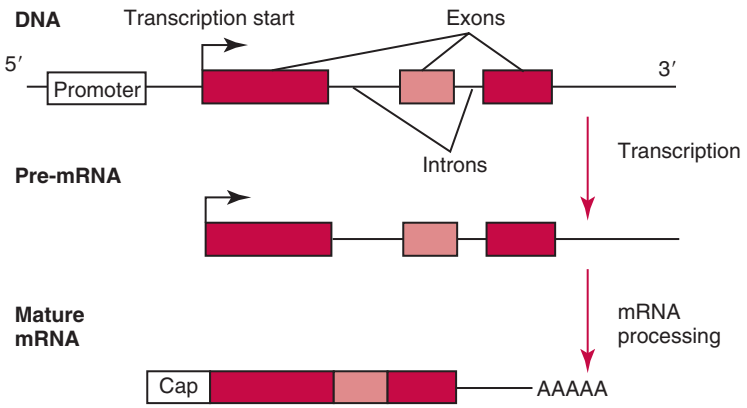

Figure 37-6 DNA transcription and mRNA processing. A gene that encodes for a protein contains a promoter region with variable numbers of introns and exons. Transcription commences at the transcription start site. Pre-mRNA is processed by capping, polyadenylation, and intron splicing and becomes a mature mRNA.

modification depending on its functional class. We shall discuss the fate of the ncRNAs in a later section of this chapter. Here we focus on describing subsequent processing of the protein coding RNAs, which are referred to as mRNA. First, the 5′ end of the RNA molecule is modified by the addition of 7-methylguanosine residues to form a structure called a *cap* (Figure 37-6). The 3′ end is modified by the addition of multiple adenine bases, called the *poly(A) tail* (see Figure 37-6). Both the cap and the tail are necessary for translation of mRNA into protein, and they protect the mRNA molecule from degradation by exonucleases. The coding region of a gene (i.e., segments that will contribute to the amino acid sequence of the protein) is divided into segments called *exons* interspersed with noncoding regions termed *introns* (see Figure 37-6). The number and size of introns and exons differ among genes. Excision or splicing of the noncoding introns is carried out by a molecular complex termed a *spliceosome*. These complexes are composed of multiple small nuclear ribonucleoprotein particles. Spliceosomes mediate the cleavage and ligation of RNA at specific recognition sequences, termed *splicing donor and acceptor sequences*. After the introns have been removed, the exons are juxtaposed to each other, forming a mature mRNA molecule (see Figure 37-6) that is transported into the cytoplasm, where protein translation takes place.

Translation

Translation is the process whereby the mRNA sequence directs the amino acid sequence during protein synthesis. Amino acids are the building blocks of a polypeptide chain. To date, 22 amino acids have been reported in nature. Each amino acid is specified by a three-nucleotide sequence known as a *codon*. Because 64 possible codons are known, most amino acids are specified by more than one codon. One codon, UAA, does not code for amino acids but always signals termination of protein synthesis (a stop codon). UGA codes for a stop or for selenocysteine, and UAG codes for a stop or for pyrrolysine, depending on adjacent sequences or RNA-binding proteins. With the exception of pyrrolysine, which is the most recently identified amino acid and so far has been found in proteins of bacteria and archaea only, all other amino acids are involved in human protein synthesis.[38] The full menu of codon sequences forms the genetic code, which is shown in Table 37-1.

Translation takes place on ribosomes, which are ribonucleoprotein complexes that function as protein synthesis factories. A ribosome binds to the initiation site on mRNA to form an initiation complex. Protein synthesis begins at the translation initiation codon, AUG, which codes for the amino acid, methionine. The region of the mRNA molecule preceding the initiation codon is termed the *5′ untranslated region (5′UTR)*. The initiation codon and each subsequent codon are "read" by tRNA, short RNA molecules that have a sequence complementary to an amino acid codon (anticodon) and are bound to the amino acid molecule specified by the codon.[3] As synthesis proceeds, the appropriate tRNA anticodon base pairs with the next mRNA codon and thus brings this amino acid bound to it into close proximity of the growing peptide chain. An enzyme on the ribosome then catalyzes the formation of a peptide bond between the amino acid and the growing peptide chain. The previous tRNA is released and the next tRNA is added. The ribosome moves along the mRNA until a stop codon is reached and synthesis is complete. The ribosome and the protein product are then dissociated from the mRNA. More than one ribosome can move along an mRNA molecule at a time, forming a polyribosome. The rest of the mRNA molecule downstream to the stop codon is termed the *3′ untranslated region (3′UTR)*.

Genetics and Epigenetics

Genetic and epigenetic phenomena are intimately related and work in concert to bring about the normal development and functioning of each cell and the whole organism. In general, genetic events are related to the sequence information of DNA, and thus include the consequences of transmission of a particular DNA sequence (e.g., inheritance of DNA

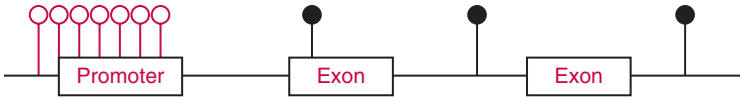

Figure 37-7 Normal DNA methylation pattern in the human genome. Sites of CpG dinucleotides are indicated by *circles*. CpG islands in association with gene promoters are generally unmethylated, but isolated CpG dinucleoctides are methylated. *Filled circles*, methylated; *open circles*, unmethylated.

TABLE 37-1 The Genetic Code (Translation of mRNA to Amino Acids During Protein Synthesis)

Nucleotide Position in the Codon					
1st	**2nd**	**3rd**			
		U	**C**	**A**	**G**
U	U	Phenylalanine	Phenylalanine	Leucine	Leucine
	C	Serine	Serine	Serine	Serine
	A	Tyrosine	Tyrosine	Stop	Pyrrolysine*
	G	Cysteine	Cysteine	Selenocysteine*	Tryptophan
C	U	Leucine	Leucine	Leucine	Leucine
	C	Proline	Proline	Proline	Proline
	A	Histidine	Histidine	Glutamine	Glutamine
	G	Arginine	Arginine	Arginine	Arginine
A	U	Isoleucine	Isoleucine	Isoleucine	Methionine
	C	Threonine	Threonine	Threonine	Threonine
	A	Asparagine	Asparagine	Lysine	Lysine
	G	Serine	Serine	Arginine	Arginine
G	U	Valine	Valine	Valine	Valine
	C	Alanine	Alanine	Alanine	Alanine
	A	Aspartic acid	Aspartic acid	Glutamic acid	Glutamic acid
	G	Glycine	Glycine	Glycine	Glycine

*The codon UGA can code for selenocysteine or stop, and the codon UAG can code for pyrrolysine or stop.

mutations or polymorphisms) or of acquisition of DNA sequence variations (e.g., accumulation of somatic mutations in aging or cancer development). These pathologies are discussed in some of the subsequent chapters. On the other hand, a broad definition of epigenetics encompasses processes that alter gene function or its interpretation by mechanisms other than those that rely on DNA sequence change.[44] Practically, epigenetics has evolved to include the study of DNA methylation, genomic imprinting, histone modifications, chromatin remodeling, ncRNA regulation, and others. Most of these processes add another dimension to gene expression control and thus play a role in all fundamental cellular events, including cell differentiation, cell growth, cell death, and DNA repair.

DNA Methylation

DNA methylation is possibly the most widely studied epigenetic phenomenon. It refers to the addition of a methyl group to the fifth carbon position of cytosine residues in CpG dinucleotides. CpG dinucleotides are present throughout the genome and may exist singly as an isolated CpG site or in clusters, termed *CpG islands* (Figure 37-7). Most CpG dinucleotides in the human genome are methylated; these include CpG sites within gene bodies, within intergenic regions, and in DNA repeat elements (see Figure 37-7).[57] Unmethylated regions of the human genome are mostly found at CpG islands located at the 5′ ends, in promoters or first exons of genes, and occasionally in some intergenic CpG islands.[12,22,57] However, it is noteworthy that not all gene promoters are associated with CpG islands, and not all promoter-associated CpG islands are unmethylated. About 56% of human genes have promoters with CpG islands.[57] Some 10% of promoter CpG islands are methylated.[12,22]

It has been well accepted that DNA methylation mediates the silencing of gene transcription. The methylation of gene promoters has been shown to hinder the association of methylation-sensitive transcription factors, thus preventing gene activation. Consequently, the promoters of actively transcribed genes are generally unmethylated, while silenced genes are associated with methylated promoters. Because gene expression varies between cell types, the profile of DNA methylation differs between cell and tissue types. Furthermore, a CpG island may be composed of varying arrangements of methylated and unmethylated CpG sites. Hence, a genomic region can be further described in relative degree of methylation using the term *hypomethylated* or

hypermethylated.[12] It has been suggested that stably silenced genes tend to be associated with densely methylated promoters, and hypomethylated gene promoters can potentially be activated.[57] Methylation of the nonpromoter regions of genes, on the other hand, is thought to suppress inadvertent transcription.[57] Furthermore, methylation of repeat elements in the genome helps to maintain chromosome stability by preventing translocations and insertions of transposons, which are repeat sequences that could randomly insert into the genome, causing gene disruptions.[13]

Because DNA methylation has implications for gene expression, aberrant changes in DNA methylation profiles may cause pathologies. For example, aberrant hypermethylation of gene promoters, particularly those of tumor suppressor genes, contributes to cancer development.[13] Hence, it is important that the DNA methylation pattern of a cell should be faithfully propagated to its daughter cells upon cell division. This process is executed by maintenance DNA methyltransferases (DNMT1).[25] DNMT1 is said to perform a "maintenance" role because the DNA methylation patterns inherited by somatic cells were originally laid down by other de novo DNA methyltransferases (DNMT3a and DNMT3b) in the early embryo.

After embryo fertilization, the genome becomes demethylated (except imprinted loci; see discussion later in this chapter) to pave the way for the establishment of developmentally related patterns of DNA methylation by de novo DNA methyltransferases. Genomic imprinting and gene dosage compensation of X-linked genes in females, termed *X-inactivation* or *lyonization*, are also mediated by DNA methylation. *Genomic imprinting* refers to the phenomenon whereby the function of each of the two alleles of a gene is determined by its parental origin. Differential methylation of the imprinted locus from the time of germ cell development allows recognition of the parental origin of imprinted alleles by cellular processes. The human insulin-like growth factor-2 H19 (IGF2-H19) locus on chromosome 15 is an example of an imprinted locus whereby the maternal allele is unmethylated and the paternal allele is methylated. Disomic inheritance of the paternal or maternal allele results in significantly different clinical outcomes, namely, Prader-Willi and Angelman syndromes, respectively (see Chapter 40).

X chromosome inactivation is an epigenetic phenomenon that occurs in female cells. Each female cell has two X chromosomes, and each male cell has only one X chromosome. The function of one of the X chromosomes in female cells is epigenetically silenced, so that the dosage of X chromosome genes in female and male cells is the same. Gene silencing on the inactive X chromosome is maintained by dense methylation of CpG island promoters. Within each female cell, either of the X chromosomes could be chosen for inactivation.

Histone Modifications

Hypermethylated CpG dinucleotides are also known to attract the binding of methyl-CpG binding proteins, such as methyl-CpG binding protein 2 (MECP2) and methyl-CpG binding domain proteins (MBD1 and MBD2), which further block the association of a number of transcription factors and thus block transcription.[24,34] It is now appreciated that these methyl-CpG binding proteins have the ability to recruit histone deacetylases, a phenomenon that leads to deacetylation of histones and ultimately represses transcription.

As discussed, histones are an integral part of nucleosomes, the basic repeating structural unit of chromatin. The amino termini of histone proteins can be modified post-translationally by processes that include acetylation, methylation, phosphorylation, and ubiquitination (see Figure 37-4).[29,34] Acetylation of the lysines on amino termini of histones H3 and H4 by histone acetyltransferases decreases histone-DNA interaction and improves accessibility of DNA to transcriptional activation. On the contrary, histone deacetylation by histone deacetylases promotes the formation of compact nucleosomes, leading to repression of transcription. Histone deacetylation is in fact a key component of the assembly of heterochromatin, the transcriptionally inactive chromatin.[19] Methylation of the ninth amino acid residue, lysine, on histone H3 generates a binding site for heterochromatin protein (HP1) and thus is another key event in heterochromatin formation. Phosphorylation of the tenth amino acid, serine, on histone H3 is important for chromosome condensation and mitosis.

Nucleosome Positioning and Remodeling

Besides histone modifications, the position of nucleosomes is known to affect the transcriptional activity of the corresponding region of DNA. It is now known that the positioning of histones is not an entirely random process. It has been demonstrated that nucleosome-free regions are present at the 5′ and 3′ ends of genes. The 5′ nucleosome-free region is thought to be the assembly point of the preinitiation complex for transcription, and the 3′ one is the location of transcription termination.[23] A nucleosome unit is located just upstream to the 5′ nucleosome-free region, and another nucleosome is located just downstream to it, close to the transcription start site. It has been observed that the location of the nucleosome nearest to the transcription start site is predictable and consistent.[23] Positioning of the nucleosomes farther downstream through the gene, however, is shown to be more random. In summary, it seems that mechanisms control the positioning of nucleosomes, so that their presence will not be inhibitory to the initiation of transcription.

During transcription, the nucleosomes along a gene undergo a series of changes successively. First, histones H2A and H3 are replaced by the histone variants, H2A.Z and H3.3. The histone tails would be acetylated and methylated. The nucleosome would then be repositioned laterally and ultimately evicted to clear the DNA for access by the transcription machinery.[23] The nucleosome may then return to the DNA after RNA polymerase II has passed through. Consequently, nucleosomes are dynamic structures that can be remodeled according to the transcriptional demands of the cell.

Noncoding RNAs

It was once thought that much of the transcriptional activity of the human genome was directed toward the production of proteins. Exons of protein-coding genes occupy only 1 to 2% of base pairs in the human genome.[28] Thus, the rest of the genome was previously thought to be "junk" DNA, serving no function, and was merely a fossil of our evolutionary past. The availability of innovative technologies in recent years has enabled researchers to study transcriptional activity or RNA expression on a genome-wide scale.[27] On the contrary, studies have revealed that almost the entire genome was transcribed.[4] Transcription takes place in both sense and antisense directions.[14,28] The same genomic region could serve as the template for many nonoverlapping or overlapping transcription units.[28] Most transcription units do not result in the production of a protein product. Researchers became aware that some of the transcribed RNA molecules serve a direct biological function. An increasing number of classes of such functional RNA molecules have been described; they are collectively termed *ncRNAs*.[58] In retrospect, rRNA and tRNA are the earliest classes of ncRNAs described. Most recently, a class of short ncRNAs, miRNAs, has become the focus of much research interest.

MicroRNA

Mature (i.e., functional) miRNAs are 21 to 24 nucleotides long. The first step in the miRNA biogenesis pathway involves the initial transcription of an RNA molecule in the nucleus by RNA polymerase II. The first transcript, termed the *primary miRNA*, may be derived from short introns or a longer primary transcript that subsequently gives rise to multiple mature miRNAs.[47] Regions of the primary miRNA that would ultimately contribute to sequences of the mature miRNA are typified by their adoption of a stem loop, also known as hairpin, configuration with imperfect base pairing between sequences on both sides of the stem. The primary miRNA is cleaved by an RNase III–like enzyme, Drosha. The resultant RNA molecule, which is approximately 70 nucleotides long, is termed the *precursor miRNA*. The precursor miRNA is exported to the cytoplasm of the cell, where another RNase III–like enzyme, Dicer, cleaves at the loop end of the molecule, thus generating a double-stranded RNA product. The double-stranded product of Dicer is 21 to 24 nucleotides long, consisting of a mature miRNA paired with its imperfect complementary strand, termed *miRNA*. Some evidence suggests that miRNA may serve some biological function, and the conclusion awaits further investigation.[11]

The mature miRNA detaches from its partner and is incorporated into the RNA-silencing complex (RISC), which includes one or more Argonaute proteins. The biological function of miRNA is effected through RISC. The miRNA pairs with the 3′ untranslated region of mRNAs, leading to repression of protein translation or mRNA degradation. The actual biological consequence is determined by the degree of complementarity (i.e., the degree of base pairing) between the miRNA and the target mRNA. mRNAs that can be influenced by a particular miRNA are referred to as the target mRNAs of the corresponding miRNA. More than 850 human mature miRNAs have now been discovered.[16] Because miRNAs can function via imperfect base pairing to mRNA, each miRNA can have an effect on multiple target mRNAs.

miRNAs modulate gene expression at the post-transcriptional level. Therefore, they are involved in many biological processes, including development and cell differentiation.[16] They regulate cell proliferation, apoptosis, and maturation. Because of their important regulatory role, aberrant expression of miRNAs has been reported for a myriad of diseases involving, for example, the cardiovascular, neurologic, musculoskeletal, endocrinologic, and immunologic systems and others.[16] More important, aberrant miRNA expression has been implicated in carcinogenesis.[16] Their association with pathologies, coupled with realization of the presence of miRNAs in plasma and serum, makes them attractive candidate biomarkers for disease diagnosis and monitoring.[6,10]

Other ncRNAs

Besides miRNA, several other novel classes of ncRNAs have been discovered. In general, the ncRNA classes are subdivided into two groups—short and long ncRNAs—based on their nucleotide lengths, using an arbitrary cutoff of 200 bases.[58] Other than miRNAs, short ncRNAs that have been described include small interfering RNAs (siRNAs), which are 21 to 22 nucleotides long and are produced by Dicer cleavage of perfectly complementary double-stranded RNA molecules. siRNAs complex with certain Argonaute proteins and are involved in gene regulation, transposon control, and viral defense.[58] Piwi-interacting RNAs (piRNAs) are 26 to 30 nucleotides long and function in the germline to regulate transposon activity and the chromatin state.[58] piRNAs are derived not from Dicer cleavage but from successive Argonaute cleavage of long ncRNAs. Promoter-associated RNAs (PASRs) and transcription initiation RNAs (tiRNAs) are 20 to 200 nucleotides and 18 nucleotides long, respectively.[58] They are transcribed from promoters and transcription start sites and may be involved in regulating gene expression.

Long ncRNAs include a broad range of transcripts longer than 200 nucleotides and may be as long as 100 kb.[42,58] Some of these long ncRNAs could be 5′ capped, 3′ polyadenylated, and spliced like mRNAs. Because this is a heterogeneous group of transcripts, their reported functions are wide ranging and include modulation of chromatin architecture, regulation of gene expression, and others.[42,58] Long ncRNAs have been shown to regulate expression of protein-coding genes by modulating histone methylation and chromatin accessibility.[58] Long ncRNAs may exert biological effects directly or as an intermediary by acting as the precursor of multiple small ncRNAs. For example, the better known long ncRNA, *XIST*, is a transcript that is expressed exclusively from the inactive X chromosome with a key role in initiating the process of X chromosome inactivation. *XIST* literally coats the X chromosome that is destined to be inactivated

and suppresses transcriptional activity.[36] However, besides acting directly, the corresponding transcript in mice, *Xist*, has been shown to anneal with its antisense partner, *Tsix*, another long ncRNA. The *Xist-Tsix* duplex is further cleaved by Dicer to produce siRNAs, which, in turn, are involved in epigenetic modifications that maintain gene silencing on the inactive X chromosome.[46] In summary, much remains to be learned about the roles of ncRNAs in physiology and pathology.

BEYOND THE NUCLEAR GENOME

The Mitochondrial Genome

Up to this point, we have focused our attention on the nuclear genome only. Yet, in fact, it is not the only genome in the cell; the mitochondrial genome is the other important genetic component of eukaryotic cells. The human mitochondrial genome is a circular piece of DNA 16.5 kb in length. Mitochondrial DNA is transmitted between generations by maternal inheritance, with the mitochondria coming from the oocytes and not (usually) from sperm. Multiple copies of mitochondrial DNA are present within each mitochondrion, and each cell contains a variable number of mitochondria, depending on the energy requirements of the particular cell type. Thus certain cell types may contain up to several thousand copies of mitochondrial DNA. This greater abundance, compared with that of nuclear DNA, makes mitochondrial DNA attractive for tests for which sample DNA is limited (e.g., crime scenes, pathogen detection, paleontology). Mitochondrial DNA is double-stranded for most of its length, except at the replication and transcription control region (the D-loop). Unlike the nuclear genome, the mitochondrial genome is not packaged into nucleosomal units. Instead, it has a unique structural organization. It encodes for 13 polypeptides, all involved in the oxidative phosphorylation pathway; two ribosomal RNAs (rRNAs); and all of the 22 tRNAs required for mitochondrial protein synthesis. Several other proteins are also required for normal mitochondrial function and are encoded by nuclear genes.

The mutation rate of mitochondrial DNA is 10 to 20 times higher than that of nuclear DNA. This high rate has been viewed as resulting from the poor fidelity of mitochondrial DNA polymerase. Germline mutations in the mitochondrial genome generally lead to neurodegenerative and/or myopathic disease, such as MELAS (myopathy, encephalopathy, lactic acidosis, and strokelike episodes) and Leber's hereditary optic neuropathy. Somatic mutations, on the other hand, are associated with aging and cancer development.[61] Consequent to the accumulation of sequence variations, more than one population of mitochondrial DNA sequences may be present in a cell. This state is termed *heteroplasmy* as opposed to *homoplasmy*, in which the cell contains a homogeneous population of mitochondrial genomes. When genetic analysis is performed for mitochondrial DNA, a note of caution is warranted on potential problems related to the presence of nuclear pseudogenes, which are DNA segments in the nuclear genome with significant homology to the mitochondrial genome.[64] The close resemblance of the nuclear and mitochondrial DNA segments may result in false-positive detection of mitochondrial DNA sequences; thus the specificity of polymerase chain reaction (PCR) systems for mitochondrial DNA detection needs to be carefully evaluated. Disorders associated with mitochondrial DNA and tests for the disorders are discussed in Chapter 40.

Circulating Nucleic Acids

Besides being confined within cellular boundaries, nucleic acid molecules are present in the blood circulation. It is now known that cell-free DNA and RNA molecules exist in human plasma. DNA, RNA, miRNA, and methylated DNA sequences derived from tumors, the unborn fetus, transplant donors, and traumatized tissues have been found in the plasma of cancer patients, pregnant women, transplant recipients, and patients suffering acute pathologies, respectively. Because cell-free nucleic acid molecules could be sampled simply through collection of a peripheral blood sample, the potential for developing molecular diagnostic applications based on their detection is vast. For details, the reader is referred to Chapter 45.

UNDERSTANDING OUR GENOME

Evident from the discussion so far, our understanding of the structure and function of the human genome has vastly expanded over the past decade. This is a consequence of the availability of high-throughput technologies that allow scientists to study almost every aspect of the human genome on a genome-wide scale. For example, both sequencing and hybridization techniques that allow the interrogation of nucleic acid pools from the entire genome have been extensively employed in research. In terms of sequencing, the so-called next-generation sequencers decode millions to billions of nucleotide fragments in a massively parallel fashion and are capable of producing giga bases of sequence output in a matter of days.[43] Regarding hybridization techniques, high-density microarrays with probes carpeting the entire genome, referred to as *tiling arrays*, are readily available.[18] Both sequencing and hybridization techniques can be coupled with various sample preparation protocols for analysis of pools of DNA, RNA, or complementary DNA (DNA generated by reverse-transcribing RNA) from the entire genome or subsets enriched with exon sequences, transcription factor–binding sites, methylated CpG sites, short RNAs, polyadenylated RNAs, and so on. Each of these experiments generates vast quantities of data. Basic management and analysis and further interpretation of such large data sets require the use of high-throughput computing. Hence, the field of bioinformatics has flourished and become an essential and fundamental component of life science research.[48]

The first of the whole genome scale project tackled by humankind was the Human Genome Project. It is the biggest biological project completed to date. Apart from its ambitious goal of deciphering the 3 billion base pairs that make up the human genetic code, it also represents a model for the planning, organization, and execution of large-scale biological

projects.[7,8] The first serious discussion of the feasibility of such a project can be traced back to the mid-1980s. It was visionary of early proponents to conceive of the project before the advent of high-throughput sequencing technologies. In fact, the proposal was suggested just years after the invention of DNA sequencing in 1977. Based on technology available at the time, sequencing of the human genome would be a mammoth task, requiring a multinational effort. In 1988, a special committee of the U.S. National Research Council of the U.S. National Academy of Sciences formulated a 15-year human genome project, costing some $200 million a year. A genetic map with 1cM resolution was accomplished in September 1994. A physical map involving 52,000 sequence-tagged sites (STSs) was completed in October 1998. The final journey to completion of this project was marked by a highly publicized race between a publicly funded group of investigators and a private effort. The public effort, undertaken by the International Human Genome Sequencing Consortium, consisted of investigators from 20 centers located in six countries: the United States, the United Kingdom, Japan, China, France, and Germany. Completion of a draft sequence was announced on June 26, 2000, and it was published in two landmark papers, one from the public team and one from the private team, in February 2001.[33,60] The final sequence was accomplished in April 2003, with 99.99% sequencing accuracy.

The Human Genome Project has far reaching implications. Technologically, it accelerated the pace of development of sequencing technologies, computational tools for alignment of stretches of DNA reads, and organization of the data. Biologically, the human race has produced a copy of its genetic code. However, many more questions stem from having the reference human genome sequence. For example, how different is the genome between individuals? With the reduction in the cost of genome sequencing and a reduction in its technical complexity, sequencing of the genomes of a handful of individuals, including that performed by Watson[63] and Venter,[37] the pioneers of the Human Genome Project, has been completed recently.[37,50,62,63] Cross-comparisons have been made between the sequences of these genomes.

To enhance understanding of human genomic diversity on a broader scale, two large-scale projects were launched. The first one, the International HapMap Project, was launched to study heritable variations (i.e., polymorphisms, patterns of linkage disequilibrium, and haplotypes) across the human genome.[15,55] The HapMap Project primarily focuses on one class of genome variations, namely, single-nucleotide polymorphisms (SNPs). Cataloguing genetic variations between different ethnic populations would help one to understand the ancestral relationships between those populations. Once identified, a catalog of SNPs is also useful in providing landmarks of genomic locations for identification of disease-causing genes.[31] If an SNP allele is found to be associated with a particular disease, the SNP allele could further serve as a marker for assessment of an individual's susceptibility (statistical probability) of developing said disease.

The second project, the 1000 Genomes Project, also aims to study genomic diversity and disease-causing genes in humans.[56] The approach is based on whole genome sequencing of 1000 individuals, and the analysis is not limited to SNPs. Most recently, researchers have embarked on another approach to identify disease-causing genes through whole genome sequencing of families.[40,54] This approach entails the comparison of genomic sequences between affected and unaffected relatives within families known to propagate a hereditary disease under investigation.

After the alphabets of the human genome have been spelled out, another obvious follow-up would be to decode the meaning of the 3 billion nucleotides (i.e., the functional aspects of the human genome). This led to the launch of the Encyclopedia of DNA Elements (ENCODE) Project (http://www.genome.gov/ENCODE/), which aims to identify all functional elements within the human genome. A feasibility study targeting 1% of the human genome has been done.[4] Data from just this 1% of the genome have already led to many surprises that overturned many of our earlier simplistic views of the genome. Just to name a few of these surprises, as discussed earlier, other than the 1 to 2% of the genome that was previously annotated as protein-coding, we have come to realize that much of the entire genome is transcribed. Promoters that activate transcription are not limited to the 5′ ends of genes but instead are distributed at various locations of the transcription unit. Transcription takes place on both sense and antisense strands with highly overlapping units. Such new information redefines many previously established concepts including very fundamental ones, for example, what is a gene?[17,49] Our renewed understanding has brought about our appreciation of the highly sophisticated and complex nature of the workings of the human genome. All this new information is facilitated by the advent of high-throughput technologies, as discussed earlier. Our macroscopic view of some functional aspects of the human genome is now improving. However, a long journey lies ahead until we can attain a full understanding of each of the specific cellular and molecular mechanisms. Although our current understanding of the wonders of the genome is very limited, it is hoped that ultimately, humankind will have a better grasp of the causative mechanisms of pathologies to facilitate our efforts in predicting, diagnosing, monitoring, and treating disease.

Other large-scale projects that researchers are currently tackling include the Human Epigenome Project, which aims to identify, catalog, and interpret genome-wide DNA methylation patterns of all human genes in all major tissues.[12] This would represent yet another major challenge because only one reference human genome is known and many methylomes are present, given the different DNA methylation profiles between cells.[35] Besides genetic polymorphisms such as SNPs, it is now known that structural variations between individuals are characterized by comparatively large regions of gains and losses in DNA and are known as *copy number variations*. Hence, a copy number variation project aims to catalog and interpret the functional implications of copy number varations.[52]

In conclusion, our understanding of the human genome will continue to expand at an unimaginable rate. This will

continue to drive changes in the way we practice medicine and diagnostics. An emerging theme shows that each individual is a unique being, and much heterogeneity is seen even within the same disease entity. Thus, it is possible that personalized medicine with individualized therapies will be the standard of the future.[20]

CHAPTER 38

Genomes and Nucleic Acid Alterations

Carl T. Wittwer, M.D., Ph.D., and Noriko Kusukawa, Ph.D.

Molecular diagnostics focuses on medically important sequence variations within a background of complex genomic structure. This chapter reviews the organization of human, bacterial, viral, and fungal genomes and the spectrum of variations in nucleic acids that are of medical concern.

HUMAN GENOME

Each human cell contains two copies of a 3 billion member sequence code of nucleic acids on 46 chromosomes.[4,5,12] Box 38-1 lists statistics for the human genome and the types of variations that are important in clinical diagnostics.

Three quarters of human DNA is intergenic, or between genes. More than 60% of this intergenic sequence consists of "parasitic" DNA regions of transposable elements 100 to 11,000 bases in length. Between 2 million and 3 million of these elements are present in each copy of the genome. They contribute to genetic recombination and chromosome structure and provide an evolutionary record of sequence variation and selection.

Segmental duplications constitute 5.3% of the human genome. They are over 1 kilobase (a thousand bases, or kb) in length and have a sequence identity of at least 90%; they are not transposable. Segmental duplications are common in the human genome and are prone to deletion and/or rearrangement, often with medical consequences.

Intergenic DNA carries most of the simple sequence repeats (SSRs) present in the genome. These repeats are known as *microsatellites* or *short tandem repeats (STRs)* when the repeat unit is 1 to 13 bases, and *minisatellites* or *variable number of tandem repeats (VNTRs)* when the repeat unit is 14 to 500 bases. SSRs are critical markers in genetic linkage studies and in forensic or medical identity testing. They are formed by slippage during replication and are highly polymorphic between individuals. The most common SSRs are dinucleotide repeats, such as ACACAC and ATATAT. On average, approximately one SSR occurs every 2000 bases.

Approximately 2% of DNA is required to maintain the structure of chromosomes and is located at chromosome centers (centromeres) and ends (telomeres). Centromeric DNA consists of many tandem copies of nearly identical 171 base pair (bp) repeats encompassing 0.24 to 5.0 Mb per chromosome. Each chromosome end is capped with several kb of the telomeric 6 base repeat TTAGGG.

Although intergenic DNA does not code for protein and was originally considered "junk," much of this DNA is transcribed to RNA, producing a complex "transcriptome" network of RNA control elements whose function and mechanics are active areas of investigation.[1]

One quarter of the human genome consists of genes. A total of 20,000 to 25,000 genes are found in the human genome. The average gene covers 27 kb, but only about 1300 of these bases code for amino acid sequences. The primary RNA transcript is processed by splicing to retain exons that are interspersed throughout the gene and have a higher GC content than noncoding regions. On average, 95% of a gene is spliced out as introns, retaining a mean of 10.4 exons, of which 9.1 are translated into proteins. Exons make up only 1.9% of the total genome, with 1.1% of the genome coding for proteins. Some important genes are present in many copies, so that overall protein expression is not affected if a chance variation occurs in one copy. If extra copies of genes lose their function, they are known as *pseudogenes*. At least as many pseudogenes as functional genes are present in the human genome. It is important to distinguish pseudogenes from functional genes because sequence variations in pseudogenes are seldom of clinical importance.

Even though 99% of the genome does not code for protein, most of it is transcribed into noncoding RNA. At least 93% of the genome is transcribed,[1] producing more than 10 times the amount of RNA that is produced from the coding segments of genes.[2] Both strands of DNA may be transcribed, and long noncoding transcripts may overlap coding regions, producing a complex transcriptome of functional RNA molecules that may variably regulate transcription of coding regions, RNA processing, mRNA stability, translation, protein stability, and secretion. In addition to long noncoding RNA, ribosomal RNA, and transfer RNA, specific classes of noncoding RNAs include small nuclear RNAs critical for splicing,

BOX 38-1 The Human Genome and Its Sequence Variation

- The human genome
  - 3.08 billion base pairs in 24 chromosomes
  - 23 chromosome pairs (46 to 244 million base pairs per chromosome)

75% Intergenic Sequences

Transposable elements	45%
Segmental duplications	5%
Simple sequence repeats [SSRs, short tandem repeats (STRs)]	3%
Structural (centromeres, telomeres)	2%
Other	20%

25% Genes That Code for Proteins

Introns	23%
Exons	1.9%
• Coding segments	1.2%
• Untranslated regions	0.7%
Number of genes	20,000 to 25,000
Average gene	27,000 base pairs
	10.4 exons with 9.1 that are transcribed
	1340 bases coding for 446 amino acids

- Sequence variants
  - 99.9% identity (1 difference every 1250 bases between randomly selected haploid genomes)

Single-nucleotide polymorphisms (SNPs): identified every 100 to 300 bases

Noncoding	97%
Average number within a gene	126
Average number within the coding region of a gene	5

Copy number variants (CNVs): involve 5 to 12% of the genome

Disease-causing variants

SNPs	68%
• Missense (amino acid substitution)	45%
• Nonsense (termination)	11%
• Splicing	10%
• Regulatory	2%
Small insertions and/or deletions	24%
Structural variants (copy number variations, inversions, translocations, rearrangements, repeats)	8%

- Epigenetic alterations
  - Variable initiation and alternative splicing
  - Cytosine methylation
- Histone phosphorylation, methylation, acetylation

Data compiled from the Human Gene Mutation Database[11] and the International Human Genome Sequencing Consortium.[4,12]

small nucleolar RNAs that modify rRNA, telomerase RNAs for maintenance of telomeres, small interfering RNAs, and microRNAs that regulate gene expression.[8,9]

MicroRNAs (or miRNAs) are noncoding but functional single-stranded RNAs that are about 22 bases long and are expressed in a tissue-specific manner. They are initially transcribed as longer precursors that undergo two rounds of truncations as they are transported from nucleus to cytoplasm in the cell. The mature miRNA is then integrated into a protein complex called the *RNA-induced silencing complex*, which regulates translation of mRNA. MicroRNAs hybridize to a 6 to 8 base sequence in the 3′ untranslated region of a target mRNA and inhibit mRNA expression, by mRNA degradation if the remaining bases are perfectly complementary, or by blocking of translation if they are imperfectly complementary. More than 700 different miRNAs have been reported,[3] and sequences encoding for miRNA have been found on every chromosome except the Y chromosome.

Variation Within the Human Genome

Consider the genome as a book. Nucleotides are the individual letters, and three bases make up each word as an amino acid codon. The words are organized into sentences or exons that are separated by periods or introns. Each sentence is further organized into paragraphs or genes. Many paragraphs constitute a chapter or chromosome, and several chapters make up a book or genome. If the DNA of any two individuals is compared, on average one spelling difference is noted every 1250 bases (i.e., approximately 99.9% of the sequence is identical between randomly chosen copies of the genome). However, different individuals (copies of the same book) vary in a subtler way. Some of the pages are copied more than once and may be scattered throughout the book. Such copy number variants involve a greater amount of text than the spelling differences, with 0.5% of the genome differing on average between two individuals when 50 kb pages are considered,[7] that is, between individuals, at least five times as many bases are affected by copy number changes than by small sequence differences.

Any sequence change (compared with a reference sequence) is called a *sequence variant* or *alteration*. If a sequence variant or alteration is present in at least 1% of a population, it is a *polymorphism*. Many sequence variants, alterations, and polymorphisms in the genome do not affect human health and are benign or silent. For example, most copy number variations do not cause disease. Furthermore, most single-base changes [also known as *single-nucleotide polymorphisms (SNPs)*] and SSRs found between genes are seldom associated with disease. Similarly, most of the SNPs within introns, except for splicing and regulatory variants, are not known to affect gene function. In addition, some of the SNPs within exons are silent alterations that do not code for a change in amino acid sequence because of the redundancy in the genetic code. Still other SNPs in exons code for amino

acid changes that do not affect protein function. Even such silent SNPs nonetheless may be of considerable interest as genetic markers.

The most commonly observed sequence variations are SNPs. Millions of SNPs have been described, and many new SNPs continue to be reported. Some SNPs are common in the population, with allele frequencies of 0.1 to 0.5 (i.e., present in 10 to 50 of every 100 haploid copies studied), although other single-base changes are very rare. Although single-base variants have been identified every 100 to 300 bases, many of these are not found frequently in the population. A vast majority of SNPs (97%) occur in noncoding regions; only 3% of SNPs are within coding sequences.

Although SNPs are the most common sequence variant, copy number variants cover more of the genome than SNPs. These copy number variants (CNVs) occur in stretches of DNA that may range from 100 bases up to several Mb (megabases, or million bases) in size. CNVs may be duplicated in tandem or may involve complex gains or losses of homologous sequences at multiple sites in the genome. CNV regions exist in every chromosome and involve 5 to 12% of the human genome.[7,10] Most CNVs are inherited and biallelic, similar to SNPs.[7] More than 6000 CNV loci have been reported, and many of them overlap with genes. Individuals differ on average at more than 200 CNV loci, and these overlap the transcribed regions of more than 100 genes.[7]

Variations That Cause Human Disease

Sequence alterations that are known to cause disease are often called *mutations*, although the more cumbersome term, *disease-causing variant*, is more politically correct and precise. About 68% of known disease-causing variants are SNPs (see Box 38-1). Most of the remaining disease-causing variants (24%) are small insertions and/or deletions. However, 8% involve more complex sequence changes, including copy number variants, inversions, balanced translocations, repeat expansions, and rearrangements.

Single-Nucleotide Polymorphisms

Most SNPs that cause disease are missense and result in an amino acid substitution, whereas significantly fewer are nonsense variants that result in premature polypeptide chain termination. Approximately 10% of disease-causing variants are SNPs that affect splicing sites and result in altered concatenation of coding sequences. Finally, less than 2% of known disease-causing variants are SNPs that affect the regulatory efficiency of transcription by altering promoter and/or enhancer regions in introns or the stability of the RNA transcript.

Small Insertions and/or Deletions

Small insertion and/or deletion variants account for about 24% of nucleic acid sequence alterations that cause disease. An *insertion* refers to the presence of extra bases, whereas *deletion* implies the absence of certain bases in comparison with a reference sequence. Insertions and deletions often cause a shift in the codon reading frame, resulting in an altered amino acid sequence downstream of the variation; this is commonly followed by chain termination from a nonsense codon. A small *indel* is an insertion and a deletion at the same locus (for instance, TG is deleted and is replaced by AGGTC).

Structural Variants

The remaining 8% of variants that cause disease are mostly large structural anomalies, including copy number variations, inversions, balanced translocations, gene rearrangements (e.g., B- and T-cell gene rearrangements), and complex polymorphic loci related to health and disease [e.g., human leukocyte antigen (HLA)]. SSR expansions (e.g., increased numbers of STRs such as trinucleotide repeats) can also cause disease.

Interest in CNV in relation to disease has increased recently as the extent of variation has become clear.[13] CNVs can involve genes or contiguous sets of genes. When the normal dosage of the gene is two, but more than two functional copies of a gene are present, then the gene is "amplified." If a dosage-sensitive gene, such as HER-2-neu *(ERBB2),* is amplified, this usually leads to overexpression of mRNA and protein, resulting in cellular abnormalities and possible progression to disease such as cancer. When the normal gene dosage is two, and loss of one of the functional copies of the gene occurs, disorders such as mental retardation and developmental delay may result. Structural variants can be determined by cytogenetic techniques, including karyotyping, fluorescent in situ hybridization, comparative genomic hybridization, and virtual karyotyping by SNP microarrays.

Haplotypes

Often, sequence variants are inherited together in a contiguous block, or haplotype. A schematic representation of alleles arranged as haplotypes is shown in Figure 38-1. Disease associations may depend not on any particular sequence variant but on the overall effect of several linked alleles that define the haplotype. For example, enzyme function depends on the haplotype that defines the amino acid sequence in the protein. When the haplotype linkage of alleles is strong, genotype determination at a single locus may identify the haplotype (and disease association) with high confidence. However, methods for determining the *cis* or *trans* phase of alleles are necessary when the haplotype linkage is weak and when the disease association and/or haplotype linkage is first being established. Haplotypes may be defined by the phases of many polymorphic loci.

Alterations in Hemizygous Genes and Mitochondrial DNA

Most human genetic material is present in two copies (on paired chromosomes), with the exception of the unpaired sex chromosome in males and genes on mitochondrial DNA. When mutations occur in single-copy *(hemizygous)* genes on the X or Y chromosomes in males, they lead to sex-linked

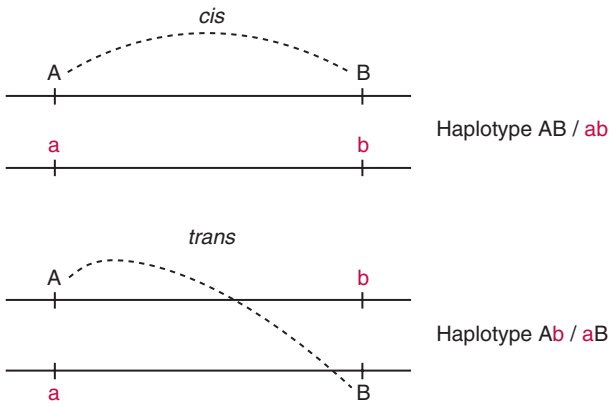

Figure 38-1 Schematic diagram of alleles arranged in haplotypes. Consider two polymorphic sites: one site is allele *"A"* or *"a,"* the other is *"B"* or *"b."* Given a doubly heterozygous genotype *(A/a, B/b)* in a diploid organism, possible haplotypes are as follows: *AB/ab,* in which *A* and *B* are on the same chromosome (*cis* configuration shown on top), or *Ab/aB,* in which *A* and *B* are on different chromosomes (*trans* configuration shown on bottom).

disorders. In contrast, the 16,500 bp mitochondrial genome is present in more than 1000 copies per cell, constituting about 0.3% of human DNA. Allele fractions may vary over a wide range when all mitochondria in a cell are considered, that is, sequence variations in mitochondrial DNA are *heteroplasmic*, meaning that the ratio of wild-type to variant alleles within a cell can vary almost continuously, sometimes resulting in a wide range of symptoms even when only one sequence variant is involved.

Human Epigenetic Alterations

In addition to the sequence alterations considered previously, epigenetic alterations, including alternative splicing and methylation, may affect gene expression. Even though the number of genes may be limited to 20,000 to 25,000, variable transcription initiation and exon splicing are estimated to produce about 90,000 mRNA transcripts and protein products.

Methylation of cytosine to form 5-methylcytosine occurs frequently; about 70% of CpG dinucleotides in the human genome are methylated. Although not inherited, interest in this "5th base" has increased as correlations with cancer have been reported.[6] CpG islands are about 1000 bases in length and often are found near the 5′ ends of genes. These regions consist of clusters of CG dinucleotides that usually are not methylated in normal cells. However, CpG methylation correlates with condensed chromatin structure and promoter inactivation; an important example is seen in tumor suppressor genes.

DNA is associated with proteins in nucleosomes. Gene expression can be altered by histone phosphorylation, acetylation, and methylation. Our understanding of epigenetic alterations and their relation to disease is rapidly developing.

BACTERIAL GENOMES

Bacterial genomes are considerably less complex than human or other eukaryotic genomes. Common bacteria have only one chromosome, usually a circular DNA double helix of 4 million to 5 million bp—about 1000 times less than the amount of DNA in a human cell. About 90% of the DNA in bacteria codes for protein. No introns are present, but multiple small intergenic regions of repetitive sequences are dispersed throughout the genome. The common bacterium *Escherichia coli* contains about 4300 genes.

In addition to the large circular chromosome that carries essential genes, bacteria carry accessory genes in smaller circles of double-stranded DNA (dsDNA) known as *plasmids*. Plasmids range in size from 1000 to more than 1 million bp. Plasmids are important in molecular diagnostics because they often encode pathogenic factors and antibiotic resistance.

The bacterial repertoire of DNA can be altered by (1) gain or loss of plasmids; (2) single-base changes, small insertions, and/or deletions, as in eukaryotic genomes; and (3) larger segmental rearrangements, including inversions, deletions, and duplications. Some genes, such as those for ribosomal RNA, are present in many copies and have been used to identify different species of bacteria. In addition, the intergenic repetitive sequences serve as multiple targets for oligonucleotide probes, enabling the generation of unique DNA profiles or fingerprints for individual bacterial strains.

VIRAL GENOMES

Viral genomes are considerably less complex than bacterial genomes. Common viruses that infect humans vary in genome size from about 5000 to 250,000 bases, or from 20 to 1000 times less than the amount of nucleic acid in *E. coli*. Because viruses use the cellular machinery of the host, they do not need as many genes. Small viruses may encode only several genes, but larger viruses can encode hundreds. The viral genome consists of DNA or RNA, and the nucleic acid may be single stranded or double stranded, linear, or circular, with one or multiple fragments and/or copies per viral particle. As in bacteria, no introns are present. In fact, in some viruses, the exons overlap with different reading frames coding different products from the same nucleic acid sequence. Noncoding regions are usually present at the terminal ends of linear genomes. Repeat segments are often found as terminal or internal repeats and may be inverted.

Sequence alterations in viruses are common. Areas of high sequence variation may be interspersed between conserved domains. Higher frequencies of variation have been correlated with lower polymerase fidelity and may allow escape from antibody recognition and from antiviral drugs. Common sequence variants in viruses include single-base changes, insertions, and deletions. Sequence diversity within a viral species may be so great that consensus sequences for molecular typing are difficult to find.

FUNGAL GENOMES

Fungi are eukaryotes, and their genomes are more complex than the genomes of bacteria or viruses. Common fungi that cause human disease have genome sizes of 7.5 to 30 million bases and 8 to 14 chromosomes, as well as mitochondrial genomes. Some fungi have diploid genomes, and others have haploid genomes. Many of their genes have introns. For instance, *Aspergillus fumigatus* (a fungus that causes allergic reactions and systemic disease with a high mortality rate) has a haploid genome of about 30 million bases with more than 9900 predicted genes on eight chromosomes. Its genes are smaller than human genes, with an average length of 1400 bp and 2.8 exons per gene.[6] Some fungi such as *Pneumocystis jiroveci* (a yeastlike fungus that causes pneumonia) cannot be cultured, and the use of nucleic acid tests is helpful in detecting them.

CHAPTER 39

Nucleic Acid Isolation

*Rossa W. K. Chiu, M.B.B.S., Ph.D., F.H.K.A.M.(Pathology), F.R.C.P.A. and Y. M. Dennis Lo, M.A., D.M., D.Phil., F.R.C.P.,(Lond. & Edin.), F.R.C.Path., F.R.S.**

Many of the key advances in our understanding of DNA and RNA have been achieved by the study of purified nucleic acids. In a molecular diagnostic laboratory, some tests can be performed directly on biological fluids, but techniques for *isolation* of nucleic acids often are critical. Nucleic acid *isolation* refers to the process of separating DNA or RNA from its surrounding materials; nucleic acid *extraction* is the technique of removing DNA or RNA from surrounding materials. With the advent of the polymerase chain reaction (PCR), molecular analyses could be performed on a variety of specimens, including whole blood, plasma, serum, tissue biopsies, cultured cells, buccal swabs, cerebrospinal fluids, amniotic fluids, and paraffin-embedded tissues. Isolation of DNA and/or RNA is usually a key preliminary step in molecular analysis.[43]

SPECIMEN PRESERVATION

DNA- and RNA-specific nucleases (DNases and RNases, respectively) can degrade DNA and RNA molecules in biological specimens. Hence, specimens should be properly preserved before molecular analyses. DNA molecules are generally stable in specimens when stored at −80 °C. However, RNA molecules are much more fragile than DNA. This is because, unlike DNA, RNA is not protected by a stable double-helical conformation, and RNA is subject to alkaline hydrolysis via the 2′ hydroxyl group of its ribose moiety. In addition, RNases are ubiquitous and difficult to inactivate or denature. Hence, special attention should be paid when one undertakes operations on RNA.[12] Tissue specimens intended for RNA analysis should be processed promptly upon collection. One preservation method is to snap-freeze the specimens by liquid nitrogen. However, snap-frozen tissues are laborious to handle in the subsequent homogenization step (see later). For example, to minimize the exposure of RNA to RNases, the frozen tissues should be ground to a fine powder before denaturants are added. Moreover, to prevent the release of RNases from thawing cells, the tissues should be kept frozen during the grinding process; thus liquid nitrogen has to be added at intervals. Alternatively, RNA can be protected by incubating tissue specimens in preservation agents such as RNA*later* (Ambion/Applied Biosystems, Austin, Tex) and PrepProtect Stabilization Buffer (Miltenyi Biotec Inc., Auburn, Calif).[33] RNA molecules in such preserved tissues are stable at room temperature for up to a week.[22] Specimen handling and transportation procedures are thereby facilitated. The preserved tissues can be directly homogenized (see later) without further processing.

Blood is the most common specimen type in a diagnostic laboratory because it is more readily available than a biopsy specimen. During peripheral blood collection and processing, ex vivo changes in gene expression and RNA degradation continue to occur, and can affect subsequent analyses.[38] To overcome such problems, vacutainer tubes prefilled with preservation agents, such as those in the PAXgene Blood RNA System (PreAnalytiX GmbH, Hombrechtikon, Switzerland), are available for immediate stabilization of RNA profiles during blood collection.[50]

Plasma and serum are routinely used for circulating nucleic acid studies (see Chapter 45). Plasma DNA has been shown to be stable in unprocessed whole blood for up to 24 hours at room temperature.[45] Plasma RNA has also been shown to be stable in unprocessed whole blood when collected in tubes containing ethylenediaminetetraacetic acid (EDTA) for up to 24 hours at 4 °C.[45] However, in contrast to short-term storage, the concentration of circulating DNA in harvested serum specimens has been reported to decrease by 0.66 copies per milliliter for each month of storage.[25] More marked degradation upon long-term storage was observed for plasma RNA.[49] To protect RNA in plasma and serum during storage, several investigators have suggested mixing RNase-inhibitory agents, such as TRIzol LS (Invitrogen, Life Technologies, Carlsbad, Calif), with specimens before storage at −80 °C.[45,49]

In urine specimens, bacterial and fungal contamination as well as calcium oxalate crystal formation can influence the yield of downstream nucleic acid isolation. Hence, long-term storage of urine specimens with EDTA at −80 °C has been recommended to resolve contamination problems and to inhibit any possible nuclease activity in urine.[20,31,42]

**The authors thank Nancy B.Y. Tsui for assistance in the preparation of this chapter.*

TISSUE HOMOGENIZATION AND CELL LYSIS

Homogenization refers to the breakdown of tissue into small fragments by mechanical or enzymatic means. Complete homogenization is essential for isolating nucleic acids with high quality and yield. For DNA isolation from soft tissues, homogenization is usually performed by incubating the specimens with digestion enzymes such as protease K at 56 °C overnight.[51] On the other hand, the roto/stator method is preferred for RNA isolation. This method involves mechanical disruption of tissues in lysis buffer, composed of phenol, sodium dodecyl sulfate, or guanidine salts (e.g., TRIzol from Invitrogen). The buffers not only lyse cells directly, they also inhibit RNase effectively during homogenization.[9]

DNA Isolation

Although various commercial protocols are available for DNA extraction, most protocols can be classified into one of a few categories that involve liquid- or solid-phase extraction. In general, solid-phase extraction methods are more commonly used because of the relative ease of operation, the ability to process large batches of specimens simultaneously, freedom from toxic chemicals, high reproducibility, and adaptability to automation. However, solution-based methods are still favored when large quantities of DNA or large sample volumes are involved.

For solution-based protocols, cellular debris and proteins are separated from the DNA fraction by solvent extraction through the use of solvents with different solubility constants. The well-known phenol-chloroform protocols are based on this principle. After centrifugation of the mixture of phenol-chloroform and sample lysate, proteins, lipids, carbohydrates, and cellular debris are separated from the DNA fraction and are settled in the bottom organic phase. DNA molecules contained in the upper aqueous phase are precipitated by ethanol and rehydrated with sterile distilled water or Tris-EDTA buffer (TE buffer). Because of the number of manual steps involved, the sample throughput of these solution-based methods is limited.

Solid-phase extraction methods are more robust and generally are based on the principle of DNA adsorption onto silica in the presence of chaotropic salts, such as guanidine thiocyanate, and ethanol.[3,37] The silica is typically coated onto membrane filters or magnetic particles. Silica-impregnated filters that are housed in plastic columns are the most commonly adopted format. DNA binds reversibly with silica, depending on the ionic strength of the environment.[41] After cell lysis and protein denaturation, DNA is precipitated by the addition of ethanol. The solution is then passed through the silica-impregnated filter, which binds and purifies DNA from other debris present in the ethanol solution. Centrifugation or vacuum manifolds can be used for the filtration step. The bound DNA is washed and subsequently eluted using nuclease-free water or low ionic strength buffers. Similarly, methods based on the use of silica-coated magnetic particles allow the isolation of ethanol-precipitated DNA by placing the solution under a magnetic field whereby DNA molecules adsorbed to the magnetic beads are retained. The DNA is subsequently eluted from the beads in low ionic strength buffer or water.

RNA Isolation

RNA analysis and therefore RNA extraction are required for studies on gene expression. Utmost care is needed to prevent RNase contamination during the process; this effort is aided by the use of RNase-free reagents, RNase-free plastic-ware, and decontamination of working surfaces and equipment with RNase-free detergents. Water treated with diethylpyrocarbonate (DEPC) for the inactivation of RNase is widely used. During the process of RNA purification, DNA digestion by DNase I is commonly incorporated as an additional step to avoid DNA contamination.

The underlying principles of RNA extraction are essentially identical to those of DNA isolation. Both solution- and solid-phase extraction protocols are available. The most commonly used solution-based method is guanidine thiocyanate-phenol-chloroform extraction.[9,10] Guanidine isothiocynate is a chaotropic agent used for protein denaturation while RNase activity is inhibited. In a mixture of guanidine isothiocynate, phenol (e.g., TRIzol from Invitrogen), sodium acetate, and chloroform in an acidic condition, total RNA is partitioned into the aqueous phase, and DNA molecules and proteins remain in the interphase and the organic phase, respectively. Total RNA in the aqueous phase is next precipitated by the addition of isopropanol. For solid-phase RNA extraction protocols, lysis/binding buffer includes chaotropic salts, such as guanidine isothiocyanate, to protect RNA. The ionic strength of the buffer is optimized to promote the binding of RNA molecules onto the silica matrix.

For specimens with high protein and lipid contents, such as plasma and serum, agglutination of lysed samples with the silica matrix can occur. In addition, genomic DNA present in the specimens competes with the RNA for binding to the silica matrix. These factors can adversely affect the isolation of RNA species that exist at trace amounts in the specimens. One such example is the extraction of cell-free fetal RNA in maternal plasma. To overcome these limitations, several investigators have developed a combined solution- and solid-phase RNA extraction protocol.[34,49] As an initial step, RNA molecules are separated from contaminants such as protein, lipid, and DNA by the TRIzol protocol. RNA molecules contained in the aqueous phase are then isolated by the silica-column method.

The guanidine thiocyanate-phenol-chloroform protocols are relevant to the isolation of total RNA, which comprises messenger RNA (mRNA), ribosomal RNA (rRNA), transfer RNA (tRNA), and small nuclear RNA. Protocols have been developed for the specific isolation of mRNA; these are based on capture of polyadenylated tails on the 3′ ends of mRNA by hybridization to cellulose-bound oligo(dT) molecules.[12] It is worth noting that most of the commercial silica-based kits are inefficient in extracting small nucleic acid species, such as microRNA. Because the binding efficiency of nucleic acids to the silica matrix is dependent on salt concentrations, pH, and

the ethanol content of the washing buffer in a size-dependent manner, most commercial kits have optimized these parameters to isolate nucleic acids larger than 150 nucleotides. Hence, microRNA extraction should be performed by using the solution-based method (e.g., TRIzol protocol) or with a silica-column protocol that has been optimized for binding microRNA molecules (e.g., mirVana from Ambion).[32]

ASSESSMENT OF NUCLEIC ACID YIELD AND QUALITY

Nucleic acid molecules absorb ultraviolet light maximally at a wavelength of 260 nm owing almost entirely to the constituent bases. Thus, DNA or RNA yield can be quantified by spectrophotometric measurement of absorbance at 260 nm, with higher absorbance values indicating higher yield. For example, a solution containing 50 mg/L of pure double-stranded DNA has an absorbance of 1.0 at 260 nm. Purity can be evaluated by assessing the ratio of spectrophotometric absorbances at 260 nm and 280 nm (A260/A280). Absorbance ratios greater than 1.8 indicate minimal contamination with proteins. The sizes of the isolated genomic DNA can be estimated by gel electrophoresis. Good quality DNA extractions are generally associated with higher molecular weight fragments (Figure 39-1). Similarly, total RNA integrity can be assessed by estimating the size distribution of the extracted RNA and the appearances of the 18S and 28S rRNA peaks (Figure 39-2). Total RNA preparations of high quality generally have a 28S/18S peak ratio greater than 2.0. With RNase degradation, the RNA size distribution is shifted toward the smaller fragments with a reduction in the 28S/18S rRNA ratio (see Figure 39-2).

In assessment of the yield and quality of DNA/RNA extracts, electrophoretic methods provide better precision and more information regarding quality, for instance, the size distribution of the isolated DNA or RNA. Modern improvements in instrumentation have led to the development of spectrophotometric and electrophoretic systems that require only the input of microvolumes of extracted DNA/RNA for assessment. One spectrophotometer for this purpose uses only 1 µL of sample for the measurement of DNA or RNA concentrations ranging from 2 ng/µL to 3700 ng/µL (ND-1000 Spectrophotometer, NanoDrop Technologies, Wilmington, Del). Automated analyzers that use prefabricated chips with microfluidic channels and are designed for capillary electrophoresis of microvolumes of DNA and RNA have become available; one example is the Agilent 2100 Bioanalyzer (Agilent Technologies Inc., Santa Clara, Calif).[36] This system allows better estimation of sizes, qualities, and concentrations of DNA and RNA when compared with the conventional slab-gel electrophoresis method. For example, the RNA integrity number (RIN) is an RNA integrity score that is calculated based on the entire electropherogram generated by the Bioanalyzer rather than only the 18S and 28S rRNA peaks.[39] The RIN has been shown to be a better estimation of RNA quality when compared with the 28S/18S ratio method.[21] The RNA integrity score has been widely adopted in studies

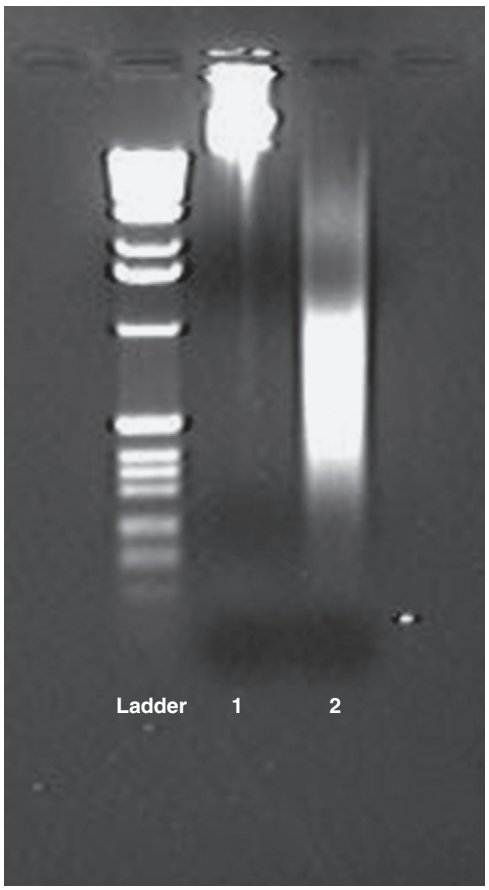

Figure 39-1 Assessment of DNA quality by gel electrophoresis. DNA extracted from two whole blood specimens was resolved on 1% agarose gel and compared with a molecular weight size marker *(ladder)*. High-quality DNA extractions are associated with high molecular weight fragments, as shown in *lane 1*. *Lane 2* illustrates DNA extracted from a degraded whole blood sample wherein the molecular weights of DNA fragments are much reduced.

in which RNA quality is critical for the reliability of the experiment, such as for gene expression microarray analysis.[30]

STORAGE OF PURIFIED NUCLEIC ACIDS

Isolated DNA can be stored temporarily at 4 °C or at −20 °C, but gradual degradation occurs over time. For prolonged storage, DNA should be stored at −80 °C or as a precipitate in ethanol at −20 °C. Similarly, RNA should be stored as aqueous form or ethanol precipitate at −80 °C. If RNA samples are intended for repeated usage, they should be stored as small aliquots to avoid repeated freeze-thaw cycles for maintaining nucleic acid integrity.

AUTOMATED NUCLEIC ACID ISOLATION

Many molecular diagnostic protocols that were originally developed by research laboratories have now been adopted by clinical laboratories. For such adoption, additional

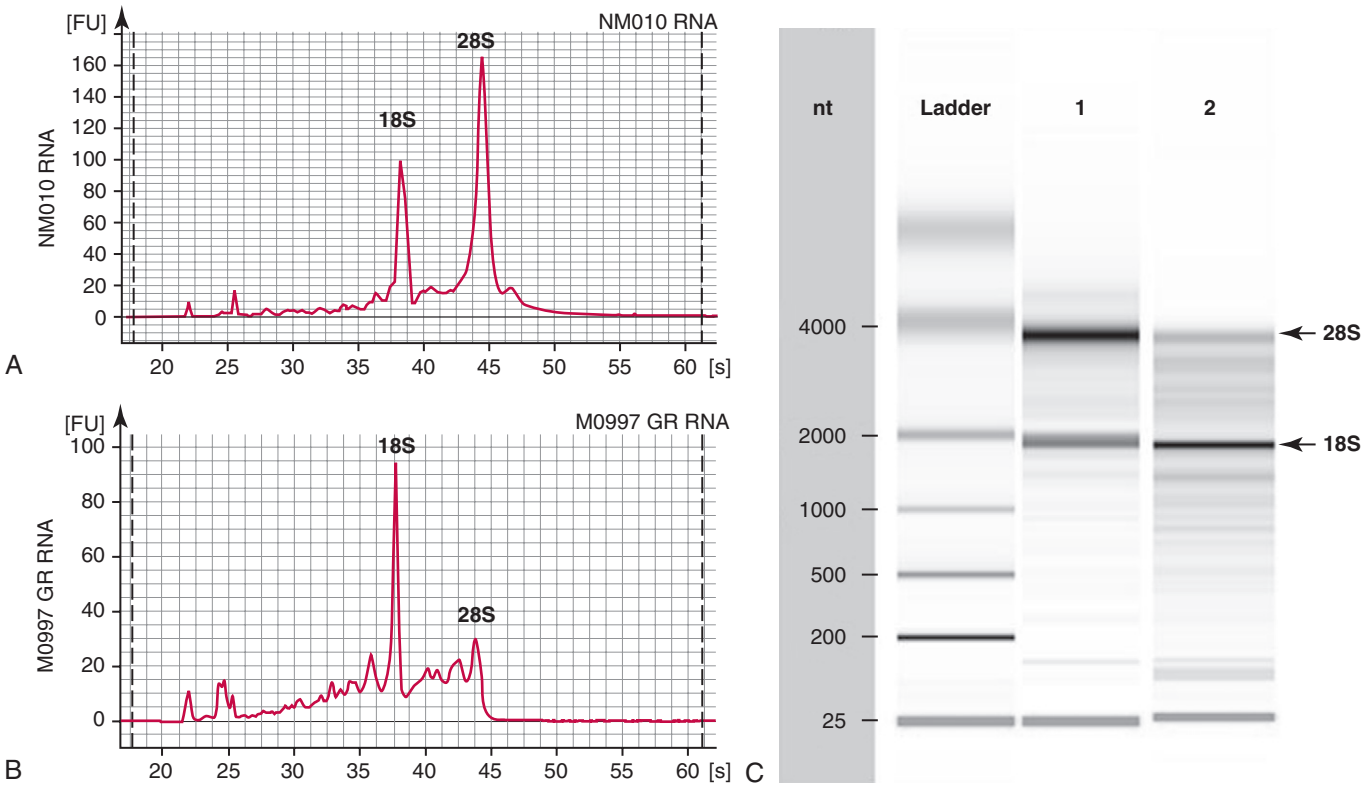

Figure 39-2 Assessment of total RNA quality by gel electrophoresis and densitometry. Total RNA extracted from two whole blood specimens was analyzed on the Agilent 2100 Bioanalyzer using the RNA 6000 Nano LabChip (Agilent Technologies Inc., Santa Clara, Calif) and was compared with a molecular weight size marker *(ladder)*. The gel electropherogram (C) is a simulated image based on the densitometry results shown in A and B. Extracted total RNA appears as a smear with two prominent bands corresponding to 18S and 28S ribosomal RNA (rRNA), respectively. A specimen with a high-quality total RNA extraction is shown in (A) and in lane 1 in (C), and is characterized by a high 28S/18S rRNA ratio with a broad size distribution of other RNA species. A second specimen demonstrating RNase degradation is shown in (B) and in lane 2 in (C), with a reduction in the 28S/18S rRNA ratio and the overall RNA signal. A shift is noted toward shorter fragments of RNA. *nt*, Nucleotides.

protocol requirements need to be considered. These requirements include the need to improve analytical throughput as well as the need to minimize manual handling, to ensure the reliability of assay performance, and to comply with regulatory or accreditation specifications. Automation of molecular diagnostic procedures is often considered and is particularly relevant to the process of nucleic acid isolation, as it involves many manual steps. Many commercial systems address the automation of this process. In general, automated nucleic acid isolation systems are based on the solid-phase extraction principles discussed previously. For example, MagNA Pure instruments from Roche Diagnostics (Branchburg, NJ)[23] adopt the use of silica-coated magnetic bead separation. The BioRobot Universal system (Qiagen, Hilden, Germany), on the other hand, is based on the use of silica-impregnated filter columns. These systems can be utilized as stand-alone instruments or can be integrated with downstream applications. For example, the MagNA Pure LC instrument (Roche Diagnostics) can be integrated with the LightCycler (Roche Diagnostics) for the performance of real-time PCR.[13] Besides the dedicated instruments described previously, open systems are available and are amenable to the setup of liquid handling steps according to end-users' specifications. Examples of such systems include those from Tecan (Durham, NC)[19] and the Biomek series from Beckman Coulter (Fullerton, Calif).[16]

A detailed evaluation of the analytical performance of an automatic nucleic acid protocol is usually required before high-throughput implementation. A number of studies have revealed that certain automated protocols may be less sensitive than manual methods of nucleic acid isolation.[5,7,40] Another relevant issue is the possibility of cross-contamination of specimens. Most systems evaluated to date have been shown to be free from the problem of cross-contamination.[5,13] These analytical factors have to be carefully considered before automatic protocols are adopted.

POINT-OF-CARE NUCLEIC ACID ANALYSIS

The automatic nucleic acid isolation systems described previously are generally designed for high-throughput usage. In contrast, another trend toward the development of compact, low-cost, and small-scale instruments for point-of-care services has been noted.[47] These instruments should be simple to operate by medical personnel or technical assistants with interventional steps reduced to a minimum. A lab-on-a-chip nucleic acid extraction platform has been developed for such a purpose.[37] This prefabricated chip contains networks of microfluidic pipelines for automatic sample and reagent flow control, as well as reservoirs containing reagents necessary for extraction procedures.[1] The only manual operation step is the injection of samples into the chip by a conventional syringe. On-chip nucleic acid isolation procedures are then automatically carried out by passing the sample through a solid-phase extraction filter.[1] To further automate the whole genetic analysis process, a nucleic acid detection module, such as those capable of preparing the reaction mixture and performing PCR amplification, can be integrated in the same microfluidic chip.[14,15]

ISOLATION OF CIRCULATING NUCLEIC ACIDS

In selecting the most appropriate protocol for one's laboratory, some of the issues worth considering include the specimen type and its available volume; the necessary yield, purity, and size of isolated nucleic acids; ease of operation; throughput and cost; whether the protocol involves the use of hazardous reagents; and whether it is amenable to automation. We are devoting this section to discuss these issues by using as an example the extraction of circulating nucleic acids in plasma.

For most applications of circulating nucleic acid analysis, the molecules of interest are those released from a tumor, fetus, or transplanted organ. However, these molecules are present in the circulation among a high background of other DNA and RNA species contributed by the blood cells.[29] As a result, the molecules of interest represent the minority population. Because a low fractional concentration of the DNA/RNA of interest would affect the reliability of their detection, special sample preservation measures are taken to minimize the number of background nucleic acid concentrations. In this regard, plasma is a preferred specimen type over serum because excessive background nucleic acids from blood cells might be released into the serum during the clotting process.[29] In addition, delays in the separation of plasma from whole blood should be avoided to minimize the release of DNA from blood cells.[24] EDTA is the anticoagulant of choice because cellular integrity is better maintained and hence the release of DNA from blood cells is less than when citrate or heparin is used.[24] Circulating cell-free DNA and RNA remain stable in unprocessed EDTA in whole blood for up to 24 hours at room temperature and at 4 °C, respectively.[45] Appropriate blood processing protocols are required to efficiently remove blood cells from the plasma.[8,18]

Concentrations of circulating nucleic acids are several orders of magnitude lower than those in a tissue biopsy specimen or in a whole blood sample.[24,35] Hence, an important factor affecting the successful adoption of plasma-based molecular diagnostics involves maximizing the yield of circulating nucleic acids during the isolation procedure. For example, the volume of sample to be used can be scaled up in each extraction.[6,44,46] When commercial nucleic acid extraction kits are to be used, the types and brands of kits that yield the best extraction efficiency should be assessed. For example, it has been demonstrated that when compared with the widely utilized QIAamp DNA Blood Mini Kit (Qiagen), the QIAamp DSP Virus Kit (Qiagen) showed an improved circulating fetal DNA yield from maternal plasma.[11,27] Studies have also revealed that the automated system of MagNa Pure LC (Roche) performed better than manual column-based procedures for DNA isolation[2] but not for RNA extraction.[7]

Apart from the isolation of *total* nucleic acids from plasma, investigators have studied the possibility of selectively isolating or enriching specific nucleic acid subpopulations. One example is the detection of the fetal-derived rhesus-D gene in the plasma of rhesus-D–negative mothers. Magnetic beads coated with oligonucleotides that specifically capture rhesus-D gene sequences have been used to enrich fetal rhesus-D gene fragments from maternal plasma.[26] Another relevant consideration is the size of circulating DNA or RNA fragments in the plasma. Both DNA and RNA exist in circulation as short fragments. Approximately 80% of DNA molecules in plasma, whether they are derived from a tumor, a fetus, or background blood cells, are 180 or fewer base pairs (bp) in length.[4] Similarly, plasma RNA molecules that are associated with a tumor, a fetus, or background blood cells are found to be fragments of the corresponding full-length transcript.[48] Hence, protocols selected for the isolation of circulating DNA and RNA should favor the isolation of low molecular weight fragments.[17,28]

Standardization of preanalytical and analytical parameters is an important consideration when diagnostic testing is offered. To standardize maternal plasma fetal DNA extraction protocols for noninvasive prenatal diagnosis, an International Workshop was conducted to evaluate the performance of fetal DNA detection across 13 different laboratories.[27] The Workshop reported that analytical and diagnostic sensitivities for fetal rhesus-D gene detection in maternal plasma were variable among different laboratories. These observations highlighted the need to standardize nucleic acid extraction procedures, as well as subsequent analytical steps, to achieve reliable diagnostic performance in clinical laboratories.

CHAPTER 40

Inherited Diseases

Cindy L. Vnencak-Jones, Ph.D., F.A.C.M.G.

Since the first description of the use of the polymerase chain reaction (PCR) for the diagnosis of sickle cell anemia in 1985, numerous applications of PCR have been described.[558] The invention of PCR combined with advances in bioinformatics, the chemistry of fluorescent molecules, and the development of DNA chip and next-generation sequencing technology has revolutionized the field of human genetics. In addition, the establishment of public databases and rapid and unrestricted communication among investigators around the world via the Internet have enabled the phenomenal growth of this medical specialty. Upon completion of the Human Genome Project in 2003, the postgenomic era spawned *personalized medicine,* or a tailored approach to healthcare based on an individual's genotype. The relevance of genetic variation has been explored in the areas of nutrigenomics—modulation of nutrition and nutritional requirements; vaccinomics—determination of disease susceptibility and efficacy and response to vaccines; and pharmacogenomics—evaluation of the drug response. A personalized genetic approach to medicine is most important in the area of targeted gene therapy for both inherited and acquired somatic diseases.

This chapter will review deoxyribonucleic acid (DNA) testing for some of the more common inherited autosomal recessive, autosomal dominant, and X-linked genetic diseases, and will discuss testing of several mitochondrial, imprinting, and complex diseases. Because molecular testing for inherited diseases has influenced virtually every discipline of clinical medicine, the reader should refer to other chapters within this textbook for discipline-specific diseases, including inherited disorders of erythrocyte enzymes (see Chapter 23) and inborn errors of carbohydrate metabolism (see Chapter 26). In this rapidly evolving area of diagnostic testing, multiple methods can be used to achieve the same sensitivity and specificity. Similar to other areas of laboratory medicine, the method chosen by the DNA laboratory is determined by the expected volume for the test, the availability of personnel to perform the assay, and the current instrumentation within the laboratory.

In conjunction with scientific discoveries that have been made in the area of human genetics, public awareness of DNA and genetic diseases has been enhanced by the media, the Internet, the judicial system, and direct-to-consumer marketing of personal genetic information services. The Genetic Information Nondiscrimination Act was passed in 2008, thereby protecting an individual from discrimination by employers and health insurance companies based on their genotype; however, many concerns and unanswered questions remain for us as scientists and for our society. Who has a right to know the results of genetic testing—the insurance company or the employer? Once we begin to unravel the interaction between genetic and environmental factors, can insurance or healthcare coverage be denied to the person who engages in a lifestyle likely to cause disease based on his or her genetic predisposition? To what extent will personalized healthcare be conducted? In this time of healthcare reform, which genetic tests will be used for routine carrier or diagnostic screening? What will be the economic impact of these tests, and how will the healthcare system absorb these costs? Can the healthcare community be trained to understand complex principles of genetics and provide comprehensive counseling? Can a person's genetic makeup predisposing him or her to aberrant behavior provide a defense in a court of law? To what extent will manipulation of genetic material be tolerated in our society? Will most couples undergo in vitro fertilization and preimplantation genetic screening to choose the embryo with the most desirable genes? What will be the fate of frozen embryos created for these services? Will cloning be allowed? Although it is difficult to predict what the future will bring, one thing is clear: the future will be both scientifically and intellectually stimulating, yet no doubt controversial.

DISEASES WITH MENDELIAN INHERITANCE

Autosomal Recessive Diseases

An individual with an autosomal recessive disease has inherited two abnormal alleles at a given locus by receiving one mutant allele from each carrier parent; the disease-causing gene is on one of the autosomes (1 to 22) and not on a sex chromosome (X or Y). Typically, the carrier parent with one abnormal allele has no clinical features of the disease, yet possesses a 50% risk of donating the mutant allele to his or her offspring. Matings in which both partners are carriers of an abnormal allele have a 25% chance of producing a child with both normal alleles, a 50% chance of having a child that has received only one abnormal allele, and a 25% chance of having an affected child. The affected patient may be

homozygous for a specific mutation by receiving the same mutation from each parent or may be a compound heterozygote by having received a different mutation within the gene from each parent. Regardless of the mechanism, the end result is the same: the patient has no normal allele. The specific mutations present in the patient largely affect the clinical severity of the disease; however, modifier genes and environmental factors also play a role in the phenotypic expression of the disease. Among pedigrees illustrating autosomal recessive disorders, males and females are equally affected, and for rare diseases, consanguinity is likely to be observed.

Cystic Fibrosis

Cystic fibrosis (CF) (Online Mendelian Inheritance in Man [OMIM #602421]) is one of the most common autosomal recessive diseases in people of Northern European ancestry with an estimated incidence in the United States of about 1 in 2500 and a carrier frequency of about 1 in 25.[5] Within other ethnic populations, the disease has an estimated incidence of 1 in 2300 Ashkenazi Jews, 1 in 8500 Hispanics, 1 in 17,000 African Americans, and 1 in 35,000 Asian Americans.[5] CF is a multisystem disorder that primarily affects the pulmonary, gastrointestinal, and reproductive organs.[455] However, the phenotypic expression of the disease is heterogeneous, ranging from meconium ileus and severe respiratory disease in infants to mild pulmonary symptoms and no evidence of gastrointestinal problems even in adulthood. Morbidity and mortality of the disease are most related to mucous accumulation; recurrent infection with pathogens, such as *Pseudomonas aeruginosa, Burkholderia cepacia, Staphylococcus aureus,* and *Haemophilus influenzae;* and excessive inflammation in the lung.[553,559] Although it was previously considered a fatal childhood disease, the U.S. Cystic Fibrosis Foundation reported that in 2008, the median survival age among ≈23,000 patients with CF who received care through 1 of 115 care centers nationwide was 37.4 years.[132] In addition, more than 45% of patients were over the age of 18.[132] The increase in survival age is due to organ transplantation, improved nutrition, and new therapies.[31,160,250,478,661] This success will continue with the likelihood of targeting infectious agents, mucous accumulation, and inflammation with pharmacotherapy and gene therapy to the lung.[16] Further, because of the complexity and frequency of the disease, most patients receive treatment from specialized care centers.[132,256] This approach provides widespread communication between healthcare providers and enables monitoring of a large population of patients with respect to treatment outcome, healthcare, and disease-specific variables.

The severity and frequency of the disease led to an intensive search for the gene. The gene was mapped to 7q31 in 1985 and was subsequently cloned in 1989.[365,374,536,545,633] The CF gene is large, containing 27 exons and producing a transcript of approximately 6.5 kb. It codes for the CF transmembrane conductance regulator protein (CFTR) of 1480 amino acids and a member of the ATP-binding cassette (ABC) transporter superfamily. CFTR consists of two repeated motifs, each containing six hydrophobic transmembrane domains and one hydrophilic intracellular nucleotide-binding fold connected by a highly charged regulatory domain site.[536] The molecule serves as a chloride ion channel and is located within the lipid bilayer, predominantly at the apical membrane of secretory epithelial cells, where it is dependent on phosphorylation by protein kinases through activation by cyclic adenosine monophosphate (cAMP).[259] In addition to epithelial chloride conductance, the molecule is involved in transport of sodium, potassium, and adenosine triphosphate (ATP) from the intracellular compartment to the extracellular surface.[556,571,609] An abnormal sweat chloride concentration is considered the gold standard for the diagnosis of CF (≥60 mmol/L in childhood).[223] However, some patients with *CFTR* mutations may have borderline (30 to 59 mmol/L) or even normal (<30 mmol/L) results.[112,290] Atypical or nonclassic CF patients may have involvement of only one organ, as in congenital bilateral absence of the vas deferens (CBAVD), pancreatitis, pulmonary disease, or nasal polyps.[498,685] Measuring the nasal potential difference is part of the algorithm to distinguish patients with a questionable diagnosis of CF from true CF patients.[142,162,333] Thus although the diagnosis of CF can be made easily in patients with characteristic clinical features and abnormal sweat chloride concentrations, in patients with atypical presentation, mutations in the *CFTR* gene cannot be excluded without complete sequence analysis of the gene.[434] The wide clinical diversity among patients with CF in part is the result of varying effects on the CFTR protein caused by more than 1600 mutations identified thus far in the *CFTR* gene.[133] However, it is possible that the "nonclassic" CF phenotype is caused by factors other than mutations in the *CFTR* gene.[255,579]

Because CF is an autosomal recessive disorder, the CF patient must have two mutant *CFTR* alleles to develop the disease. Some mutations are "private" and unique to a family; others may be common among CF patients. Patients will be homozygous with two copies of the same mutation or will represent a compound heterozygote with one copy of one mutation and one copy of a second mutation. Predictably, the type and location of the mutation have varying effects on CFTR and affect the phenotype of the patient.[6,99,455] The *CFTR* genotype and the clinical phenotype are most closely related for pancreatic involvement rather than for pulmonary manifestations of the disease, which appear to be more dependent on environmental factors and genetic modifiers.[92,121,168,563,722] Environmental modulating factors of lung disease include second-hand smoke and varying exposure to pathogens.[122,559] It is interesting to note that patients with idiopathic chronic pancreatitis have a higher incidence of *CFTR* mutations than the expected carrier frequency and have more severe disease.[8] Pancreatitis in these patients may result from CF with a second *CFTR* gene mutation not detected, or could represent a complex disease resulting from a predisposing mutation in several genes.[358] *CFTR* genotypes in infertile males with only the genital form of CF—CBAVD—usually have a mutation associated with a severe phenotype on one allele and a mutation associated with a mild phenotype on the second allele. The most frequently reported *CFTR*

genotype in this population is the 5T polymorphism in intron 8 (corresponding to a sequence of five thymidines).[112,524] The 7T and 9T alleles are more common than the 5T variant, which is observed in only ≈5% of *CFTR* alleles. The 5T variant affects mRNA splicing and can cause exon 9 to be deleted; without it, the chloride channel is not functional.[115,144,608] An adjacent polymorphic TG dinucleotide sequence [(TG)9 to (TG)13] regulates the efficiency of mRNA splicing, with the higher number of TG repeats [(TG)13] associated with decreased efficiency of splicing.[254] Thus, the 5T-(TG)12 or (TG)13 allele is more commonly associated with an abnormal phenotype than is the 5T-(TG)11 allele.

The types of mutations in *CFTR* can illustrate the association of the genotype with the phenotype. More than half of all mutations are missense or frameshift mutations, and more than 9% occur in exon 13.[133] Mutations can be divided into five classes.[455] Patients with class 1 mutations have defects in protein production, and class 2 mutations are associated with defective processing of CFTR. In both cases, CFTR trafficking to the cell membrane does not occur, and both class 1 and class 2 mutations are typically associated with a severe phenotype. Class 3 and 4 mutations have CFTR expression at the cell membrane, but channel activity is reduced. Class 3 mutations can be associated with a more severe phenotype and result from defective regulation; class 4 mutations can be mild and result in diminished conduction of ion flow. Class 5 mutations are associated with abnormal splicing and thus reduced amounts of normal *CFTR* messenger RNA (mRNA). These mutations may be associated with a severe phenotype (621+1G>T) or a mild phenotype (2789+5G>A). The most common mutation, deltaF508, seen in about 70% of CF chromosomes in Caucasians of Northern European descent, affects processing of CFTR and prevents its trafficking to the apical membrane.[111] Prevalent mutations G542X and W1282X cause premature translation termination and thus truncation of the protein.[270] The frequently observed mutation G551D results in CFTR that reaches the apical membrane but improperly regulates the chloride channel.[688]

DNA testing for the identification of *CFTR* mutations is performed for a variety of reasons (Box 40-1). It is performed to confirm the diagnosis of disease in patients with equivocal sweat chloride results, or in instances when insufficient material is collected. A diagnosis of CF can be considered in the patient with only the presenting symptom of chronic pancreatitis. Alternatively, in the known CF patient, mutation analysis can be requested to help predict the prognosis because some genotype-phenotype correlations exist. At the same time, identifying the mutations segregating within a family enables preimplantation diagnosis or prenatal testing for subsequent pregnancies and carrier or diagnostic testing for other at-risk family members. Similarly, state-sponsored newborn screening programs have detected infants with CF and at the same time have identified at-risk family members and have enabled genetic testing. Most important, newborn screening allows for early diagnosis and intervention through treatment to prevent malabsorption of nutrients and to minimize lung damage from infection.[578] Neonatal screening for CF is based on the immunoreactive trypsinogen (IRT) assay and is used to detect elevated levels of this pancreatic enzyme from dried blood spots. States vary in their newborn screening algorithms. In some, a positive result is followed by IRT retesting; in others, blood from the newborn is submitted for *CFTR* mutation analysis.[497,597] A sweat chloride test is ultimately performed for confirmation of CF but may not always be effective in infants younger than 2 weeks.[497] Some families referred for prenatal CF testing have no family history of CF. Rather, in these families, hyperechoic (hyperechogenic) bowel may be diagnosed in the fetus on routine ultrasonography. In one study of 209 fetuses, 7 were subsequently given the diagnosis of CF, which is about 84 times the estimated risk of CF in the general population.[457]

The most challenging and controversial DNA testing for CF is carrier screening for preconception and expectant couples. Carrier screening in these circumstances was recommended in October 2001 by the American College of Obstetricians and Gynecologists (ACOG) in conjunction with the American College of Medical Genetics (ACMG).[14] With the heterogeneity of *CFTR* mutations, testing for more than 1600 mutations in this population would be a daunting task. For this reason, a core panel of 25 mutations was proposed as a minimum standard for CF carrier screening. The mutations initially proposed included those with an estimated prevalence of at least 0.1% of CF mutant alleles and a CF carrier detection rate of about 88% for non-Hispanic Caucasians.[14] However, in 2004, the core panel was revised to 23 mutations with the removal of mutations 1078delT and I148T-3199del6, which are not present at a frequency representing 0.1% of all CF alleles (Table 40-1).[451,607,682] The intent of the screening panel is to identify individuals at risk for classical CF, not CBAVD; thus it is recommended that 5T/7T/9T status be evaluated only in the presence of mutation R117H. In this case, the panel would allow distinction between R117H-5T and R117-7T individuals. This in turn would enable proper genetic counseling and prenatal testing options for individuals who are R117H-5T and at risk of having an offspring with CF if their reproductive partner is also a carrier of CF. Although CF is more common in the Caucasian and

Ashkenzai Jewish population, the standard of care recommended by the ACOG is to make CF testing available to all preconception or expectant couples, especially because it is becoming more difficult to assign a single ethnicity to a patient to best determine her carrier risk.

For *CFTR* mutation testing, a variety of assay platforms are commercially available and varying numbers of mutations are detected.[147] Further, because the detection rate of the panel is lower in some ethnicities, laboratories serving those populations should consider supplementing this screening panel with additional mutation analysis.[611]

Social issues associated with population screening for this genetic disease are in part rather specific to this program (such as the enormous number of mutations in this huge gene), but many others are illustrative of issues that surround genetic testing in general. Issues surrounding this program include (1) the inability to detect CF carriers with *CFTR* mutations other than the 23 included in the screening panel, (2) the need for appropriate genetic counseling of patients before they consent to the analysis, (3) the need for proper understanding of the possibility of a false-negative result, (4) stigmatization of being a "carrier" of a genetic disease, (5) threats to confidentiality of results, (6) effects on health insurability, and (7) a possible increase in the number of abortions following the identification of previously unknown affected fetuses. In addition to these social and/or ethical issues, opposition to this screening panel has arisen over the set of mutations included in the panel, because those currently selected under-represent the mutations found in minorities.[191,224,282,287,288] It is likely that mutations in the *CFTR* screening panel will continue to change as carrier screening evolves and the program is critically evaluated.

It is the standard of care for all prenatal cases that DNA extracted from the fetus is tested for the presence of maternal contamination, because the presence of maternal DNA could interfere with interpretation of the results. This is best performed by using PCR amplification for highly polymorphic short tandem repeat loci coupled with capillary electrophoresis (Figure 40-1). As important as the accuracy of the laboratory results is the interpretation of these results. For carrier screening, with no family history of CF and no mutation detected, it is important for the patient to understand that a residual risk of being a carrier remains (Table 40-2).[5] This is especially important for patients in ethnic groups for which the *CFTR* mutation detection level is reduced. Further, it is very important to know relevant family history when interpreting and reporting rest results to provide accurate genetic risk assessments regarding a residual carrier risk for

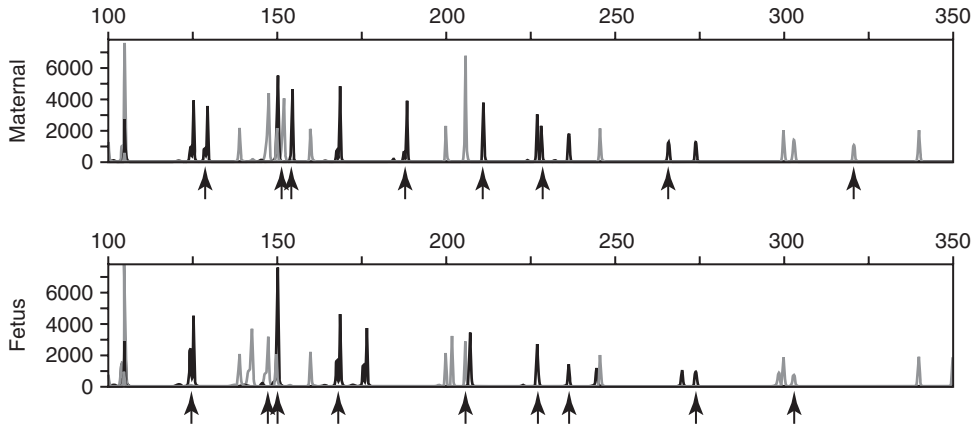

Figure 40-1 Electropherograms obtained following polymerase chain reaction (PCR) amplification of maternal and fetal DNA at nine independently segregating loci and one gender-specific marker. Extracted maternal and fetal DNA was amplified by PCR using a multiplex PCR assay with fluorescent labeled primers (AmpFLSTR Profiler Plus ID PCR Amplification Kit, Applied Biosystems, Foster City, Calif). Amplicons were detected following capillary electrophoresis on an ABI 3130*xl* Genetic Analyzer and were analyzed using GeneMapper version 3.7 software (Applied Biosystems). *Arrows* in the *upper panel* denote maternal alleles absent in the fetal DNA specimen. *Arrows* in the *bottom panel* indicate maternal alleles inherited by the fetus.

TABLE 40-2 Cystic Fibrosis Mutation Carrier Risk

	Ashkenazi Jewish	Non-Hispanic Caucasian	Hispanic Caucasian	African American	Asian American
Detection rate of ACOG/ACMG 23 mutation panel	94%	88%	72%	65%	49%
Estimated carrier risk in population	1/24	1/25	1/46	1/65	1/94
Estimated carrier risk after no mutation detected on screening panel	1/400	1/208	1/164	1/186	1/184

a negative result, because the mutation segregating within the family could be one not detected by the test panel, and a false-negative result could occur.[486]

Hereditary Hemochromatosis

Hereditary hemochromatosis (HH) (OMIM #235200) is an autosomal recessive disorder of iron regulation that can result in excess iron deposition in otherwise healthy tissue primarily of the liver, heart, joints, pituitary gland, and pancreas. Affected individuals can absorb approximately 3 to 4 mg of iron per day compared with the normal rate of 1 to 2 mg per day, and although the average male has body iron storage of about 5 g, affected individuals can accumulate as much as 30 g. Symptoms associated with this disease occur during mid to late adulthood, but the diagnosis of HH is often delayed because early symptoms of weakness, lethargy, joint pain, and abdominal pain are nonspecific. Complications of the disease include hepatic cirrhosis, diabetes mellitus, hypopituitarism, hypogonadism, arthritis, and cardiomyopathy.[615] Moreover, patients are at increased risk for hepatocellular carcinoma.[366] The disease is more common in men than in women presumably because of physiologic iron loss during menstruation and pregnancy. However, other sex-related differences may be involved. The phenotypic expression of the disease appears to be dependent on both genetic and environmental factors. Although regular blood donation may be protective against HH, infection with hepatitis C, obesity-related steatosis, increased consumption of dietary iron or vitamin C (an enhancer of iron uptake), and, most notably, excessive alcohol intake can increase the likelihood of symptoms in the presence of an affected genotype.[519,704] Management of the disease may include therapeutic phlebotomy, chelation therapy or erythrocytopheresis to reduce iron stores, and dietary avoidance of red meats, iron supplements, and excess vitamin C, as well as uncooked seafood (to avoid *Vibrio vulnificus* infection); alcohol intake should be minimal.[43,80] Single-nucleotide polymorphisms (SNPs) in transforming growth factor-β_1 and myeloperoxidase have

been implicated as modifiers of disease progression to liver fibrosis and cirrhosis, yet the primary genetic risk factor for *HFE*-related disease remains the presence of a Y chromosome.[704] The identification of modifier genes for this disease is an area of active interest and may involve SNPs in genes associated with iron metabolism.[127]

Laboratory testing for hemochromatosis most often includes determination of transferrin saturation (TS) [(serum iron/total iron binding capacity) × 100]; saturation greater than 55 to 60% is considered abnormal for men, and saturation greater than 45 to 50% is abnormal for women. Serum ferritin (SF) levels are also ordered, with serum ferritin greater than 300 μg/L abnormal for men, and values greater than 200 μg/L abnormal for women. Elevated levels of transferrin saturation and serum ferritin often lead to genetic testing. If genetic testing is positive, a liver biopsy follows to determine the amount of stainable iron and the degree of injury.[332]

In 1976, Simon and associates reported an association of human leukocyte antigen (HLA)-A3 and HLA-B14 antigens with idiopathic hemochromatosis, which suggested that the HH gene was located near the major histocompatibility complex (MHC) on chromosome 6p.[590] Classic genetic studies confirmed linkage of the HH gene to the HLA locus, and in 1996, Feder and colleagues cloned the HH gene, *HFE*.[196,335,389] Although *HFE* (6p21.3) remains the primary gene associated with abnormal iron regulation, other autosomal recessive disorders involving the genes *TfR2* (transferrin receptor 2), *HJV* (hemojuvelin), and *HAMP* (hepcidin), as well as an autosomal dominant disorder involving ferroportin 1, have been reported.[32] Additional genes may be associated with inherited forms of abnormal iron metabolism.

The *HFE* gene protein, HFE, encodes a β_2-microglobulin–associated protein with structural resemblance to MHC class I proteins. The *HFE* gene contains seven exons spanning about 10 kb, with a 2.7 kb mRNA that is highly expressed in the hepatocyte. The 40 kDa HFE protein is composed of 348 amino acids and is involved in the highly regulated hepcidin-ferroportin pathway for iron homeostasis.[496] As such, when bound to transferrin receptor 1 (TfR1), HFE is silenced. However, when plasma transferrin is saturated, HFE dissociates from TfR1, making TfR1 available for binding and cellular uptake of iron. Once no longer bound to TfR1, HFE binds to TfR2 and other proteins, possibly HJV, and various bone morphogenetic proteins (BMPs) and their receptors to form an *iron-sensing complex*. This complex signals for the expression of hepcidin, a 25 amino acid liver hormone, using the SMAD signaling pathway. Hepcidin, now upregulated from the iron overload, binds to ferroportin, causing it to be internalized and degraded, thereby maintaining iron within the enterocytes and macrophages.[496]

A founder effect, suggested by linkage disequilibrium between HLA haplotypes and the *HFE* gene, was confirmed in two studies by the identification of homozygosity for a common mutation, G-to-A base pair substitution, in 148 of 178 (83%) and 121 of 147 (82.3%) HH patients.[60,196] This mutation results in a cysteine-to-tyrosine substitution at amino acid 282 (C282Y) in HFE and disrupts disulfide bridges required for normal interaction with β_2-microglobulin on the cell surface, which allows for high-affinity transferrin binding to the uncomplexed transferrin receptor.[196-198] The allele frequency of this mutation is 5 to 10% in Caucasians, 1% in Hispanics, and less than 1% in African Americans.[513] Although carriers of this mutation have been reported to have a twofold increased risk for acute myocardial infarction compared with noncarriers, they do not have higher transferrin saturation or ferritin than C282Y noncarriers.[450,635]

A second base substitution of C-to-G in exon 2 and resulting in a histidine (H)-to-aspartic acid (D) substitution at codon 63 (H63D) has been identified in a higher percentage of C282Y-negative HH patients than would be expected based on the frequency of this mutation in the population.[196] This mutation is observed in 89% of HH chromosomes that do not have mutation C282Y compared with an allele frequency of 15 to 17% in Caucasian control *HFE* genes.[196,513] HFE, with this alteration, is expressed at the cell surface, but its interaction with the transferrin receptor is altered, resulting in increased iron deposition within the cell.[196,669] The frequency of mutation H63D is less in African Americans (0.026) and Hispanics (0.10).[513] Mutation H63D is associated with increased risk of developing a mild form of hemochromatosis, but appears to have little effect in causing iron overload when inherited by itself (wild-type and/or H63D), which represents 2.5% of HH chromosomes, or when two copies of the mutation are inherited (H63D/H63D), which is seen in 1.4% of HH patients.[419] Although many compound heterozygotes (C282Y/H63D) in the general population are asymptomatic, H63D may contribute to disease when inherited with mutation C282Y because 1 to 5% of HH patients have this genotype, although these patients display variability in liver histologic findings and iron indices.[58,334,347,419,566]

A third mutation in the *HFE* gene is associated with a mild form of hemochromatosis.[30,299,461] This A-to-T mutation results in a serine-to-cysteine substitution at codon 65 (S65C) in exon 2 and is in close proximity within the gene to the previously described *H63D* mutation. In one study, mutation S65C was detected in 2.49% of normal controls yet was identified in 10 of 128 (7.8%) HH chromosomes that had neither C282Y nor H63D.[461] Although C282Y is the primary mutation in *HFE*-associated HH, compound heterozygotes C282Y-H63D and C282Y-S65C have an increased risk of developing HH, thus suggesting their role in the development of HH.

DNA analysis of the *HFE* gene is done using a variety of methods and in most laboratories includes testing only for mutations C282Y and H63D (Figure 40-2). Once *HFE* mutation analysis has confirmed the cause of HH in the patient, transferrin saturation (TS), serum ferritin, and DNA testing of at-risk family members can identify those who may benefit from earlier treatment and dietary restrictions.[89] This is especially important because morbidity among first-degree relatives of *HFE*-related hemochromatosis patients is greater than in the general population.[329]

Because HH is a common disorder with clinical symptoms that can be prevented with easy and inexpensive early

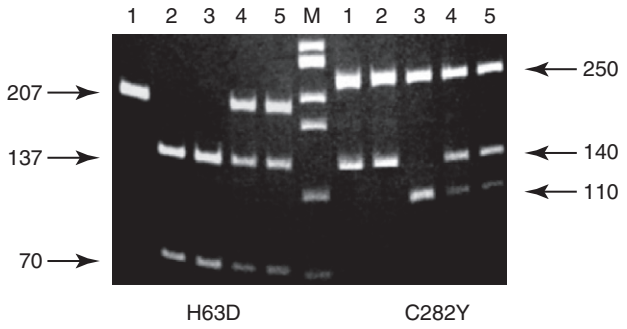

Figure 40-2 Detection of mutations H63D and C282Y in the *HFE* gene. Patient DNA is amplified by polymerase chain reaction (PCR) using oligonucleotide primer pairs that flank mutation H63D or C282Y, respectively. For detection of mutation H63D, 207 base pair (bp) PCR products are digested with restriction endonuclease *Bcl*I and are subjected to electrophoresis on a 5% polyacrylamide gel *(left)*. Mutation H63D results from a C-to-G base substitution and destroys a *Bcl*I site, thereby preventing digestion of 207 bp fragments into 137 bp and 70 bp fragments. Detection of mutation C282Y uses digestion of 390 bp amplified products with restriction endonuclease *Rsa*I and electrophoresis on a 5% polyacrylamide gel *(right)*. Mutation C282Y results from a G-to-A base substitution and creates an *Rsa*I site within the amplicons cleaving 140 bp fragments to 110 bp and 30 bp fragments. In patient 1 *(lane 1)*, the H63D-specific 207 bp amplification products are not digested with *Bcl*I to yield wild-type bands of 137 bp and 70 bp, thereby indicating that the restriction site has been lost in both alleles. Conversely, the C282Y-specific amplicons from patient 1 yield exclusively wild-type bands of 250 bp and 140 bp fragments. Genotype for patient 1 is interpreted as mutation H63D, wild-type C282Y on both alleles. Genotype for patient 2 *(lane 2)* is wild-type H63D, wild-type C282Y on both alleles. Genotype for patient 3 *(lane 3)* is wild-type H63D, mutant (m) C282Y on both alleles. Patient 4 *(lane 4)* is a compound heterozygote with mH63D, wild-type *C282Y* on one allele and wild-type H63D, mC282Y on the second allele. *Lane 5* represents control DNA heterozygous for mutations H63D and C282Y.

intervention, population-based DNA screening for HH may be appropriate and has been considered.[93,120] Yet, although homozygosity for the *HFE* mutation C282Y is close to 1 in 250 in the general population, making hemochromatosis one of the most common inherited genetic disorders, significant clinical heterogeneity is observed and varies from severe disease to an asymptomatic phenotype with only abnormal iron indices. In one study of 41,000+ patients attending a health clinic in the United States, only 1% of C282Y homozygotes developed clinical hemochromatosis. However, the penetrance of C282Y homozygotes displaying iron overload–related disease in a large study of more than 31,000 people between 40 and 69 years of age was reported to be 28% in males compared with only 1% in females by the age of 65.[10] Further, this study showed that patients with serum ferritin levels greater than 1000 μg/L are at increased risk for developing *HFE* gene-related disease compared with subjects with less than 1000 μg/L. Although clinical expression of the disease is reduced, more than 50% of homozygotes of both sexes will have elevated TS and SF levels. However, these two studies indicate wide variability of true penetrance of this disease. Thus, because of incomplete penetrance, many people with mutations will not have and will never develop iron overload.[59] Inability to predict who will develop disease is the primary reason why population-based genetic screening is not done routinely in the United States. This is a topic of much debate.[9] Targeted screening to adult Caucasian men of Northern European ancestry combined with TS and SF has been proposed.[512] Targeted screening for family members of C282Y homozygotes has been suggested.[330] In the United Kingdom, genetic testing for C282Y and H63D was determined to result in significant cost savings when incorporated into the diagnostic strategy of potentially affected patients and in testing of their offspring.[128] Phenotypic measurements of transferrin saturation or serum ferritin could be more appropriate than genotype studies for population-based screening for HH, but these results can also be misleading in that iron overload can occur from a host of other conditions unrelated to hemochromatosis and mutations in *HFE*.[699]

Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) is an autosomal recessive neurodegenerative disorder with an estimated incidence of 1 in 10,000 births and a carrier frequency of 1 in 40 to 1 in 50. The disease is characterized by progressive symmetric degeneration of spinal cord motor neurons of the anterior horn region and results in skeletal muscle weakness and atrophy.[415] Wide variability in age of onset and motor function impairment has been noted in SMA, and four clinical phenotypes have been identified. Type I (OMIM #253300) is the most severe and the most common (50%); it is associated with age of onset younger than 6 months and death in early childhood. These children have profound hypotonia and no control of head movement, and they are unable to sit. Intercostal muscle weakness leads to respiratory failure and tongue fasciculation, dysphagia, and fatigue, making feeding difficult, worsening the condition, and increasing the risk of aspiration pneumonia. SMA type II (OMIM #253550) is intermediate in its severity and has an age of onset between 7 and 18 months. These children can sit and some can stand, although none can walk independently. Death typically ensues in adolescence. SMA type III (OMIM #253400) has onset of disease after 18 months and a mild phenotype with gradually progressive disease and a normal life expectancy. SMA type IV (OMIM #271150) is the mildest of all forms and is characterized by muscle weakness initially in the second or third decade of life and a normal life span.

The gene for SMA, survival motor neuron I *(SMN1)*, was mapped to 5q11.2-13.3 in 1990 and cloned in 1995.[86,393,438] This gene contains 9 exons (numbered 1, 2a, 2b to 8) spanning about 28,000 bases and encodes a 1.7 kb mRNA transcript producing a 38 kDa protein composed of 294 amino

acids that is widely expressed in the nucleus and cytoplasm.[404] The SMN protein forms a multiprotein complex with other proteins, some of which are referred to as Gemins, and is enriched in the nucleus in size and number to form Gems.[46,589] The SMN complex is essential for the biogenesis of small ribonucleoproteins into the spliceosome, a structure that is required in the nucleus for the removal of noncoding sequences during pre-mRNA splicing.[505] In addition, SMN interacts with a whole host of other proteins, indicating that it plays an important role in a variety of cellular functions, including transcription and apoptosis. SMN is essential during embryogenesis in that its absence results in embryonic lethality in *SMN1* knockout mice.[567] It is not understood why it plays such an important role in the cell and is expressed in many tissues, yet deficiency of SMN almost exclusively affects the lower motor neurons. This would suggest that SMN may function in a role unique to motor neurons.[189,717] In most cases, SMA results from homozygous deletions of *SMN1*. Some cases result from gene conversion of *SMN1,* and in less than 5% of cases, patients are compound heterozygotes with an *SMN1* deletion on one allele and loss of function or point mutation on the second allele. In rare cases, a point mutation in *SMN1* is present on both alleles. Reduced amounts of functional SMN in SMA patients limit the formation of the SMN complex, thereby affecting snRNP assembly and ultimately normal mRNA splicing.[201,697,720] *SMN1* is contained within a large inverted repeat sequence that contains the highly homologous *SMN2* gene. *SMN2* differs from *SMN1* by only five bases; it lies in the opposite orientation and is centromeric to *SMN1*.[415,500] It is believed that *SMN2* arose by gene duplication, and that the *SMN2-SMN1* configuration is unique only to primates.[544] Although the five bases that differ between *SMN1* and *SMN2* do not affect the amino acid sequence of the protein; a C-to-T transition in exon 7 of *SMN2* corresponding to codon 280 causes alternative splicing and the deletion of exon 7 in 80 to 90% of *SMN2* transcripts.[408] The C-to-T transition enables the binding of heterogeneous ribonucleoproteins, thereby acting as a splicing silencer element and causing the exclusion of exon 7 from the transcript.[354] In addition, an *SMN2*-specific nucleotide in intron 7 contributes to excision of exon 7 in *SMN2* transcripts.[355] Thus despite the fact that most SMA patients have intact *SMN2* genes, they still have disease, because most *SMN2* transcripts do not contain exon 7; thus they produce negligible functional SMN protein. Without the amino acids encoded by exon 7, SMN is unstable and is unable to efficiently oligomerize to form the SMN complex.[409]

The *SMN2* gene is in part a modifier of the severity of SMA, and its affect is based on the *SMN2* gene copy number.[423,622,681] Some *SMN1* deletion alleles also contain an *SMN2* deletion, whereas other *SMN1* deletion alleles may have two or even three copies of *SMN2*. In patients with milder forms of the disease, three or four copies of *SMN2* may be present. Increased gene copy numbers are therefore producing more *SMN2* transcript, some of which will translate to functional SMN protein, thereby providing some normal SMN protein for required cellular functions. Although *SMN2* copy number primarily influences SMA severity, other factors appear to be contributory. Males with identical biallelic *SMN1* deletions and identical *SMN2* copy numbers appear to be more severely affected than females, and the SMA phenotype is variable even within families whose members share identical genotypes.[337] Phenotypic variability could be explained by recent findings of differences in DNA methylation at the *SMN2* locus.[278] In addition, absence of the adjacent neuronal apoptosis inhibitory protein (NAIP) gene may modify the SMA phenotype, causing more severe disease when it is also deleted.[180,554,681] NAIP is deleted in 1.8% of SMA carriers, yet is homozygously deleted in 67% of SMA patients with type I disease.

Treatment for SMA is mostly supportive for the management of respiratory insufficiency, nutritional deficiency, and orthopedic needs.[95] Because *SMN2* serves to modify the SMA phenotype, it can also provide a therapeutic target for future treatment. One approach is to reduce aberrant splicing of *SMN2*.[367] This was successfully performed in the mouse model of SMA to increase normal SMN levels using bifunctional RNA.[47,443] An alternative strategy would be to increase the expression level of *SMN2* using histone deacetylation inhibitors.[140] Because of the frequency and severity of the disease, therapeutic research is ongoing and many clinical trials are in progress.[95]

DNA testing for SMA is performed at multiple laboratories using a variety of techniques.[218] Establishing diagnostic or carrier testing can be complicated by (1) the polymorphic nature of the *SMN* locus, with alleles containing varying copy numbers of both *SMN1* and *SMN2* genes; (2) the degree of homology between *SMN1* and *SMN2*; (3) a small percentage of affected alleles with point mutations rather than deletions within *SMN1*; and (4) a 2% rate of de novo cases, which most frequently occur during paternal meiosis. A common diagnostic assay for SMA includes PCR amplification coupled with restriction endonuclease digestion with *DraI* and gel electrophoresis.[646] Only amplicons derived from *SMN2* will contain the restriction site; those generated from *SMN1* will not. Because most SMA affected patients have *SMN1* deletions involving exon 7, no bands corresponding to *SMN1* are observed. Although this assay is simple and robust, it is not quantitative and cannot determine the *SMN2* copy number, nor can it identify patients with point mutations within the gene. *SMN2* copy number is important for prognosis and for interpretation of at-risk pregnancies. Further, this assay cannot distinguish SMA carriers from controls—a task that is important for determining recurrence risk and for distinguishing an inherited mutation from a de novo mutation. Thus in some scenarios, quantitative methods such as real-time PCR, multiplex ligation-dependent probe amplification, denaturing high-pressure liquid chromatography, fluorescent PCR coupled with capillary electrophoresis, or DNA sequencing must be used.[238,312,610,674,713] Population-based carrier screening for SMA has been proposed but is not currently the standard of care.[521] With prospects of therapeutic treatment for SMA and early age of onset for the disease, newborn screening for SMA has also been proposed.[523] This

testing would allow early identification of patients and would enable timely treatment intervention, thereby minimizing the severity of the disease. Although it is theoretically sound, widespread newborn screening for SMA is not widely available.

Autosomal Dominant Diseases

In autosomal dominant conditions, a single abnormal allele is sufficient to cause disease despite the presence of a normal allele. An individual with an autosomal dominant disease may have inherited an abnormal allele from an affected parent, or alternatively, the mutant allele may have risen de novo as a new mutation during gametogenesis in an unaffected parent. The disease-causing gene is on one of the autosomes (1 to 22) and is not on a sex chromosome (X or Y). An affected individual possesses a 50% risk of donating the mutant allele to an offspring. Different mutations within the gene have varying effects on the protein, so that affected patients can have variability in clinical expression of the disease. In some instances, known mutant gene carriers have no clinical symptoms of the disease in a phenomenon referred to as *reduced penetrance,* yet they possess a 50% chance of having an affected child. Differences in phenotypic expression of the disease despite an identical mutation are most likely explained by the effects of other genes (modifier genes) and/or environmental influences. Among pedigrees illustrating autosomal dominant inheritance, both males and females are affected and male-to-male transmission is observed.

Achondroplasia

Achondroplasia (ACH) (OMIM #100800) is the most common nonlethal form of human genetic dwarfism with a worldwide incidence of 1 in 10,000 to 1 in 30,000.[308] ACH is inherited as an autosomal dominant disorder with 100% penetrance and is characterized by short-limbed dwarfism (rhizomelic form), macrocephaly, frontal and biparietal bossing, bowing of the lower extremities, and normal intelligence. The mean adult height is 131 cm for men and 124 cm for women, with a standard deviation of 5.6 and 5.9 cm, respectively. Close monitoring of patients is essential to prevent morbidity and mortality arising from complications of the disease.[48] Infants with this disease can die within the first year of life from central apnea caused by compression at the craniocervical junction; two copies of the mutant allele are often lethal.[241,473,502] Children undergoing surgical decompression of the craniocervical junction have decreased mortality and demonstrate improvement in neurologic function. During the first 5 years of life, affected children are at risk of death from compression of the brainstem and/or the upper cervical spinal cord. In adult patients, the leading cause of death is heart disease, and life expectancy is about 10 years less than for the general population.[707]

More than 90% of patients are born to parents of normal height. These patients represent sporadic cases arising as de novo mutations—a phenomenon associated with the "paternal effect" and advanced paternal age (older than 35 years).[137,229] Moreover, the estimated germline frequency of the common de novo disease causing mutation may be the highest observed in human beings.[692] The observed paternal effect associated with ACH has been thought to occur as the result of lifelong spermatogonial stem cell divisions, and thus an increase in production of mutant sperm as the male grows older.[131] Analysis of DNA extracted from testicular biopsy samples from older subjects supports this conclusion.[137] Alternatively, it has been proposed that sperm bearing ACH gene mutations may have a selective advantage in spermatogonial cells.[242] With both the paternal effect and a high mutation rate, when two affected siblings born to normal-sized parents shared a 4p haplotype derived from their unaffected father, Sobetzko and coworkers suggested that two de novo, independent, sporadic events had occurred, or that paternal gonadal mosaicism was present.[596] In a second reported family, recurrent affected siblings were shown to arise from paternal germline mosaicism rather than recurrent de novo mutations.[469] In one unusual report, it was concluded that siblings with achondroplasia born to unaffected parents were a result of germline mosaicism from the mother.[286] Although the mother had no clinical features of achondroplasia, a mutant allele was detected in the DNA extracted from her peripheral blood.

In 1994, the gene for achondroplasia was mapped to the telomeric region of chromosome 4p (4p16.3) using linkage studies on multigenerational families.[209,657] The fibroblast growth factor receptor 3 gene *(FGFR3),* mapped to this region and previously considered as a candidate gene for Huntington's disease (HD), was evaluated as a candidate gene for achondroplasia and was reported to contain mutations in patients with achondroplasia.[586,626] The *FGFR3* gene consists of 17 exons and encodes an mRNA of 4000 base pairs (bp). A different set of mutations in the *FGFR3* gene, causing varying effects on the function of *FGFR3,* have been associated with related forms of dwarfism, including thanatophoric dysplasia type I (OMIM #187601) and type II (OMIM #187601), hypochondroplasia (OMIM #146000), and a severe form of achondroplasia with developmental delay and acanthosis nigricans.[274,307]

The *FGFR3* protein product, FGFR3, is one of four human fibroblast growth factor (FGF) receptors and contains three extracellular immunoglobulin-like domains, a single transmembrane domain, and a split intracellular tyrosine kinase domain.[342] FGFR3 is a tyrosine kinase receptor that, when bound to 1 of 22 possible FGFs and heparan sulfate–bearing proteoglycans on the cell surface, induces dimerization of receptor monomers, activates tyrosine kinase activity, and promotes phosphorylation of tyrosine residues in the cytoplasmic domain, which in turn induces multiple signaling pathways, including STAT, MAPK, PLC-γ, and PI3K-AKT.[308,617] Signaling through FGFR3 is complex and is not completely characterized, but FGFR3 is thought to negatively regulate chondrocyte proliferation through apoptosis and differentiation.[124,145,533] Precisely which FGFs serve as ligands for FGFR3 is not known. Different proteoglycans on the cell surface, various isoforms due to alternative splicing, and different FGFs at different stages of development and at different

locations of the growth plate give rise to added diversity of FGFR3 ligand binding and subsequent effects.

The primary mutation in achondroplasia results in a defect in normal internalization and ubiquitination and lyosomal degradation of the mutant receptor. Thus it is retained on the cell surface and has uncontrolled and prolonged phosphorylation of FGFR3 signaling in chondrocytes.[274,453] Hence, chondrocyte maturation and terminal differentiation are inhibited. As such, therapies are directed toward the increase in short stature. New therapies can be directed toward the molecular bases of disease, including (1) chemical inhibitors of FGFR3 tyrosine kinase activity, (2) antibodies that prevent binding of FGF ligands to FGFR3, and (3) targeting of regulators of various FGF-induced signaling pathways.[143,263,307]

In the original report identifying the *FGFR3* gene as the cause of achondroplasia, 15 of 16 patients had a G-to-A transition mutation at nucleotide 1138 (c.1138G>A), and the only patient who did not have this mutation instead had a G-to-C transversion mutation at the same position (c.1138G>C).[586] Both mutations result in a glycine-to-arginine substitution in the transmembrane domain of FGFR3 at codon 380. The frequency of the G-to-A transition mutation at codon 380 in achondroplasia patients is well documented and represents more than 95% of the mutation detected in this population.[55,551] This base pair may be prone to mutation because a cytosine residue in a CpG dinucleotide is known to be a hot spot for transition mutations.[41,64,166] If the cytosine residue is methylated (i.e., as 5-methylcytosine), it can spontaneously deaminate to thymine to introduce the change from a G:C base pair to an A:T base pair in subsequent replications of DNA. Because most *FGFR3* mutations causing achondroplasia are c.1138G>A or c.1138G>C, DNA testing includes targeted mutation analysis for both mutations using a variety of techniques.[218] Testing can be performed postnatally to confirm the diagnosis of achondroplasia. Prenatal DNA testing may be requested by couples in which one is affected with ACH and the risk of an affected child is 50%. Alternatively, preimplantation genetic diagnosis can be performed for ACH.[12] In addition, prenatal testing can be requested by unaffected parents with a previous affected child, who may be concerned about germline mosaicism, although the risk of recurrence in these cases would be considered low. Pregnancies involving mating between two affected individuals are not uncommon. Prenatal DNA testing can be requested by these couples because they have a 25% chance of having a child homozygous for an *FGFR3* gene mutation—a potentially lethal condition. This situation presents difficult choices for the couple. In one study, attitudes of affected individuals and their relatives toward termination of the pregnancy based on prenatal findings indicated that if the fetus was homozygous mutant for ACH, 40% would consider termination compared with 41% who would not; 19% were unsure of what they would do.[240] In this same study, if the fetus was heterozygous for a mutation causing achondroplasia, 5% would consider termination and 86% would not; 8% were unsure what they would do. Last, if the fetus was determined to be normal, having not received a mutation from either parent to cause this disease, 90% responded that they would not consider termination of the pregnancy, but 3% would; 6% were unsure of what their decision might be.

Huntington's Disease

Huntington's disease (HD) (OMIM#143100) is an autosomal dominant, late-onset neurodegenerative disorder with an incidence of about 3 to 10 per 100,000 in most populations of European origin. First described by George Huntington in 1872, the disease is progressive and is characterized by frequent involuntary, rapid movements (chorea) and dementia.[320] The mean age of onset is between 35 and 44 years, but approximately 25% of patients first display symptoms after the age of 50, and about 10% of patients have juvenile HD with age of onset before 20 years.[279,465] The median survival time is 15 to 20 years after onset of symptoms. In the first few years of the disease, symptoms include mood disturbances, cognitive deficits, clumsiness, and impairment of voluntary movement.[279] The next stage of the disease is associated with slurred speech (dysarthria), hyperreflexia, chorea, gait abnormalities, and behavioral disturbances such as intermittent explosiveness, apathy, aggression, alcohol abuse, sexual dysfunction and deviations, and increased appetite.[207] As the disease advances, bradykinesia, rigidity, dementia, dystonia, and dysphagia are present. In the late stages of HD, weight loss, sleep disturbances, and incontinence occur.

In 1983, Gusella and associates reported linkage between DNA marker D4S10, on the short arm of chromosome 4, and HD, based on studies from a large kindred in Venezuela.[261] Subsequently, more DNA markers were identified, and the region of the genome containing the HD gene was narrowed to 4p16.3.[50,126,225,420,680] Through an international collaborative effort, and 10 years after its initial localization, the HD gene, *IT15,* was cloned.[321] The molecular basis for HD was determined to be expansion of a glutamine-encoding CAG trinucleotide repeat; this was subsequently confirmed in a worldwide study by the identification of expanded CAG-repeat alleles in HD patients from 565 families, representing 43 national or ethnic groups.[377] In this initial international study, the median CAG-repeat length was reported to be 44 in affected patients and 18 in controls. Normal CAG repeats range from 10 to 26, repeats of 27 to 35 are considered intermediate or "mutable," repeats of 36 to 39 are associated with reduced penetrance of the disease, and repeats of 40 or greater are associated with HD (Figure 40-3). HD is one of about 20 inherited neurologic diseases associated with trinucleotide repeat instability.[83,491] In HD, the number of CAG repeats is inversely correlated with age at onset of the disease. Patients with onset as early as 2 years of life have a repeat number approaching 100 or greater, and late-onset-disease patients have repeat numbers of 36 to 39.[19,81,169,321,377,594] However, an autopsy confirmed that the diagnosis of HD was reported in a 65-year-old male with as few as 29 CAG repeats.[364] Although the CAG-repeat number accounts for the majority of variance in age of onset for HD (≈70%), the remainder of the variance is due to modifier genes or environmental factors. Analysis of the large Venezuelean HD kindreds encompassing 18,149

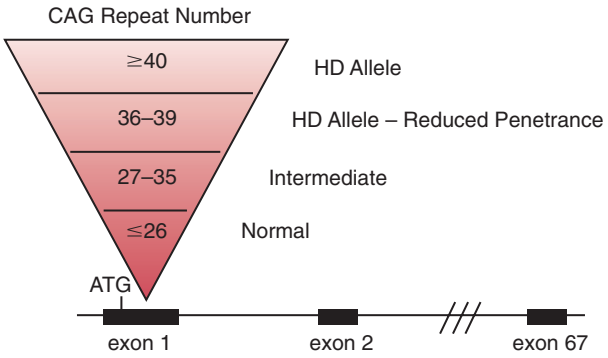

Figure 40-3 Schematic representation of the polyglutamine-encoding CAG repeat in exon 1 of the HD gene and associated alleles. A CAG-repeat number ≤26 is considered normal. CAG-repeat numbers of 27 to 35 are intermediate, and although they are not associated with an abnormal phenotype, these alleles are prone to meiotic expansion to an HD allele. CAG repeats of 36 to 39 are considered HD alleles but with reduced penetrance, indicating that both unaffected and affected patients have been reported with alleles of this size. CAG repeats ≥40 are associated with HD with complete penetrance.

individuals spanning 10 generations indicated that 40% of the remainder of the variance is due to modifier genes, and 60% to environmental factors.[643] The largest genome-wide scan to identify modifying loci was performed on these Venezuelean kindreds.[216] Most significant LOD scores (logarithm of the odds ratio) were identified at chromosomal regions 2p25, 2q35, 5p14, and 5q32, suggesting the physical location of candidate modifying genes.

New mutations for HD (the presence of an affected individual in the absence of a family history) occur from expansion of CAG-intermediate alleles and occur almost exclusively through expansion during paternal transmission.[233] Although intermediate alleles are present in about 1% of the population, it appears that flanking DNA sequences may influence the instability of these alleles by enhancing the formation of hairpin loop structures and causing replication slippage.[114,234] Single sperm analysis studies have demonstrated 11% instability (9% expansions and 2.5% contractions) in CAG repeats of 30 compared with 0.6% instability (contractions only) seen in average-sized alleles of 15 to 18 repeats.[392] These studies indicate that an increase in instability occurs as the repeat number increases. This concept is further supported by observations that CAG repeats of 36 showed 53% instability, and CAG repeats from 38 to 51 had instability ranging from 92 to 99%. In addition, *cis*-elements may play a role in CAG-repeat instability in *IT15*.[678] Warby and colleagues identified a common haplotype (A) of 22 tagged single-nucleotide polymorphisms (tSNPs) that was more common on HD (95%) and intermediate (83%) alleles in patients of European origin than on normal (53%) alleles from the same population. Onset of symptoms occurs at progressively younger ages in successive generations of affected families, a pattern called *anticipation*. Anticipation is explained by meiotic expansion of the unstable CAG repeat during transmission by the affected parent, resulting in an even higher CAG-repeat number in the offspring and an earlier age of onset. In addition, although 69% of affected father-child pairs show expansion, only 32% of affected mother-child pairs demonstrate expansion. Further, <2% of maternal expansions result in a change of >5 repeats, whereas up to 21% of paternal transmissions increase by >7 repeats.[376] The affected parent in most cases of juvenile-onset HD is the father. However, the largest reported CAG-repeat number of ≈130 occurred via maternal expansion of 70 CAG repeats.[467] An increase in the CAG-repeat number is also associated with more rapid progression of disease and greater neuropathologic severity in the striatum.[213,508] However, it is interesting to note that homozygotes with two expanded CAG-repeat alleles do not have more severe disease than heterozygotes.[377,464,690]

The HD gene protein, huntingtin (htt), consists of 3144 amino acids with a molecular mass of ≈349 kDa, is ubiquitously expressed in all tissue, and predominantly resides in the cytoplasm with lesser amounts in the nucleus.[148,262,302,627,655] With universal distribution, it is not known how and/or why the primary phenotype is neuronal loss. In neurons, htt is associated with synaptic vesicles and microtubules and is abundant in dendrites and nerve terminals. Huntingtin interacts with multiple proteins, indicating its function in intracellular trafficking and cytoskeletal organization, as well as in endocytosis, apoptosis, and transcription regulation.* Mutant HD alleles are effectively transcribed and translated, but as a result of the increase in glutamine residues, the protein is misfolded.[564] Thus, abnormal folding may result in aberrant protein-protein interaction of mutant htt with any of its protein partners and could contribute to the pathogenesis of HD. In addition, neuronal mitochondrial dysfunction may play a role in the disease process.[85,675] Further, aggregates of fragmented mutant htt form neuronal nuclear inclusion bodies (IBs), which may be toxic to the cells.[156] Recent data, however, suggest that IBs may result from a normal cellular process to handle abnormal and toxic proteins, and that their formation is facilitated by proteasomal chaperones.[448,550] HD remains an incurable disease; however, various therapeutic strategies have been proposed and/or attempted in animal models. Such strategies include allele-specific silencing of mutant *IT15* mRNA; small molecules targeted toward mutant htt; and cell transplantation therapy.[360,620,719]

DNA testing for HD is performed with the use of PCR so that the exact CAG-repeat number can be determined.[321] Soon after the initial report, it was discovered that the accuracy of determining the CAG-repeat number by PCR was compromised by inclusion of a polymorphic CGG repeat immediately downstream from the CAG repeat. Because the CGG repeat was contained within the amplified sequence, the length of the amplicon could be altered and overestimated.[20,555] Upon this discovery, a new primer pair was identified that flanked the CAG repeat, yet excluded the problematic polymorphic CGG repeat and provided accurate assessment of

BOX 40-2 Ethical Issues Associated With Presymptomatic DNA Testing for HD

Patients must be 18 years of age.
The decision to proceed with testing must be voluntary and informed.
Genetic counseling regarding benefits/pitfalls of testing is required.
A support partner is needed for the patient for counseling and the testing process.
Diagnosis of Huntington's disease (HD) in the family should be confirmed by DNA testing before presymptomatic testing.
Psychiatric assessment of patient is necessary before testing.
Follow-up genetic counseling is recommended after delivery of results.
Discrimination by insurance carriers or employers may occur following completion of testing.
Prenatal testing of fetus is controversial; preimplantation diagnosis is available.

the CAG-repeat number.[679] However, in contrast to earlier years, when PCR involved the use of ^{32}P-labeled primers for this and similar assays, currently the most common method involves the use of PCR with fluorescently labeled primers and capillary electrophoresis[664] (Figure 40-4). Guidelines for diagnostic testing by clinical laboratories with reference to standardization and interpretation have been developed.[518]

Besides the technical and interpretive difficulties associated with HD testing, many ethical issues exist as well, primarily as they relate to presymptomatic testing (Box 40-2). The first policy statement on ethical issues related to genetic testing for HD was adopted in 1989 at a joint meeting with representatives from the International Huntington Association and the World Federation of Neurology.[325] At that time, the gene had not yet been cloned, and predictive testing was performed using linkage studies; the at-risk patient was quoted the likelihood of inheriting the mutant allele. These tests were less than perfect and provided, at best, results in only 60 to 75% of families. Moreover, the possibility of recombination allowed erroneous predictions to occur.[280,463] In other families, living affected members were not available, or markers were not informative. Once the gene had been cloned and direct mutation analysis was possible, risk assessments were reversed in a small percentage of patients.[11]

Following cloning of the gene and the availability of direct mutation analysis, guidelines for predictive testing were re-evaluated, and changes were proposed by the International Huntington Association and the World Federation of Neurology Research Group on Huntington's Chorea.[326] Direct predictive testing was preferred over linkage studies and was readily accepted by the HD community.[33] The approach used for HD has become the model for predictive testing for late-onset single-gene disorders, and similar formats have been applied to other late-onset inherited diseases, including the autosomal dominant cerebellar ataxias and less common, dominantly inherited, fatal familial insomnia.[232,640] If an HD-causing expanded CAG-repeat allele is identified in the

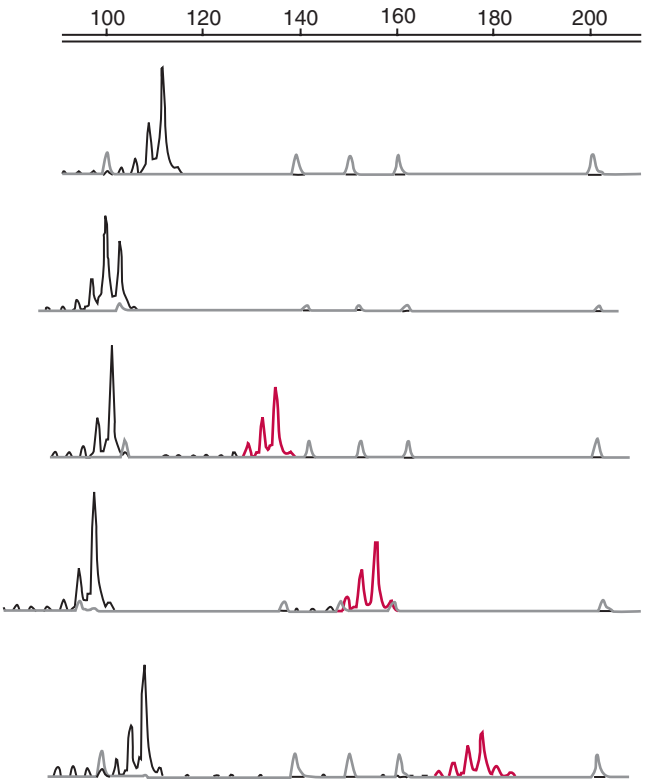

Figure 40-4 Electropherograms representing various patterns observed in patients referred for Huntington's disease (HD) testing. The polyglutamine-encoding CAG repeat in exon 1 is amplified by polymerase chain reaction (PCR) using flanking oligonucleotide primers, one of which is labeled with a fluorescent dye. Amplicons are subjected to electrophoresis on a 5% denaturing polyacrylamide gel on an ABI 377 DNA sequencer and are analyzed using GeneScan software, version 3.1 b3 (Applied Biosystems, Foster City, Calif). Amplicons 100 base pairs (bp) in length contain 18 CAG repeats and flanking DNA. Patient 1 *(row 1, top)* has amplicons 112 bp in length and has 22 CAG repeats on both HD alleles. Patient 2 *(row 2)* has 97 bp and 100 bp amplicons, corresponding to CAG repeats of 17 and 18. The diagnosis of HD can be ruled out in these two patients. Patient 3 *(row 3)* has 97 bp and 133 bp amplicons corresponding to CAG repeats of 17 and 29. The results would not support a diagnosis of HD. However, a CAG repeat of 29 is considered intermediate and can undergo meiotic expansion to an HD allele. Patient 4 *(row 4)* has CAG repeats of 19 and 38, as depicted by amplicons 103 bp and 160 bp in length. In the symptomatic patient, these results would support the diagnosis of HD. However, in the presymptomatic patient, the phenotype of this HD allele with reduced penetrance cannot be predicted with certainty. Patient 5 *(row 5)* has CAG repeats of 21 and 44 because amplicons 109 bp and 178 bp in length were detected. These results would confirm the diagnosis of HD. Genetic counseling regarding the implications of DNA findings in patients 3, 4, and 5 is indicated.

asymptomatic patient (≥40 years), the median age of onset in HD patients with the patient's corresponding CAG-repeat number can be quoted to the patient.[81] Predictive testing should be performed only on adults and only with informed consent. Informed consent implies that the patient has been thoroughly counseled and clearly understands both the advantages and the disadvantages of knowing the results. Advantages of having this test include but are not limited to removal of uncertainty regarding whether patients have or have not inherited the mutant allele and the feeling of relief for those who have not inherited a mutant HD allele. This information can help patients appropriately plan their personal and career paths. Disadvantages of knowing this information include but are not limited to (1) the feeling of "survivor's guilt" in those who learn that they have not inherited a mutant allele and other family members have; (2) fear from learning that they have inherited a mutant HD allele and will develop this incurable disease; (3) risk of discrimination in employment or health insurance coverage if the results are disclosed; (4) worry about a 50% chance of passing this gene on to their offspring; and (5) uncertainty of developing disease if they have inherited a mutant HD allele containing 36 to 39 CAG repeats.

It is important to note that the guidelines indicate that the patient should be accompanied by a trusted friend or loved one throughout the counseling and testing procedure. This person can provide stability to the patient by being able to intimately speak to the patient about the situation and discuss the information shared at the counseling sessions. Most important, as a part of this process, the partner will be present when the results of testing are revealed and can provide comfort and support as needed both then and in the following days, weeks, or months. Ultimately, however, it is the patient's decision to proceed with this testing and to accept both the benefits and pitfalls of knowing this information. The patient's decision to proceed must be his or hers, without coercion from family members, clinicians, friends, or employers.

For at-risk individuals requesting mutation studies, it is important that their mental stability is considered for the safety of the patient; a psychiatric assessment is often part of the testing protocol because HD test results can precipitate depression. Results of the psychiatric evaluation can influence the timing of the DNA test, postponing it until such time when the patient is considered mentally able to deal with the possibly devastating news. Suicidal tendencies associated with HD range from 9.1% in at-risk individuals displaying a normal neurologic examination to as high as 23.5% in at-risk individuals with neurologic findings consistent with "possible Huntington's disease."[503] Suicidal thoughts in patients with confirmed HD range from 16.7% in the early stage of disease to 21.6% later in the disease, when independence diminishes.[503]

If possible before presymptomatic mutation testing, the diagnosis of HD should be confirmed in an affected member of the family to be certain that the disease in the family is indeed HD. Excluding HD cannot rule out a different, dominantly inherited neurodegenerative disease in the family for which the patient likely retains a risk of development. Because HD is a delayed-onset disease, as the asymptomatic at-risk patient ages, the risk of testing positive with an expanded CAG repeat decreases.[276] Thus should the patient elect not to have predictive testing, the genetic counselor can provide information regarding the probability that an HD mutation exists, which, based on the individual's age, may provide some comfort to the patient. Most individuals who seek presymptomatic testing have a mean age of ≈40 years and are more often female.[631] It is also not uncommon for one to begin this multistep counseling process and withdrawal from the study without receiving test results.[631] Counseling in families with no prior family history of HD can be complicated. In these cases, the expanded CAG repeat appears to be de novo. Multiple factors can explain this phenomenon, including (1) expansion of an intermediate (27 to 35) or reduced penetrance allele (36 to 39); (2) premature death of an adult asymptomatic individual; (3) misdiagnosis in other family members; (4) alternative paternity; and (5) undisclosed adoption. For appropriate at-risk assessment of individuals with these pedigrees, it is important to try to determine the likely explanation; however, in some cases, it may not be known, and thus counseling for the risk of HD should be prudent.

Prenatal testing for HD, another complicated issue associated with this disease, may not be provided in all laboratories that perform routine HD testing. If a molecular genetics laboratory chooses not to provide prenatal testing (e.g., because of the possibility of termination of a pregnancy for a late-onset disorder, or because it constitutes presymptomatic testing of the child should the parents choose not to terminate), it is the responsibility of the laboratory to identify an alternative laboratory for testing to which the patient can be referred. Before cloning of the HD gene, prenatal testing was performed using linkage studies, and the likelihood that the child would develop HD was "excluded" if the child had inherited an HD haplotype from an unaffected grandparent.[447,638] The concept of exclusion testing was difficult to understand, however, and not all families were heterozygous for the DNA markers, thereby making the test inconclusive. In some instances, the status of the parent at risk for developing the disease was also revealed. Moreover, testing could in theory lead to abortion of 50% of fetuses who had not inherited HD but rather had inherited the normal HD allele from the affected grandparent. To eliminate some of the controversy of prenatal testing for HD, preimplantation genetic diagnosis (PGD) can be performed. In PGD, in vitro fertilization is used to produce embryos that then undergo a single cell biopsy for analysis of their HD genes. Once PCR has been used to determine the HD CAG-repeat numbers, embryos with normal HD alleles are implanted. This method, which combines direct mutation analysis and PGD, eliminates the necessity for prenatal testing to determine the HD status of the fetus, because the HD alleles of the fetus are known to be normal, and the need for termination of a pregnancy is eradicated. Further, this method can be performed without

disclosing the HD status of the asymptomatic, yet at-risk parent. However, this approach of nondisclosure PGD can pose ethical problems for testing personnel.[76] In some testing centers, PGD may be performed by direct mutation analysis in families in which the at-risk parent is knowledgeable regarding his or her carrier status, and embryos with only normal HD alleles are implanted. Alternatively, in families in which the parent is unaware of his or her HD status, PGD can be performed using exclusion testing, whereby only embryos who have not inherited an affected allele are implanted, and information regarding the HD CAG repeat numbers in all tested embryos is not disclosed to the parents.[76,575,576]

Marfan Syndrome

Marfan syndrome (MFS) (OMIM #154700) is an autosomal dominant multisystem connective tissue disorder with primary manifestations involving the ocular, musculoskeletal, and cardiovascular systems and an estimated worldwide incidence of 1 in 5000.[146,155,348] Common ocular features of MFS include myopia, bilateral ectopia lentis, and retinal detachment. In addition, patients with MFS are at increased risk for cataracts at a younger age. Skeletal abnormalities arise from bone overgrowth and joint hypermobility. MFS patients are tall with frequent clinical findings including pectus excavatum or pectus carinatum, arm span-to-height ratio greater than 1.05, and a reduced upper body-to-lower extremity ratio. Scoliosis is present and can be mild to severe and is progressive. Morbidity and early mortality of the disease are linked to cardiovascular manifestations of the disorder, which are characterized by progressive dilation of the aortic root, predisposition to aortic dissection, mitral valve prolapse with or without regurgitation, and dilation of the pulmonary artery. Wide phenotypic variability is observed, with some patients presenting as neonates and others remaining undiagnosed until adulthood. An early diagnosis is associated with an improved long-term outcome.[694] Unfortunately, it is not uncommon to first diagnose MFS in a patient at autopsy when associated with sudden premature death due to aortic dissection and/or rupture.[372,539]

The diagnosis of MFS is based on family history of the disease, although as many as 25% of cases of MFS can arise from a new mutation and thus a negative family history of disease.[154] In the absence of a documented family history of MFS, the clinical diagnosis of MFS is made using the Ghent nosology in adults.[141,146] The MFS diagnosis relies on specific significant clinical manifestations involving two organ systems and minor involvement of a third organ system.[146] Because most clinical manifestations increase with age, these criteria may be less applicable to diagnosis in the pediatric community.[188]

Classic MFS is associated with mutations in the fibrillin gene *(FBN1)* mapped to 15q21.1.[154,298,351] The gene spans 237,414 bp, is composed of 65 exons, and encodes a 10 kb mRNA, prefibrillin-1.[62] *FBN1* is ubiquitously expressed in connective tissue.[62] The ≈350 kDa, 2871 amino acid extracellular glycoprotein, fibrillin-1, self-assembles into macroaggregates to serve as the primary structural component of 10 to 12 nm diameter microfibrils in elastic and nonelastic tissue.[62,313] In elastic tissue, microfibrils make up the scaffold for elastin assembly within the extracellular matrix. In nonelastic tissue, including the ciliary zonule of the eye and of basement membranes, they have an anchoring function and provide tensile strength.[526] Fibrillin-1 contains several motifs, including cysteine-rich calcium binding epidermal growth factor-like domains interspersed with eight cysteine motifs. These motifs are interspersed by transforming growth factor-β (TGF-β) binding protein (LTBP) domains. LTBPs interact with fibrillin-1 and together bind TGF-β to inactivate and thereby prevent signaling through the SMAD 2/3 pathway.[243,314,526] Studies on the MFS mouse deficient in fibrillin-1 demonstrated that reduced LTBP–fibrillin-1 complexes led to the inability to sequester latent TGF-β and resulted in increased activity and dysregulation of TGF-β.[474]

Mutations in *FBN1* are heterogeneous, with more than 600 reported throughout the gene. Phenotype-genotype studies have shown that neonatal MFS and severe MFS, with an earlier age of diagnosis, have an increased likelihood of ectopia lentis, ascending aortic dilation, aortic surgery, mitral valve anomalies, and scoliosis, and a reduced life expectancy, and are associated with mutations spanning exons 24 to 32.[186,187,636] This region of the protein contains the longest stretch of epidermal growth factor (EGF)-like domains and is thought to be important for microfibril biogenesis. More specifically, one study suggested that neonatal MFS is most frequently associated with exon 25 mutations.[186] In this study, in-frame missense mutations were often associated with more severe complications of MFS than were mutations predicted to cause premature truncation of the protein.[186] Further, many of the missense mutations affected highly conserved cysteine residues within the EGF-like domains. It is interesting to note that wide phenotypic variability is observed even for individuals harboring the same recurrent mutation, suggesting the role of modifier genes in the MFS phenotype.[186] The likely effect of yet to be identified modifier genes on the MFS phenotype explains the lack of consistent genotype-phenotype correlations. Further, the lack of consistent genotype-phenotype correlations provides little prognostic value for individual patient management.

Management of patients with MFS is similar to that of patients with other inherited multisystem disorders, involving a team approach with specialists in many areas of medicine. It is now believed that the pathogenesis of MFS is due to the increased availability of TGF-β; therefore, treatment for MFS includes the use of TGF-β antagonists. Studies using this approach on the MFS mouse model have been reported not only to stop the progression of disease but also to reverse the cardiovascular consequences of FBN1 deficiency.[264] As a result, the antihypertensive drug losartan is being used clinically for MFS patients; it acts as an angiotensin II type 1 receptor inhibitor to inhibit excessive TGF-β signaling.[82]

TGF-β signaling also requires the action of matrix metalloproteases to allow for proper release and interaction of TGF-β with its receptor complexes. Thus, targeted treatment through inhibition of matrix metalloproteinase-2 and -9 has also been successfully employed.[116]

FBN1 is one of the largest human genes, and although it is labor intensive and costly, DNA sequencing is the gold standard for DNA testing for Marfan syndrome. Thus, many laboratories invoke a prescreening approach to identify the region of interest within the gene that may harbor a mutation. If an area of interest is detected, DNA sequencing is performed for mutation identification.[318] Using this method, full *FBN1* gene sequencing can be reserved for those patients for whom no mutations are identified by gene scanning approaches to prevent a false-negative result from gene scanning techniques. It is important to note that the presence of an *FBN1* mutation does not imply a clinical diagnosis of MFS because mutations in this gene can be associated with isolated ocular, skeletal, or cardiovascular features also seen in MFS patients.[214] These patients do not meet the clinical criteria of MFS but rather are collectively referred to as having *type I fibrillinopathies. FBN1* mutation detection in this patient population is variable.[605] Despite extensive *FBN1* analysis, as many as 30% of MFS patients will have no mutation detected. These cases could reflect patients with *FBN1* mutations that are contained within regions of the gene that cannot be detected by current screening techniques; patients who do not meet the strict Ghent diagnostic criteria; or patients with genetic heterogeneity whereby mutations in other genes cause the MFS phenotype.[260,407] Once an *FBN1* mutation has been identified within a family, predictive testing for at-risk family members as well as prenatal or preimplantation genetic diagnosis can be performed.

X-Linked Diseases

In X-linked diseases, the mutant allele resides on the X chromosome. In X-linked recessive diseases, females are carriers of the disease with one normal and one mutant allele but typically are not affected. Males receiving the mutant allele from their mothers and having only one X chromosome have no normal allele and thus are affected. All daughters of affected males are carriers of a mutant allele. The carrier female has a 25% chance of transmitting her normal allele to a son, a 25% chance of having an affected son, a 25% chance of having a daughter who carries the mutant allele, and a 25% chance of having a daughter who receives her normal allele. In the absence of a family history, an affected male can have a mutant allele that arose de novo as a new mutation during formation of the egg. Roughly one third of all cases of X-linked disorders represent new mutations, indicating that the mother is not a carrier of a mutant allele and is not at risk for subsequent affected children. In pedigrees associated with X-linked recessive conditions, typically only males are affected, and male-to-male transmission of the disease is not seen. In less frequent, X-linked dominant diseases, one copy of the mutant allele is sufficient to cause disease despite the presence of a normal allele. Further, in males with only a mutant allele, these diseases are often lethal.

Hemophilia A

Hemophilia A (HA) (OMIM #306700) is an X-linked recessive bleeding disorder caused by a deficiency of coagulation factor VIII (FVIII); it affects approximately 1 in 5000 males worldwide.[245] The disease is characterized by prolonged bleeding after injury or surgery, renewed bleeding after the initial bleeding has ceased, and, in severe cases, spontaneous bleeding into the joints. The severity of the disease is classified according to the amount of FVIII coagulant activity present in the plasma; severe, moderate, or mild disease corresponds to FVIII activity levels of <1%, 1 to 5%, or 5 to 30%, respectively. Severe disease is seen in 50% of patients; 10% have moderate disease and 40% have mild disease.[22] In the patient with severe or moderate hemophilia A disease, the activated partial thromboplastin time (aPTT) will be prolonged, while all other routine coagulation tests will be normal. In patients with mild hemophilia A disease, however, aPTT is often normal. Age at diagnosis is typically younger in cases of severe disease and in cases with a family history of disease.[106] Most patients with severe disease are diagnosed in the first year of life; patients with mild disease may not be diagnosed until several years later. Diagnosis may also be delayed because about 30% of cases arise as a new mutation in the absence of a family history. As an X-linked disease, HA typically presents in males; however, females with the disease have been reported. Carrier females can present with severe disease caused by (1) skewed X-chromosome inactivation, in which the X chromosome with the mutant *FVIII* gene is not inactivated because of its involvement in an X-autosome translocation; (2) an X inactive transcript gene, *XIST,* mutation; or (3) the presence of a mutant *FVIII* gene on each of the X chromosomes.[61,454,572,644,696]

The clinical phenotype of HA is variable for both frequency and type of bleeding and is most often associated with the baseline plasma FVIII level for the patient. Treatment for bleeding episodes consists of intravenous infusions of FVIII concentrate given as quickly as possible to prevent pain, disability, and chronic joint disease. For children with severe hemophilia, the standard of care is to provide prophylactic infusions of FVIII concentrate within the first 2 years of life to maintain their clotting activity above 1% and to decrease the number of spontaneous bleeding episodes.[416] As a result, clotting factor consumption has increased dramatically over the years and is quite costly, but this regime has significantly decreased hemophiliac arthropathy and has extended the life span to near normal.[206] Management of 30% of patients with severe disease is complicated by immunoglobulin (Ig)G antibody formation, termed *inhibitors,* to exogenous FVIII that is caused by repeated infusions. These antibodies can rapidly neutralize infused FVIII. Inhibitor formation generally occurs early in treatment, usually before the 15th infusion, and is suspected when a poor response to FVIII infusion therapy is observed.[362,623] The formation of inhibitors is dependent on

the type of FVIII mutation, as well as on other genetic and environmental factors.[623] A risk stratification score was recently devised to assist with identification of patients at high risk for inhibitor formation, thereby enabling individualized treatment strategies to minimize inhibitor formation.[623] Before the use of recombinant FVIII, management of the disease was further complicated in patients who had contracted bloodborne pathogens, human immunodeficiency virus, and/or hepatitis C virus from contaminated plasma–derived FVIII concentrates. Great interest in gene therapy for hemophilia A remains, despite limited success thus far.[310,662] However, Margaritis and associates reported promising results using in vivo adeno-associated viral vector delivery of continuously expressed recombinant FVIIa in the canine model of HA, thus bypassing FVIII-FIX and avoiding the risk of FVIII inhibitor formation.[427]

The *FVIII* gene is found on Xq28 and was cloned in 1984.[228] This gene spans more than 186,000 base pairs and includes 26 exons.[21] The *FVIII* gene is predominantly expressed in the liver and encodes a 9 kb mRNA transcript.[652] The mature 2332 amino acid FVIII protein is produced after cleavage of a 19 amino acid N-terminal leader peptide. The protein is divided into several domains, referred to as A1, A2, B (heavy chain), A3, and C1 and C2 (light chain).[652] FVIII circulates in the plasma, and is protected and stabilized through noncovalent binding to the complex multimeric glycoprotein von Willebrand factor (vWF) through binding at the C2 domain. In the intrinsic coagulation pathway, proteolytic activation of FVIII occurs following cleavage by thrombin at multiple sites, where it participates as a cofactor with activated factor IX to catalyze the conversion of factor X to factor Xa.[193] The B domain of the protein is removed in the activated form, and the other components are held in a complex with Cu^{2+}.[245] Factor Xa hydrolyzes and activates prothrombin to thrombin. As the concentration of thrombin increases, FVIIIa is ultimately cleaved by thrombin and inactivated. This dual action of thrombin on FVIII regulates the formation of the FVIIIa, IXa, and X complex, thus regulating the clotting cascade. A deficiency of coagulation FVIII then leads to uncontrolled bleeding.

A plethora of nucleotide substitutions and gene deletions, insertions, and rearrangements throughout the *FVIII* gene account for more than 1000 mutations reported in patients with hemophilia.[285] The type of mutation, its location within the gene, and ultimately its effect on the functional activity of the FVIII protein account for much of the clinical heterogeneity that is observed with this disease.[239,246,634] Gross rearrangements of the *FVIII* gene, including intrachromosomal inversions or large deletions and duplications, are typically associated with severe disease.[239] Small deletions and insertions are also common in severe HA. Missense mutations are most frequently observed (95%) in patients with moderate and mild disease.[239] Further, patients with null mutations, large deletions, nonsense mutations, and common intron 22 inversions are most susceptible to inhibitor formation and have more complicated disease management issues.[362] Patients with nonsense mutations in the 5′ region of the gene have a lower risk of inhibitor formation than those with mutations involving the 3′ region of the gene.

Before the early 1990s, routine screening of coding, splice junctions, the promoter region, and the polyadenylation site of the gene could detect the mutation in most patients with mild to moderate disease, yet the disease-causing mutation in about half of those with severe disease remained elusive.[291] In 1993, a common inversion mutation was identified in approximately 45% of patients with severe disease.[386,472] The *int22h*-related inversions arose from genetic recombination between a small intronless gene within intron 22, gene A, and one of two additional copies of gene A located approximately 500 kb upstream from the *FVIII* gene. The mechanism for the inversion involves flipping of the tip of the X chromosome, allowing pairing between homologous sequences and genetic recombination between one of the upstream copies of gene A and the copy of gene A within intron 22. Consequently, the *FVIII* gene is divided into two parts, with exons 1 to 22 widely separated and in an opposite orientation and thus inverted from exons 23 to 26. Most (>75%) inversion mutations involve the distal copy of gene A upstream from the *FVIII* gene as compared with the adjacent proximal copy of gene A.[386] Rossiter and colleagues showed that this genetic recombination between homologous intragenic and extragenic copies of gene A occurred as a new mutation predominantly during male meiosis with a male-to-female ratio of 302 : 1.[549] Because Xq is unpaired with a homolog during male meiosis, it is able to flip on itself for an intrachromosomal recombination event. The role of this mutation as a primary cause of severe hemophilia A disease was subsequently confirmed by analysis of DNA from patients with hemophilia from around the world.[23] Additionally, this mutation has been identified in the Chapel Hill dog colony with hemophilia A disease and presumably arose from the same mechanism of genetic recombination between homologous sequences.[412] Subsequently, a second, less common inversion mutation resulting in about 1% of cases with severe disease was identified.[34] This inversion results from homologous recombination between a segment in intron 1 *(int1h1)* and a 1041 bp repeat that is 140 kb telomeric to *FVIII*.

In the mid-1980s, after the discovery of the *FVIII* gene and before our current DNA technologies were developed, DNA testing for hemophilia A primarily involved the use of linkage studies and restriction fragment length polymorphisms to determine the carrier status of at-risk females in the family and to perform prenatal testing.[24,698] Although accurate, these studies could be complicated by (1) the large number of family members required for participation in the analysis, (2) a limited number of alleles for each marker [limiting the chance that key members of the family would be informative (i.e., heterozygous) for a given marker], and (3) genetic recombination between the informative marker and the *FVIII* gene mutation, which could affect the accuracy of the results. Moreover, in the absence of a family history, the carrier status of the mother of a sporadic case was uncertain (although as many as two thirds of these mothers might be carriers). PCR and analysis of polymorphic microsatellite repeats within the

FVIII gene increased the number of families in which linkage studies could be performed and significantly improved turnaround times.[388]

The most significant improvements in DNA testing included the identification of the inversion mutation in families with severe disease and the ability to offer direct mutation analysis as opposed to linkage studies.[339,665] As a result, the carrier status of the mother of a sporadic case with a detectable inversion mutation could now be determined with certainty, and her risk for carrying another affected son could be precisely predicted to be 25% (Figure 40-5). In addition, prenatal and carrier testing results would be completely informative and accurate and would not be subjected to the inaccuracy of linkage studies caused by the possibility of genetic recombination. Subsequently, a PCR assay was developed for detection of the inversion mutation. It eliminated the necessity for labor-intensive and expensive Southern blot analysis and significantly improved turnaround times.[405,406,548]

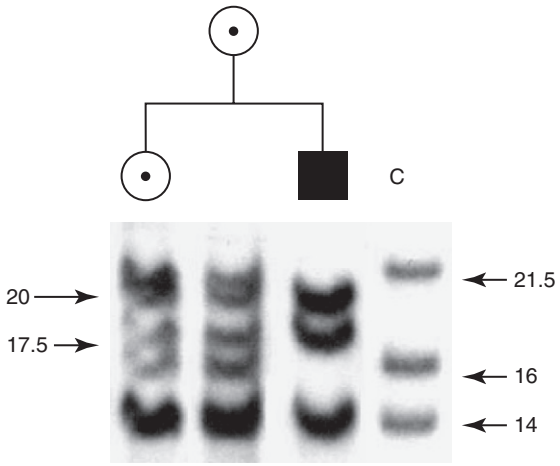

Figure 40-5 Southern blot analysis for the detection of a common inversion mutation present in the DNA of about 50% of patients with severe hemophilia A disease. Patient DNA is digested with restriction endonuclease *BclI*, blotted to a nylon membrane, and is hybridized with a ^{32}P-labeled probe corresponding to sequences in intron 22 of the factor VIII gene. Autoradiography was performed at –70 °C for 24 hours. Normal control DNA *(lane C)* yields bands 21.5 kb, 16 kb, and 14 kb in length. The pattern observed for the affected male *(shaded box)* in this family yields an altered banding pattern with bands of 20 kb, 17.5 kb, and 14 kb. Bands of these sizes confirm the presence of an inversion mutation resulting from homologous recombination between a copy of gene A within intron 22 of the factor VIII gene and the distal copy of gene A 5′ to the factor VIII gene. DNA analysis of the patient's mother and sister indicates that they are carriers of the inversion mutation with bands at 21.5 kb, 16 kb, and 14 kb generated from their wild-type allele and bands at 20 kb, 17.5 kb, and 14 kb generated from their mutant allele. Identification of the inversion mutation in this family will facilitate accurate carrier screening in other at-risk females in this family.

DNA testing for HA involves the use of a variety of techniques, including PCR to detect common inversion mutations, multiplex ligation-dependent probe amplification (MLPA) to identify deletions and duplications, and DNA sequencing to uncover the abundant numbers of missense, nonsense, and splice-site disease-causing mutations in this gene.[239] The testing algorithm for the proband is initially based on the clinical presentation of the patient.[522] For patients with severe disease, screening begins for inversion mutations involving introns 22 and 1. If negative, the *FVIII* gene is screened for the disease-causing mutation. In contrast, if the patient has moderate or mild disease, testing for common inversion mutations would not be necessary. Identification of the mutation in the affected male confirms the diagnosis, detects patients at high risk for inhibitor formation, and identifies the mutation segregating within the family. The ability to perform direct mutation analysis enables future prenatal or preimplantation genetic diagnosis studies or carrier studies for at-risk females in the family. Although the causative mutation in most patients can be identified through a combination of various screening techniques, in as many as 5% of patients the causative *FVIII* gene mutation is not identified.[373] In these situations, linkage studies may be required for prenatal, preimplantation, or carrier studies. These patients may have mutations buried in *FVIII* gene introns, or in 5′ upstream sequences, or perhaps at other gene loci whose proteins interact with the FVIII molecule.

Duchenne Muscular Dystrophy

Duchenne muscular dystrophy (DMD) (OMIM #310200) is a fatal X-linked recessive disorder characterized by progressive skeletal muscle wasting. The incidence of DMD is about 1 in 3500 male births, making it the most common severe neuromuscular disease in man. Classic DMD presents in early childhood, most often with motor delay or an abnormal gait. This is followed by progressive myopathic weakness with pseudohypertrophy of calves, and grossly elevated serum creatine kinase (>10× normal) as a result of degenerating muscle fibers. A muscle biopsy can confirm the diagnosis and shows variation in fiber size, necrosis, inflammation, fibrosis, and fiber regeneration. Immunohistochemistry staining using antibodies directed against different epitopes of dystrophin shows complete or almost complete absence of carboxy-terminal antibodies in the majority of DMD patients. Progressive weakness first affects the lower extremities such that most DMD patients are wheelchair bound between 10 and 15 years of age. Continual degeneration and regeneration of muscle eventually lead to the replacement of muscle tissue by adipose and connective tissue, causing progressive disease. Scoliosis is common and affects respiratory function. Chronic respiratory insufficiency develops in all patients, and cardiac disease can include dilated cardiomyopathy due to cardiac fibrosis and/or rhythm and conduction abnormalities. Death usually occurs in the third decade of life as the result of respiratory and cardiac failure. In some patients, however, only the heart is affected, causing DMD-associated dilated cardiomyopathy. In addition, one third of DMD patients have an IQ

below 70. The primary treatment for DMD patients consists of corticosteroids to combat muscle weakness, angiotensin-converting enzyme inhibitors and β-blockers for cardiac disease, and noninvasive ventilation for respiratory care. A national newborn screening program requiring informed parental consent is ongoing in Wales and is performed by measuring plasma creatine kinase from dried blood spots.[499] This approach has been used to identify affected males before the onset of clinical signs, to prevent delay in the diagnosis, and to offer immediate medical intervention and genetic services to the patient and family. In the United States, although DMD is a candidate condition for which newborn screening could be considered, insufficient data are available regarding the cost-effectiveness of screening, as well as the possible risks and potential benefits, and such screening is not being performed.[361] Because DMD is an X-linked recessive disorder, most carrier females are asymptomatic. However, some may have muscle weakness and elevated serum creatine kinase levels (2 to 10× normal). Varying degrees of clinical symptoms in females depend on the degree of inactivation of the X chromosome harboring the mutant *DMD* gene in various tissues where the DMD protein is expressed.[301] Females with severe disease most often result from a carrier female with skewed lyonization or an X-autosome translocation involving the *DMD* gene.*

Cytogenetic abnormalities in DMD patients and DNA linkage studies localized the DMD locus to Xp21.† By mixing DNA enhanced for X-linked genes from a 49,XXXXY cell line with DNA from a patient with DMD and a cytogenetic deletion in Xp21, Kunkel and colleagues cleverly used subtraction hybridization to clone the DNA corresponding to the patient's deletion.[382] During hybridization, Xp21 sequences from the cell line had no complementary sequences with which to anneal in the patient's DNA, thus they were available for cloning. The *DMD* gene (Xp21.2) is complex and is the largest gene in the human genome, spanning 2.4 megabases. It is interesting to note that it contains 79 exons, representing less than 1% of the gene, it encodes a 14 kb mRNA, and it has multiple tissue-specific promoters.[67,293] The full-length protein product, dystrophin, contains 3685 amino acids, has a molecular weight of 427 kDa, and contains four distinct domains, including actin-binding, central rod, cysteine-rich, and the unique COOH-terminal domain. Dystrophin is expressed predominantly in skeletal and cardiac muscle but is also expressed in neuronal tissue.[670] However, various dystrophin isoforms and splice variants are found in nonmuscle organs throughout the body.[67] Dystrophin is a cytoskeletal protein and a critical component of the dystrophin-glycoprotein complex (DGC), which also includes dystroglycans, sarcoglycans, sarcospan, dystrobrevins, and syntrophins.[138,182,670]

The DGC interacts with a host of cytoskeletal, transmembrane, extracellular, and trafficking proteins, as well as with cell signaling proteins.[181,184,670] In skeletal muscle, DGC plays a structural role by connecting the actin cytoskeleton to the extracellular matrix, stabilizing the sarcolemma during repeated cycles of contraction and relaxation, and transmitting force generated in the muscle sarcomeres to the extracellular matrix.[172] The DGC is also important for Ca^{2+} homeostasis.[45] In the absence of normal dystrophin and the DGC, the sarcolemmal integrity is compromised, and an influx of extracellular calcium triggers calcium-activated proteases and fiber necrosis and abnormal intracellular signaling.[38,184,304,606] The *DMD* animal models, including canine *(cxmd)* and mouse models *(mdx),* are an important resource for understanding the pathogenesis of DMD disease and for developing treatments.[38,167] Cerletti and coworkers described the use of mouse skeletal muscle progenitor cells to restore muscle fibers and regain normal dystrophin expression in the *mdx* mouse.[69,104] In addition to stem cell therapy for muscle growth and regeneration, other forms of treatment are being investigated. One method is the use of drugs to enable read-through of stop codons arising from nonsense mutations to prevent premature truncation of the protein.[402] Another promising molecular approach is the use of synthetic antisense oligonucleotides designed to redirect mRNA splicing and induce exon skipping of a specific mutation containing exons, thereby producing a partially functioning dystrophin protein.[244,449] Gene therapy using both viral and nonviral vectors to introduce the normal *DMD* gene are also being studied.[77,309,673]

Because of the tremendous size and diversity of mutations within the *DMD* gene, DNA testing for DMD presents a challenge for clinical laboratories.[394] DNA testing often is not required for diagnosis because morphologic and immunohistochemical studies of biopsied muscle tissue are well characterized and are considered diagnostic. However, DNA testing enables identification of the mutation segregating within the family and is required for carrier detection of at-risk females and for prenatal testing. Intragenic deletions, often encompassing multiple exons, represent 65% of mutations, affect the translational reading frame of the protein, and lead to a truncated and nonfunctional protein.[2] Duplications of the gene are observed in about 5% of patients. Deletions and duplications can be rapidly detected using multiplex PCR or fluorescence in situ hybridization.[53,105,458,654] More recently, the multiplex ligation-dependent probe amplification assay has been developed to screen for all 79 exons.[387] This method is simple and rapid and reliably determines whether the exon is present, deleted, or doubled when compared to control DNA. This technique is particularly useful for carrier detection in at-risk females by providing an accurate method for quantification of exon copy number. Alternatively, quantitative real-time PCR can be used to identify carrier females.[343] Direct sequence analysis is required for detection of the remaining 30% of mutations. Because of the sheer size of the gene, laboratories may first employ a screening technique to localize the likely area of the gene containing the disease-causing mutation prior to sequencing.[295]

Becker muscular dystrophy (BMD) (OMIM #300376) is a milder and less common form of muscular dystrophy with an

*References 75, 249, 532, 659, 710, and 714.
†References 35, 139, 208, 249, 659, and 714.

estimated incidence of 1 in 18,500 births. BMD is an allelic variation of DMD that is caused by different mutations within the *DMD* gene and is associated with a milder phenotype with a mean age of death in the mid-40s.* About 85% of BMD patients have deletions within *DMD,* 5 to 10% have a duplication, and 5 to 10% have a small insertion, deletion, or point mutation. Patients with deletions involving the distal rod domain of dystrophin (exons 45 to 60) show the mild BMD phenotype and in some cases remain free of symptoms until their 50s. However, BMD patients with deletions involving the amino-terminal domain of dystrophin (exons 1 to 9) have a more severe BMD phenotype with an earlier age of onset and more rapid progression of disease.

Patients with X-linked dilated cardiomyopathy have mutations at the dystrophin locus and *DMD*-associated dilated cardiomyopathy (DCM).[200,203,446,460,490] DCM is a rapidly progressive, fatal disease with an onset of symptoms early in the third decade of life.[205] Mutations associated with DCM are varied and involve the promoter region and exon 1, or splice sites, as well as exonic duplications and deletions.[205]

For families in which no mutation is detected, carrier and prenatal testing can be offered using DNA linkage studies. However, because the intragenic recombination frequency for this gene is estimated to be about 12%, these studies require the use of multiple intragenic, as well as 5′ and 3′, flanking markers for accurate carrier or prenatal results.[4] Particularly difficult are sporadic cases of DMD or BMD in which no other family member with DMD or BMD is known, and no mutation in the affected individual is detected. Generally, one third of sporadic cases are thought to represent a new mutation in the mother's gamete from which that individual was derived. Thus neither the mother nor female siblings would be carriers, and the risk to the mother for a second affected son would be considered minimal. In addition, in mutation-negative families, carrier assessment involves measurement of serum CK activity and linkage studies.[323] Linkage studies are complex, require participation of multiple family members, and are confounded by inaccuracy caused by meiotic recombination or germline mosaicism. Serum CK is, by definition, above the reference interval (defined as the 95th percentile of a healthy reference group of age-matched women) in ≈1 of 20 noncarrier women. Moreover, serum CK decreases in DMD carrier women as they age.

In 1987, Bakker and associates first described the phenomenon of germline mosaicism, in which no *DMD* gene mutation is present in lymphocyte DNA, but a *DMD* gene mutation is present in germline tissue.[36] Presumably these mutations occur during mitosis in germline proliferation, which explains the report of multiple affected children of women whose lymphocyte DNA contains no *DMD* mutation.

Fragile X Syndrome

Fragile X syndrome (OMIM #309550) is one of the most commonly inherited forms of mental retardation, with an estimated incidence of ≈1 in 4000 males and ≈1 in 4000 to 8000 females.[580] The name of the condition reflects the cytogenetic abnormality of a breakpoint or fragile site in the X chromosome. The clinical syndrome was first described by Martin and Bell in 1943 in a family with sex-linked mental retardation in both males and females who had no dysmorphic features.[428] The disease was later redefined by Lubs, who noted the presence of a marker X chromosome in the leukocytes of some mentally retarded males following incubation of cells in cell culture media depleted of folate and thymidine; the marker segregated with mental retardation within the family.[414] The chromosomal locus for this fragile site would later be localized to Xq27.3.[277] Common clinical features associated with fragile X syndrome are mental retardation, delayed motor and speech development, macro-orchidism, long face, prominent forehead and jaw, large ears, flat feet, and abnormal behavioral characteristics such as hyperactivity, hand flapping, temper tantrums, persevering speech patterns, poor eye contact, and occasionally autism.[151] These features often are less frequent and milder in affected females than in affected males because of random X inactivation of their abnormal fragile X gene and expression of their normal gene in half of their tissue.

As a sex-linked disease, fragile X syndrome has a complicated inheritance pattern. Affected females are heterozygous for the mutation, and unaffected males can transmit the mutation through the family. For this reason, Sherman and colleagues proposed that fragile X syndrome was an X-linked dominant disorder with reduced penetrance (79% for males and 35% for females), but the penetrance of the disease appeared to increase in subsequent generations within a family.[582,584] The mechanism of this "Sherman paradox" was resolved when the gene causing fragile X syndrome, *FMR1* (*F*ragile X *M*ental *R*etardation 1), was cloned in 1991.[54,378,484,660,711] *FMR1* was the first gene discovered to cause disease through expansion of an unstable trinucleotide repeat sequence. The unstable CGG repeat is located in the 5′ untranslated region (5′UTR) of the *FMR1* gene in exon 1. The gene spans 38 kb, with 17 exons, encodes a 4.4 kb mRNA transcript, that contains 190 bp of the 5′UTR.[176] *FMR1* mRNA is expressed in neural and non-neural tissues during both embryonic and postnatal development.[401] The FMR1 protein, FMRP, is a 71 kDa RNA-binding protein (RBP) with three RNA-binding domains, KH1 and KH2 and an RGG box; it is associated with polyribosomes as part of a messenger ribonucleoprotein complex, where it serves to suppress the translation of specific mRNAs.[40,202,384,398,592] Binding about 4% of total mRNA, it is primarily observed in the cytoplasm but shuttles between the cytoplasm and the nucleus. It is suggested that FMRP binds specific RNA ligands then recruits the RNA-induced silencing complex to selectively repress translation of targeted mRNA.[103,328,432]

In addition, FMRP is involved in synaptic plasticity through regulation of mRNA transport into dendrites to regulate local protein synthesis of specific RNAs in response to synaptic stimulation signals; most notable is its ability to inhibit the effects of metabotrophic glutamate receptor 5 (mGluR5).[44,152,676] Thus, loss of function of FMRP in fragile X

*References 2, 52, 96, 125, 294, and 709.

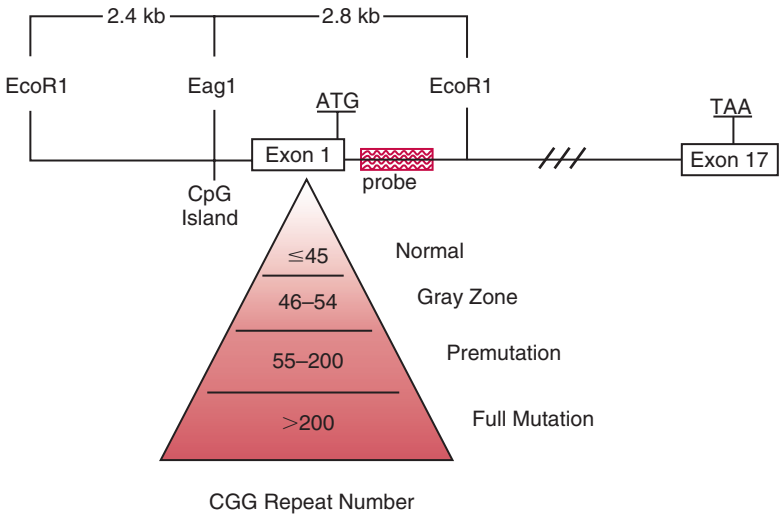

Figure 40-6 Schematic representation of the CGG repeat in exon 1 of *FMR1* and associated alleles. A CGG-repeat number less than or equal to 45 is normal. A CGG-repeat number of 46 to 54 is in the gray zone and has been reported to expand to a full mutation in some families. A CGG-repeat number of 55 to 200 is considered a premutation allele and is prone to expansion to a full mutation during female meiosis. A CGG-repeat number in excess of 200 is considered a full mutation and is diagnostic of fragile X syndrome.

patients results in abnormal translation profiles and altered synapse structure and signaling.[66,531]

FMR1 alleles contain blocks of CGG repeats usually 7 to 13 repeats in length, which can be interspersed with single AGG repeats.[383,595] Allelic diversity results from the variable numbers and lengths of these CGG-repeat blocks. No distinct boundaries separate the repeat number categories; however, normal alleles have 5 to 45 repeats; gray zone alleles have 46 to 54; premutation alleles have 55 to 200; and full mutation expansion alleles contain more than 200 repeats[422] (Figure 40-6). Individuals with a normal number of CGG repeats do not have fragile X syndrome, nor are they at risk of having an affected child. Individuals with 46 to 54 repeats represent alleles in the upper range of normal or a smaller than average premutation allele. These individuals do not have fragile X syndrome, yet may have a slightly increased risk of repeat instability and expansion to a full mutation in their offspring in some families. Premutation alleles are unstable and can expand to a larger allele in the premutation range when transmitted or can expand to a full mutation allele and an offspring with fragile X syndrome.[481] Although rare, premutation alleles have been reported to undergo rather drastic contractions (82 to 33, 95 to 35, 145 to 43, 130 to 10, and 70 to 54).[84,481] The risk of CGG expansion from a premutation to a full mutation allele is dependent on several factors, including the number of pure uninterrupted CGG repeats, the number and position of interspersed AGG repeats, haplotype background, and less well-characterized heritable factors.*

In a large collaborative study among 13 laboratories in 8 countries and involving more than 1500 premutation carrier females, the smallest premutation alleles shown to expand contained 59 repeats with no AGG interruptions.[481] Most data from humans suggest that expansion occurs before zygote formation, but the possibility that CGG expansion will occur very early in embryogenesis cannot be excluded.[424,456] CGG expansions of premutations to full mutations are largely confined to maternal transmissions to the offspring, and the sex of the fetus has no apparent effect on this process.[481] Expansion occurs during DNA replication and results from hairpin formation and slippage within the expanded CGG-repeat sequence corresponding to the lagging strand, but it likely involves other factors and processes as well.[237,687] Premutation repeat alleles transmitted in males remained stable in 16% of cases, decreased in size in 22% of transmissions, and expanded to a larger premutation allele in 62% of transmissions.[482]

Premutation carriers do not have fragile X syndrome. However, although *FMR1* is overexpressed in these individuals, FMRP appears to be significantly diminished, suggesting reduced translation efficiency.[363] Diminished FMRP levels in premutation carriers are negatively correlated with the repeat number, and overexpression of *FMR1* has a positive correlation with the repeat number. It is interesting to note that ≈20% of premutation carrier females have primary ovarian insufficiency with cessation of menstrual periods before 40 years of age.[612,700] However, this clinical finding is not observed in full mutation carrier females, nor in their nonpremutation carrier sisters.[581] Further, a positive association of ovarian insufficiency and CGG repeat size indicates that *FMR1* RNA toxicity may mediate these clinical symptoms.

Premutation carrier males exhibit fragile X–associated tremor/ataxia syndrome (FXTAS), a neurodegenerative syndrome characterized by progressive intention tremor, cerebellar gait ataxia, parkinsonism, neuropathy, cognitive decline, psychiatric features, and generalized brain atrophy.[74,266,268]

*References 94, 173-175, 179, 284, 482, and 583.

FXTAS occurs in about one third of premutation carrier males over the age of 50; also, 17% of males between the ages of 50 and 59 and as many as 75% of males older than 80 years are affected.[331] FXTAS can be seen in premutation carrier females but is observed at a lower percentage.[266,267] The lower incidence of FXTAS in females may be explained by the presence of a second X chromosome and a normal *FMR1* gene in approximately half of all cells. Although patients with FXTAS may demonstrate a neuropsychiatric illness, the existence of a distinct neuropsychologic phenotype in premutation carriers without FXTAS remains controversial. Most recently however, Hunter and coworkers showed that premutation males and females younger than 50 years appear to have no significant difference in their neuropsychologic profile compared with nonpremutation carriers,[319] although this study showed that premutation carrier females may have an increased number of symptoms associated with attention-deficit hyperactivity disorder (ADHD). Thus, although FMRP is decreased, increased concentrations of *FMR1* transcript may be toxic to the cell and may have a gain-of-function affect.[266]

The molecular basis of fragile X syndrome includes expansion of the 5′UTR CGG repeat and hypermethylation coupled with histone deacetylation of this region and the adjacent CpG island in the promoter region of the *FMR1* gene, resulting in transcriptional silencing of the gene and no production of FMRP.[54,119,515,516,614] Males with full expansion alleles but incomplete methylation—"mosaic males"—may have severe mental retardation or a milder phenotype.[433,552] One report describes two males from unrelated fragile X syndrome families who although they had the full mutation allele did not have the fragile X phenotype.[618] In vitro analysis indicated that their alleles lacked the complete specific epigenetic methylation-deacetylation patterns observed in abnormal *FMR1* genes. These results are interesting because expanded repeats may trigger chromatin remodeling and may recruit cellular mechanisms to cause epigenetic changes.[381] Although in vitro reactivation of the *FMR1* gene has been reported to occur by inducing DNA demethylation and the reassociation of acetylated histones, reactivation of *FMR1* may not be sufficient to restore FMRP concentrations because transcripts with large repeats may not be efficiently translated.[113,363]

DNA testing for fragile X syndrome using Southern blot analysis of peripheral blood enables detection of the majority of cases of fragile X syndrome (Figure 40-7). PCR analysis with capillary electrophoresis is used to complement the testing by providing the precise CGG-repeat number. However, because of the CG-rich sequence, large full mutation alleles are difficult to amplify by PCR. As the CGG-repeat length increases, the risk of expansion from a premutation to a full mutation in premutation carrier females increases. Thus PCR testing to determine the exact CGG-repeat number is most useful for determining the risk of an affected offspring during genetic counseling of a premutation carrier female. Although a woman with a premutation CGG repeat of 55 to 59 is given about a 5% risk of expansion to a full mutation, a woman with a repeat length of 70 to 79 is given a 31% risk of expansion, and a woman with a CGG-repeat length greater than 100 is given close to a 100% chance of expansion.[481] Chorionic villus samples or amniotic fluid can be tested, but the methylation pattern expected in adult tissue may be absent. Although expansion of the CGG repeat in 5′UTR of *FMR1* accounts for more than 99% of all cases of fragile X syndrome, CGG deletions and point mutations have also been described.[686] The American College of Human Genetics has published guidelines for testing in the laboratory.[422]

DNA testing for *FMR1* is requested for children with (1) the fragile X phenotype, (2) developmental delay, (3) mental retardation, or (4) autism. Fragile X DNA testing is performed for carrier testing in at-risk pregnant or preconception females with a family history of fragile X or mental retardation of unknown cause. Carrier testing is performed on patients with clinical suspicion of FXTAS. In addition, a pilot newborn screening test for fragile X syndrome was conducted to determine the feasibility of this testing.[561] In this study, two families were identified, and the incidence of disease was 1 in 730 births. Because of the carrier frequency of FXS, a population-based carrier screening program has been considered but would require significant planning, educational resources, and counseling programs to be established before such testing could be implemented. [441]

Treatment of patients with FXS includes therapies for behaviors related to ADHD, anxiety, aggression, and seizures.[265] A better understanding of the molecular function of FMRP may lead to targeted treatment options in the future.

DISEASES WITH NONMENDELIAN INHERITANCE

Mitochondrial DNA Diseases

Mitochondria are organelles ubiquitous to the cytoplasm of all eukaryotic cells of animals, higher plants, and some microorganisms. Mitochondria generate energy for the cellular processes by producing ATP through oxidative phosphorylation (OXPHOS); they are important in maintaining both calcium homeostasis and various intracellular signaling cascades, including apoptosis.[199,511,598] The matrix of the mitochondrion is surrounded by a cardiolipin-rich inner membrane, and both are enclosed by a second outer membrane. Within the matrix are copies of mitochondrial deoxyribonucleic acid (mtDNA). Each mitochondria contains between about 2 and 10 copies of mtDNA, so with hundreds of mitochondria per cell, an estimated 10^3 to 10^4 copies of mtDNA exist within each cell, with brain, skeletal, and cardiac muscle having particularly high concentrations. Alterations in mtDNA copy number or mutations in mtDNA are associated with both inherited and acquired diseases.[117,153,577] The mtDNA is a double-stranded, circular molecule containing 16,569 base pairs that encodes 37 genes, including two ribosomal RNAs (rRNA), 22 transfer RNAs (tRNA), and 13 subunits required for the OXPHOS system, with seven belonging to complex I, one to complex III, three to complex IV, and two to complex V.[17] Most subunits involved in the OXPHOS system are nuclear-encoded, as are several nuclear gene products that regulate mitochondrial gene

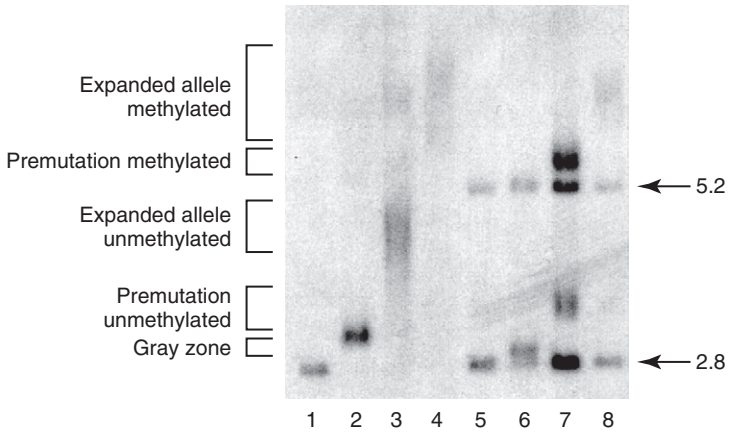

Figure 40-7 Southern blot analysis for the diagnosis of fragile X syndrome. Patient DNA is simultaneously digested with restriction endonucleases *EcoR*I and *Eag*I, is blotted to a nylon membrane, and is hybridized with a ^{32}P-labeled probe adjacent to exon 1 of *FMR1* (see Figure 40-6). *Eag*I is a methylation-sensitive restriction endonuclease that will not cleave the recognition sequence if the cytosine in the sequence is methylated. Normal male control DNA with a CGG-repeat number of 22 on his single X chromosome *(lane 1)* generates a band about 2.8 kb in length, corresponding to *Eag*I-*EcoR*I fragments (see Figure 40-6). Normal female control DNA with a CGG-repeat number of 20 on one X chromosome and a CGG-repeat number of 25 on the second X chromosome *(lane 5)* generates two bands: one at about 2.8 kb and a second at 5.2 kb. *EcoR*I-*EcoR*I fragments approximately 5.2 kb in length represent methylated DNA sequences characteristic of the lyonized chromosome in each cell that is not digested with restriction endonuclease *Eag*I. DNA in *lane 2* contains an *FMR1* CGG-repeat number of 90 and is characteristic of a normal transmitting male. The banding pattern observed in lane 3 is representative of a mosaic male with a single X chromosome with a full mutation (>200 repeats). However, the full mutation in some cells is unmethylated; in other cells, the full mutation is fully methylated, hence the term *mosaic*. In those cells in which the full mutation is unmethylated, digestion by both *Eag*I and *EcoR*I occurs, and in those cells in which the full mutation is fully methylated, digestion of the DNA by *Eag*I is inhibited. The banding pattern observed in *lane 4* is diagnostic of a male with fragile X syndrome, illustrating the typical expanded allele fully methylated in all cells. *Lane 6* is characteristic of a female with a normal allele and a CGG-repeat number of 29 and a larger gray zone allele with a CGG-repeat number of 54. *Lane 7* is the banding pattern observed from a premutation carrier female with one normal allele having a CGG-repeat number of 23 (band at about 2.8 kb) and a second premutation allele with CGG repeats of 120 to about 200 (band at about 3.1 kb). In premutation carrier females, in cells in which the X chromosome with the premutation allele is lyonized, the normal 5.2 kb *EcoR*I-*EcoR*I band is larger because of the increased CGG-repeat number and is about 5.5 kb in length. *Lane 8* is diagnostic of a female with fragile X syndrome with one full expansion mutation allele that is completely methylated and transcriptionally silenced on one X chromosome but with a second normal allele with a CGG-repeat number of 33.

expression. It is interesting to note that the mitochondrial genetic code is slightly different from the universal code. For example, in mtDNA, TGA codes for tryptophan, rather than a termination codon, and all mitochondrial-encoded polypeptides contain codons requiring only 22 mitochondrial-encoded tRNA molecules for translation, rather than the 31 predicted by Crick's wobble hypothesis.[42] The high copy number of mtDNA per cell coupled with a small genome and highly polymorphic sequence variations between individuals makes mtDNA sequence analysis an ideal tool for forensic studies.[439,639]

Mitochondria-related diseases have an incidence of 1 : 1000 to 1 : 5000 and can result from mutations in nuclear DNA (85 to 90%) or, as first reported in 1988, can result from mutations in the mitochondrial genome (10 to 15%).[300,671,716] Mutations in mtDNA occur at a higher rate than nuclear DNA, probably because of differences in chromatin structure, lack of DNA repair machinery, and the continual generation of reactive oxygen species. Mitochondrial genetics is different from mendelian genetics in several aspects. First, all mtDNA is maternally inherited, with mature oocytes having the highest mtDNA copy number per cell at 10^5 and with sperm

having the lowest mtDNA copy number per cell at 10^2. After fertilization, sperm mtDNA is selectively degraded so that only maternal mtDNA remains. Thus if a mother is carrying an mtDNA mutation, it will be transmitted to all of her children, but only her daughters can transmit the disease to their offspring. Although this is considered the rule, paternal mtDNA inheritance has been reported and may result from incomplete degradation of sperm mtDNA in early embryogenesis.[569,570] If an mtDNA mutation arises, it will exist among a population of normal mtDNA. This coexistence of normal and mutant mtDNA copies within the same cell is referred to as *heteroplasmy* and is the second unique feature of mitochondrial genetics. Third, during cell division, the proportions of normal and mutant mtDNA can shift as mitochondria, and their accompanying genomes are partitioned into daughter cells. Thus in development and differentiation, the proportions of normal and mutant mtDNA can vary among cells and tissues within the body. Last, the percentage of mutant mtDNA required within a cell, tissue, or organ system to produce a deleterious phenotype is referred to as the *threshold effect.* The threshold for disease varies between people, energetic requirements for tissue, and the mtDNA mutation. As is evident, genetic counseling for families with mtDNA disorders is complicated by an inability to accurately predict phenotype caused by the phenomena of heteroplasmy and the threshold effect.

Two types of mtDNA mutations exist: those that affect mitochondrial protein synthesis (tRNA and rRNA genes) and those within the protein-encoding genes themselves.[153,702] Direct sequencing of mtDNA is considered the gold standard for mutation detection, but this method may be unable to detect a low percentage of mutant mtDNA in a heteroplasmic state. Alternatively, a simple and effective method referred to as *temporal temperature-gradient gel electrophoresis,* coupled with PCR and DNA sequencing, can detect heteroplasmic mutations as low as 4%.[703] Although mtDNA mutations are now associated with a significant number of inherited diseases, acquired mtDNA deletions are associated with the aging process, and mitochondrial dysfunction is associated with neurodegenerative diseases and cancer.[231,527] Many somatic mtDNA mutations occur via damage by oxygen free radicals produced as byproducts of aerobic metabolism.[15,534]

Leber Hereditary Optic Neuropathy

Leber hereditary optic neuropathy (LHON) (OMIN #53500), the most common mitochondrial disease, is the first linked to maternal inheritance through a mutation in the mtDNA.[671] LHON is characterized by acute or subacute bilateral loss of central vision caused by focal degeneration of the retinal ganglion cell (RGC) layer and, in some individuals, impairment of optic nerve function.[712] The specific nature of the disease in terms of RGC degeneration is unknown, but it could be due to differences in superoxide regulation.[292] Age of onset is typically in the second to fourth decade of life, and after initial symptoms, both eyes are usually affected within 6 months. Approximately 50% of males and only 10% of females who possess the mtDNA mutation will develop disease.[712] In addition, yet to be defined environmental factors, nuclear-encoded modifier genes that affect mtDNA expression, mtDNA products, or mitochondrial metabolism may modify the phenotypic expression of LHON. The explanation for differences in rates between genders has not been determined but could be related to genes on the X chromosome.[315] Genetic counseling in LHON is complicated in that the amount of mutant mtDNA transmitted by heteroplasmic females cannot be predicted, and testing cannot predict which individuals will develop visual symptoms.[322] LHON can be confused with autosomal dominant optic atrophy (OMIN #165500), which shares a similar ocular phenotype but results from mutations primarily in the gene *OPA1* (3q28-29). It is interesting to note that OPA1 is a nuclear-encoded mitochondrial protein required for mitochondrial fusion, maintenance of cristae architecture, and regulation of apoptosis.[598]

LHON is a disorder caused by OXPHOS deficiency. Although many mutations have been associated with this disease, mtDNA mutations G3460A, G11778A, and T14484C represent 95% of those identified.[421] Mutation G11778A was the first described, is the most common, and accounts for at least 50% of cases. In most affected individuals, LHON mutations appear to be homoplasmic, with only mutant mtDNA detected, but in 15% of cases, the mutations are heteroplasmic, with a mixture of both normal and mutant mtDNA detected.[593,663] Each of the common mutations affects a subunit of the nicotinamide adenine dinucleotide : ubiquinone oxidoreductase in complex I of the OXPHOS pathway. The mechanism by which these mutations cause the LHON phenotype is not well understood.[476]

Clinical DNA testing for LHON-associated mutations is widely available and utilizes an array of techniques.[18,218,462] If the patient's mtDNA is negative for the three common mutations, testing for other mtDNA mutations associated with LHON should be considered.[462,712] DNA sequencing of the entire mitochondrial genome may be required but is labor intensive and costly, so it should be pursued only when clinical suspicion for LHON is high.[18,476]

Leigh Syndrome

Leigh syndrome (LS) (OMIM #256000), or subacute necrotizing encephalopathy, is a progressive neurodegenerative disorder that most often leads to death before the age of 5. In contrast to LHON, most patients present within the first year of life with hypotonia, failure to thrive, psychomotor regression, ocular movement abnormalities, ataxia, and brainstem and basal ganglia dysfunction caused by severe dysfunction of mitochondrial energy metabolism. The clinical phenotype for LS is variable in patients with the same pathogenic mtDNA mutation and largely results from differences in the percentages of mutant mtDNA among organs and tissues within an individual (Figure 40-8).[632]

LS exhibits extensive genetic heterogeneity, with disease-causing mutations identified in both nuclear-encoded genes and mtDNA, making both mendelian and maternal patterns of inheritance possible for this syndrome.[157] Mutations in mitochondrial-encoded genes affecting complexes I, IV, and

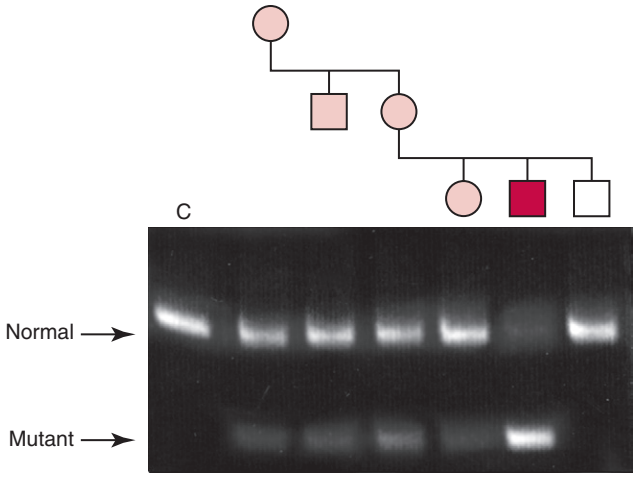

Figure 40-8 Detection of varying degrees of heteroplasmy for mitochondrial deoxyribonucleic acid (mtDNA) mutation A8344G in a family with Leigh syndrome. Mitochondrial DNA was extracted from a peripheral blood specimen from an affected male with Leigh syndrome and from family members. Mitochondrial DNA was amplified using an oligonucleotide primer pair that flanks mitochondrial mutation A8344G. The A-to-G base substitution creates an *Nae*I recognition site (GCCGGC) that is not present in normal control mtDNA (C). Amplicons from each member of the family and from the control were digested with *Nae*I and subjected to gel electrophoresis. The virtual absence of undigested amplicons in the affected male *(red box in pedigree)* indicates the presence of almost 100% mutant mtDNA in the cells from this specimen and coincides with the severe phenotype of Leigh syndrome in this patient. In contrast, his sister, mother, and grandmother with 30%, 40%, and 20% mutant mtDNA suffer only from migraine headaches. His uncle, with 30% mutant mtDNA present, suffers from attention-deficit hyperactivity disorder and learning disabilities. Heteroplasmy, or variation in the percentages of normal and mutant mitochondria, largely explains observed phenotypic differences in this family.

V, as well as several tRNA genes, or nuclear-encoded genes affecting the pyruvate dehydrogenase complex, the respiratory chain complexes I, II, and IV, or coenzyme Q have been reported.[204] The most common mitochondrial-encoded mutation associated with Leigh is seen in the *ATPase 6* gene (complex V) with a common T>G transversion mutation at nucleotide 8993. The most common nuclear-encoded mutation associated with Leigh syndrome is in the *SURF1* gene, which encodes a cytochrome oxidase assembly factor. Regardless of which gene is involved, the overall prognosis of these patients is generally poor, and treatment of mitochondrial disease is in its infancy.[375] Because of the lethality of Leigh syndrome, preimplantation genetic diagnosis can be considered and has been successfully performed with the implantation of a disease-free embryo.[642]

Clinical DNA testing for mitochondrially inherited LS includes targeted mutation analysis for a common mutation or DNA sequencing of the mitochondrial genome.[218] Because of the heterogeneity of nuclear-encoded genes associated with LS, testing is limited to a few locations within the United States and most frequently involves DNA sequence analysis of the entire coding region of multiple genes.[218]

Imprinting

Imprinting refers to the differential marking or "imprinting" of specific paternally and maternally inherited alleles during gametogenesis, resulting in differential expression of those genes. Such imprints on the DNA during gametogenesis must be maintained through DNA replication in the somatic cells of the offspring, must be reversible from generation to generation, and must influence transcription. DNA methylation is the primary mechanism for genomic imprinting. The number of imprinted genes in the human genome is estimated to be fewer than 200, and most are clustered around imprinting control centers. Alterations in normal imprinting patterns can result in disease.

Prader-Willi and Angelman Syndromes

Prader-Willi syndrome (PWS) is a complex multisystem, neurogenetic disorder with an incidence of 1 in 15,000 to 30,000.[98] Prenatally, the affected fetus exhibits diminished movement, peculiar fetal position, and often polyhydramnios.[63] At birth, dysmorphic features, small hands and feet, and hypogonadism are observed. The affected child is lethargic with persistent hypotonia that results in poor feeding and failure to thrive. Development is delayed for both motor skills and language, and this delay continues throughout life, with a mean IQ of 60 to 70. Early in childhood, a unique and characteristic insatiable appetite that is hypothalamic in origin presents. Obesity soon ensues with associated complications and is the major cause of morbidity, mortality, and sleep disorders. In addition, patients have short stature and abnormal body composition characteristic of growth hormone deficiency. This aspect of the disorder can be treated with exogenous growth hormone, although many other aspects of this disease are difficult to manage and require a multidisciplinary approach.[235,403] The syndrome is associated with specific behavioral characteristics, and some patients can have psychiatric disorders; both of these situations present challenging management issues.

Angelman syndrome (AS) is another neurogenetic disorder with a similar incidence in the population as PWS; it is characterized by severe mental retardation (IQ<40), inappropriate bouts of laughter, absence of speech, gait ataxia, progressive microcephaly, dysmorphic facial features, and epilepsy.[336] Unique electroencephalographic (EEG) patterns are seen in most AS patients at younger than 2 years of life and can be helpful in diagnosing the condition. As many as 6% of patients with both mental retardation and epilepsy may have AS. Some of the phenotypic features associated with AS can be nonspecific or can occur separately in other syndromes or nonsyndromic conditions; thus, it is the combination of

many of these and the associated laughter, unique smiling, and happy demeanor of the AS patient that aids in making the diagnosis. Feeding problems and/or truncal hypotonia may be present at birth, and sleep disturbances and abnormal food-related behaviors can be displayed in older children. Apparent from the characteristic physical findings, PWS and AS are clinically distinct syndromes; yet each results from genetic changes involving a 4 Mb region on chromosome 15q11-q13.[306] Within this region are multiple genes that are imprinted with gene expression dependent on parental origin. PWS results when the paternal allele on 15q11-q13 is missing, defective, or epigenetically silenced through DNA methylation, and only the inactive maternal allele remains. In contrast, AS results from loss of function of the maternally expressed allele in this region.

Multiple paternally expressed genes for PWS exist in 15q11-q13. Most notable is the *SNURF-SNRPN* locus and >70 C/D box small nucleolar RNA (snoRNA) genes.[306,493] Extensive DNA methylation and histone H3 Ly59 demethylation at the CpG island regulate the single transcriptional unit encoding these genes on the maternal allele, leading to transcriptional silencing of this allele. The *cis*-acting regulatory region referred to as the *imprinting center (IC)* controls resetting of parental imprints in the 15q11-13 region during gametogenesis. SNRPN is involved in mRNA splicing in the brain, and SNURF (*SNRPN* Upstream Reading Frame) is found in the nucleus, contains 71 amino acids, may bind RNA, and has a C-terminal motif similar to ubiquitin. SnoRNAs are noncoding RNA molecules that modify both rRNA and snRNA by methylation of the ribose 2′ hydroxyl group of specific nucleotides, which may vary between them.[371] Sahoo and associates described a patient with a Prader-Willi phenotype and de novo deletion of 174,584 bp comprising all 29 snoRNAs of the HBII-85 snoRNA cluster and the proximal 23 of the 42 snoRNAs of the HBII-52 cluster on his paternal allele.[557] This finding provided convincing evidence that deficiency of HBII-85 snoRNAs causes the main features of PWS. This finding is significant in that it is also the first disorder associated with a deficiency of snoRNA.[509] Perhaps other paternal-only expressed genes in this region, such as *NDN,* which encodes necdin, a protein important for neuronal differentiation and a suppressor for cell proliferation; *IPW,* which encodes a 2.2 kb RNA but is not translated into a polypeptide; *MKRN3,* which encodes makorin ring zinc-finger protein 3; and *MAGEL2,* which encodes melanoma antigen-like gene 2, could have additive roles in the phenotype of PWS.[346,391,468,477,689]

Loss of normally expressed paternal genes in 15q11-q13 resulting in PWS can occur by several mechanisms. Most commonly, PWS (70%) results from a de novo deletion following unequal homologous recombination involving one of the three common breakpoints on the paternal allele. This would render the zygote monosomic for these genes, and the zygote would possess only the maternal copy of this region. Alternatively, 25 to 30% of cases of PWS are caused by uniparental disomy (UPD). In the case of PWS, although two copies of the genes located in 15q11-q13 exist, both are maternal in origin, arising in most cases from meiosis I nondisjunction followed by postzygotic mitotic loss of the third, paternally derived chromosome 15 via a process referred to as *trisomy rescue.* This mechanism rescues the zygote from trisomy 15, a condition that is incompatible with life.[541] Although the fetus is genetically complete with two chromosome 15's (disomy), both chromosomes are received from the same parent (uniparental), and no normal expression of paternally expressed genes occurs in this imprinted region. In about 1% of cases, PWS results from microdeletions encompassing the paternal IC. Or, in some cases, no DNA mutation is detectable, but rather, an abnormal imprint occurs.[87,88] A mutation involving the IC prevents this *cis*-acting control center from resetting the imprint in the germline. These mutations will result in PWS, because if they are present on the maternal chromosome of phenotypically normal fathers, they will be transmitted to offspring, as now the paternal chromosome will maintain the maternal imprint and will be silenced. Finally, less than 1% of PWS cases are caused by chromosomal rearrangements disrupting the genes in the 15q11-q13 region.[613] Some genotype correlations have been noted. It is interesting to note that PWS patients with uniparental disomy are more likely to have psychotic episodes, compulsive behaviors (e.g., skin-picking), and autism spectrum disorders than are PWS patients with deletions.[170,658,683]

The genes *UBE3A* and *ATP10A* are located downstream and in the opposite orientation to *SNURF-SNRPN* in 15q11-q13; both are predominantly maternally expressed in brain.[370,440] The *UBE3A* gene contains 16 exons and encodes E6-AP (E6-associated protein), a member of the E3 ubiquitin ligase family, which is involved in the ubiquitin proteasome pathway for degradation of a diverse range of yet unidentified protein substances.[431] Three protein isoforms that differ at the N-termini result from alternative splicing.[708] It is interesting to note that even though the paternal *UBE3A* allele is imprinted in some parts of the brain, it is expressed in other tissues throughout the body.[667] Studies on mice suggest that E6-AP may localize to the dendritic spines and may function to regulate spinal development or synaptic plasticity.[158] Deregulation of ubiquitination from lack of E6-AP could result in an inability to degrade or functionally alter targeted proteins. Similar to PWS, most AS patients (70%) have a deletion of the critical 15q11-q13 region. However, unlike PWS, in which a deletion occurs on the paternal allele, in AS, a deletion occurs on the maternally derived chromosome 15. Inversion mutations involving this region have been identified in a subset of mothers of AS patients with a deletion.[226] It is likely that the presence of these inverted DNA sequences in these women predisposed this region to deletions in their offspring by interfering with normal homologous synapses, or by pairing homologous chromosomes, during meiosis.

In 7% of AS patients, the syndrome is attributed to uniparental disomy from the inheritance of two paternally derived chromosome 15's. As a consequence, with two paternal *UBE3A* genes silenced, no functional UBE3A protein is present. In 3% of AS patients, an imprinting defected has

been described.[87,305] A cytogenetic rearrangement has been detected in about 1% of AS cases, and in 11% of cases, a mutation in the *UBE3A* gene itself has been reported.[190] It is odd that a small number of AS cases and of another imprinting disorder at chromosome 11p15, Beckwith-Wiedemann syndrome, have been associated with assisted reproductive technologies, but the exact mechanism by which this occurs is not known.[425] Although mutations causing AS can arise de novo, they can be silently transmitted through several generations. For example, if a *UBE3A* mutation arose de novo on a paternal allele transmitted to a son, the son could transmit the mutation to a son or daughter to produce a normal phenotype. However, although this son could transmit the silenced *UBE3A* mutation to his offspring, his sister could donate her mutated *UBE3A* and her paternally derived allele to her offspring, and the child would have AS. In about 10 to 15% of patients with a firm diagnosis of AS, the cause of the disease has not been established. Clinical presentation does correlate with the underlying genetic cause for some features of the disease. AS patients with deletions are more likely to have hypopigmentation of skin, eye, and hair or microcephaly and are more likely to be severely affected.[410] A more severe phenotype may arise because of haploinsufficiency of nonimprinted *UBE3A* adjacent and co-deleted genes. In contrast, AS patients arising from UPD have normal head circumference and are mildly affected.

Diagnostic testing for individuals suspected of having AS or PWS can involve a variety of techniques. Determining the genetic mechanism for the cause of the disease is important in determining recurrence risks for the family.[91] Under most circumstances, initiation of testing with methylation-specific PCR (mPCR) is one scenario that can be used and may be the most cost-effective approach[452] (Figure 40-9). In methylation-specific PCR, genomic DNA is treated with sodium bisulfite before PCR to convert unmethylated cytosine residues to uracil without altering the methylated cytosine residues (those silenced in the 15q11-13 region). Subsequent PCR reactions use oligonucleotide primers specific to DNA strands that contain uracil (unmethylated) or cytosine (methylated).[379,656] Methylation-specific PCR provides a rapid and reliable diagnostic test to rule out PWS or AS. If the result is negative, more than 99% of those with PWS and about 80% of AS patients can be ruled out. Alternatively, aberrant CpG methylation can be commonly detected with the use of methylation-specific MLPA.[483] PWS patients with a chromosomal rearrangement disrupting the genes in this area will not be identified by this test. Similarly, AS patients with a *UBE3A* mutation, a chromosome rearrangement disrupting the genes in this region, and those with AS resulting from an unknown cause will not be diagnosed with this method. However, if the result is positive, fluorescent in situ hybridization (FISH) studies can be performed to detect a deletion within 15q11-13, and/or uniparental disomy DNA testing should be done to determine the genetic mechanism of disease for appropriate genetic counseling of the family. Alternatively, real-time PCR can be used to identify and characterize the deletion, and PCR analysis of short tandem repeats coupled with capillary electrophoresis can be used to detect uniparental disomy.[222,459] Mechanisms and tests for PWS and AS are summarized and contrasted in Table 40-3.

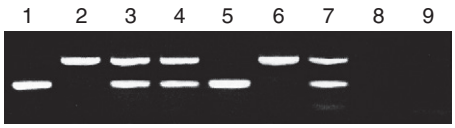

Figure 40-9 Methylation-specific polymerase chain reaction (PCR) assay for the diagnosis of Prader-Willi syndrome (PWS) and Angelman syndrome (AS). Extracted DNA is treated with sodium bisulfate before amplification using multiplex PCR and oligonucleotide primers specific for modified DNA. Normal individuals show amplicons representing their methylated maternal allele and amplicons from their unmethylated paternal allele. PWS patients show only the maternal allele, and AS patients show only the paternal allele. Results observed following PCR amplification and gel electrophoresis of patients referred for PWS and AS testing. Patient DNA with patterns diagnostic of AS *(lanes 1 and 5)* and PWS *(lanes 2 and 6)* and patients referred for AS or PWS but who have normal methylation patterns *(lanes 3 and 4)* are shown. Normal control DNA patterns and a negative control reaction in which no template DNA was added are indicated in *lanes 7 and 8,* respectively. No amplification products are observed in unmodified normal control DNA *(lane 9),* illustrating the specificity of PCR primers prepared specifically for sodium bisulfate–modified DNA. *(Courtesy Jack Tarleton, PhD, Director of Genetics Laboratory, Fullerton Genetics Center, Mission Hospitals, Asheville, NC.)*

Complex Diseases

A complex or multifactorial inheritance pattern indicates interaction of one or more genes with one or more environmental factors. Multifactorial diseases can be more prevalent in some families with several affected family members, but the disease does not follow typical mendelian inheritance patterns. Disease may present in multiple family members because of sharing of similar disease-predisposing alleles and often sharing of similar daily habits, routines, and diet. The degree of genetic and environmental contribution to a disease process varies among complex diseases, and identification of causative genetic and environmental factors is challenging. Further, it is difficult to assess the relative importance of genetic and environmental influences in the development of a disease, although twin studies are often used. Among twins who were raised together, a greater concordance of disease among monozygotic (MZ) twins—who share all of their genes—than in dizygotic (DZ) twins, who share 50% of their genes, provides strong evidence of a genetic component of the disease. Conversely, disease concordance less than 100% in MZ twins is strong evidence that nongenetic factors play a role in the disease. Large genome-wide association (GWA) studies are being used to identify common genetic variants that play a role in the pathogenesis of common complex

TABLE 40-3 Molecular Mechanisms and Tests for Prader-Willi and Angelman Syndromes

Molecular Mechanism	Angelman Syndrome (Frequency)	Prader-Willi Syndrome (Frequency)	Methylation-Specific PCR Result	Possible Detection Methods
Deletion (≈4 Mb) of chromosome 15q11-13	70% (maternal)	70% (paternal)	Abnormal	High-resolution cytogenetics or FISH
Uniparental disomy	7% (paternal)	25 to 30% (maternal)	Abnormal	PCR for microsatellite analysis
Imprinting center defect	3%	1 to 2%	Abnormal	IC sequencing
UBE3A mutation (specific to AS)	11%	N/A	Normal	*UBE3A* sequencing
Chromosomal rearrangement in chromosome 15q11-13 region	<1% (maternal)	<1% (paternal)	Normal	High-resolution cytogenetics or FISH
No detectable abnormality	10 to 15%	Very few cases	Normal	N/A

AS, Angelman syndrome; *FISH,* fluorescent in situ hybridization; *IC,* imprinting center; *N/A,* not applicable; *PCR,* polymerase chain reaction.
Modified from a table prepared by Allison Presley, MD, University of Virginia.

diseases.[275] Examples of largely adult-onset complex diseases include type 1 diabetes, rheumatoid arthritis, Parkinson disease, hypertension, alcoholism, and thrombophilia.

Thrombophilia

Deep vein thrombosis (DVT) occurs in about 1 per 1000 individuals, and associated complications, including pulmonary embolism, account for about 50,000 deaths per year.[588] Venous thrombosis results from disruption of normal hemostasis. As a complex or multifactorial disease, thrombophilia is caused by the interaction of genetic and environmental factors and/or acquired conditions, including the use of oral contraceptives, trauma, obesity, immobility, pregnancy, advancing age, or surgery.[283,400] Protein products of many genes are involved in the anticoagulation and coagulation pathway to regulate hemostasis. Yet it is sequence variants in the factor V (FV) (lq23) and prothrombin (PT) (11p11-q12) genes that are associated with DVT, represent the most frequent lifelong genetic cause of thrombophilia, and are common in the Caucasian population.[57,517] Patients with mutations in both genes have increased risk of a recurrent DVT and may require different management than patients with a mutation in only one of these two genes.[149] Despite the known presence of these mutations and some environmental and/or acquired factors, it is impossible to predict a patient's clinical course even within members of the same family. This illustrates our lack of understanding of the interaction between known and uncharacterized risk factors in predisposition to a complex disease. Activated protein C in conjunction with its cofactor, protein S, plays a key role in the anticoagulant system by inactivating membrane-bound factors Va and VIIIa. The inability to inactivate procoagulant factors Va or VIIIa can disturb hemostasis, heighten the coagulation pathway, increase the generation of thrombin, and promote clot formation.[135] In 1993, Dahlbäck reported that familial thrombophilia caused resistance to activated protein C (APC).[136] In 1994, Bertina and colleagues observed linkage of the FV gene with the APC resistance phenotype and reported a G-to-A base substitution at nucleotide 1691 (c.1691G>A) in exon 10 of the FV gene (OMIM #188055).[57] This nucleotide change results in an arginine-to-glutamine substitution at codon 506 (R506Q) in the FV protein and is commonly referred to as FV Leiden, named for the Dutch city in which it was discovered.[57]

The c.1691G>A substitution is common in the Caucasian population of Northern European descent, with a frequency of 3 to 5%, but it is rare in Asian, African, or indigenous Australian populations.[57,303,528,535] Because c.1691G>A occurs on the same FV gene haplotype, it is speculated that the G-to-A substitution occurred as a single event approximately 21,000 to 34,000 years ago, after the evolutionary divergence of non-Africans from Africans and of Caucasians from Mongoloids.[723]

The arginine residue at codon 506 is one of three peptide bonds (Arg306, Arg506, and Arg679) cleaved by APC to inhibit factor Va activity to decrease affinity for factor Xa and reduce efficiency in catalyzing the conversion of prothrombin to thrombin.[134,352,426] Substitution of a glutamine residue at this site prolongs APC inactivation of factor Va by approximately 10-fold, thereby shifting the balance of hemostasis to favor coagulation and increasing thrombin production.[281] In addition, R506Q prolongs APC-mediated protein S inactivation of FVIII.[648]

Heterozygous c.1691G>A carriers have a lifelong 7.9-fold increased relative risk of venous thrombosis compared with increased risk for homozygotes as high as 80-fold.[400,546] However, the FV Leiden does not confer increased risk for arterial thrombosis.[350] The mean age of onset of symptoms associated with thrombosis is 44 years for heterozygotes and 31 years for homozygotes.[546] Further, although it is transmitted as a dominant trait because thrombophilia is a complex disease resulting from the interaction of genetic and environmental and/or acquired factors, many heterozygote carriers can remain asymptomatic.[248,546]

Also in Leiden, Poort and coworkers in 1996 described a genetic variant (c.20210G>A) in the 3′ untranslated region of

the PT gene (OMIM #176930) in 18% of patients with a documented family history of venous thrombosis.[517] In this population-based case-controlled study, the presence of c.20210G>A resulted in a hypercoagulable state with increased levels of plasma prothrombin (>1.15 kU/L) and a 2.8-fold lifelong increased risk of venous thrombosis. Similar to FV Leiden, this allele is largely confined to Caucasian populations and is rare in Asians, Africans, and indigenous populations of Australia.[724] Likewise, it is hypothesized that c.20210G>A represents a founder mutation after the divergence of Africans from non-Africans and of Caucasians from Mongoloid subpopulations approximately 24,000 years ago.[724]

Prothrombin, also referred to as factor II, is the precursor of thrombin and plays a primary role in fibrin production and clot formation. The G-to-A substitution does not change the coding region of the protein, rather it enhances processing of the 3′ end of pre-mRNA and thus functions as a gain-of-function mutation, culminating in increased mRNA accumulation and increased synthesis of protein.[217] This aberration of RNA metabolism results in increased synthesis of prothrombin and can enhance clot formation. The risk of venous thrombosis is increased 16-fold in c.20210G>A carriers using oral contraceptives, and the risk of cerebral vein thrombosis increases 149-fold in c.20210G>A carriers using oral contraceptives.[429,430] In the Caucasian population, this base substitution is present in 6.2% of patients with venous thrombosis compared with 2.3% of controls.

Inherited together, c.1691G>A and c.20210G>A convey at least a 20-fold increased risk for a venous thromboembolic event (VTE). They are commonly seen together in thrombophilia patients, thus supporting the additive genetic effects associated with complex diseases.[49,101,149,177,628] In addition, the presence of both mutations is associated with a sixfold increased risk of ischemic heart disease.[684] Further, women with one or both of these mutations are at increased risk of preeclampsia and have a higher rate of recurrent preeclampsia in subsequent pregnancies.[165,185] Treatment of the patient with a VTE typically involves the initial use of both heparin and vitamin K antagonists.[135] After several days, heparin is discontinued and vitamin K antagonist (warfarin) therapy is continued for 3 to 6 months or longer, depending on the type of thrombotic event, the precipitating factors, and the combination of genetic and other risk factors. Treatment is regularly monitored to avoid overdosing and possible bleeding complications using prothrombin time, and results are reported as the international normalized ratio (INR).

DNA testing for c.1691G>A and c.20210G>A in clinical laboratories is most often performed by any one of several common methods, including the Invader assay, PCR coupled with restriction-endonuclease digestion and gel electrophoresis, and real-time PCR.[57,273,390,517,691] However, many other techniques have been described.[37,68,164,289,501] Any testing platform is acceptable for clinical use as long as the procedure has been properly validated in the laboratory and follows appropriate quality assurance guidelines.[252]

DNA-based testing for factor V may be requested on a patient following the factor V Leiden-specific functional assay (Coatest APC resistance, Chromogenix AB, MöIndal, Sweden) to confirm the diagnosis and to distinguish between heterozygotes and homozygotes. Similarly, DNA testing can be ordered in place of the functional assay, especially for patients with lupus anticoagulant and a markedly prolonged baseline aPTT (which may interfere with the assay).[715] The clinical utility of knowing the FV or PT genotype is debated because it may not affect the clinical management of patients.[444] However, most experts believe that testing is appropriate for targeted patients such as those with (1) venous thrombosis or pulmonary embolism before 50 years of age; (2) venous thrombosis at an unusual site (hepatic, mesenteric, portal, or cerebral veins); (3) recurrent VTE; (4) VTE and a strong family history of thrombotic disease; or (5) VTE in pregnancy or associated with contraceptive use.[252,435,520] Routine screening before hormone use is not routinely performed, nor is it cost-effective.[647] Modifications to patient management after knowledge of this information may involve length of treatment with anticoagulants and management of other procoagulation risk factors. Use of DNA testing for these two common mutations in the pediatric thrombosis patient is less well defined because often multiple coexisting risk factors exist, and patient management is not currently provided on the basis of test results.[525]

Benefits from DNA testing in the adult include identification of individuals at risk for recurrent events, especially in situations that predispose to thrombosis, such as oral contraceptive use, management of pregnancy complications, or hormone replacement therapy, and in identification of at-risk family members,[150,520] although it is not clear whether this knowledge improves VTE-related outcomes of these individuals or the management of family members who have been genotyped.[573] Screening is not recommended for the general population or for newborns, nor is prenatal screening advised. Although factor V mutation is present in more than 50% of families with thrombosis, inherited defects in protein C, protein S, and antithrombin are detectable in approximately 10 to 15% of families with venous thrombosis. These latter, less common deficiencies can be diagnosed through laboratory assays and do not typically involve DNA testing because of the heterogeneity of mutations in these genes.[51,72,530] Mutations at two other factor V arginine-cleavage sites have been reported, but these mutations are rare and are not part of routine FV DNA testing.[107,693]

Inherited Breast Cancer

Mutations in *BRCA1* (OMIM #113705) or *BRCA2* (OMIM #600185) predispose patients to breast and ovarian cancer. In addition, *BRCA2* mutation carriers are at increased risk for pancreas cancer, and males are at increased risk for prostate and male breast cancer. The incidence of mutations in these genes within the population is estimated to be about 1 in 500. The combined frequency of two founder mutations in *BRCA1* (185delAG, 5382InsC) and one in *BRCA2* (6174delT) in the Ashkenazi Jewish population is as high as almost 3%.[540] Breast carcinoma is second only to lung carcinoma as a cause of cancer-related death among women in the Western

hemisphere. Although most cases are sporadic (average lifetime risk, 12%), about 15% show familial clustering, and only about 5% demonstrate a distinct inheritance pattern. *BRCA1* mutations are associated with younger age at onset (average age, 43); they have a higher histologic grade with a high mitotic index, show a syncytial growth pattern, along with pushing margins, foci of necrosis, a high degree of aneuploidy, and lymphocytic infiltrate, and are usually negative for the expression of estrogen (ER), progestin (PR), and HER-2.[385] *BRCA2* mutation carriers have a slightly later age of onset (average age, 48) and exhibit higher overall grade, but these tumors are less distinct from sporadic breast cancer and more often are ER and PR positive.[385] In families in which breast cancer is segregating, but in which no *BRCA1* or *BRCA2* gene mutation has been detected, other genes that predispose to breast cancer are likely to be involved but have not yet been identified.[653]

The inability to identify breast cancer susceptibility genes in these families may reflect (1) genetic heterogeneity in the family with mutations in several genes; (2) low penetrance of these mutations, making it difficult to distinguish family members without mutation from asymptomatic carriers in the studies; (3) an autosomal recessive mode of inheritance; or (4) breast cancer acting as a complex disease that results from the interaction of several genes and lifestyle/environmental factors, thereby making it difficult to tease out the genetic component of the disease. Lifestyle/environmental factors that have been shown to affect breast cancer susceptibility include smoking, age at menarche and menopause, childbearing, breast feeding, hormonal contraception, and hormone replacement therapy. A candidate gene approach looking at genetic variation in DNA repair genes and large genome-wide association studies have identified multiple possible breast cancer susceptibility loci.[7,171,215,272,625] The significance of these findings requires additional studies, but the results of these and other studies begin to provide potential insight into the pathogenesis of this complex disease.

Offspring of *BRCA1* and *BRCA2* carriers possess a 50% chance of inheriting the predisposing cancer gene mutation. However, inheritance of the mutation does not convey certainty of developing cancer. *BRCA1* and *BRCA2* gene mutations are highly penetrant with a lifetime risk of breast cancer of about 65% and about 45% for *BRCA1* and *BRCA2*, respectively.[25] For the development of ovarian cancer, *BRCA1* mutation carriers have about a 39% risk, and *BRCA2* mutation carriers have an 11% chance.[25] Penetrance of disease is determined by both environmental and genetic factors. However, little is known regarding the identity of genetic modifiers; thus an intense, multicenter effort is under way for their characterization.[110,316] It is interesting to note that some susceptibility loci identified in sporadic breast cancer have been linked to *BRCA1* and *BRCA2* mutation carriers.[28] Homozygosity for a single-nucleotide polymorphism (SNP) c.-98G>C that affects splicing within the 5′UTR of *RAD51* was identified as increasing the risk of disease among *BRCA2* heterozygotes and homozygotes with hazard ratios of 1.17 and 3.18, respectively.[27] RAD51 interacts with BRCA1 and BRCA2 in the repair of double-stranded DNA. Although *BRCA1* and *BRCA2* genes are associated with the most common cause of hereditary breast cancer, much less common yet other highly penetrant genes and associated syndromes include *TP53*, Li-Fraumeni syndrome; *STK11*, Peutz-Jeghers syndrome; *PTEN*, Cowden syndrome; and *CDH1,* causing hereditary diffuse gastric cancer and familial lobular breast cancer.[538] Mutations in other genes involved in DNA repair such as *ATM, CHEK2, BRIP1, PALB2,* and *RAD50* also convey moderate susceptibility to breast cancer with odds ratios of between 2 and 4.[538]

Using DNA linkage studies, Hall and coworkers mapped the gene for early-onset familial breast cancer to 17q21.[269] In 1994, *BRCA1* was cloned; it was later confirmed by several other investigators as the susceptibility gene in breast and ovarian cancer kindreds.[100,212,445] The *BRCA1* gene spans 80 kb and is composed of 24 exons; 22 encode the 7.8-kb mRNA that is translated into a protein of 1863 amino acids. The large exon 11 (3427 bp) accounts for 63% of the coding portion of the gene. It is interesting to note that exon 11 is alternatively spliced in a number of tissues. In families in whom linkage to *BRCA1* was excluded, a second susceptibility locus at 13q12-13, *BRCA2,* was proposed and subsequently cloned.[621,705,706] The *BRCA2* gene, unrelated in sequence to *BRCA1,* spans 70 kb, contains 26 exons, encodes an 11.5-kb mRNA, and is translated into a protein of 3418 amino acids.

BRCA1 and *BRCA2* are considered tumor suppressor genes that require inactivation of both alleles for progression to neoplasm. In a patient with familial breast cancer, a mutant allele is inherited, and the second allele (the patient's wild-type allele) is inactivated through loss of the second allele (i.e., LOH). It is interesting to note that somatic mutations in these genes are not common in tumor DNA from sporadic breast cancer cases. However, LOH and epigenetic changes have been documented in a subset of sporadic breast and ovarian tumors, and RNA-binding protein HuR, which is commonly overexpressed in sporadic breast cancer, has been shown to post-transcriptionally regulate *BRCA1* expression.[102,562,603] BRCA1 and BRCA2 are large multifunctional proteins, expressed in a wide variety of tissues, where they are localized to the nucleus.[258] Each interacts with numerous proteins in complex and separate systems involved in DNA repair, transcriptional regulation of the response to DNA damage, protein ubiquitination, and chromatin remodeling.

Mutations in *BRCA1* and *BRCA2* are heterogeneous and are located throughout each gene.[78] The range of mutations varies greatly among different populations, with founder mutations observed in many ethnic groups.[399,471,616] In Ashkenazi Jewish breast and ovarian cancer families, the mutations 185de1AG and 5382insC are primarily observed in *BRCA1,* and in families in whom these mutations are not present, identification of other *BRCA1* mutations is rare.[514] *BRCA2* mutation 6174de1T has been observed in 6 of 80 (8%) Ashkenazi Jewish women diagnosed with breast cancer before age 42 as compared with 0 of 93 non-Jewish women diagnosed with breast cancer at the same age.[475] *BRCA1* mutation 943ins10 is a founder mutation of West African origin, and

mutation 2804delAA, estimated to have occurred about 32 generations ago, is seen in Dutch and Belgian families.[436,487,504] The *BRCA2* mutation 999del5 is common in the Icelandic population, whereas the founder *BRCA2* mutations S2835X and 5802del4 are common in Japanese breast cancer families.[324,341] In contrast, *BRCA1* and *BRCA2* mutations are less commonly associated with familial breast cancer in Taiwanese and Chinese populations.[109,721]

Testing for disease-associated mutations is made more difficult by the heterogeneity of disease-causing mutations and the complexity of the *BRCA1* and *BRCA2* genes. Moreover, some gene variations may be family specific and may not result in an obvious biological functional change to the protein. Further, small families or unavailable DNA specimens from multiple family members may prevent additional studies to support segregation analysis of the DNA variant with disease, to confirm it as the disease-causing mutation in the family. Variants of uncertain significance (VUS) have been reported for *BRCA1* and *BRCA2,* and various mathematical and histologic models have been proposed to assist in the classification of VUS.[296,601] The development of functional assays and the maintenance of locus-specific databases will assist in determining the pathogenicity of variants and in disseminating their clinical significance throughout the clinical and research community.[129,247] Most *BRCA1* and *BRCA2* disease-associated mutations result in premature truncation of the protein and thus loss of function. Genotype-phenotype correlations indicate that *BRCA1* mutation carriers, with truncating mutations 3′ to codon 1358 and 5′ to codon 800, have a decreased ovarian-to-breast cancer ratio, and those with mutations between these 5′ and 3′ regions have a higher ovarian-to-breast cancer ratio.[297] Similarly, in *BRCA2,* mutations centrally located between nucleotides 4075 and 6503 of exon 11 cause an increased risk for ovarian cancer.[600] About 10% of patients with epithelial ovarian carcinoma (EOC) have a *BRCA1* or *BRCA2* germline mutation. These tumors tend to have serous histology, high response rates to chemotherapy, longer treatment-free intervals between each line of therapy, and improved overall survival compared with nonhereditary EOC.[619] It is interesting to note that some rare biallelic mutations in *BRCA2* can be associated with a Fanconi anemia (FA-D1) phenotype, while heterozygosity for a *BRCA2* mutation results in breast and/or ovarian cancer.[311] Other groups of FA patients have germline mutations in genes whose protein products interact with BRCA2.[529] Further, the type of *BRCA1* or *BRAC2* mutation in the affected patient may be used to determine the most appropriate drug and treatment plan.[488,637]

DNA sequencing of *BRCA1* and *BRCA2* genes is both laborious and costly. To minimize time and expense, some laboratories may use one or more of a variety of techniques to rapidly screen these genes for alterations, while maintaining maximum sensitivity in mutation detection and achieving a high throughput of specimens.[90,219] Once a region of the gene has been identified as containing a possible DNA perturbation, DNA sequence analysis of that particular region is performed to precisely identify the base or bases involved. Some testing algorithms may begin with mutation-specific screening assays that look specifically for common founder mutations when information regarding the ethnicity of the patient is provided. Alternatively, some laboratories prefer no prior gene screening technique and choose to perform DNA sequence analysis of the entire gene to maximize mutation detection and prevent a possible false-negative result caused by the presence of a mutation not detected by screening techniques. When a mutation has been identified as the disease-causing mutation within the family, at-risk family members will be tested specifically for that mutation, and complete *BRCA1* and/or *BRCA2* gene analysis is not required.

Clinical testing for *BRCA1* and *BRCA2* gene mutations should be considered for a woman if (1) multiple cases of breast cancer (<50 years of age) and/or ovarian cancer (any age) are present in her family, in more than one generation; (2) she has breast or ovarian cancer and is younger than 40 years; (3) both breast and ovarian cancers are present in her or in a family member; (4) she has breast and/or ovarian cancer and is of Ashkenazi Jewish descent; (5) she has a male relative with breast cancer; (6) she has a family member with a known *BRCA1* or *BRCA2* mutation, or (7) she has breast cancer and a family history of *BRCA1*- or *BRCA2*-related tumors.[568] *BRCA1* and *BRCA2* testing should also be performed on any man with breast cancer.[568] However, it is important to note that some mutations have been found in families who do not meet these criteria. Further, clinical testing for *BRCA1* and *BRCA2* mutations within the United States is currently available only at a single location within the United States because of exclusive licensing of patented genes. Absolute control of diagnostic testing at one location for these genes is an issue of much debate.[56]

In presymptomatic cases, extensive genetic counseling that addresses both positive and negative aspects of genetic testing must be provided to the patient before genetic testing is undertaken. Counseling often involves the participation of family members, usually spouses. Based on the family history, the genetic counselor should inform the patient of the likelihood that a *BRCA1* or *BRCA2* mutation could be segregating within the family, and that the risk of disease(s) may be associated with various mutations; an overview of prevention and surveillance options available for mutation carriers should be presented.[543] Mathematical models are available to determine the likelihood that a *BRCA1* or *BRCA2* mutation will be found that is based on the pedigree; these models should be used to assist in counseling.[26,192,495] In addition, counseling may be needed for psychologic issues, including fear of cancer or medical procedures, past experiences involving loved ones with cancer, and feelings of guilt about possibly transmitting a cancer-causing gene to children.[73] Continued anxiety and uncertainty regarding some test results should be discussed as well. For example, in some instances, when DNA from an affected family member is not available for testing, the presymptomatic patient must clearly understand that a negative result could imply a false negative because of the inability to detect the specific *BRCA1* or *BRCA2* gene mutation segregating within the family or the possibility of a

mutation in another breast cancer susceptibility gene that may be present in the family. As previously discussed, there exists the possibility of identifying a DNA variant of uncertain significance.

As important as pretest counseling is post-test counseling to explain the test results, answer additional questions, and provide referral to various follow-up services as needed. In addition, the genetic counselor should always be available for further future questions that may arise after the patient has had time to synthesize the results of the disclosure counseling.

Management of the mutation-positive woman is complex and often involves a multidisciplinary approach. The woman may wish to undergo risk reduction surgery, including some type of prophylactic mastectomy and/or salpingo-oophorectomy. Alternatively, she may choose to utilize increased surveillance and prevention strategies for the early detection of breast and ovarian cancer. Surveillance for breast cancer should include annual mammography and breast magnetic resonance imaging and biannual clinical breast examinations.[542,547] Surveillance for ovarian cancer should include transvaginal ultrasound and CA125 measurement every 6 months.[542] Although surveillance may be the choice of some patients, prophylactic surgeries have proved more effective in cancer prevention.[161,437] In addition to facing increased risk of cancer for themselves, most *BRCA1* and *BRCA2* mutation carriers are concerned about transmitting a gene mutation to their offspring. However, one survey showed that only a minority of *BRCA1* or *BRCA2* carriers would be interested in assisted reproductive technologies to minimize the risk of passing a mutant allele on to their children.[604] Although preimplantation genetic diagnosis is available for inherited breast and ovarian cancers, the ethical use of this technology for these adults with late-onset disease is debated.[480]

Inherited Colon Cancer

Colorectal cancer (CRC) is the third leading cause of cancer death in the United States with approximately 150,000 new cases each year. About 3 to 5% of CRC cases are associated with inherited mutations linked to highly penetrant colon cancer syndromes. In as many as one third of cases, familial clustering is observed, thereby suggesting the involvement of less penetrant susceptibility genes and environmental factors. The molecular basis of sporadic and inherited CRC involves two major and distinct pathways: one of chromosomal instability and one associated with microsatellite instability. The original model of chromosome instability proposed in 1990 to explain the pathogenesis of most sporadic tumors (>85%) has been further characterized to reveal a complex chain of events whereby normal colon lining (mucosa) is transformed into adenomatous and then into malignant mucosa via the inactivation of tumor suppressor genes and the activation of genes involved in tumor cell proliferation.[195]

The *chromosomal instability (CIN) pathway* begins with loss of function of the adenomatous polyposis coli *(APC)* tumor suppressor gene product, most often caused by a somatic inactivating gene mutation on one allele followed by a second inactivating mutation such as a chromosomal deletion encompassing the second *APC* allele and adjacent flanking DNA on chromosome 5q (Figure 40-10).[195] Because *APC* is involved early in the tumorigenic process, it has been referred to as the "gatekeeper."[369] The cascade of events proceeds with continued activation of the *KRAS* (Kirsten rat sarcoma virus) proto-oncogene on 12p12.1 through somatic gene mutations (most frequently occurring in codon 12, 13, or 61), which, in the presence of *APC* inactivation, increase growth and proliferation of the cell. Subsequent inactivation of the tumor suppressor gene *DCC* (deleted in colon cancer), frequent loss of adjacent tumor suppressor genes on 18q, including *SMAD4* and *SMAD2,* and inactivation of tumor suppressor gene *TP53* on 17p are identified in late adenoma and carcinoma.

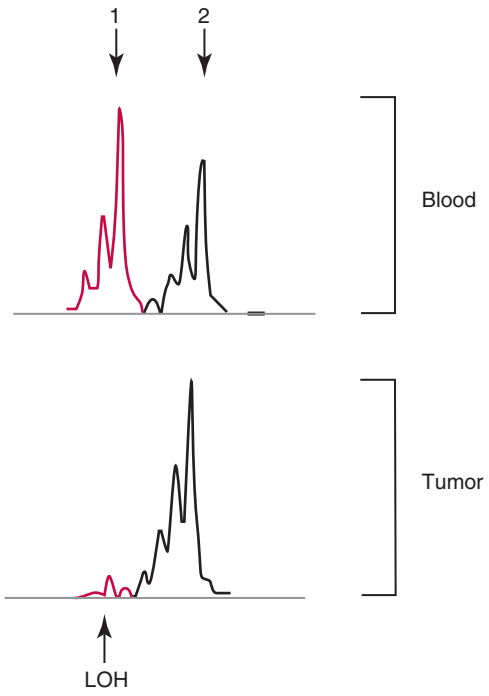

Figure 40-10 Electropherograms illustrating loss of heterozygosity (LOH) in tumor DNA. Patient DNA is extracted from peripheral blood and tumor tissue and is amplified by polymerase chain reaction (PCR) using an oligonucleotide primer pair specific for a polymorphic, microsatellite repeat locus contained within the chromosomal region and thought to be deleted during tumorigenesis. One of the primers within the pair is labeled with a fluorescent dye. Amplicons are subjected to electrophoresis on a 5% denaturing polyacrylamide gel in an ABI DNA sequencer and are analyzed using GeneScan software 3.1 b3 (Applied Biosystems, Foster City, Calif). Constitutive DNA from the patient's blood illustrates heterozygosity for this marker with amplicons represented by alleles 1 and 2. In DNA from the tumor, a single peak representing a typical homozygous pattern is observed. Thus LOH is present in tumor DNA. This loss signifies loss of the second allele and indicates loss of this region on the chromosome.

The *microsatellite instability (MSI) pathway* in sporadic CRC arises from mutations or altered expression of genes involved in DNA mismatch repair (MMR). MMR is a ubiquitous DNA repair process that occurs in all dividing cells. As a result of an altered and thus dysfunctional MMR system, DNA replication errors, primarily within microsatellite repeats or repetitive sequences, remain uncorrected and accumulate. Expansion or contraction of the microsatellite-repeat number in noncoding areas of the genome is of little significance. However, if changes occur within coding microsatellites of the genome and specifically within targeted genes whose protein products are involved in cell growth (TGFβR2), apoptosis (*BAX*), and DNA repair *(MSH6)* then CRC may result.[701]

Inherited CRC syndromes occur as the result of an inherited mutation in one of the genes involved in the CIN or MSI pathway. Although several CRC syndromes exist, the two most common are autosomal dominantly inherited familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC).[108] Tumors in FAP kindreds and tumors displaying CIN more frequently are found in the distal part of the colon (left-sided), whereas tumors in HNPCC families and tumors displaying MSI more commonly occur in the proximal part of the colon (right-sided).

FAP (OMIM #175100) is characterized by hundreds to thousands of adenomatous polyps throughout the large bowel and has an estimated incidence of 1 in 8000.[65] FAP accounts for less than 1% of CRC observed in the United States. In about 25% of cases, no family history exists, indicating that these cases arise as the result of a new mutation; however, there is no tendency for paternal versus maternal origin of the mutated allele.[65,537] Polyps first appear during the second decade of life.[510] CRC ultimately develops approximately 10 to 15 years after the onset of polyposis, with the median age of CRC in untreated FAP patients being about 40.[65,510] It is the sheer number of polyps in these patients that increases the likelihood that one will progress to cancer. Further, patients with FAP have about a 1 to 2% risk of developing malignant extraintestinal manifestations of disease, including papillary thyroid carcinoma, hepatoblastoma, brain tumor, and pancreatic cancer.[253] In addition, these patients have a 7 to 20% lifetime risk of developing benign extraintestinal manifestations of the disease, including adrenal or desmoid tumors, osteomas, and dental abnormalities.[253] Desmoids have been reported as a cause of death in as many as 21% of patients with FAP.[344] It is important to note that close clinical surveillance of FAP patients and at-risk family members is critical to reducing CRC, CRC-associated mortality, and mutant APC-associated complications.[650] The gene responsible for FAP, adenomatous polyposis coli *(APC),* was ultimately cloned in 1991, following linkage to chromosome 5q21 in FAP kindreds in 1987.[70,251,368,479] The *APC* gene spans 8535 base pairs, contains 15 exons, and encodes a protein of 2843 amino acids with a molecular weight of about 312 kDa. The APC protein is a multidomain, multifunctional protein that plays a key role in regulating the β-catenin level in the Wnt signaling pathway.[666] This tumor suppressor protein is also involved in other cellular processes, including cell adhesion and migration, signal transduction, microtubule assembly, and chromosome segregation.[29] However, the main tumor suppressor function of *APC* appears to be its regulation of β-catenin. Many *APC* truncation germline mutations affect the glycogen synthase kinase-3β, APC, and axin complex, which is unable to phophorylate cytoplasmic β-catenin for ubiquitin-dependent degradation. This, in turn, results in lack of β-catenin regulation and constitutive Wnt signaling, promoting cell proliferation and suppression of apoptosis.[29,357]

Studies on FAP families indicate that more than 700 germline mutations exist; more than 95% result in truncated proteins because of a nonsense mutation (30%) or a frameshift mutation, and most are contained within the 5′ half of the gene.[317] The penetrance of most mutations is 80 to 90% of the lifetime risk of colon cancer. Two hot spots for mutations occur at codons 1061 and 1309 representing 11% and 13% of all mutations, respectively. Genotype-phenotype correlations exist for some *APC* mutations. The AAAAG deletion at codon 1309 is associated with a younger age of onset.[97] Approximately 10% of patients who have truncating mutations at the extreme 5′ end of the gene (codons 1 to 163) or mutations at the carboxyl-terminal end of the gene (codons 1860 to 1987) have the attenuated form of the disease—attenuated FAP (AFAP). These patients develop a smaller number of polyps (5-100) and have a 10-year delay in the development of both polyps and cancer.* FAP patients with mutations between codons 1250 and 1464, or truncating mutations between codons 1403 and 1578, have a severe phenotype and are at increased risk for extracolonic disease.[159,466] Intra- and interfamilial phenotypic variability exists even in the presence of an identical mutation and may be explained by a modifier gene or genes.[130,221]

In 2002, *APC* mutation-negative FAP patients were found to have biallelic mutations in the base excision repair gene *MUTYH* or *MAP* (OMIM #604933).[13,560] This gene is located on 1p34.3-p32.1 and encodes an adenine-specific DNA glycosylase, which removes adenine when it is inappropriately paired with guanine, cytosine, or oxidatively damaged DNA containing 8-oxo-7,8-dihydroguanine. This results in G:C to T:A transversion mutations in the *APC* and *KRAS* genes.[13,345] Most patients with these mutations have fewer than 100 polyps. Following screening for common mutations in this gene, data from a multicenter case-controlled study showed that compared with *MUTYH*-negative CRC patients, an increased proportion of *MUTYH* homozygous or compound heterozygous patients tended to have a greater proportion of right-sided, synchronous tumors with an earlier age of onset (mean, 51.7 ± 9.5 years).[118] Although this is an autosomal recessive condition, this study showed that *MUTYH* heterozygous carriers are at increased for CRC, thus indicating that early clinical surveillance may be indicated in this population as well.[118,489] Clinical care of these patients should be similar to that provided for those with FAP or AFAP.

The protein truncation test can be used to test for *APC* mutations because most mutations cause a frameshift in the protein and result in a truncated product.[227] However, most DNA laboratories use sequence analysis of the entire coding region of the gene coupled with multiplex ligation-dependent probe amplification for the detection of exonic insertions or deletions. Sensitivity of about 80 to 90% can be achieved for patients with classic FAP, but it may be as low as 20% in patients with AFAP.[210] If the mutation within the family can be identified, it is recommended that the family be referred for genetic counseling. Many studies have reviewed genetic testing associated with FAP.[163] Most of these studies found that a majority of individuals choose to have presymptomatic testing, yet clinically relevant levels of anxiety and depression can be observed after positive results are received.[163] DNA testing is recommended in at-risk family members as young as 10 to 12 years of age.[220] Genetic testing can significantly alter the 50% pretest risk for disease to a risk of 0% or 100%. Although DNA testing on an asymptomatic minor typically is not endorsed by the genetic community, in this scenario, early identification of the mutation in these patients will clearly affect their clinical management because intense screening programs and possible prophylactic colectomy can be initiated in that decade of life. Family members who test negative for the mutation do not have increased risk of CRC and can avoid intensive screening programs. Further, in some FAP mutation–positive families, preimplantation genetic diagnosis can be used to prevent the birth of a child with an inherited predisposition to FAP or another cancer syndrome.[602] If the mutation in the family cannot be identified, DNA linkage studies may be useful for presymptomatic identification of at-risk family members. If the mutation in the family cannot be identified, and if DNA linkage studies are not informative or available, screening with sigmoidoscopy is recommended every 1 to 2 years, starting as early as age 12. Further, when repeatedly negative sigmoidoscopy results are obtained, the frequency of such examinations can be reduced in each subsequent decade of life. It is important to distinguish AFAP from MAP families because at-risk individuals within the pedigree may shift. In AFAP, the risk to offspring is 50% a priori, whereas in the MAP family, the patient's children have a much lower risk of developing CRC because in most cases, a second mutation in their alternate *MUTYH* allele must be inherited from the other parent.

The most common inherited CRC susceptibility syndrome is HNPCC (OMIM #120435), which represents about 2 to 3% of all CRC cases. In contrast to FAP, HNPCC is characterized by a few polyps that possess an accelerated transformation potential to carcinoma in as little as 1 to 2 years. HNPCC is inherited as an autosomal dominant disorder with a penetrance of 80 to 85%. HNPCC is sometimes referred to as *Lynch syndrome* because of Dr. Lynch's observation of an autosomal dominant predisposition to early-onset CRC with proximal involvement and cancers of other organs in two large Midwestern kindreds.[418] HNPCC patients have a lifetime risk of 70 to 80% of developing CRC, thereby suggesting a role for other factors in this disease process.[257] To assist clinicians in identifying patients in HNPCC kindreds, and to help standardize the ascertainment and study of these families, the International Collaborative Group on HNPCC developed the Amsterdam criteria (AC) in 1991.[649] Basically, criteria for inclusion as an HNPCC family included at least three affected members spanning two successive generations with the diagnosis of colon cancer before the age of 50. In addition, one affected individual must be a first-degree relative of two other individuals, and because this mode of inheritance is consistent with autosomal dominant, the diagnosis of FAP must be excluded.

Because some HNPCC families were excluded by these stringent criteria, and because these criteria did not account for the risk to these patients for cancers of other organs as well, an expanded, more inclusive set of criteria was subsequently developed in Bethesda in 1998, as the Amsterdam criteria II in 1999, and as the Revised Bethesda Criteria (RBC) in 2004.[71,641,651] According to the RBC, tumors from individuals should be tested for microsatellite instability to identify a member of an HNPCC family under the following circumstances: (1) the patient is younger than 50; (2) regardless of age, synchronous, metachronous colorectal, or other HNPCC-associated tumor, including endometrium, ovary, stomach, hepatobiliary system, small bowel, ureter, renal, pelvis, and brain, is present; (3) CRC in someone younger than 60 shows a histology of tumor-infiltrating lymphocytes, Crohn's-like lymphocytic reaction, mucinous/signet ring differentiation, or a medullary growth pattern; (4) CRC occurs in one or more first-degree relatives with an HNPCC-associated tumor, and one is diagnosed before age 50; or (5) CRC occurs in two or more first- or second-degree relatives with HNPCC-related tumors, regardless of their age.[641] Use of the RBG for MSI testing has enhanced the detection of microsatellite instability and the potential to identify HNPCC cases.[236] Although these guidelines reflect improvement, some index cases are still missed, causing some investigators to propose a molecular approach to identifying these patients.[349]

The first MMR gene was mapped to 2p15-16 using large HNPCC kindreds.[506] Simultaneously, MSI was noted in a subset of sporadic CRC.[327,624] MMR genes associated with HNPCC include *MSH2* (2p15-16), *MSH6* (2p15-16), *MLH1* (3p21), *hPMS1* (2q31), *hPMS2* (7p22), and *hMLH3* (14q24.3); however, more than 90% of HNPCC mutations are observed in *hMSH2* and *hMLH1*.[417] In addition, *MLH1* and *MSH2* mutations have been identified in families with Muir-Torre syndrome (MTS), which is characterized by sebaceous gland neoplasia, other skin tumors, and other HNPCC-associated tumors, and is considered a variant of Lynch syndrome.[3] Patients with biallelic germline mutations in an MMR gene resulting in constitutional mismatch repair deficiency syndrome have childhood hematologic or brain tumors, early-onset CRC, and light-brown café au lait spots on the skin.[695]

HNPCC-related MMR gene mutations are diverse and are located throughout these genes.[507] Almost all errors made during DNA replication are repaired through the proofreading 3′-to-5′ exonuclease activity of DNA polymerase.

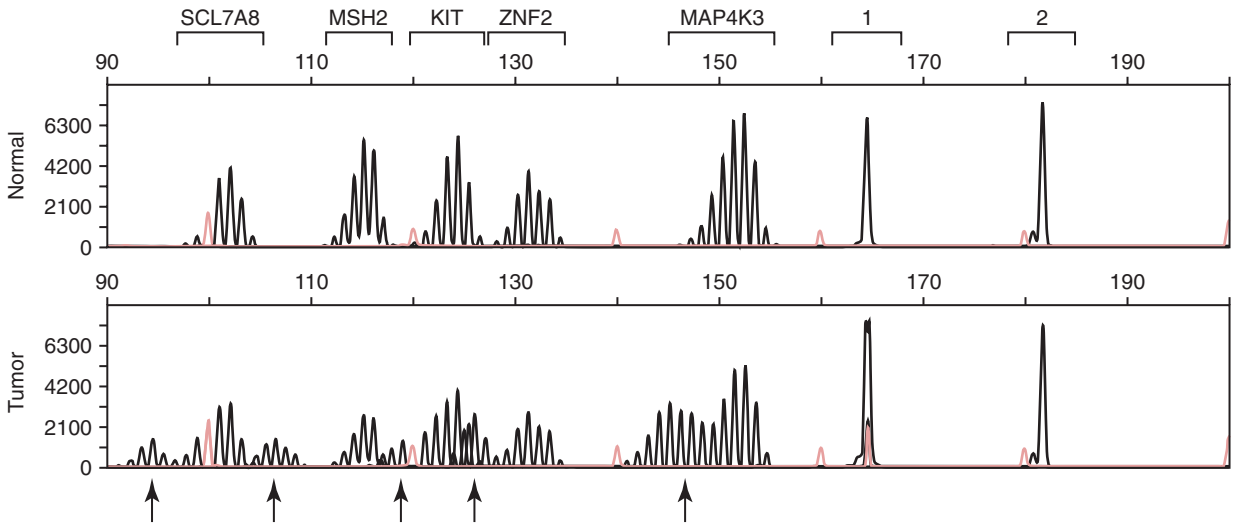

Figure 40-11 Electropherograms illustrating microsatellite instability (MSI) in tumor DNA. Patient DNA is extracted from peripheral blood or normal tissue and is compared with DNA extracted from tumor tissue. DNA is amplified in a multiplex polymerase chain reaction (PCR) assay using fluorescent labeled primers corresponding to 5 mononucleotide loci *(SCL7A8, MSH2, KIT, ZNF2, MAP4K3)* and two pentanucleotide loci (1 and 2) (Promega Corporation, Madison, Wis). Amplicons were detected following capillary electrophoresis on an ABI 3130*xl* Genetic Analyzer (Applied Biosystems, Foster City, Calif) and were analyzed using Gene Mapper v.3.7 software (Applied Biosystems). *Arrows* denote a shift in polymerase chain reaction (PCR) products at 5/5 mononucleotide loci, indicating microsatellite instability. Identical patterns between normal and tumor DNA at the polymorphic pentanucleotide markers suggest that normal and tumor DNA is derived from the same individual.

Uncorrected errors of mismatched bases between the two strands are repaired before cell division by the MMR proteins.[340] In addition to providing the repair of a mismatched base pair, the MMR system repairs "loop outs" from unmatched bases that can occur during replication of a microsatellite or small repetitive sequences. When the normal function of MMR proteins is altered through DNA mutations, mismatched bases generated through DNA replication are not fixed, leading to strands of DNA of different lengths. In the case of HNPCC, a germline mutation in one of the six known MMR genes is inherited, causing one allele to be nonfunctional. In the tumor tissue of these patients, the second allele has been rendered inactive through a somatic mutation or LOH. Uncorrected somatic replication errors thus accumulate in noncoding and insignificant locations throughout the genome, but significantly in coding regions of genes involved in cell growth and signaling and in the DNA of genes involved in DNA repair.

Although MSI is identified in ≈90% of cases of HNPCC-related CRC, it is observed in approximately 15 to 20% of cases of sporadic CRC.[1] MSI in sporadic CRC is attributed to epigenetic silencing of *MLH1* expression through biallelic methylation.[380,630] Thus a category of CRC consisting of the CpG island methylator phenotype (CIMP) has been recognized.

Testing of tumor tissue for MSI is often the first laboratory step in the investigation of HNPCC patients, because MSI is a measure of MMR deficiency that indicates probable defects in MMR genes through germline and somatic changes. Because mononucleotide microsatellite repeats are more susceptible to errors resulting from MMR enzyme deficiencies, testing for MSI most often includes multiplex analysis at multiple mononucleotide loci (Figure 40-11). MSI is characterized by the expansion or contraction of DNA sequences through the insertion or deletion of repeated sequences. If MSI is detected at two or more of the five loci, or more than 30%, the tumor has a "high" frequency of MSI. If MSI is detected at one locus, or less than 30%, the tumor has a "low" frequency of MSI. If MSI is not detected at any locus, the tumor is considered to be microsatellite stable. If MSI is detected, it is necessary to determine whether the MSI results from an inherited MMR germline mutation, or from somatic CpG methylation and inactivation of an MMR gene. Because somatic CpG methylation is frequently associated with mutation V600E in the *BRAF* proto-oncogene, V600E mutation analysis is often performed (Figure 40-12).[411,485] If MSI is present but a *BRAF* mutation is not detected, MMR gene mutation analysis is considered, requiring the submission of a peripheral blood specimen to screen for germline mutations in *MLH1, MSH2, PMS2,* and *MSH6*. To minimize the cost of screening all four genes for mutations, immunohistochemistry (IHC) testing can be performed on tumor tissue to identify the likely defective protein, thereby indicating which gene should be screened for using DNA sequence analysis. However, the best laboratory method for the identification of

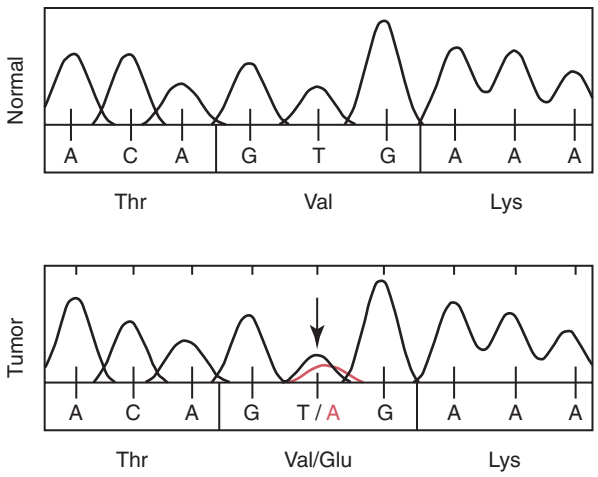

Figure 40-12 DNA sequencing results for *BRAF* mutation c.1799T>A. DNA extracted from normal tissue and paraffin-embedded colon tumor tissue was amplified for exon 15 of the *BRAF* gene by polymerase chain reaction (PCR) and was sequenced using the BigDye Terminator v3.1 cycle sequencing kit (Applied Biosystems, Foster City, Calif). Amplicons were subjected to capillary electrophoresis on an ABI 3030*xl* Genetic Analyzer (Applied Biosystems). The *arrow* indicates the presence of mutation c.1799T>A, resulting in substitution of glutamic acid for valine at codon 600 in the tumor tissue.

HNPCC patients and their families, MSI versus IHC, is still debated.[183,271,494,585,718] It is important for patient care that a systematic and comprehensive approach be developed and followed.

HNPCC-associated gene mutations are heterogeneous, consisting predominantly of point mutations, which impair the activity of the protein, or deletions, which result in premature truncation of the protein and loss of function.[317] An inherent problem with DNA sequence analysis is the identification of sequence variants without obvious biological significance. Thus, it is difficult to assign a pathologic role to these variants without functional assays to confirm their relevance in the disease process. Studies have shown that most of these variants are associated with splicing defects.[629] Further, a database has been developed to assist clinicians in interpreting these variants and to facilitate communication between investigators.[492]

Genotype-phenotype correlations for *MLH1* and *MSH2* from two large European and U.S. studies representing 236 *MLH1* and 330 *MSH2* mutations led to similar conclusions.[230,356] These studies showed that (1) CRC is more prevalent with *MLH1* mutations and is diagnosed at a younger age in males; (2) endometrial cancer is equally present in *MLH1* and *MSH2* families; and (3) extracolonic tumors, excluding endometrial tumors, are more prevalent with *MSH2* mutations. It is interesting to note that a study of *PMS2* mutation carriers reported a lower penetrance of disease with highly variable clinical characteristics, including a wide range of HNPCC-related tumors and a wide age of onset ranging from 23 to 77 years.[574]

If a mutation is identified, at-risk adult family members can pursue presymptomatic testing. Genetic counseling is important to reduce distress associated with test results.[359] Similar to presymptomatic testing for other adult-onset disorders, the counseling session should include verification of the family history and discussion of the clinical course of the disease, including risk of developing the disease and issues associated with disease management. Discussions should be incorporated into the session, including how the patient will act upon both positive and negative results, feelings of survivor guilt or stigmatization, and the possibility of discrimination for insurance and employment. If a germline mutation is detected, a colonoscopy should be performed every 1 or 2 years, or at 5 years younger than the youngest age of diagnosis in the family.[470] Because the risk of endometrial cancer is 40 to 60% for at-risk women with Lynch syndrome, screening for endometrial cancer annually with endometrial aspiration biopsy and transvaginal ultrasound beginning at 30 to 35 years of age is recommended.[565] Further, prophylactic hysterectomy and bilateral salpingo-oophorectomy can be considered. Alternatively, if genetic testing is not pursued, relatives should begin an intensive screening program with a colonoscopy every 1 to 2 years, starting at between 20 and 30 years of age, and then annually after age 40. If no mutation is detected in the proband, presymptomatic DNA testing for family members is not recommended. Some testing strategies may result in false-negative results caused by the inability of the assays employed to identify all mutations at these loci. However, some mutation-negative families may have germline mutations in other, yet unknown MMR genes.[338] Although detection of a mutation in a family that meets HNPCC criteria is not always possible, careful surveillance of at-risk family members in mutation-negative families is considered critical.

REPORTING OF TEST RESULTS

As the preceding pages make clear, DNA testing for inherited diseases is complex, and it is most important to convey the results of a genetic test thoroughly. Results must be presented in a manner that can be easily and accurately understood by a professional whose expertise is not genetics, because in many instances, primary care providers will be communicating test results to the patient. Unfortunately, however, with the increasing clinical demand for genetic testing and the increasing numbers of laboratories performing such tests, uniformity in communicating these complex results to referring clinicians does not exist. However, efforts are ongoing to develop standardized and comprehensive, yet "clinician-friendly," reports.[413] The Molecular Pathology Laboratory Inspection Checklist of the College of American Pathologists (CAP) indicates that failure to include pertinent information within the patient report constitutes a deficiency.[123]

A comprehensive genetic report should include the patient's name; medical record number and/or birth date; sex of the patient; ethnicity of the patient (if relevant); type of specimen and date received; specimen's laboratory

identification number; laboratory test requested; name and address of laboratory performing the test; name and address of referring physician, hospital, or genetic counselor; date of report; brief interpretation of the results; and a descriptive comments section explaining the test results. Although preparation of the comments can be labor-intensive, the comments section is vital to a genetic report and should include the following: (1) brief clinical history of patient (indicating the reason for referral); (2) detailed explanation of the method (citing literature if possible); (3) description of the patient's results using standard nomenclature; (4) sensitivity and specificity of the assay (e.g., number of mutations analyzed, percentage of mutations not detected, possibility of genetic heterogeneity, chance of genetic recombination); (5) clinical significance of the results (e.g., recurrence risk, genotype-phenotype correlation or penetrance, with citations of literature if possible); and (6) a statement that genetic counseling for the patient is recommended to discuss the implications of the results for the health and management of the patient, and when mutations are identified, to inform the patient of the potential risk of disease for other family members.

Because many assays performed in clinical DNA laboratories have been developed by the laboratory and are not approved by the U.S. Food and Drug Administration (FDA), reports must include a disclaimer that states, "This test was developed and its performance characteristics determined by [laboratory name]. It has not been cleared or approved by the U.S. Food and Drug Administration." In addition, the CAP recommends inclusion of these additional statements: "The FDA has determined that such clearance or approval is not necessary. This test is used for clinical purposes. It should not be regarded as investigational or for research. This laboratory is certified under the Clinical Laboratory Improvement Amendments of 1988 (CLIA 88) as qualified to perform high complexity clinical laboratory testing." Last, the report should be reviewed and signed by the laboratory director.

Glossary

Allele—An alternative form of a gene found at a specific location on a chromosome.

Crossover—*See* "Recombination."

Diploid—Having a full set of (paired) chromosomes (46 chromosomes in humans, half from each parent).

DNA marker—A polymorphic locus that is easily assayed, yielding reproducible results.

DNA methylation—The addition of a methyl residue to the 5′ position of the pyrimidine ring of a cytosine base to form 5-methylcytosine; this most often occurs at CpG DNA sequences. DNA methylation can serve as a mode of gene regulation by preventing gene transcription.

Downstream—A DNA sequence located 3′ to another DNA sequence.

Gene deletion—A circumstance in which all or part of a gene is lost.

Gene dosage—The number of copies of a particular gene. In most cases, there are two copies of each gene; therefore, a fixed amount of the protein product is produced from that gene. In situations in which more or fewer copies of the gene are present, ultimately an increase or decrease in the protein product occurs.

Gene duplication—A condition in which all or part of a gene is repeated.

Gene inversion—A rearrangement of the gene or part of the gene, causing the orientation of the DNA sequences in the gene to be reversed in relation to the flanking chromosomal DNA sequences.

Haploid—Having a single set of chromosomes, as in gametes (eggs and sperm) (i.e., half the number of chromosomes in a mature somatic cell).

Haploinsufficiency—In the presence of a loss-of-function DNA mutation, the remaining normal allele is unable to produce sufficient quantities of the protein product of the specific gene, and disease results.

Homologous sequences—DNA sequences that share a similar order of DNA bases. If two sequences are 95% homologous, 95% of their bases are identical at a particular location.

Linkage disequilibrium—The occurrence of two alleles from two loci inherited together on a chromosome more frequently than would be predicted by chance.

Linkage studies—A method using DNA markers physically adjacent (i.e., "linked") to a disease gene. Through this "indirect" analysis, the disease gene can be tracked through a family to determine the disease status of at-risk individuals without the need for knowledge of the disease-causing mutation segregating within the family.

Meiosis—Two-step process of cell division that produces gametes (ova in females and sperm in males) with one half the number of chromosomes of the parent cell. Contrast with mitosis.

Microsatellite repeat markers—Highly polymorphic DNA sequences of short repeats generally comprising <6 bases. These repeats are widely prevalent in both coding and noncoding regions of the human genome.

Mitosis—Process of cell division that produces daughter cells that are genetically identical to the parent cell with the same number of chromosomes as the parent cell. Contrast with meiosis.

Nondisjunction—Failure of chromosomes to separate during cell division.

Penetrance—Percentage of individuals who carry the disease genotype and have symptoms of the disease. *Complete penetrance* implies that all individuals who possess the abnormal allele will develop the disease, whereas *incomplete or reduced penetrance* indicates that not all individuals who have the disease allele will become symptomatic. Incomplete penetrance of a disease suggests that other genetic loci and/or environmental factors can influence or modify the pathogenesis of the disease.

Primer—A short oligonucleotide designed to anneal to single-stranded DNA and from which DNA polymerase can add deoxynucleotide triphosphate (dNTP) in a

complementary fashion to the template DNA. A primer pair flanks the target DNA to be amplified in PCR and creates the specificity of the reaction.

Recombination—Crossing over between DNA sequences that results in an exchange of information between two alleles. This process occurs in meiosis between homologous chromosomes and during mitosis between sister chromatids. *Homologous recombination* refers to this process when it occurs between similar sequences in corresponding regions. Crossing over between misaligned yet similar sequences is called *unequal homologous recombination* and results in a duplication on one allele and the reciprocal deletion on the alternate allele.

Restriction fragment length polymorphism—A polymorphism in the DNA sequence that creates or destroys a restriction endonuclease recognition site, thereby enabling detection by altered base-pair lengths of digested DNA fragments.

Skewed X-inactivation (lyonization) —A process by which inactivation of the X chromosome is not random.

CHAPTER 41

Identity Assessment

Thomas M. Williams, M.D., Howard J. Baum, Ph.D., Victor W. Weedn, M.D., J.D., and Malek Kamoun, M.D., Ph.D.

Identity testing exploits variations present within the human genome to distinguish among individuals. Identity assessment has six basic uses: (1) to confirm or refute that a sample is from a specific person in forensic testing; (2) to identify unknown human remains or victims of a mass disaster; (3) to resolve questions regarding the identity of a clinical specimen; (4) to select donors for a planned transplant recipient to minimize rejection and improve graft survival via histocompatibility testing; (5) to assess whether hematopoietic cells are donor- or recipient-derived following stem cell transplantation; and (6) to identify the parents of a child.

VARIATION IN THE HUMAN GENOME

Identity testing began with the use of serologic methods to identify variations in proteins that differ among individuals. The discovery of the genetic basis for these protein differences and of genetic variability at loci not encoding proteins, coupled with technical advances, allowed the field to move to direct analysis of DNA. Genetic variation among individuals is extensive, with about one sequence difference for every 400 to 1250 nucleotides on autosomal chromosomes. Variants of a genetic locus in a population are referred to as *alleles*. A locus is said to be polymorphic when the least common allele has a frequency ≥0.01 in a population. Although several alleles may be found in a population for an autosomal locus, an individual may have at most two alleles at that locus. Individuals may have one or two alleles for X-linked loci.

Genetic Variation Useful in Identity Testing

Several classes of genetic variants are found in the genome; some are more useful than others for identity testing. Most of the variants used occur in the noncoding genetic regions, such as introns, regulatory domains, and regions between genes, whereas some variants occur in gene domains transcribed into RNA, that is, the exons. Highly repetitive sequence elements that contribute to the structure of centromeres and telomeres and hundreds of thousands of copies of transposable elements that move about the genome over time may vary among individuals. However, these repetitive sequence elements generally are not useful for identity testing.

Several million single-nucleotide polymorphisms (SNPs) have been identified in the genome (see Chapter 38). A subset of SNPs can be identified based on the ability of a restriction endonuclease to digest double-stranded DNA at the site of the variation. These SNPs are referred to as restriction fragment length polymorphisms (RFLPs). SNPs and most RFLPs are not very useful for identity testing because they usually have only two alleles.

Variable numbers of tandem repeat loci (VNTRs) or minisatellite loci consist of repeated sequences of DNA. The core sequence is from 8 to 80 nucleotides long. The core is repeated from 4 to 40 times, thus forming 4 to 40 alleles. The allele size difference can be detected as an RFLP if the locus containing the VNTR is digested with a restriction endonuclease, which cuts the DNA outside of the VNTR, and the resulting restriction fragments are hybridized to a labeled DNA probe in Southern hybridization assays. VNTRs are attractive for identity testing, because the loci usually have a number of different alleles with relatively high allele frequencies. Minisatellite regions are commonly near the telomeric end of the chromosome and have core repeats of 8 to 80 base pair lengths, resulting in DNA fragment lengths of 0.5 to >20 kilobases.

Short tandem repeat (STR) or microsatellite loci consist of DNA sequence motifs that have core repeats of two to seven base pairs.[6,15] Examples include the dinucleotide 5′ CACACACA 3′ and the tetranucleotide 5′ TTTATTTATTTA 3′. Thousands of STRs are scattered throughout the genome. Because they are flanked by unique sequences, each can be specifically amplified with the polymerase chain reaction (PCR) for analysis. In populations of individuals, multiple alleles may be present based on differences in the numbers of repeated motifs at the locus. STRs have many characteristics that make them ideal for identity testing: (1) they can be analyzed in fluorescent automated systems; (2) alleles can be assigned in a definitive manner following analysis; (3) STR loci are almost always transmitted in families in a Mendelian fashion; (4) the loci may have 10 or more alleles, often with substantial allele frequencies, making them highly informative and making it easier to resolve mixtures of DNA; and (5) extensive information is available about allele frequencies in many human populations for STRs commonly used in identity testing.[7]

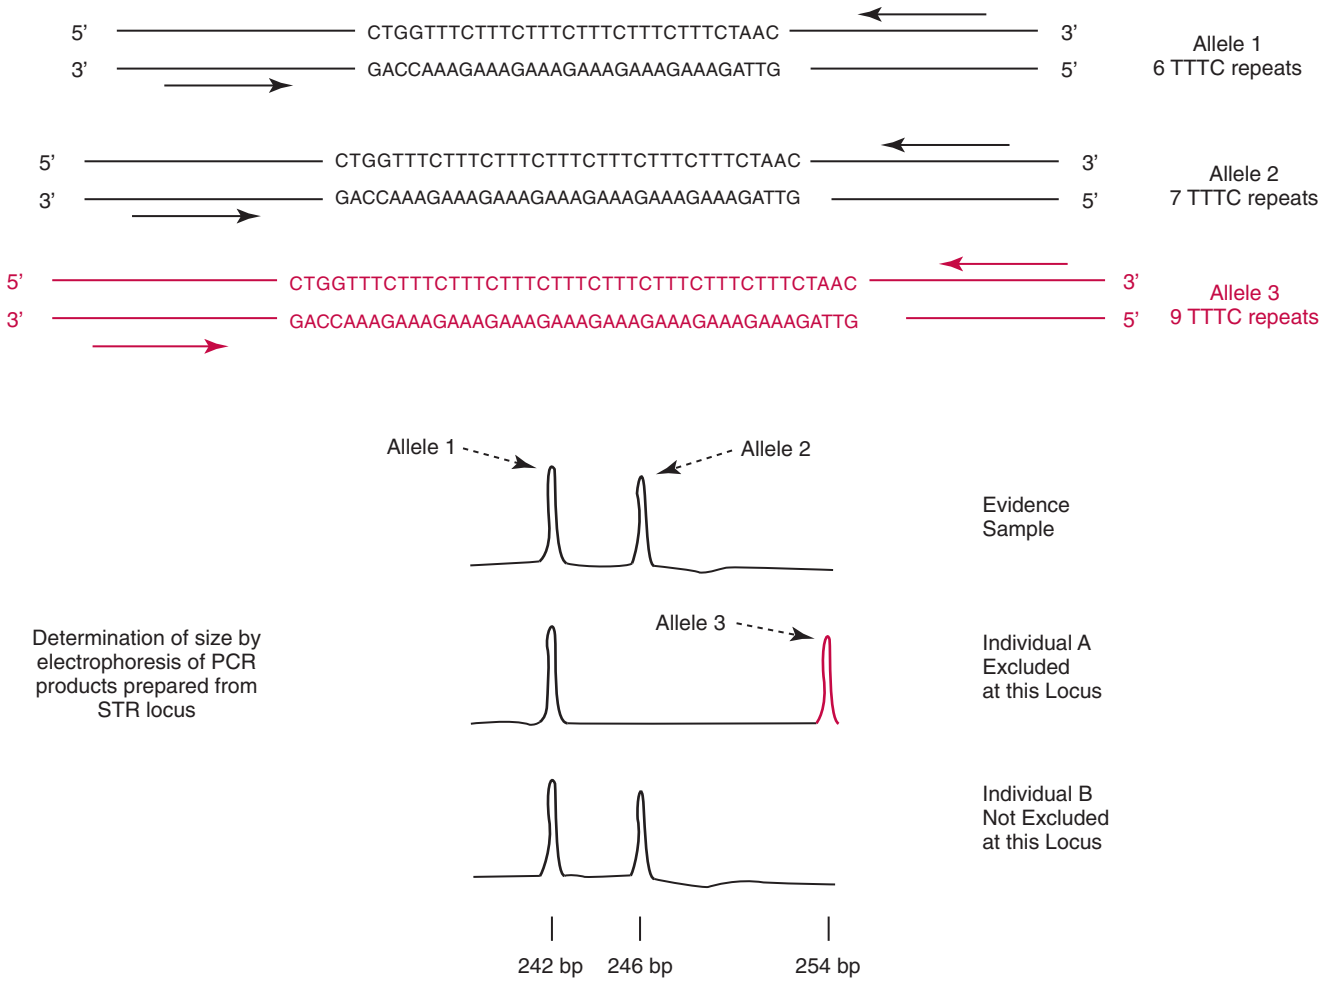

Figure 41-1 Identity testing via short tandem repeat (STR) analysis. An STR locus can be specifically amplified with the polymerase chain reaction (PCR) using primers binding to unique sequences adjacent to the repeat motif in the genome. In the example shown, the polymorphic repeat is the tetramer TTTC. Three example alleles with 6, 7, and 9 repeats at this locus are shown. The genotype for an individual or for an evidence sample can be determined by performing PCR with a fluorescently labeled primer and sizing the products on a high-resolution gel with laser detection. PCR products should differ in size from each other by multiples of 4 nucleotides (nt). Use of several fluorescent dyes and PCR products of different sizes allows multiplexing for simultaneous assessment of a number of independently segregating STR loci.

Commercially available STR systems employ tetrameric and pentameric repeat loci, which produce fewer artifactual bands and are characterized by roughly equal amplification of both alleles within an individual (Figure 41-1). Fragments can be labeled during PCR amplification with fluorescently tagged primers that facilitate multiplexing.

Apart from STRs distributed across the whole genome, two special genetic regions with sufficient sequence variability for identity testing include the human leukocyte antigen (HLA) loci within the major histocompatibility complex (MHC) and mitochondrial DNA. The HLA loci described in the "Transplantation Testing" section later in this chapter are interesting in that the polymorphisms are densely packed and are preferentially located in the exons rather than the introns of these genes on chromosome 6. Mitochondrial genome variation is also useful in forensic identity testing and is described in that section.

Exclusion of Tested Individuals

Identity testing frequently excludes the tested person with almost absolute reliability. Exclusion results can indicate that a suspect did not commit a murder or rape, or that an alleged man did not father a child. The exclusion is based on the presence of alleles at a locus that make it impossible for him or her to be a contributor to the tested sample. For example, if the person has the alleles j and k at the autosomal locus L, then, in the absence of mutations, it is not possible for him to be the major contributor to an evidence sample with the

alleles m and n at L, or to be the father of a child with the alleles m and p at L. In practice, laboratory protocols require that exclusion be based on incompatible results for at least two loci to rule out mutation events or other sources of error. In this context, "impossible" implies a situation in which samples have been collected correctly and have not been mislabeled, testing has been performed accurately, and results have been interpreted and reported appropriately.

Likelihood of Inclusion of Tested Individuals

If a tested individual has genotypes at several loci that are identical to the genotypes found in an evidence sample, then that person is not excluded as the contributor to the sample. Inclusion of a tested individual in identity testing is based on a probability calculation that relies on knowledge of the allele frequencies in human populations for the tested loci. For each locus, the likelihood that a random person of relevant ethnicity would have a genotype identical to that found in the evidence sample can be calculated. If the tested loci independently segregate during meiosis, the overall probability that a random person rather than the accused is responsible can be calculated by multiplying the likelihoods for each locus. When several loci are tested and each has many possible alleles, it becomes extremely likely that an individual whose genotypes match those found in the evidence sample is the person who contributed the DNA to the sample. For genetically linked systems such as mitochondrial DNA testing or Y chromosome STRs, inclusion statistics are calculated using the upper bound confidence level of the database frequency of the entire haplotype. In these systems, the loci do not independently segregate during meiosis.

Discriminatory power is the ability of an identity testing system to distinguish an individual or group from the rest of the population. The power of discrimination of a locus or testing system should not be confused with accuracy. ABO blood group typing is accurate but poorly discriminating, in that this locus results in only a few phenotypes of generally high frequency in populations. Current identity test systems that employ a number of highly polymorphic loci may have powers of discrimination that exceed 1×10^{-14}, making it very unlikely that any unrelated individual on earth other than a nonexcluded suspect or his identical twin could be the source of an evidence sample. However, likelihoods of this magnitude should be viewed with knowledge that a variety of potential problems extraneous to the testing technology, involving sample collection and labeling and test interpretation and reporting, may lead to an erroneous result.

Parentage calculations are often performed using Bayesian methods that consider the prior probability that an individual is the father of a child. It is obvious, for example, that the prior probability of a man living in Boston is the father of a coworker's child is much greater than that of a Beijing inhabitant with no overt connection to the mother. Most crime laboratories in the United States do not report calculations using Bayesian analyses, but instead report population phenotypic frequencies for Caucasian, African American, and Hispanic populations, and sometimes a likelihood ratio that an individual is the source of a DNA specimen. Many times, forensic evidence samples contain a mixture of DNA because they are collected in the real world and not under controlled laboratory conditions. In a mixed sample, if the individual constituents of the mixture cannot be separated, a forensic laboratory will calculate a likelihood ratio or a probability of exclusion, which determines the percentage of the population who could not contribute to the mixture. When questions arise regarding assumptions that must be made during the calculation of inclusion probabilities, laboratories generally choose the conservative option that favors the accused individual.

Samples Employed for Identity Testing

A sample for identity testing can be any specimen that contains DNA. Samples obtained from an individual for parentage testing or as a reference sample to be compared with DNA prepared from evidence are usually peripheral blood or buccal mucosa or objects contaminated with human cellular remains or body fluids. Samples useful for forensic testing, engraftment assays, and the identification of clinical samples may range from plucked hairs to dried biological fluid stains to bone marrow aspirates to paraffin-embedded tissue. Although subject to degradation over time in the presence of enzymes, acidic or basic conditions, or high temperature, DNA is a remarkably stable molecule that can be recovered and successfully analyzed from solutions, surfaces, and cells, sometimes decades or centuries after it was deposited.

FORENSIC DNA TYPING

DNA testing has revolutionized criminalistics.[19,33] Only fingerprint evidence can sometimes rival the ability of DNA as trace evidence left at a scene to identify a perpetrator. As a general rule, other trace evidence merely links an article, instrument, or material to a scene. The origin of DNA-based identity testing is generally traced to a 1985 article in *Nature* by Alec Jeffreys.[18] He coined the term "DNA fingerprint" and suggested that the hybridization of DNA probes to polymorphic genetic loci could be exploited for forensic purposes. Jeffreys first applied his techniques to civil and criminal cases in England. In the United States, DNA-based identity testing was introduced via commercial laboratories and later the Federal Bureau of Investigation (FBI). Today approximately 200 forensic DNA typing laboratories have been established in the United States, along with many other DNA laboratories around the globe. Forensic DNA testing is also used to identify decomposed unknown human remains through kinship analysis and can be used to identify victims of a mass disaster.[4]

Forensic Applications

Forensic testing differs from clinical laboratory testing in several ways: (1) the forensic question is usually one of identity rather than one of presence or absence of a trait or analyte quantification, as is done in most clinical laboratory analyses; (2) specimens received by forensic laboratories are much

TABLE 41-1 DNA Typing Systems and Their Characteristics

Genetic Systems	Time Frame	PCR-Based	Discrimination	Comments

more diverse than the typical blood, fluid, and tissue samples handled by clinical laboratories; (3) clinical samples are collected under controlled circumstances, while evidence from which DNA must be isolated may be exposed to the environment in a variety of ways. This can lead to degradation of the sample. Experiments may be necessary to validate testing for a particular case; (4) forensic samples may include a mixture of DNA such as a vaginal swab containing female epithelial cells and sperm from one or more donors. In addition, a surface may contain more than one biological fluid such as blood from a victim and saliva from someone else; (5) evidentiary material cannot be replenished and may be present in only trace amounts. Testing may consume the sample, and thus complete or repeat testing may be impossible; and (6) forensic identity testing is scrutinized in a judicial environment, requiring complete accounting for chain of custody following its collection and strict validation of procedures.

Most other laboratories perform routine analyses of samples collected in defined ways. Forensic identity testing must contend with much greater variability in samples and testing conditions.

Genetic Systems Used in Forensic Identification

Numerous genetic systems that are employed by forensic laboratories are summarized in Table 41-1.[3,24]

VNTR Analysis by RFLP

Jeffreys described a method to create a barcode-like DNA fingerprint based on VNTRs. Because the probes used bind to several loci in Southern hybridization experiments and produce numerous bands per probe, they are termed *multilocus probes.* In the United States, laboratories have preferred single-locus probe (SLP) systems that hybridize only to a single genetic locus. However, Southern hybridization–based RFLP analysis is expensive, labor intensive, difficult to automate, and less sensitive than PCR-based methods. Finally, RFLP is sensitive to DNA degradation—an important issue with environmentally exposed forensic specimens. RFLP tests have been largely abandoned in favor of the more efficient PCR-based assays discussed later.[5]

Short Tandem Repeats

Most identity testing performed today relies on the PCR. PCR testing is inherently sensitive, allowing routine analysis of nanogram quantities of genomic DNA and often successful testing of picogram quantities (one cell contains 5 to 10 pg of DNA). Low copy number (LCN) STR analysis[8] detects quantities of DNA down to the single cell level PCR, which underlies the characterization of STR and other loci for forensic identity testing loci described in this and later sections.

STR testing is quick, less expensive, more forgiving with respect to technical skills needed, less sensitive to DNA degradation, and more amenable to automation in comparison with the Southern hybridization methods described earlier. Although less discriminating than RFLP genetic markers, STR analysis can be made as powerful as Southern RFLP analysis through the use of large numbers of informative loci.

The National Institute of Justice provided funding for the initial application of STRs in forensics. STRs were used in forensic casework during the first Persian Gulf War and were widely adopted for testing by forensic laboratories in the United Kingdom and the United States in the mid to late 1990s.

The FBI laboratory's combined DNA index system (CODIS) blends forensic science and computer technology into an effective tool for investigating violent crimes. CODIS enables federal, state, and local crime laboratories to exchange and compare DNA profiles electronically, thereby linking crimes to each other and to convicted offenders. The FBI convened a panel of forensic scientists in 1998 that chose a panel of 13 STR loci for use in the National DNA Index System. These 13 core loci have become the standard for casework and databanking for most forensic laboratories around the world (Table 41-2). They have been commercialized as kits in a variety of formats. STRs are now routinely used in crime laboratories globally and typically yield discriminatory values of one in trillions to sextillions.

Low copy number STR testing is currently being used in the United Kingdom, Australia, New Zealand, and the United States. Its extreme sensitivity is both an advantage and a disadvantage. Very small samples can be detected, but because of the small amounts of DNA analyzed, the system suffers

TABLE 41-2 List of Short Tandem Repeat (STR) Core Loci

Core Loci	Currently Available Commercial STR Kits		
	MiniFiler	Identifiler	Powerplex 16

from stochastic effects. Contamination and secondary transfer are potential problems with this system. Another approach to increase the sensitivity of degraded DNA samples is the use of mini STRs, which essentially are the same tandem repeats used in the commercial kits described previously, but the flanking PCR primers are moved closer to the tandem repeats. This results in amplification of smaller fragments, which decreases the likelihood that degradation will affect an STR. Greater sensitivity has been seen with mini STRs.

Gender Markers and Y Chromosome Markers

Amelogenin is a low molecular weight protein found in tooth enamel. The amelogenin gene is useful as a gender marker. The X chromosome amelogenin gene differs from its homolog on chromosome Y by a six–base pair polymorphism, allowing the distinction between individuals with 46,XY and 46,XX karyotypes. Males will display amelogenin locus heterozygosity; females will exhibit homozygosity. Reagents for assessing the amelogenin locus are incorporated into commercially available STR kits.

Y chromosome polymorphic loci can be used as identifying loci found only in males. In this way, male-specific DNA obtained from a vaginal swab can be typed without the usual *differential extraction,* in which the DNA from spermatozoa is released after the female fraction has been isolated from epithelial cells. Y chromosome loci useful for identity testing include STRs or SNPs (described later in this chapter). Laboratories typically employ commercially available panels of 12 to 17 Y chromosome STRs for analyses (Table 41-3). Y chromosome SNPs are in development.

Y chromosome polymorphic loci are linked, resulting in discriminatory power that is significantly less than that of a panel of independently segregating somatic STR loci. Discriminatory values can be increased by using a large panel of Y chromosome markers in conjunction with a large database of typed individuals.

Mitochondrial DNA

Mitochondrial genomes are circular double-stranded DNA molecules that are 16,569 bp long and are present as one or more copies within the mitochondria of a cell. Thus mitochondrial DNA (mtDNA) is present in hundreds to thousands of copies per cell. mtDNA, unlike chromosomal DNA, does not undergo meiosis and does not participate in genetic recombination events. mtDNA remains stable over generations, except for the acquisition of mutations at a rate 10 to 20 times that of nuclear DNA.

mtDNA is transmitted to children via oocytes. Although it is generally thought that mitochondrial DNA is exclusively derived from the mother, a minor contribution from the father is occasionally present, particularly in disease states. The normal state of mitochondria is generally thought to be one of *homoplasmy,* in which all the mtDNA has the same sequence. However, because of mutational events, a state of *heteroplasmy,* in which more than one mtDNA sequence is present in the same tissue, may exist. High-level heteroplasmy is generally on the order of 30% of the mtDNA sequence before it is reported. Unrecognized low-level heteroplasmy is common. Heteroplasmy appears to be somewhat tissue-specific rather than uniform throughout the body. Thus two

shed hairs may show discrepant mtDNA sequences. Because of heteroplasmy, one or two nucleotide mismatches between two individuals are not an absolute basis for exclusion of a tested individual.

In the human mitochondrial genome, only approximately 1200 bases in the region of transcription origin (15971-579), known as the *displacement loop (D-loop)* or the *control region,* are noncoding. This D-loop consists of two hypervariable regions that contain the majority of polymorphisms useful for identity (HVI: 16024-16365; HVII: 73-340). Polymorphisms outside this region can also be employed for testing. mtDNA polymorphisms are typically identified for forensic testing via DNA sequencing of hypervariable regions.[15] This method is expensive, labor intensive, and highly sensitive to contamination.

The mtDNA sequence obtained from a specimen is compared with a reference sequence (revised Cambridge sequence, www.mitomap.org/MITOMAP, accessed May 24, 2010). As in the case with Y chromosome STRs, because mtDNA polymorphisms are linked, individual polymorphism frequencies cannot be multiplied together to generate a likelihood of identity such as by independently segregating chromosomal locus allele frequencies. Instead the mtDNA haplotype identified in a sample is compared with those deposited in a database to derive a frequency statistic. Many mitochondrial haplotypes in the database are unique. Because the database has more than 6000 entries, it can be fairly stated that many mitochondrial haplotypes have a discriminatory value greater than 1 in 6000. However, 18 common haplotypes have population frequencies greater than 0.5%, including a haplotype present in 7% of the population. In aggregate, these common haplotypes account for 20% of all haplotypes.

mtDNA is useful primarily for identity testing in four contexts. First, a sample may be available that contains mitochondrial but not nuclear DNA. For example, shed hairs that do not have roots generally contain only mtDNA. Second, when the DNA within a specimen, such as skeletal remains, is substantially degraded, the high copy number and small size of mtDNA make it more likely to yield a result than nuclear DNA. Third, mtDNA analysis may become essential when only a distant relative is available for a reference specimen. In this example, nuclear DNA requires samples from multiple close kindred, but mtDNA matching would require only a distant maternal relative. Fourth, in database searches of unidentified human remains or missing person relatives, the algorithms for the search often produce several matches, and mitochondrial DNA analysis is needed to identify the true match.

Single-Nucleotide Polymorphisms

A DNA locus whose polymorphism extends over a short region can be preferable for identity testing because it may remain intact and available for analysis in the face of extensive levels of DNA degradation. These loci are particularly amenable to automation and chip technology using hybridization, polymerase extension, or ligation reaction assays. Despite a four-base possibility, most are biallelic with a dominant and a nondominant allele. A large set of SNPs must be used to obtain significant discriminatory values. SNPs are not used in forensic laboratories at this time but are likely to be used in the near future. Unfortunately, because of its biallelic nature, SNPs are not able to discriminate mixtures of DNA. As mentioned previously, many forensic samples contain mixtures, sometimes of more than two individuals, because they are collected under real-world conditions.

Other Systems

Other systems are being pursued for forensic identity testing, generally for phenotypic information. The Alu family of mobile elements constitutes 5% of the human genome. These elements repeatedly insert themselves into the human genome. Polymorphisms occur within these elements, so that the age of the element can be inferred. In Alu systems that are inherited, recent polymorphisms become markers of descent, and older elements (without the Alu insertion site) are markers of root ancestry. Similarly, the L1 family of long interspersed elements (LINEs) can be used to trace evolutionary ancestry. In combination with other genetic systems, Alu and LINE markers will provide some statistical inference about human evolution and race and ethnicity that may be helpful to investigators.

Instrumentation Used in Forensic Laboratories

Most forensic DNA testing is performed with the use of capillary electrophoretic (CE) systems. These systems have a substantially faster run time and higher resolution than slab gels. Several genetic analyzers are commercially available through various vendors.

Instrumentation under development for forensic testing generally focuses on a goal of miniaturization, yielding ultrafast and portable assays that would be useful for field testing. These technologies use miniaturized capillary arrays by etching microchannels into large chips, resulting in an ultrafast CE array that has run times of seconds and produces sharper bands than conventional CE instruments.

Currently being validated by the FBI and its regional mitochondrial laboratories is an electrospray ionization time-of-flight mass spectrometer, which can detect STRs and any SNPs within the STR region. At this time, SNPs within the STR are not detected and are not used for identity testing. This instrument will be used first for mitochondrial sequencing, which is essentially SNP detection, and later will be used for STRs.

Quality Assurance and Accreditation in Forensic DNA Analysis

Crime laboratories are regulated only because they receive federal grants or submit DNA results to the National DNA Index System (NDIS) through the Combined DNA Index System software. Therefore every state or local governmental DNA laboratory in the United States is regulated, but not every general crime laboratory. The DNA Identification Act

of 1994 gave the FBI regulatory oversight of DNA profiles entered into the national database. The legislation called for a DNA Advisory Board that produced recommended standards, based largely on guidelines of the FBI's Technical Working Group on DNA Analysis Methods (TWGDAM). The Scientific Working Group on DNA Analysis Methods (SWGDAM), which has replaced the TWGDAM, now advises the FBI Director to create standard revisions. These standards are now called FBI Quality Assurance Standards, and every forensic DNA laboratory must comply with them.

One aspect of the FBI Quality Assurance Standards is a requirement for accreditation. Forensic Quality Systems Inc. and the American Society of Crime Laboratory Directors/Laboratory Accreditation Board (ASCLD/LAB) accredit crime laboratories to International Organization for Standardization (ISO) 17025 standards. Each laboratory must meet more than 500 separate standards, in addition to the FBI Quality Assurance Standards, to be accredited. ASCLD/LAB requirements include minimal educational credits and experience, proficiency testing twice a year per analyst, and annual audits. All testing requires a technical and an administrative review. Judicial scrutiny provides another layer of critical review of those cases heard in court. Defense review and challenge, however, vary greatly.

Proficiency test providers for forensic laboratories in the United States include the Collaborative Testing Service, the College of American Pathologists, and Orchid Cellmark.

Standard reference materials from the National Institute of Standards and Technology (NIST) are available for PCR-Based Profiling DNA Standard (SRM 2391b), Mitochondrial DNA Sequencing (SRM 2392, 2392-I, and 2394), Human DNA Quantitation (SRM 2372), and Y chromosome testing (SRM 2395). Standards require annual NIST-traceable comparisons.

Statistical Interpretation

In the early days of DNA-based identity testing, significant challenges were launched regarding the interpretation of DNA typing results.[9,13,20,34] Questions included whether loci exhibit Hardy-Weinberg equilibrium, and whether allele frequencies vary significantly among ethnic groups. Current forensic genetic systems have not demonstrated significant deviation from Hardy-Weinberg equilibrium. These systems show greater intragroup allelic diversity than between-group diversity. A National Research Council panel was created to address these issues.[22] The resultant report (so-called NRC I) introduced a *ceiling principle* to ensure the conservativism of the frequency estimates, which itself generated considerable controversy. This led to NRC II, which articulated the current standards of statistical analysis.[23] Statistical formulas are routinely applied to Caucasian, Black, and Hispanic population databases. Specialized databases also exist for Native American Indian and for Pacific and African populations. Current statistical formulas assume that populations are substructured or inbred and correct for this occurrence. In a substructured population, mates are not chosen randomly from the population. Instead, a person will choose a mate of similar religious, ethnic, or geographic origin, such as by marrying within his or her own religion. In a substructured population, an individual is more likely to marry a distant relative such as a second, third, or fourth cousin, because selection of a mate is limited, leading to an inbred population.

Convicted Offender Databases

In the United States, all 50 states now have convicted offender databases. Initially, most databases exclusively contained sexual offenders, but the recent trend is to expand the databases to include all felons and some misdemeanors. States have begun to consider collecting DNA evidence in connection with lesser crimes, such as burglaries, to help solve these cases, to potentially interdict the progression to more serious future offenses, and to identify "hits" in the databases linked to past serious crimes. Twenty-one states and the federal government have recently adopted legislation allowing collection of DNA specimens on arrest or detention. Several states are allowing the release of names of convicted offenders who do not exactly match a crime scene sample (low stringency searches) on the premise that if there is a near database match, then a relative of the convicted offender may have left the sample. This approach has solved several crimes in the United States and in the United Kingdom.

DNA profiles are placed in the NDIS. If a "hit" is determined, the local crime laboratories of the involved states are contacted to discuss details. Identifying information other than the DNA profile is not entered into the system. Uploading of DNA profiles triggers quality assurance requirements and legal constraints on the use of DNA specimens and profiles.

The use of identity testing and linked databases in crime investigation has been aggressively pursued in the United Kingdom. U.K. forensic scientists maintain that approximately 50% of biological specimens from crime scenes result in hits in their databases, suggesting that a relatively small group of professional criminals perpetrate most crimes. They believe that DNA-based testing may be a more efficient tool for investigating crimes than traditional methods, such as canvassing neighborhoods.

Legal Issues

Early challenges to the practice and interpretation of DNA-based forensic identification have faded as the public, attorneys, and judges have become more knowledgeable about this technology. The most common challenges today involve issues regarding sample collection, preservation of the evidence, chain-of-custody documentation, and validation studies. New applications of DNA-based testing to assess ethnicity, to infer phenotypic features from evidence, to release the names of arrestees or potential family members of convicted offenders, or to identify an assailant from very small samples, such as fingerprints,[32] are likely to cause controversy in the future.

USE OF DNA TESTING FOR THE IDENTIFICATION OF CLINICAL SPECIMENS

Identity testing can also be used to confirm the identity of a clinical or anatomic pathology laboratory patient specimen.[27,29] Occasionally, questions arise regarding the identity of specimens in the clinical laboratory. DNA prepared from a peripheral blood or buccal mucosa specimen can be compared with the pathology specimen to confirm that it is derived from the same patient. The authors have encountered a variety of scenarios resulting in requests for this specialized identity service. (1) A patient lost confidence that her breast biopsy results were hers following a series of reporting errors involving the spelling of her name and her birth date. (2) A biopsy of a colonic lesion revealed adenocarcinoma. The subsequent colectomy specimen was devoid of a tumor. (3) A gastrectomy was performed after a biopsy diagnosis of adenocarcinoma. No tumor was seen in the gastrectomy specimen. (4) Multiple blocks from two breast lumpectomy procedures were processed. Because of labeling errors, it was unclear to which patient the various paraffin-embedded blocks belonged. (5) A young male fractured his femur and developed osteomyelitis. Curettings from the fracture site demonstrated acute inflammation as well as a fragment of tissue that appeared to be a squamous cell carcinoma.

In cases 1 to 4, identity testing with STRs demonstrated that all specimens in question truly belonged to the involved patients. In case 5, testing after microdissection of tissue fragments revealed that the squamous carcinoma "floater" had been derived from another individual. The availability of identity testing in situations such as these can be a significant benefit for involved patients and healthcare providers.

In prenatal testing for inherited disorders, chorionic villus sampling (CVS) performed early in pregnancy is sometimes employed as a source of fetal DNA for testing. Testing for a disorder such as cystic fibrosis may reveal that the genotypes for the mother and the fetus are identical, for example, that they are both heterozygous carriers of a cystic fibrosis mutation. This result is entirely consistent with the usual segregation of chromosomes during meiosis. However, it is possible that the CVS material was not derived largely from the fetus but consists of decidual cells primarily from the mother. If the father is a carrier of a cystic fibrosis mutation, this may result in failure to diagnose cystic fibrosis in a fetus. Identity testing can be employed to confirm that tested cells have a genotype distinct from that of the mother and are a valid sample from the fetus. Some advocate that identity testing should be performed to detect maternal contamination on all prenatal specimens.

TRANSPLANTATION TESTING

Obtaining well-matched tissue enhances transplanted organ and bone marrow survival. Human leukocyte antigen (HLA) alleles determine the tissue compatibility for acceptance of transplanted graft donated from another person (allograft). HLA genes encode highly polymorphic cell surface molecules that are strong alloantigens. An allograft is rejected as the result of an immune response directed against HLA alloantigens, which are expressed on the graft but are absent from the host.

Genetic Features of HLA Genes

The HLA genes are located within a genetic complex designated as the major histocompatibility complex (MHC). The extended MHC includes about 7.6 Mb on the short arm of chromosome 6 (6p21.3). Of the 421 loci, 252 (60%) are classified as expressed genes on the basis of complementary DNA (cDNA) and/or expressed sequence tag evidence.[16,17] The MHC is divided into three subregions containing different types of genes (Figure 41-2). With 58 (23%) of the expressed genes, the class III region is the most gene-dense subregion of the extended MHC and of the human genome.[17] Many of the MHC genes are involved in regulation of the immune response.[17] HLA variation is a critical determinant of susceptibility to a large number of infectious and autoimmune diseases.[10,17] The genes encoding the HLA class I (A, B, and C) and class II (DR, DQ, and DP) molecules are the most polymorphic loci in the human genome (see Figure 41-2 and Table 41-4). This polymorphism made the HLA loci an attractive and powerful early resource for identity testing.

HLA genes are codominantly expressed, and most individuals are heterozygous at HLA class I and class II loci. Most of the sequence diversity for HLA class I loci is seen in the second and third exons, and for the class II loci, in the second exon. These domains encode the peptide-binding regions of HLA molecules. The pattern of allelic sequence diversity noted in class I and class II loci is unusual; most alleles differ from their closest neighbor by multiple substitutions, with some alleles differing in the second and third exons by as much as 15%. This pattern is suggestive of segmental exchange of nucleotide motifs between alleles of the same locus. As a result, different HLA alleles are mosaic-like combinations of subsets of all polymorphisms.[12,21,28]

Although a very large number of alleles (e.g., >785 for HLA-DRB1) can be found in the worldwide population, a much smaller number (e.g., 30 to 50 for HLA-DRB1) is present with allele frequencies greater than 0.5% in most individual populations. Different populations tend to have different frequency distributions of alleles and exhibit different patterns of linkage disequilibrium. This variability exists among both racial and ethnic groups.

The HLA genes exist in linkage disequilibrium, also referred to as *gametic association.* Gametic associations are regularly found between certain HLA alleles of A and B, C and B, B and DRB1, and DRB1 and DQB1 loci. HLA genes are transmitted in families as haplotypes. The number of possible haplotypes is vast. However, because of linkage disequilibrium, the number of haplotypes found in a population is limited.[21] Genetic recombination or crossing over in the HLA region is a relatively rare event, occurring for the most part at a rate not greater than 1% per meiosis between A and B, and between B and DRB1. Recombination can also occur

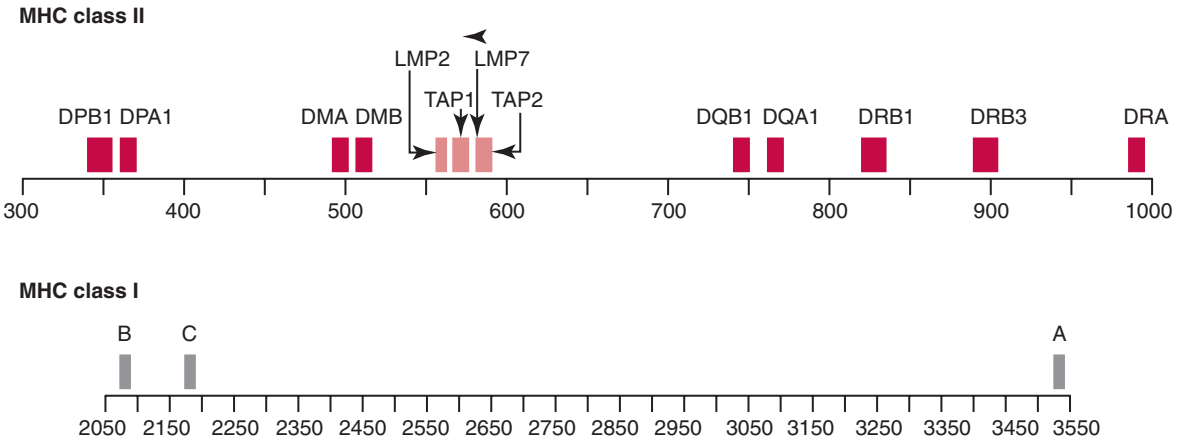

Figure 41-2 Map of the human major histocompatibility complex (MHC) region. The organization of the most important class I and class II genes of the MHC is shown, with approximate genetic distances given in thousands of base pairs (kb). Genes are ordered from telomere *(right)* to centromere *(left)*. The human leukocyte antigen (HLA) class I supercluster comprises the classical class I genes (HLA-A, -B, and -C). Not shown in this class I region are the nonclassical class I genes (HLA-E, -F, -G, HFE, and 12 pseudogenes) and the class I–like genes (MICA, MICB, and five pseudogenes). At the centromeric end of the MHC region is the class II region, which contains all expressed class II genes and several nonfunctional genes. Separating the class I and class II regions is a 1 megabase region of DNA containing the class III genes *(not shown)*.

TABLE 41-4 Names of the Most Important HLA Class I and Class II Genes and Their Encoded Polypeptides Ordered from Telomere to Centromere

Name	Previous Equivalents	Encoded Polypeptide
HLA-A		Class I α-chain
HLA-C		Class I α-chain
HLA-B		Class I α-chain
MICA	MICA, PERB11.1	Class I chain-related gene
MICB	MICB, PERB11.2	Class I chain-related gene
HLA-DRA	DR α	DR α-chain
HLA-DRB3	DRβIII	DR β3-chain determining DR52 specificities
HLA-DRB1	DRβI	DR β1-chain determining specificities DR1, DR2, DR3, DR4, DR5, etc.
HLA-DQA1	DQα1, DQ1A	DQ α-chain
HLA-DQB1	DQβ1, DQ1B	DQ β-chain
TAP2	RING11, Y1, PSF2	ABC (ATP-binding cassette) transporter (associated with antigen presentation)
PSMB8	LMP7, RING10	Proteasome-related sequence (role in loading class I molecules with peptides)
TAP1	RING4, Y3, PSF1	ABC (ATP-binding cassette) transporter (associated with antigen presentation)
PSMB9	LMP2, RING12	Proteasome-related sequence (role in loading class I molecules with peptides)
HLA-DMB	RING7	DM β-chain (control peptide loading by class II molecules)
HLA-DMA	RING6	DM α-chain (control peptide loading by class II molecules)
HLA-DPA1	DP1A	DP α-chain
HLA-DPB1	DP1B	DP β-chain

between A and C, and between B and C (0.6% and 0.2%, respectively).

Historical Applications of HLA Typing

HLA allele identification has been used for transplantation and for forensic, parentage, and chimerism testing. The latter three are of historical interest and are discussed in this section.

Forensic DNA Testing

The first case in the United States in which DNA-based identity testing was used, *Pestinikas v. Pennsylvania* (1986), involved HLA-DQA1 oligonucleotide, dot-blot hybridization analysis for forensic identification. This commercially available DQA1 system was later modified with five additional non-HLA genetic loci, resulting in discriminatory power of

approximately 1 in 2000. The relatively low discriminatory power and problems with interpreting mixtures resulted in the migration of forensic laboratories to other methods and genetic loci as described previously.

Parentage Testing

Use of HLA loci for parentage testing has been replaced by methods described later in this chapter. The polymorphism of the loci was first inferred from antisera that distinguished among antigenic specificities. These specificities were especially numerous within the Class I loci, and it was recognized that they could be exploited in identity testing. Typically, a panel of serologic reagents was employed that defined HLA loci and red cell antigens. The emergence of many highly informative non-HLA polymorphic loci that could be conveniently genotyped led to reduced utility of HLA loci for parentage testing in the 1990s.

Chimerism

Chimerism is defined as mosaicism with coexistence of cells derived from two different individuals. Although HLA loci can be used to study the engraftment of transplanted hematopoietic stem cells (see later in this chapter), other more convenient loci are genotyped for this purpose. These other loci are essential when the transplant donor/recipient pair consists of HLA-identical siblings or allele-matched unrelated individuals.

Transplantation

Matching the HLA alleles of donors and recipients for renal transplantation improves long-term graft survival of kidneys from living related and unrelated donors and from deceased donors. For example, the half-life survival for a graft from an HLA-identical sibling is 23 years compared with a one haplotype–related donor with a half-life of 12.8 years.[12,30] It is important to note that the effect of HLA matching remains significant even with the most recent forms of immunosuppression. The effect of HLA matching on the survival of heart and lung transplants is statistically significant. In contrast, the effect of HLA matching for liver transplants is uncertain.

Hematopoietic cell transplantation (HCT) is employed to treat several classes of disorders, such as leukemia and hereditary immune deficiencies. HLA compatibility between donor and recipient in HCT affects not only the ability to achieve sustained engraftment of donor HCT, but also the risk of developing acute and chronic graft-versus-host disease (GVHD). Post-transplant risk of graft failure, GVHD, and mortality can be affected by quantitative and qualitative characteristics of donor-recipient HLA allele mismatching. In allogeneic stem cell transplantation, the donor is an individual who is genetically nonidentical and either related or unrelated to the recipient. Three different categories of donors are usually considered in the following order of preference: HLA genotypically identical siblings, HLA mismatched relatives, and unrelated donors, matched or mismatched. The goal when screening for an HLA-matched sibling donor is to identify which of any siblings have inherited the same HLA haplotypes from their parents.

When a matched sibling donor does not exist for a patient requiring allogeneic HCT (70% of cases), searching for extended family members or donors from an unrelated bone marrow registry would be the next option. Identifying a patient's haplotypes by testing the immediate family can help predict the probability of finding matching donors and can assist in developing a search strategy, because some alleles and haplotypes are more common than others, and they are distributed at different frequencies in different racial and ethnic groups. When searching for a donor, for some alleles, an allele-level match is more likely to be found among persons of a particular ethnicity. The National Marrow Donor Program (NMDP) matching algorithm, HapLogic, is based on this principle. The NMDP recommends that when possible, patients and adult donors (marrow or peripheral blood stem cells) should be fully matched (8 of 8 loci) at high resolution for HLA-A, -B, -C, and -DRB1. Matching for cord blood units is less stringent.

Registries of volunteer bone marrow donors and cord blood exist in most developed countries (http://www.marrow.org). Currently, approximately 65% of patients can find an acceptable donor among the more than 7 million individuals registered in the United States–based NMDP. However, patients belonging to racial groups that are not well represented in these registries have a considerably decreased probability of finding a donor (http://www.marrow.org).[3]

DNA-Based HLA Allele Identification

Most of the common molecular diagnostic methods have been used to identify HLA alleles. Strategies based on oligonucleotide probe hybridization, DNA sequencing, and allele-specific DNA amplification have become the most commonly used for HLA typing. Each of these methods relies on amplification with PCR of genomic DNA of relevant regions of an HLA gene from the tested individual.[12] Samples for testing usually consist of peripheral blood but may include any tissue containing nucleated cells.

Typing methods involve the design of primer pairs that are able to amplify all alleles at the target HLA locus with the polymorphic sequence motifs situated between the primer sites. Laboratories usually amplify at least exons 2 and 3 of class I genes and exon 2 of class II genes. Some prepare larger amplification products that include exon 1 and/or exon 4 of class I genes. Amplification primers may be located within exons or introns. Primers positioned in introns allow complete analysis of exons and inspection of exon/intron junctions for splice-site polymorphisms. Primers must be carefully chosen to attain locus-specific amplification because HLA loci are the products of gene duplication and divergence and retain substantial homology. Further, many HLA loci have closely related pseudogenes that do not encode functional polypeptides but may result in nonspecific PCR products.[12]

The PCR products prepared are subsequently analyzed by a variety of methods. They can be hybridized to oligonucleotide probes in reverse or forward dot-blot assays. The panel

of probes is chosen to cover critical polymorphic positions in the HLA gene tested. A typical format for this method today is a multiplexed series of fluorescent microspheres coated with oligonucleotide probes that are hybridized to amplicons prepared from the HLA loci and detected in a flow cytometer. The pattern of reactivity of the panel can then be analyzed to assign allele identities.[12]

Alternatively, amplicons can be directly sequenced via dideoxynucleotide chain termination methods. This approach is increasingly attractive for allele level typing because of the large numbers of alleles known to exist at the HLA loci. The homozygous or heterozygous sequence obtained can be compared with a library of known sequences of alleles for allele assignment.[35]

A third commonly employed method, sequence-specific primer PCR (SSP-PCR) employs pairs of PCR primers chosen so that their 3′-most nucleotide or nucleotides are complementary to a polymorphic position that distinguishes an allele or an allele group from other alleles. If the individual possesses the allele(s) of interest, the PCR will lead to a product whose size and presence are typically identified by agarose gel electrophoresis or can be detected with real-time methods. Typing can be performed by choosing many pairs of primers in independent reactions to cover all allele groups.[12]

Commercial reagents and software for analysis of results are available for each of these three methods. Laboratories tailor HLA typing assays to the specific applications discussed previously. Choice of methods depends on typing volume, turnaround requirements, and the resolution needed.

Interpretation of HLA Test Results

An international nomenclature committee assigns each HLA allele an identifying number of at least four digits, with additional digits used if required to uniquely specify an allele. Fields in the identifying number are separated by colons, with each field providing a different form of information. For example, HLA-DRB1*13:01 is an allele found at the DRB1 locus in which the first two digits "13" describe the serologic antigen carried by an allotype, and the third and fourth digits "01" identify a specific subtype based on nucleotide sequence. Allele names are assigned in the order in which DNA sequences are first discovered and determined. Alleles whose names differ in the first four digits must differ in one or more nucleotide substitutions that change the amino acid sequence of the encoded protein. Alleles that differ only by synonymous nucleotide substitutions (also called *silent* or *noncoding substitutions*) within the coding sequence are distinguished by the digits in a third field. For example, HLA-A*02:171:01 and A*02:171:02 encode identical proteins but differ in sequence. Alleles that differ only by sequence polymorphisms in the introns or in the 5′ or 3′ untranslated regions that flank the exons and introns are distinguished by the use of a fourth field. In addition to the unique allele number, optional suffixes may be added to an allele to indicate its expression status. Alleles that have been shown not to be expressed—Null alleles—have been given the suffix "N."

The number of alleles at the HLA class I and class II loci and a listing of serologically defined specificities and their allele equivalents are shown in Table 41-5; updates of the numbers of these alleles are available online at http://www.ebi.ac.uk/imgt/hla (accessed May 11, 2009). The alleles of each of the HLA antigens are numbered according to the original serologic nomenclature. HLA alleles are now designated by a superscripted asterisk after the locus of origin and a number corresponding to the particular allele (e.g., HLA-A*0201). Parallel testing using serologic and DNA genotyping of HLA alleles has led to the use of one nomenclature for the description of low-resolution typing in which the HLA assignment might include more than one possible related allele (e.g., HLA-A A*02) and a nomenclature reflecting the high-resolution allelic typing. Thus different HLA allele subtypes (e.g., for A*02) can appear indistinguishable when

TABLE 41-5 HLA Allele Numbers

HLA Class I

Gene	*A*	*B*	*C*
Alleles	965	1543	626

Nulls	0	2	1	0

tested by serology or with a limited panel of nucleic acid probes so a generic or low-resolution typing is obtained. New HLA alleles are named by an international nomenclature committee. Annual HLA nomenclature reports with frequent updates are available at the Website given in this paragraph.

Quality Assurance and Quality Control Issues

Quality control and assurance programs for HLA testing should be similar to those for other types of PCR-based testing. The NMDP and the American Society for Histocompatibility and Immunogenetics (ASHI) maintain a cell repository of a subset of known alleles (http://www.ashi-hla.org/; accessed April 20, 2009). As in other PCR-based testing, strict measures to prevent contamination of pre-PCR areas with genomic DNA and PCR products are essential. Testing for contamination arising from products prepared in SSP-PCR can be challenging because the many PCR reactions necessary to type an individual often result in products varying in size and composition. Measures to prevent contamination in PCR-based testing have been widely described; such information is available online at the ASHI Website.

Proficiency Testing

Several proficiency testing programs are available in the United States. These include the College of American Pathologists (CAP), ASHI, and the Southeastern Organ Procurement Foundation. Each offers comprehensive programs to assess the ability of laboratories to correctly identify HLA alleles. The University of California at Los Angeles has offered an international cell exchange program for many years. Laboratories are challenged to correctly type samples that often include unusual or recently described alleles.

Accreditation and Certification of Laboratories and Professionals

Clinical histocompatibility laboratories are high-complexity laboratories that in the United States must have a Clinical Laboratory Improvement Amendments (CLIA) license. Laboratories may be inspected and accredited by CAP or ASHI. The United Network for Organ Sharing, NMDP, and CLIA all have designated ASHI with deemed status for purposes of accreditation of HLA laboratories. Laboratories are generally directed by individuals with a PhD, an MD, or both degrees. ASHI administers a program to assess the qualifications of doctoral level individuals to direct ASHI-accredited laboratories. Directors can take a certifying examination administered by the American Board of Histocompatibility and Immunogenetics (ABHI). The ABHI also certifies laboratory staff as histocompatibility technologists and specialists. Information is available on the ASHI Website.

CHIMERISM AND HEMATOPOIETIC CELL ENGRAFTMENT ANALYSIS

Successful HCT effectively results in chimerism with the recipient's hematopoietic cells derived from the donor. With the exception of monozygotic twins, it is virtually always possible to use polymorphic loci on chromosomes to distinguish between DNA prepared from cells derived from the recipient and DNA obtained from donor cells. This is true even for siblings if enough loci are studied. Suppose the father and the mother of two siblings have alleles j and k and s and t, respectively, at a locus. The likelihood that the two siblings will inherit an identical genotype at this locus is 1 in 4. The likelihood that the siblings will be identical for other studied loci for which the parents are similarly heterozygous is also 1 in 4. In this particular example of complete parental heterozygosity, the risk that no locus will be found at which the two siblings can be distinguished is $¼^N$, where N is the number of independently segregating loci tested. Commercial engraftment testing reagents that include 9 to 16 independently segregating loci will virtually always reveal at least a single locus at which donor and recipient cells can be distinguished.

Methods for Performing Engraftment Analysis

Sources of DNA for engraftment testing are typically peripheral white blood cells or bone marrow aspirates. It is crucial to obtain genomic DNA samples from the recipient before the transplant to determine his or her native genotypes at the tested loci. Then post-transplant samples can be compared with "pure" specimens from the donor and from the pretransplant recipient. If a pretransplant sample from the recipient is not available, another sample such as buccal cells may be obtained. Care should be taken in interpreting results from these alternate sources, however, because donor-derived inflammatory cells may be present.

Testing can be performed on genomic DNA isolated from the entire cell population of the specimen. Alternatively, the sample can be sorted by flow cytometry or immunorosetting to assess engraftment of specific cell lineages.[14] For example, engraftment of T-cell versus non–T-cell components can be assessed after flow cytometry sorting based on expression of the CD3 surface molecule, a T-cell marker.

DNA typing methods used in engraftment analysis are summarized in Table 41-6. These methods have evolved similarly to those used for identity testing in general. Initial methods relied on Southern blotting to detect RFLPs or VNTRs. These labor-intensive hybridization assays have been largely replaced by PCR-based methods.

One PCR-based strategy is to amplify a series of VNTR loci with subsequent separation of the DNA fragments on polyacrylamide gels.[26] Alleles can be assigned via comparison with size standards after staining with ethidium bromide. The sensitivity of this method for detecting a small admixture of donor or recipient DNA is roughly 10%. Sensitivity can be increased to the <1% to 1% range with silver staining of the amplification products.

As described earlier in this chapter for forensic identification, fluorescent detection of PCR products derived from STR, or microsatellite loci, has been adopted by many laboratories for engraftment assays.[25] This method is attractive because of the ability to automate the assay, the extensive characterization of these loci in a variety of populations, and their high degree of polymorphism. Surveys from the

TABLE 41-6 DNA Typing Methods Used in Engraftment Testing

Method	Description	Comment
RFLP analysis of VNTR loci	Digest genomic DNA with restriction endonuclease and detect polymorphic VNTR loci by Southern blotting	Highly informative identity testing method also used in early forensics, now discarded because of its labor-intensive nature
PCR analysis of VNTR loci	Amplify VNTR loci and size by gel electrophoresis	This assay can be quite sensitive when bands are detected by silver staining.
STR analysis	Multiplex amplification of several STR loci with sizing by fluorescent detection	Becoming the standard method in the field because of its efficiency and partial automation
Cytogenetics	Interphase analysis of X and Y chromosomes with fluorescent in situ hybridization	May be useful when donor and recipient are of different genders

PCR, Polymerase chain reaction; *RFLP,* restriction fragment length polymorphism; *STRs,* short tandem repeats; *VNTRs,* variable numbers of tandem repeat loci.

proficiency testing programs described later indicate that most laboratories providing clinical engraftment testing currently analyze STR loci.

When the donor and the recipient are of different genders, analysis of sex chromosomes in post-transplant hematopoietic cells can be useful in engraftment testing. Cytogenetic analysis of chromosomes in interphase cells with X- and Y-specific probes may be performed with fluorescent in situ hybridization assays. The percent donor or recipient cells can be determined by assessing the ratio of cells with XX signals to those with XY signals. Alternatively, PCR-based analysis of X and Y chromosome loci can be carried out. For example, the reappearance of Y-specific amplification products in a male whose donor was his sister may indicate relapse of a malignancy. Polymorphic loci on chromosome X can be studied similarly to the autosomal STR previously discussed.

Selection and Interpretation of Short Tandem Repeat Loci

Engraftment testing is accomplished by preparing genomic DNA from donor and pretransplant and post-transplant recipient specimens and performing PCR amplification of selected STR loci. Amplification reactions are typically multiplexed using fluorescently labeled commercially available reagents as described for forensic identity testing. Products are then separated via high-resolution slab or capillary electrophoresis on an automated genetic analyzer. Comparison of DNA fragment sizes with a reference ladder allows software to assign alleles for each locus.

Analysis of a donor sample and a pretransplant recipient sample allows the laboratory to identify which STR loci are informative (nonidentical genotypes) for the pair. A post-transplant sample can then be studied. If only fluorescent peaks from the donor are observed, the cells studied are donor in origin. Rarely, only recipient peaks will be seen, consistent with a recipient origin of the cells. These assays can detect admixtures of cell populations down to approximately 3%. Therefore, results indicating that a sample has been obtained exclusively from the donor are often reported as ≥97% donor. If fluorescent peaks derived from both the donor and the recipient are seen, the sample must be a mixture of cells from the two individuals.

The percent recipient in a mixed sample can be calculated by summing the intensities of the informative recipient peaks and dividing by the sum of the intensities of the informative recipient and donor peaks. Many laboratories then average the percent recipient for each locus to arrive at a final result. Some laboratories run a calibration curve of artificial mixtures of donor and recipient DNA for each tested pair. Other laboratories validate the assay with calibration curves for a number of control "donor" and "recipient" mixtures, and do not run new calibration curves for each new donor-recipient pair.

Applications of Microsatellite Locus Testing to Engraftment Analysis

Several clinical questions can be answered with engraftment testing.[31] Is engraftment of donor cells proceeding well in the weeks following a stem cell transplant? In the setting of a history of successful engraftment, do subsequent studies demonstrate a resurgence of recipient-derived hematopoietic cells indicating a relapse? Has stable chimerism developed following transplantation with the production of hematopoietic cells derived from both the donor and the recipient?

Correlation of engraftment testing results with the clinical history is crucial for interpretation of results. Thus appropriate communication between the engraftment testing laboratory and the transplantation team is essential. Consultation with a hematopathologist may be helpful in interpreting results in complex cases.

A result indicating 85% donor cells and 15% recipient cells might be equally consistent with an engrafting marrow 3 weeks after transplantation or with relapse 6 months following transplantation. The date of the transplant in relation to sample collection, the conditioning regimen used before transplant, and evidence from peripheral smear or bone marrow aspirate examination may be helpful in interpreting results. Unusual history, if unknown, can cause considerable confusion. For example, some recipients may have received more than one stem cell transplant or may have had a donor who is an identical twin.

Interpretation of an engraftment result from a single sample can be difficult. Multiple samples collected at intervals after transplantation may reveal changes in the fractions of donor and recipient over time that can be correlated with the evolving clinical picture.

Proficiency Testing

Proficiency testing programs for engraftment testing are offered by CAP and ASHI. Challenge specimens are typically artificial mixtures of genomic DNA from two related or unrelated individuals. In both surveys, participant laboratories have demonstrated a high degree of agreement for challenge samples. The standard deviation from the mean of participant results in a 50-50 mixture of "donor" and "recipient" cells is typically ±2 to 4%. For mixtures that approach the sensitivity threshold of the assay (e.g., 6% recipient, 94% donor), somewhat broader standard deviations may be seen.

Quality Assurance and Quality Control

Quality control and assurance programs for engraftment testing should be similar to those for other types of identity testing. Assays may require as little as 1 ng of genomic DNA. Thus strict measures to prevent contamination of pre-PCR areas with genomic DNA and PCR products are important.

Accreditation

Accreditation of programs may be provided through ASHI or CAP. Because engraftment testing is a variant of identity testing, the standards used are often those written for paternity and other forms of identity testing. However, because engraftment testing deals with subpopulations of cells and the relative proportions of cells, organizations such as ASHI have developed accreditation standards specifically for engraftment testing.

PARENTAGE TESTING

Questions regarding the parentage of minor and adult children arise frequently in modern society. Generally at issue is whether a particular man is the father of a child. As discussed in the chapter introduction, parentage testing allows an individual to be excluded or not excluded as the parent of a child. If not excluded, the likelihood that he is the father can be calculated. The same methods can be applied to the search for a mother, a situation that sometimes arises when an adopted person is trying to find his or her biological parents. Court-ordered or privately sought parentage testing is usually performed to facilitate decisions regarding responsibility for the financial support of a child. However, individuals may wish to establish parentage for other reasons; an example is the settlement of an estate. Laboratories that perform other types of identification tests for purposes unrelated to parentage (e.g., HLA typing for transplantation) should be aware of the possibility of inadvertently uncovering "false paternity."

Methods, Instrumentation, and Sample Requirements

Methods for parentage testing have evolved considerably over time, similar to other human identification applications. Early methods relied on serologic techniques to identify red cell antigens, such as ABO and MNS groups and the highly polymorphic HLA antigens found on most cells. Since 1990, a substantial migration of parentage laboratories to DNA-based methods has occurred, especially to those based on analysis of STR alleles. The significant advantages of these PCR-based assays with detection of fluorescently labeled DNA fragments on automated genetic analyzers have been discussed in the section on forensic identification. SNPs have also been introduced in commercial parentage laboratories.

Selection and validation of testing methods are key issues in parentage testing. Specific requirements for paternity testing may be mandated by local laws and agreements. Thus the choice of methods and genetic systems should be based on an agreement between the client(s) and the laboratory.

Nonstandardized methods should not be used as the sole methods within a paternity testing laboratory. Also, a nonstandard method should be used only if it can be documented that the method is used in at least one other laboratory, thus making it possible to obtain a second opinion based on repeated testing.

Similar to other forms of identity testing, a sample for parentage testing may be any specimen containing chromosomal DNA. In practice, programs generally perform testing on peripheral blood samples or buccal smears. Buccal smears are increasingly preferred as they offer a noninvasive means of sample collection, which is especially convenient when testing minors.

Reporting of Test Results

In addition to the usual parentage test reports, laboratories are occasionally asked to provide interpretative reports when less than complete information is available. The usual report is discussed next, and interpretive reports are discussed afterward.

Test Reports

Results should include all information requested by the client and necessary for the interpretation of test results and all information required by the method used. If the weight of evidence is calculated, this must be based on likelihood ratio principles, such as the paternity index.[2,11]

Exclusion of a Tested Man

Standard parentage testing involves genotyping of several polymorphic loci in samples from a trio consisting of the mother, child, and presumed father. Inspection of the alleles found in the mother and child at the genetic loci analyzed reveals alleles that must have been contributed by the child's biological father. If the accused father does not have an obligatory allele at one of the tested loci, he is excluded as the biological father. Laboratories require the absence of an

obligatory allele for at least *two* loci in a tested man to exclude him as the father. The requirement of multiple loci reduces the possibility of an error caused by a technical problem or by a rare mutation at one of the examined loci.

The power of an analyzed locus to exclude a tested man depends on the number of alleles found at the locus and allele frequencies in human populations. ABO typing can exclude a tested man but has a relatively poor probability of exclusion of about 15%. HLA and VNTR loci have many alleles, and a single locus may have a greater than 90% probability of excluding a falsely accused man. The STR loci have an intermediate number of alleles. A single STR locus typically has a 30 to 60% likelihood of excluding a wrongly accused man. The ease of STR analysis makes these loci attractive for parentage testing even with their lower exclusion power. If several STRs that independently segregate during meiosis are studied, a cumulative probability of exclusion can be calculated that is based on the product of exclusion power for each tested locus. The use of 9 to 16 unlinked, and therefore independent, STRs provided in commercially available human identity reagents generally results in at least a 99% probability of exclusion of a falsely accused man.

Inclusion of a Tested Man

The alleles found at the analyzed loci may be entirely consistent with the accused man being the biological father of the child. In this case, the likelihood that he is truly the father rather than a random individual who is not excluded can be calculated. A number of assumptions underlie accurate calculations of the likeliness of paternity. Tested individuals must be properly identified, testing must be accurate, and allele frequencies in relevant populations must be well characterized.

The probability of paternity (W) and the paternity index (PI) are two closely related values that express the likelihood that the tested man is truly the father, rather than another man who by chance shares alleles at a tested locus. Calculation of the PI takes into account allele frequencies at the locus in relevant populations. If multiple independent loci are analyzed, a cumulative PI based on the products of individual loci can be calculated. Government entities typically require that the PI be greater than 100:1 and that the probability of paternity be greater than 99% for inclusion of a man. Other evidence bearing on the probability that a man is the father before testing is performed can be integrated with test results using Bayesian analysis to calculate a posterior probability of paternity. The prior probability that an accused man is the father is typically set at 50%, but a range of likelihoods given different prior probabilities (e.g., 10 to 50%) can be calculated for comparison.

Opinions, Interpretations, and Problems

Standard parentage testing requires samples from the trio previously described. However, in many cases, the mother, child, and putative father may not all be available for testing. If a sample cannot be obtained from the mother, it may still be possible to exclude a tested man or to calculate his probability of paternity. For example, the finding of locus L genotypes 1,3 for the child and 4,5 for the tested man is inconsistent with the hypothesis that he is the father, whether or not we know the mother's genotype. Similarly, when the accused man is not available, testing performed for individuals related to him may be used to calculate the likelihood that he is the biological father of the child in question.

Although STRs and VNTRs are usually transmitted in a faithful mendelian fashion, mutations can occur. A child and a tested man may be encountered who share an allele at all but one of the tested loci. The possibility that the man is truly the father and that a mutation has occurred at the mismatched locus should then be entertained. If additional loci are tested and no additional genetic inconsistencies are discovered, the likelihood of paternity can be calculated by considering the frequency of mutations at the mismatched locus. Alternatively, additional genotyping may reveal more exclusions, making it unlikely that the tested man is truly the father. Laboratories should apply procedures for estimating the uncertainty of measurement. The measurement of uncertainty of tests should be known and should be included in the interpretation of test results.

Quality Assurance and Quality Control

Quality control and assurance measures for parentage testing are similar to those for other types of human identity testing. Positive identification of samples, prevention of DNA contamination, use of control alleles of known size, and validation of software employed for genetic analysis and calculation are among measures common to identity testing programs. Population distribution data for the systems used must be documented. In addition, mutation frequencies of the systems used must be documented and used appropriately.

Policy and Procedures for Resolution of Complaints

The laboratory should have a policy and a procedure for the resolution of complaints received from clients or other parties. Paternity testing programs involving knowledge of sensitive family information results may be employed in legal proceedings. Samples and records, including information stored electronically, must be handled carefully to ensure their privacy, confidentiality, and security. Laboratory procedures for documenting the identity of individuals who contribute samples for study and the chain of custody of specimens should be very detailed.

Accreditation

Recommendations and standards for paternity testing are formulated by government agencies or professional organizations [e.g., the Standards for Parentage Testing Laboratories of the American Association of Blood Banks (AABB)]. The AABB administers a laboratory inspection and accreditation program.[1] ASHI and CAP also publish relevant standards. CAP and AABB jointly offer a proficiency testing survey.

CHAPTER 42

Molecular Methods in Diagnosis and Monitoring of Infectious Diseases

Aaron D. Bossler, M.D., Ph.D., and Angela M. Caliendo, M.D., Ph.D.

In the short time since their introduction, nucleic acid tests have profoundly impacted the management of infectious diseases. In contrast to microbial culture methods, molecular methods are rapid, allowing early decisions about treatment to be based on data about the pathogen(s) in an individual patient. Molecular methods have provided a means to detect pathogens that could not be easily detected by traditional methods using culture, antigen detection, or serology. By providing rapid identification and in some cases quantification of pathogen nucleic acids, these methods have transformed the clinical practice of assessing the risk of disease development, determining disease prognosis, and predicting and monitoring response to therapy.

Interpretation of the results of molecular assays for infectious diseases requires an understanding of the biology of the target organism, the pathogenesis of related infectious disease(s), and the advantages and limitations of the technology used. An advantage of molecular methods is their exquisite sensitivity for the detection of pathogen nucleic acids whether from viable or nonviable organisms. The nucleic acids of the organism may persist for varying lengths of time after adequate treatment of an infection. Therefore, one of the challenges can be interpreting the significance of a positive molecular test result. For example, *Chlamydia trachomatis* DNA can be detected in the urine of patients for as long as 3 weeks after initiation of appropriate therapy.[48] Similarly, herpes simplex virus (HSV) DNA can be detected in the cerebrospinal fluid (CSF) of patients with encephalitis for 2 weeks or longer after initiation of acyclovir therapy.[84] Thus, in this case and most others, monitoring response to therapy with qualitative assays has limited clinical utility and is best done using quantitative methods. Detection of the nucleic acid of a pathogen does not ensure that the organism is the cause of the disease. The organism may be part of the normal flora, colonizing a specific area or causing infection but not disease. For example, interpretation of molecular tests for the detection and quantification of herpesviruses after primary infection is complicated by the fact that these viruses establish a life-long latent infection. Early studies evaluating the clinical utility of cytomegalovirus (CMV) DNA assays used very sensitive qualitative methods and peripheral blood mononuclear cells as the specimen of choice. As a result, CMV DNA was detected in immunocompromised patients with disease, as well as in those without CMV disease. Studies are needed to establish viral load values that distinguish between latent infection, asymptomatic disease, and active disease.

A common application for quantitative molecular assays involves monitoring of disease progression or response to therapy over time. To determine whether changes in quantitative values are clinically significant or are due to expected variability of the measurement, one must consider the analytical variability of the test and biological variability of the pathogen. For example, for the current human immunodeficiency virus (HIV)-1 viral load assays, to allow for both assay and biological variability, a change in the viral load must exceed 0.5 $\log_{10}$ (or a threefold change in concentration) to represent a biologically significant change in viral replication.

Interpretation of a negative result requires consideration of assay sensitivity and efficiencies of nucleic acid extraction and amplification. A false-negative result may be due to inhibition of or decreased efficiency of amplification, and proper controls are important. Insufficient sample, inappropriate specimen type, inappropriate timing of sample collection, and degradation of nucleic acid during transport and handling are other sources of false-negative results.

Factors that need to be considered when a positive result is interpreted include assay specificity and contamination. Specificity of molecular infectious disease assays is related to the primers and probes used during amplification and detection/quantification steps. If primers allow amplification of nucleic acids from other pathogens normally present in a patient specimen, false-positive results are possible. Although uncommon, problems with primer specificity have been

reported; primers designed to amplify the 5′ untranslated region of the enterovirus genome have also been shown to amplify rhinovirus RNA.[129] This will not be an issue if the assay is used only for cerebrospinal fluid, but it will likely cause false-positive results if respiratory specimens are tested.

False-positive results can also occur as the result of carryover contamination of amplified products. This is not a problem with signal amplification methods, but it can be of significant concern for target amplification methods, such as polymerase chain reaction (PCR), nucleic acid sequence-based amplification (NASBA), transcription-mediated amplification (TMA), and strand displacement amplification (SDA). The use of real-time assays, which do not require postamplification handling of the product, greatly reduces the risk of carryover contamination. Cross-contamination of clinical specimens with target DNA during specimen collection, transport, and processing can occur with any method. Strict attention to good laboratory practices is needed to minimize the risk of cross-contamination.

Molecular infectious disease tests are used in a variety of ways including identification of pathogens, particularly those that do not grow using conventional methods or that grow very slowly; monitoring of response to therapy; assessment of risk of disease development; and determination of disease prognosis. The balance of this chapter will review nucleic acid testing as it applies to specific pathogens, with a focus on those pathogens for which nucleic acid testing is considered the standard of care.

CHLAMYDIA TRACHOMATIS AND *NEISSERIA GONORRHOEAE*

Chlamydia trachomatis (CT) and *Neisseria gonorrhoeae* (GC, for gonococcus) will be discussed together because several of the available nucleic acid tests for these pathogens are multiplex assays. Although both CT and GC can cause a variety of clinical infections, here we will focus on genital infections.

Detection of CT is a challenging and important public health issue. CT is a major cause of genital infections, with an estimated 1 million cases occurring annually among sexually active adolescents and young adults in the United States.[53] More than half of the infections are asymptomatic.[144] Even when symptomatic, the diagnosis can be missed as the manifestations are protean. In males, CT infection may present as urethritis, epididymitis, prostatitis, or proctitis[17,105] and as cervicitis, endometritis, and urethritis in women, with 10 to 40% of infections in women progressing to pelvic inflammatory disease (PID) if untreated.[122,145] Related complications include chronic pelvic pain, ectopic pregnancy, and infertility. In the United States, CT infection is a likely cause of most secondary infertility in females. In pregnant women, there is the additional risk of transmitting the infection to the newborn during labor and delivery, leading to pneumonia or conjunctivitis in the newborn.

GC, too, may present in various ways, and the clinical presentations overlap those of CT. Males may have acute urethritis with discharge, epididymitis, prostatitis, and urethral strictures. In women, GC infection can produce cervicitis, which if left untreated can lead to PID, abscesses, or salpingitis.

Traditional methods for the diagnosis of CT infection include cell culture, antigen detection by immunofluorescence-based techniques, enzyme immunoassay, and, more recently, nonamplified nucleic acid detection. These traditional methods have been replaced in many laboratories by amplified nucleic acid tests, which provide greater sensitivity in detecting CT from genital specimens. For GC, which was traditionally diagnosed based on culture methods that relied on selective culture media, nucleic acid testing does not offer significant improvement in sensitivity compared with culture when culture is performed under ideal conditions. GC is a fastidious organism, however, and is highly susceptible to extreme temperatures and desiccation, which can lead to decreased sensitivity of detection by culture, particularly when specimen transport is required prior to culturing.[76] Nucleic acid testing for GC offers a sensitive and reliable alternative to culture.

Nucleic Acid Testing for CT and GC

In addition to high diagnostic and analytical sensitivity and specificity, nucleic acid testing offers several advantages over conventional culture and antigen detection methods for the diagnosis of CT and GC. Testing for both pathogens can be done on a single specimen, and for some multiplex assays, testing is performed in a single reaction. Unlike the infectious organism itself, the DNA and RNA of GC and CT are quite stable in commercial transport devices, thus accounting for some of the increased diagnostic sensitivity of these assays compared with culture. The stability of nucleic acid avoids the necessity of immediate transport to the laboratory, and specimens may be stored refrigerated or at room temperature prior to transport. Transport and storage requirements vary among tests, so it is important to refer to the package insert for specific details. An additional advantage of nucleic acid testing is the use of urine specimens, which for women allows testing to be done without the need for a pelvic examination. In males, urine offers a convenient and diagnostically sensitive alternative to collection with a urethral swab and increases the likelihood that asymptomatic males will agree to be tested.

Tests for the detection of CT and GC from clinical specimens (Table 42-1) use a variety of specimens, including cervical and vaginal swabs, urethral swabs, and urine from both asymptomatic and symptomatic individuals. Not all assays are cleared by the U.S. Food and Drug Administration (FDA) for use in the United States for all conditions, and the current assays are not FDA-cleared for oral, rectal, respiratory, or conjunctival specimens. Performance characteristics vary among assays (details are available in the package inserts), but some general comments can be made. The diagnostic sensitivity of the tests varies according to the specimen type and whether the patient is asymptomatic or symptomatic. Interpretation of the results of nucleic acid testing for CT can be challenging because many studies have shown these assays to be more diagnostically sensitive than culture, which was

previously used as the gold standard for clinical trials. For males, the diagnostic sensitivity of testing urine specimens is nearly equivalent to that of testing urethral swabs.[16,29,36,72,155] A limited volume (20 to 50 mL) of first-passed urine is preferred because larger volumes will lead to a decreased concentration of the organism in the sample and thus reduced diagnostic sensitivity. With proper specimen collection, male urethral swabs and urine specimens have a sensitivity of nearly 100% for the detection of GC or CT infection. For women, cervical swab specimens provide the highest sensitivity for the detection of GC and CT infection, with many studies showing a sensitivity of 90 to 95%.[29,36,86,115] Urine specimens can be used, but they generally result in a lower diagnostic sensitivity than cervical swabs (75 to 85%).[29,36,86,115] An alternative to urine testing in women is the use of self-collected vaginal swabs, which have been shown in some studies to have a diagnostic sensitivity that is equal to that obtained with cervical swabs; several of the tests have been cleared for use with vaginal swabs.[65,134]

Decisions regarding the selection of a specific amplification test for the detection of CT and GC should not be based solely on the cost of reagents. Other key factors to consider include test performance characteristics, such as diagnostic sensitivity and specificity, and applicability for urine and swab specimens in both symptomatic and asymptomatic individuals. (In the United States, FDA clearance for various specimen types and individuals varies among methods.) Ideally the test should include an internal control, particularly if a crude lysate is used in the assay. Other factors to consider are degree of automation, ease of use, work flow issues, and space and equipment needs.

False-Positive Test Results

For several of the GC assays, reduced specificity is due to cross-hybridization of primers with nongonococcal *Neisseria* species.[56,104] The ProbeTec test (Becton-Dickinson, Franklin Lakes, NJ) has been reported to produce false-positive results with *N. flavescens, N. lactamica, N. subflava,* and *N. cinerea*, and the AMPLICOR assay (Roche Diagnostics, Indianapolis, Ind) can produce false-positive results with *N. flavescens, N. lactamica,* and *N. sicca*. There is concern about generating false-positive results with pharyngeal specimens that may contain these nongonococcal species of *Neisseria.* However, *N. cinerea, N. lactamica, N. subflava,* and *N. sicca* have also been isolated from genital mucosa, so it is possible to generate false-positive results from genital specimens.

Other sources of false-positive results include carryover contamination of amplified product and cross-contamination during specimen collection, transport, or processing. Concerns over these issues have led to discussion of confirmatory testing for CT and GC, because false-positive results can have psychosocial or medicolegal ramifications. False-positive

results in a low-prevalence population can significantly reduce the predictive value of a positive result. For example, although the specificity of nucleic acid testing for GC or CT generally ranges from 98 to 99%, the positive predictive value may be as low as 60 to 70% in a population with a low prevalence.

Nucleic acid testing for the detection of CT or GC should not be used as a test of cure. Because DNA can persist in urine samples for up to 3 weeks after completion of therapy,[48] test of cure using nucleic acid testing is discouraged. If this must be done, then testing should be delayed for at least 3 weeks after therapy is begun to allow time for clearance of the DNA of the pathogen.

False-Negative Test Results

False-negative results from inhibition of amplification are a consideration for both GC and CT testing and have been reported for both cervical swabs and urine specimens.[30,89,127] Inhibition rates may vary considerably depending on the amplification method used and are related, in part, to the method used for nucleic acid extraction.[89] For tests that use a crude lysate in testing (such as the AMPLICOR and ProbeTec tests), inhibition rates tend to be higher than those seen with the APTIMA Combo test (Gen-Probe Inc., San Diego, Calif), which uses a target capture method to purify nucleic acid. For assays that test a crude lysate, it is useful to amplify another nucleic acid sequence as an internal control (or "amplification control") to assess for inhibition of amplification. Results are reported as negative for GC or CT only when amplification of the internal control is documented.

A variant strain of CT has been identified in Sweden with a 377-base-pair deletion in the cryptic plasmid, which is the target for several of the CT tests. This deletion leads to false-negative results with some but not all of the tests that target the cryptic plasmid. Tests that target other regions of the organism are not affected. The ability of a test to detect this variant is important when a test is chosen, particularly if this variant is commonly found in the geographic area where the test will be used.[91,124]

Liquid Cytology Specimens

Performing CT and GC testing for liquid cytology specimens is a matter of interest because a single specimen can be used for cervical cytology (PAP smear) and for CT and GC testing.[8] The latter two tests would be performed on the liquid specimen that remained after completion of the PAP and human papillomavirus testing. However, several drawbacks to this approach must be considered. The instruments used to prepare liquid PAP smears were not designed to control for cross-contamination during processing, and this may lead to false-positive results. CT and GC testing would not be performed until after the PAP smear and human papillomavirus testing were completed, which could delay diagnosis and treatment of CT or GC infection. Moreover, the remaining specimen may be inadequate to complete CT and GC testing, thus requiring the patient to make a return visit for collection of an additional sample. Removing an aliquot for CT and GC testing before PAP testing is performed may be helpful in overcoming some of these issues, provided adequate volume of sample remains for PAP testing. This approach does not completely remove the risk of cross-contamination, so specimens must be handled in a manner consistent with procedures used in molecular laboratories, such as uncapping and aliquoting one specimen at a time.

Recommendations on Laboratory Testing for CT and GC

In January of 2009, an expert panel was convened by the Association of Public Health Laboratories in cooperation with the Centers for Disease Control and Prevention to update recommendations on laboratory diagnostic testing for CT and GC (document available at www.aphl.org; Laboratory Diagnostic Testing for *Chlamydia trachomatis* and *Neisseria gonorrhoeae*). Several of the new and updated recommendations are as follows:

1. Urine is the preferred specimen in males. Vaginal swabs are the preferred specimen for screening females, because the sensitivity of tests with vaginal specimens is equal to or superior to that with cervical swabs.
2. Nucleic acid testing (NAT) is recommended for the detection of rectal and oropharyngeal infections caused by CT and GC. Because currently available CT and GC tests are not cleared for this specimen type, laboratories must perform a validation study to establish the performance characteristics of the test. A NAT test with minimal cross-reactivity with commensal *Neisseria* species should be used.
3. Routine repeat testing of NAT-positive screening tests is not recommended.
4. NAT testing is superior to culture for the detection of CT in cases of adult rape or abuse. For GC, positive results of tests that have significant cross-reactivity with nongonococcal *Neisseria* species should be retested with a different NAT.
5. In cases of pediatric sexual abuse, NAT for CT has been shown to be superior to culture. For GC, positive results of tests that have significant cross-reactivity with nongonococcal *Neisseria* species should be retested with a different NAT.

HUMAN PAPILLOMAVIRUS

Human papillomaviruses (HPVs) are small, double-stranded DNA viruses that infect squamous epithelium, subverting normal cell growth and potentially leading to squamous cell carcinoma.[98] Anogenital HPV infections are common in both men and women. It is estimated that more than 24 million men and women in the United States are currently infected with HPV. HPV is a sexually transmitted infection; it is most common among sexually active young women ages 15 through 25 years. In one study, cervicovaginal HPV was found in up to 43% of sexually active college women during a 3-year period.[63] Infections, however, are usually transient, and progression to cancer requires persistence of viral

infection over several years. The types of HPV that are spread through sexual contact are classified as low risk or high risk for progression to malignancy, and there are multiple types. Infections with low-risk HPV such as types 6 and 11 can lead to benign genital warts or condyloma acuminata and have a low likelihood of progressing to malignancy. In contrast, high-risk types such as types 16, 18, and 45 are associated with development of squamous cell carcinoma of the anogenital region and oropharynx. The cervix is particularly affected, and worldwide cervical squamous cell carcinoma continues to cause significant morbidity and mortality (5% of cancer deaths).

Productive infections usually result in cytologic and histologic changes including cellular and nuclear enlargement, nuclear hyperchromasia, and perinuclear halos (koilocytosis). These changes can be identified on a stained smear of cells collected from the cervix (the "Pap smear," developed by Dr. George Papanicolaou in the 1940s) or in a biopsy taken during colposcopy or a loop electrosurgical excision procedure (LEEP). The Pap smear has been used very successfully to identify women with cervical cancer and, more important, for the detection of precursor lesions, so that biopsy or excision can be performed to remove the lesion earlier in the disease process, before metastasis can occur.

The histologic types of squamous precursor lesions are divided into three categories: (1) mild dysplasia, or cervical intraepithelial neoplasia (CIN)1; (2) moderate dysplasia, or CIN2; and (3) severe dysplasia, or carcinoma in situ, or CIN3. In the Bethesda System for Cytologic Classification, squamous precursor lesions are divided into low-grade and high-grade squamous intraepithelial lesions (LSIL and HSIL). LSIL corresponds with CIN1, and HSIL corresponds to CIN2 and CIN3. Frequently, the cytologic evaluation demonstrates mildly atypical cells that do not meet these criteria and are referred to as *atypical squamous cells of undetermined significance (ASCUS);* these cells may correspond to an early HPV infection. The prevalence of ASCUS on Pap smears is approximately 5 to 10%, with rates as high as 20% reported in sexually active women. Not all women with a cytology result of ASCUS progress to cervical cancer.

Primarily as a result of the ALTS trial (ASCUS and LSIL Triage Study), performed in the late 1990s, HPV testing now plays an important role in assessing which women with ASCUS are at highest risk of developing cervical cancer. The 2006 Guidelines recommend that women 20 years or older in whom ASCUS is found on Pap testing should be tested for the presence of high-risk HPV.[167] Those women testing positive for high-risk HPV DNA should undergo further clinical and pathologic examination (colposcopy), and those testing negative for HPV DNA can be followed according to routine practice. The Guidelines also recommended that women 30 years or older with a normal Pap and a negative HPV test result could have less-frequent examinations (every 3 years), and those with an HPV-positive test result could have (1) repeat Pap or HPV testing in a year, or (2) HPV genotyping performed; if found to be positive for type 16 or 18, they should be referred for immediate colposcopy.

Nucleic Acid Testing for HPV

Three tests for the detection of HPV DNA and one for genotype identification of HPV 16 and 18 have been cleared by the FDA for use in the United States: Hybrid Capture 2 (Qiagen Inc., Valencia, Calif), Cervista HPV HR (Hologic Inc., Danbury, Conn), cobas® HPV Test (Roche Diagnostics) and Cervista HPV-16 and -18 Genotyping test. All four tests have been cleared by the FDA for use with ThinPrep PreservCyt liquid-based cytology media (Hologic Inc.), but not with the other commonly used SurePath media (Becton-Dickinson). The Hybrid Capture 2 (HC2) test relies on hybridization of an RNA probe to the HPV DNA, followed by use of an antibody for capture of the duplex (RNA-DNA) hybrids, and then detection with chemiluminescent signal amplification. The test uses a pool of RNA probes spanning the entire genome that are specific for 13 high-risk HPV types (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68). The specific type is not identified. The test uses a 96-well microtiter plate format and can be performed manually or with the semiautomated Rapid Capture system (Qiagen) for reagent and plate handling. It is also cleared for use on Digene specimen transport media (STM). The HC2 test has been used in several large studies and reproducibly demonstrates high sensitivity of 93 to 96%, but false-positive results occur as a result of cross-reaction with low-risk HPV types.[23]

The Cervista HPV HR assay also uses a signal amplification method that is based on Invader technology (Hologic Inc.) and detects the same 13 high-risk types, along with HPV 66. A combination of DNA probes and invader oligonucleotides targeting the late gene (L)1 sequence and secondary fluorescently labeled probes are divided into three phylogenetically related reactions that are performed on 96-well microtiter plates. Unlike the HC2 assay, this assay includes an internal control with each reaction. Both assays have low limits of detection of around 3000 to 5000 genome copies per milliliter. The Cervista HPV HR assay appears to have less frequent cross-reactivity with low-risk types. Studies comparing the two assays demonstrate concordance of 82 to 88%. The Cervista HPV-16 and -18 Genotyping test is the first assay cleared by the FDA for HPV genotyping; it uses the same Invader technology.

The cobas HPV Test is the first real-time PCR method FDA-approved for cervical cancer screening. It utilizes a multiplexed primer and hydrolysis probe (TaqMan-based chemistry) assay to individually detect both HPV types 16 and 18 simultaneously with the 12 other high-risk HPV types using different fluorescently labeled probes. The assay includes detection of the human beta-globin gene as an internal control for extraction and amplification adequacy. The cobas 4800 system utilizes automated bead-based nucleic acid extraction and PCR reaction assembly. The sensitivity and specificity have been reported similar to the HC2 and Cervista HPV HR assays.

Other manufacturers that are developing HPV tests or performing clinical trials for FDA submission include Abbott, AutoGenomics, and Gen-Probe. Several of these tests are already available outside the United States. The assays use

tahir99-VRG & vip.persianss.ir

various methods such as real-time PCR, transcription-mediated amplification, and array hybridization for detection and genotyping.

HUMAN IMMUNODEFICIENCY VIRUS TYPE 1

Human immunodeficiency virus type 1 (HIV-1), the causative agent of the acquired immunodeficiency syndrome (AIDS), is an RNA virus belonging to the genus *Lentivirus* of the family Retroviridae. Replication of the virus is complex and involves reverse transcription of the RNA genome into a double-stranded DNA molecule or provirus, which is integrated into the host genome. HIV-1 enters the cell using CD4 as a receptor and CXCR4 or CCR5 as a coreceptor. In general, CCR5 coreceptors are found on macrophages, and CXCR4 coreceptors are found on T cells. Determining the cellular tropism of the virus has become important, now that a new antiretroviral drug targets the CCR5 coreceptor. The HIV-1 reverse transcriptase enzyme does not have proofreading capabilities, leading to the marked genetic diversity of HIV-1. Several distinct genetic subtypes or clades have been identified and are categorized into three groups: major (M), outlier (O), and N (nonmajor and nonoutlier). The major group is divided into nine clades (A, B, C, D, F, G, H, J, and K) and circulating recombinant forms (CRFs), which are determined on the basis of sequence diversity within the HIV-1 *gag* and *env* genes.[42] Group M virus is found worldwide, with clade B predominating in Europe and North America, clade C in Africa and India, and clade E in much of Southeast Asia. Complex replication cycles and genetic diversity are two factors that influence the design and interpretation of HIV-1 molecular assays.

The management of HIV-1 infection has been revolutionized by tests performed to measure the concentrations of HIV-1 RNA in blood (viral load testing) and tests for resistance to antiviral drugs. With these tools, it is possible to maximize the effectiveness of antiretroviral therapy for an individual.

HIV-1 Viral Load Testing

Viral load testing became the standard of care around 1996, followed by resistance testing. The clinical utility of viral load testing (usually using blood plasma) has been well established. Testing is used (1) to determine when to initiate antiretroviral therapy, (2) to monitor response to therapy, and (3) to predict time to progression to AIDS. Higher viral loads are associated with more rapid progression to AIDS and death.[99,100,111] Viral load testing is used routinely in decisions regarding when to initiate antiretroviral therapy and in monitoring response to therapy. Current treatment guidelines [U.S. Department of Health and Human Services (DHHS) Panel on Antiretroviral Guidelines, http://AIDSinfo.nih.gov] recommend initiating therapy for individuals on the basis of several factors, including concentrations of CD4-positive cells in blood (CD4 cell counts), viral loads, and symptoms.

The current standard for treating HIV-1–infected individuals is to use combinations of highly active antiretroviral drugs. Multiple classes of drugs are used, including nucleoside reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), fusion inhibitors, integrase inhibitors, and CCR5 entry inhibitors. Current guidelines (DHHS Panel on Antiretroviral Guidelines, http://AIDSinfo.nih.gov) recommend an initial regimen of two NRTIs and either an NNRTI or a PI. This combination therapy is often referred to as *highly active antiretroviral therapy,* or *HAART.* Initial use of these effective drug combinations in individuals who have not been treated with them before ("naive" individuals) is expected to decrease viral loads by at least 100-fold, or 2 $\log_{10}$ copies/mL. The goal of therapy is to achieve viral loads below the limit of detection of currently available assays (50 copies/mL), although this is not always possible in all individuals, particularly in those with very high pretreatment viral load values, or in those who have failed prior therapeutic regimens. Guidelines for the use of HIV-1 RNA viral load values in clinical practice have been published[131] and are frequently updated (http://www.aidsinfo.nih.gov/, http://www.iasusa.org). In general, a plasma HIV-1 viral load should be measured before therapy is begun (baseline), and then again at 2 to 8 weeks after initiation of therapy to determine the response to therapy. Testing is then repeated at 3- to 4-month intervals to evaluate continued effectiveness of the regimen. Any increase in viral load should be confirmed with repeat testing because a variety of other illnesses can transiently increase viral load. When a significant increase in viral load has been documented, HIV-1 resistance testing should be considered (see later).

The use of HIV-1 viral load testing for *diagnosing* acute HIV-1 infection in adults is more controversial. Currently available viral load assays are approved by the FDA for use only in patients known to be infected with HIV-1, but they have clear utility in the diagnosis of acute infection, which is defined as the period after exposure to the virus but before seroconversion, that is, while the enzyme-linked immunosorbent assay (ELISA) and Western blot assays for antibodies to HIV-1 are negative or indeterminate. In this "window period," additional testing is required and viral load assays are often used. Individuals with acute infection are often symptomatic with a mononucleosis-type syndrome, which may include fever, fatigue, rash, lymphadenopathy, and oral ulcers.[77] During this acute infection, the plasma concentration of viral RNA is very high, usually 10^5 to 10^7 copies/mL, and viral load measurements are a useful diagnostic tool. Acute HIV-1 infection should be suspected in an individual presenting with appropriate symptoms and risk factors. In these individuals, testing for acute HIV-1 infection would include an ELISA and a viral load assay. Care must be taken to correctly interpret these test results, because individuals with acute HIV-1 infection would be expected to have a negative or indeterminate ELISA and/or Western blot, and a very high viral load (>100,000 copies/mL). The concern with using viral load testing to diagnose acute HIV infection is that false-positive results have been reported.[37] In one study, false-positive results (usually lower than 2000 copies/mL) were found when

tahir99-VRG & vip.persianss.ir

the VERSANT bDNA test (Siemens Healthcare Diagnostics, Deerfield, Ill) was used.[37] Before acute HIV infection is diagnosed, individuals must be educated regarding the limitations of these tests and must give informed consent prior to testing. To minimize the likelihood of reporting a false-positive result, repeat testing should be done on all specimens with a detectable viral load, and an HIV-1/-2 ELISA should be obtained at the time of viral load testing. It is critical to remember that patients with acute retroviral syndrome should have very high concentrations of HIV-1 RNA.

Available HIV-1 Viral Load Assays

HIV-1 viral load assays that are currently approved by the FDA are listed in Table 42-2. (FDA-approved devices have been found by the FDA to be safe and effective for a defined clinical use. Many of the other tests described in this chapter are FDA-cleared devices; they have been deemed substantially equivalent to an existing "predicate" device.) In addition to conventional molecular tests [AMPLICOR MONITOR, and VERSANT], two real-time HIV-1 viral load tests have been approved by the FDA. The lower limit of quantification differs among the assays, although most tests reach levels of 40 to 50 copies/mL. The reportable concentration range of each of the conventional AMPLICOR assays is limited, so both an ultrasensitive and a standard version of the test are needed to cover the clinically important range of viral load values. Viral load assays must be able to accurately quantify the various viral subtypes. In the United States and Europe, subtype B predominates, although infections with non-B subtypes are becoming more common and are certainly an important cause of HIV-1 infection globally. The VERSANT bDNA assay will accurately quantify HIV-1 subtypes A through G,[71] and the AMPLICOR reverse transcriptase polymerase chain reaction (RT-PCR), version 1.5 (Roche Diagnostics), will perform accurate quantification of subtypes A through H.[71,109,113,114] The real-time RT-PCR tests have been designed to detect genetically diverse types and subtypes of HIV-1. The COBAS TaqMan test (Roche Diagnostics) quantifies all subtypes of group M and group N viruses and many CRFs.[137] Version 2 of the COBAS TaqMan test is now available and has a lower limit of quantification of 20 copies/mL and accurately quantifies Group O virus and a broader range of CRFs compared to the version 1 test. The RealTime TaqMan test quantifies all group M and N viruses, CRFs, and group O virus.[54,149] Real-time viral load tests have several other important advantages compared with conventional viral load tests, including broader linear range, greater automation, and decreased risk of carryover contamination. Viral load values obtained with the different assays may not always agree, so it is recommended that one assay is chosen when patients are monitored over time.

Analytical characteristics of viral load assays have been examined in several studies.[14] The intra-assay imprecision (SD) of the assays is approximately 0.12 to 0.2 $\log_{10}$, with the VERSANT bDNA assay showing the best precision. The biological variation (as SD) of the virus in patients not receiving therapy is approximately 0.3 $\log_{10}$ copies/mL.[88,131] For the AMPLICOR (version 1.0) assay, the total variation was approximately 0.26 $\log_{10}$, including intra-assay, interassay, and biological variation, with biological variation accounting for 56 to 80% of the total variation.[15] Changes in viral load must exceed 0.5 $\log_{10}$ (a fivefold change) or more to suggest a change in viral replication rather than a change in viral load attributable to analytical and day-to-day biological variation. Reporting viral load results as $\log_{10}$ copies/mL is recommended[33] and will assist in preventing clinicians from

TABLE 42-2 Quantitative HIV (Viral Load) Assays Approved by the FDA*

Test	Amplification Method	Linear Range
AMPLICOR HIV MONITOR v. 1.5 test (Roche Diagnostics, Indianapolis, Ind)	RT-PCR†	Ultrasensitive: 50 to 100,000 copies/mL Standard: 400 to 750,000 copies/mL
COBAS AMPLICOR HIV-1 MONITOR v. 1.5	RT-PCR RT-PCR	Ultrasensitive: 50 to 100,000 copies/mL Standard: 400 to 750,000 copies/mL
COBAS AmpliPrep/ COBAS Amplicor HIV-1 MONITOR v. 1.5	RT-PCR	Ultrasensitive: 50 to 100,000 copies/mL Standard: 500 to 1,000,000 copies/mL
COBAS AmpliPrep/ COBAS TaqMan HIV-1 version 1	Real time RT-PCR	48 to 10,000,000 copies/mL
COBAS AmpliPrep/ COBAS TaqMan HIV-1 version 2	Real time RT-PCR	20 to 10,000,000 copies/mL
VERSANT HIV-1 RNA 3.0 Assay (Siemens Healthcare Diagnostics, Tarrytown, NY)	bDNA‡	75 to 500,000 copies/mL
RealTime TaqMan HIV-1 (Abbott Molecular, Des Plaines, Ill)	Real-time RT-PCR	40 to 10,000,000 copies/mL

overinterpreting small changes in viral load. This is particularly important for values near the limit of quantification, where assay variability is the greatest. A variety of acute and opportunistic infections and vaccinations can transiently increase HIV-1 RNA in plasma,[39,111,147] so it is recommended not to measure viral load for monitoring of individuals who are acutely ill and those who have been recently vaccinated.

Viral load testing is routinely performed on plasma specimens, and ethylenediaminetetraacetic acid (EDTA) is the anticoagulant of choice. Acid-citrate-dextrose is also an acceptable anticoagulant, but blood anticoagulated in heparin is unacceptable for most tests. Viral load testing can be done on specimens other than plasma, including serum, dried blood (or plasma) spots on filter paper, CSF, and genital secretions. The assays have not been approved by the FDA for all of these specimen types, and testing of these specimens is usually reserved for research studies. It is critical to handle clinical specimens properly to minimize the risk of RNA degradation during specimen collection and transport. Plasma should be separated within 6 hours of collection and ideally stored at −20 °C, although plasma viral RNA is stable at 4 °C for several days. For laboratories performing testing from specimens collected at remote sites, sample handling can require careful attention. Special blood collection containers, or tubes, are available that contain a gel that provides a physical barrier between the plasma and cells after centrifugation. The tubes can be shipped without the need to transfer the plasma into a separate tube.[64] Vacutainer brand plasma preparation tubes (PPTs) (Becton-Dickinson), similar to plasma separation tubes (PSTs), are an example of such a container. Tubes should not be frozen prior to pouring off of the plasma, as this may lead to a false increase in results of viral load assays.[47,52]

Qualitative and Proviral HIV-1 RNA Testing

Both qualitative RNA and proviral DNA tests are useful for the diagnosis of HIV-1 infection in newborns (Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection, http://AIDSinfo.nih.gov). Because maternal immunoglobulin (Ig)G crosses the placenta, an uninfected child of an HIV-positive mother may be seropositive into the second year of life. The diagnosis or exclusion of HIV-1 infection requires use of testing at several different time points, usually (1) shortly after birth (14 to 21 days), (2) at 1 to 2 months, and (3) at 4 to 6 months after birth. The diagnosis of HIV-1 infection requires two positive RNA or DNA tests performed on separate blood samples regardless of age. RNA and DNA tests have different strengths and weaknesses. HIV-1 DNA tests may be less sensitive for the detection of non-B subtype infections than are HIV-1 RNA tests, particularly the FDA-approved APTIMA HIV-1 RNA Qualitative Assay (Gen-Probe), which is the first qualitative NAT approved by the FDA for the diagnosis of acute HIV-1 infection. Proviral DNA tests are also useful for the diagnosis of neonatal infection because they remain positive when the infant is receiving antiretroviral therapy. Currently, no proviral DNA tests have been approved by the FDA; the AMPLICOR HIV-1 DNA PCR assay (Roche Diagnostics) is available as a research-use-only (RUO) test.

The APTIMA test has also been approved for the diagnosis of acute HIV-1 infection in adults, for confirming a repeatedly positive antibody screen, or for resolving indeterminate Western blots. This test targets both the 5′ long terminal repeat (LTR) and the *pol* gene of the HIV-1 genome, and it detects all HIV-1 group M, N, and O viruses. The test is analytically sensitive with a limit of detection of 30 copies/mL. One reason this test has not been widely adopted in clinical laboratories is that it is a manual test, and the volume of testing in any given laboratory is very low, so this type of testing is often sent to referral laboratories.

HIV-1 Resistance Testing

Six general classes of antiretroviral drugs are used in clinical care: nucleoside reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), fusion inhibitors, integrase inhibitors, and CCR5 entry inhibitors. Viral resistance can occur with each of these classes of drug, particularly when viral replication is not maximally suppressed during therapy. The current standard of care is to use regimens that contain a combination of drugs because resistance is less likely to occur on the complex regimens than on monotherapy.

A variety of studies have evaluated the clinical utility of antiviral resistance testing in HIV-1–infected individuals. Several early prospective randomized clinical trials of genotypic resistance testing were conducted with persons who had failed therapy with multidrug regimens including PIs and NRTIs. In both the VIRADAPT[32,40] and GART[6] studies, selection of the salvage regimen was determined by using genotypic resistance testing (genotype arm) or by considering which antiretroviral drugs had been used in prior treatment regimens (control arm). Response rates in the genotype arms were higher than in the control arm. For example, in the VIRADAPT study, patients in the genotype arm had a greater decrease in viral load 6 months after salvage therapy was initiated, and more of them (32% vs. 14 %) had plasma viral loads <200 copies/mL.[32,40] The HAVANA trial helped establish the utility of expert advice in interpreting genotypic resistance data by comparing genotype resistance testing, expert advice, or both with the standard of care for selecting a regimen in patients failing therapy.[154] Although either genotyping or expert advice improved response compared with the control group, the best response was seen in the group receiving both genotyping and expert advice. The VIRA3001 study, a prospective randomized trial that compared standard of care versus phenotypic resistance testing in patients who failed a PI-containing regimen, found a better virologic outcome for patients in the phenotypic arm.[34] Although some trials of resistance testing have not shown improved clinical outcomes compared with standard of care,[59,101,103] the results of randomized trials favor use of resistance testing.

Guidelines for the appropriate use of HIV-1 resistance testing in adults have been established and are regularly updated (DHHS Panel on Antiretroviral Guidelines, http://

tahir99-VRG & vip.persianss.ir

AIDSinfo.nih.gov). Resistance testing is recommended in the following situations: (1) when changing antiretroviral regimens, (2) before initiating therapy in patients who have never received therapy, (3) during management of patients who have not obtained an optimal decrease in viral load values, and (4) before initiating therapy in all pregnant women.

HIV-1 resistance testing can be done by genotypic or phenotypic methods. Genotypic assays identify specific mutations or nucleotide changes that are associated with decreased susceptibility to an antiviral drug. The effective use of genotypic resistance testing requires an extensive understanding of the genetics of antiretroviral resistance. This discussion will be limited to automated sequencing methods, because this is the method used in the overwhelming majority of genotypic resistance testing performed for management of patients. Currently available FDA-cleared assays will detect mutations in the reverse transcriptase and protease gene; modifications of existing assays will be needed to detect resistance mutations associated with other classes of drugs such as fusion inhibitors.

The first step in genotypic assays is the isolation of HIV-1 RNA from plasma, followed by RT-PCR amplification and sequencing of reverse transcriptase and protease genes. Analysis of the results involves sequence alignment and editing, mutation identification by comparison with wild-type sequence, and interpretation of the clinical significance of the mutations identified. Most clinical laboratories performing genotypic resistance testing rely on commercial assays that provide reagents and software programs to assist with interpretation of the results. Two assays have been cleared by the FDA: the Trugene HIV-1 Genotyping Kit and OpenGene DNA Sequencing System (Siemens Healthcare Diagnostics) and the ViroSeq HIV-1 Genotyping System (Abbott Molecular, Des Plaines, Ill).

Interpretation of genotypic resistance testing is complex. Interpretation of resistance mutations uses "rules-based" software that takes into account cross-resistance and interactions of mutations. The commercially available systems generate a summary report that lists the various mutations that have been identified in the reverse transcriptase and protease genes, and each drug is reported as resistant, possibly resistant, no evidence of resistance, or insufficient evidence. A comprehensive discussion of the specific mutations associated with each antiretroviral drug and the interactions of mutations is beyond the scope of this chapter, but is available from a variety of sources (http://www.iasusa.org, http://hivdb.stanford.edu/).

Phenotypic resistance assays measure viral replication in the presence of antiretroviral drugs. Results of phenotypic assays are typically reported as the inhibitory concentration of a drug that reduces in vitro HIV-1 replication by 50% (IC_{50}). The IC_{50} is usually reported as the fold change in IC_{50} relative to a wild-type strain. Initially, phenotypic assays required the isolation of infectious HIV-1 from a blood specimen. Newer phenotypic assays use high-throughput automated assays based on recombinant DNA technology. For these assays, HIV-1 RNA is amplified from a plasma specimen, eliminating the need for a viral isolate. This testing is not performed in clinical laboratories, and the technology is available from only two commercial laboratories. For the PhenoSense assay (Monogram Biosciences, South San Francisco, Calif), the protease and reverse transcriptase genes are amplified using RT-PCR and are inserted into a modified HIV-1 vector that has a luciferase reporter gene in place of the viral envelope gene.[117] Drug resistance is assessed by quantification of luciferase expression in the presence of various concentrations of antiretroviral drugs. The reproducibility of the assay is such that increases in IC_{50} greater than 2.5-fold can be reliably detected in the assay. The other assay (Antivirogram, VIRCO Lab Inc., Bridgewater, NJ) combines patient and HIV-1 vector sequences using in vitro recombination.[34] Viral replication is measured using a reporter gene system. Based on replicate studies performed by the company, reduced susceptibility is defined as a greater than fourfold increase in IC_{50} compared with wild-type virus. This technical cutoff often differs from the cutoff that is associated with clinical resistance to a drug, which is referred to as the *clinical cutoff*. The change in IC_{50} associated with clinical failure may differ for each drug tested. For example, with the protease inhibitor lopinavir, the IC_{50} that correlates with clinical resistance may be in the range of a 10-fold or greater increase in IC_{50},[156] compared with twofold for the NRTI didanosine (ddI). It is likely that IC_{50} cutoffs will continue to be modified as more clinical outcomes data become available. Results of phenotypic assays include not only the change in IC_{50} value, but an interpretation of whether there is an increase or decrease in susceptibility compared with wild-type virus. Phenotypic tests are available to measure susceptibility to NRTIs, NNRTIs, PIs, fusion inhibitors, and integrase inhibitors.

A "virtual phenotype" is also available commercially for assessing HIV-1 drug resistance. With a virtual phenotype, rather than performing a phenotypic assay directly, the information is inferred from the genotypic assay. Results of the genotypic assay are entered into a database containing matching genotypic and phenotypic results from thousands of clinical specimens, and the closest matching phenotypic results are averaged and reported as the virtual phenotype.

Both phenotypic and genotypic assays are used in clinical care. Some clinicians prefer phenotypic testing because it is a direct measure of viral susceptibility; others prefer genotypic testing because the development of a mutation may precede phenotypic expression of resistance.[62] Other advantages of genotypic testing include relatively rapid turnaround time (a few days), easier availability, and lower cost compared with phenotypic testing. Providers often use genotypic testing routinely and rely on phenotypic testing for patients who have failed multiple regimens and have very complex genotypic results. If both assays are used, it is important to remember that the results of the two assays may not agree, as the presence of a resistance mutation does not ensure its expression in a phenotypic assay.

A limitation of currently used genotypic and phenotypic assays is that they can detect only those mutants that make

tahir99-VRG & vip.persianss.ir

up at least 20% of the total viral population. Regimens chosen based on resistance testing may not always be effective because the minority populations will quickly predominate in the presence of drug. Drug selection pressure is also needed for some resistance mutations to persist at detectable concentrations in the viral population; when drug therapy is discontinued, the wild-type virus may quickly predominate. For this reason, it is recommended that specimens for resistance testing be obtained while the patient is on antiretroviral therapy.

The minimum viral load required for reliable resistance testing is approximately 1000 copies/mL. Because genotyping assays are especially sensitive to RNA degradation, care must be taken to properly handle the specimen after collection. Guidelines outlined for collection and transport of specimens for testing in viral load assays should be followed for resistance testing.

HIV-1 Tropism Testing

Maraviroc, the new CCR5 inhibitor, is effective only against HIV-1 that uses CCR5 as a coreceptor for entry into the cell. Virus may use CCR5 (R5-tropic) or CXCR4 (X4-tropic) of both (dual/mixed-tropic) coreceptors. The tropism test must be performed before therapy with maraviroc is initiated, as the drug is not effective against virus that is X4-tropic or dual/mixed tropic. Two tropism assays are commercially available: Trofile (Monogram Biosciences) and Sensitrop II HIV Co-Receptor Tropism Assay (Pathway Diagnostics, Malibu, Calif). The Trofile test is a cell-based assay in which pseudoviruses are constructed using the *env* gene sequence amplified from the patient's plasma. This pseudovirus is then used to infect cells that express CXCR4 or CCR5. The tropism is determined according to which cell populations the pseudovirus infects.[160] The Sensitrop assay uses a heteroduplex tracking assay (HTA) along with sequencing to identify minor viral populations that may be CXCR-4 tropic. HTA is performed using labeled probes with coreceptor-specific sequence combinations that are annealed to denatured PCR products derived from the total viral population and separated by gel electrophoresis. Mismatches with the probe result in altered migration of the heteroduplex and reveal distinct subpopulations of coreceptor-specific viral genomes.

HERPES SIMPLEX VIRUS

Herpes simplex virus (HSV), a member of the herpesvirus family, is a double-stranded DNA virus. Following primary infection, the virus remains latent in sensory neurons and can be reactivated under a variety of situations, including stress, trauma, sun exposure, and various immunocompromised states. HSV types 1 and 2 produce various clinical syndromes involving the skin, eye, central nervous system (CNS), and genital tract. Although nucleic acid testing has been used to detect HSV DNA in all of these clinical manifestations, this discussion will focus on the use of HSV PCR for the diagnosis of CNS infections, because nucleic acid amplification testing is widely viewed as the standard of care for their diagnosis.

HSV causes both encephalitis and meningitis. In adults, HSV encephalitis is usually attributable to infection with HSV type 1, while HSV meningitis is most commonly caused by HSV type 2. HSV encephalitis is a severe infection with high morbidity and mortality; treatment with acyclovir reduces mortality from approximately 70% in untreated infection to 19 to 28%. Neurologic impairment is common (about 50%) in those who survive.[161,162] HSV encephalitis may reflect primary infection or reactivation of latent infection. HSV meningitis is usually a self-limited disease that resolves over the course of several days without therapy. In some patients the disease may recur as a lymphocytic meningitis over a period of years.[150,161]

Neonatal HSV infection occurs in 1 : 3500 to 1 : 5000 deliveries in the United States.[161] It is most commonly acquired by intrapartum contact with infected maternal genital secretions and is usually due to HSV type 2. In the newborn, three general presentations of the disease are known: (1) skin, eye, and mouth disease, which accounts for approximately 45% of infections; (2) encephalitis, which accounts for 35%; and (3) disseminated disease, 20%. Because disseminated disease is often associated with neurologic disease, CNS disease occurs in about 50% of newborns with neonatal HSV infection.

HSV encephalitis cannot be distinguished clinically from encephalitis caused by other viruses such as West Nile Virus, St. Louis encephalitis virus, and Eastern equine encephalitis virus. Historically, the gold standard for the diagnosis of HSV encephalitis required brain biopsy with identification of HSV by cell culture or immunohistochemical staining. This approach provided high sensitivity (99%) and specificity (100%), but it required an invasive procedure, and several days elapsed before results were available. Cell culture of CSF has a sensitivity of less than 10% for the diagnosis of HSV encephalitis in adults. Tests that measure HSV antigen or antibody in CSF have diagnostic sensitivities of 75 to 85%, and diagnostic specificities of 60 to 90%.[161] Because of the limitations of conventional methods, there was interest in assessing the clinical utility of PCR for the detection of HSV DNA from CSF of patients with encephalitis.

Nucleic Acid Testing for HSV

The two largest studies compared HSV PCR on CSF specimens versus brain biopsy[4,84] in patients with suspected HSV encephalitis. The sensitivity and specificity of PCR were greater than 95%, and the sensitivity of HSV PCR did not decrease significantly until 5 to 7 days after the start of therapy. PCR is positive early in the course of illness, usually within the first 24 hours of symptoms, and in some individuals, HSV DNA can persist in the CSF for weeks after therapy is initiated.[4,84,163]

The clinical utility of HSV PCR has also been established for the diagnosis of neonatal HSV infection. In one study,[79] HSV DNA was detected in the CSF of 76% (26 of 34) of infants with CNS disease; 94% (13 of 14) of those with

tahir99-VRG & vip.persianss.ir

disseminated infection; and 24% (7 of 29) of infants with skin, eye, or mouth disease. The persistence of HSV DNA in the CSF of newborns for longer than 1 week after therapy is initiated is associated with a poor outcome.[90] Based on these findings, detection of HSV DNA in CSF by PCR has become the standard of care for the diagnosis of HSV encephalitis and neonatal HSV infection. In newborns with disseminated disease, HSV DNA may be detected in serum or plasma specimens, and it can be a useful diagnostic tool in newborns if it is not possible to do a lumbar puncture. Although the sensitivity of HSV PCR is high, it is not 100%, so a negative PCR test may not rule out neurologic disease due to HSV, particularly if the pretest probability is high. In this situation, it is important to consider repeat testing.

As with HSV encephalitis, HSV meningitis cannot be distinguished clinically from other viral meningitides, although recurrence of viral meningitis is a strong clue that HSV may be the etiologic agent. Unlike HSV encephalitis, HSV meningitis has not been the subject of large studies evaluating the clinical utility of PCR for diagnosis. Nonetheless, because the sensitivity of cell culture of CSF specimens is only 50%, HSV PCR of CSF is commonly used in the evaluation of meningitis and has been described as accurate in anecdotal reports.[135,150]

Molecular tests for the detection of HSV DNA from genital specimens have been cleared by the FDA, importantly none of these tests have been cleared for use with CSF specimens. Several companies provide primers and probes as analyte-specific reagents (ASRs), which can be used as components in laboratory-developed tests (LDTs).

Molecular tests are often designed to detect HSV types 1 and 2 with equal sensitivity. Distinguishing between HSV types 1 and 2 may not be necessary because the clinical management of CNS disease is the same for both infections. Primers used for the detection of HSV DNA commonly target the polymerase, glycoprotein B, glycoprotein D, or thymidine kinase genes. It is important that the primers not amplify DNA from other herpesviruses that are associated with neurologic disease; these include cytomegalovirus, varicella zoster virus, human herpes virus type 6, and Epstein-Barr virus.

HSV PCR assays need low detection limits (several hundred copies/mL of specimen) to be useful in evaluating neurologic disease. This is particularly true for the diagnosis of meningitis, where CSF concentrations of DNA tend to be lower than those seen with encephalitis. HSV neurologic disease rarely occurs in individuals without an increased CSF white blood cell count or protein concentration.[140] Caution should be exercised in applying this generalization to immunocompromised individuals, as they may not mount a typical inflammatory response to HSV infection. Although HSV PCR of CSF specimens is clearly the gold standard for the diagnosis of neurologic disease, results should be interpreted with caution because neither sensitivity nor specificity is 100%. Test results should always be interpreted within the context of the clinical presentation of the patient. If results do not correlate with the clinical impression, repeat testing should be performed.

ENTEROVIRUS 2

Enteroviruses are a diverse group of single-stranded RNA viruses belonging to the Picornavirus family. This group includes polioviruses, enterovirus types A through D, and parechovirus (human echovirus). Numerous clinical presentations are seen with the nonpolioviruses, including acute aseptic meningitis, encephalitis, exanthems, conjunctivitis, acute respiratory disease, gastrointestinal disease, myopericarditis, and sepsis-like syndrome in neonates. Diagnoses typically are based on clinical presentation and/or culture methods. Cell culture methods have several drawbacks, including the requirement to inoculate multiple cell lines because no single cell line is optimal for all enterovirus types, the inability to grow some enterovirus types in cell culture, the limited diagnostic sensitivity of cell culture (65 to 75%), and the long turnaround time of 3 to 8 days for those enteroviruses that do grow in cell culture.[31] The long turnaround time for culture means that results are rarely available in a time frame to influence clinical management. Nucleic acid testing offers several important advantages over cell culture, including improved sensitivity and turnaround time. As a result, nucleic acid testing is considered the new gold standard for the diagnosis of aseptic meningitis and neonatal sepsis syndrome due to enterovirus.

Nucleic Acid Testing for Enteroviruses

Two methods are used for the detection of enteroviral RNA from clinical specimens: reverse transcriptase PCR (RT-PCR) and nucleic acid sequence-based amplification (NASBA). The primers used in clinical testing most commonly target the highly conserved 5′ untranslated region of the gene (5′ UTR)[128,130] and will detect polioviruses and enteroviruses. These primers will not detect parechoviruses (formerly echovirus types 22 and 23), although these viruses can cause aseptic meningitis. In general, molecular assays have good detection limits ranging from 0.1 to 50 tissue culture infectious doses 50 (TCID50) per assay.* The assays are quite specific, but sequence similarities may allow amplification of some types of rhinoviruses.[11,158] Currently, two tests for the detection of enteroviruses from CSF specimens have been cleared by the FDA: the NucliSENS EasyQ Enterovirus (bioMérieux) and Xpert EV (Cepheid, Sunnyvale, Calif). A clinical evaluation of the NASBA assay showed it to be more sensitive than CSF viral culture for the detection of enterovirus, and it had a specificity of 100%.[169] Likewise, the Gene Xpert enterovirus test has been shown to have a sensitivity of 97% and a specificity of 100% for the diagnosis of enteroviral meningitis.[81] The Gene Xpert test has the advantage of being very simple to perform: the specimen and reagents are added to a cartridge, which is inserted into the instrument. Nucleic acid extraction, amplification, and detection are fully automated, and results are available within about 2½ hours. The system permits random access, which allows for on-demand testing.

tahir99-VRG & vip.persianss.ir

Nucleic acid testing for the diagnosis of enteroviral infection has been evaluated in a variety of clinical studies,[1,2,78] with testing showing a sensitivity equal to or greater than that of cell culture, a high specificity, and faster turnaround times than cell culture. Several studies have suggested that the use of molecular methods for the diagnosis of enteroviral infection in infants and pediatric patients can lead to an overall cost savings by reducing the use of antibiotics and of imaging studies.[57,92,107,120] To maximize the benefits for patient care and cost savings, testing should be available on a daily basis.

As mentioned earlier, many molecular assays detect rhinoviruses, and most detect polioviruses. These two factors can lead to unexpected and misleading positive results when respiratory or stool specimens are tested. The diagnosis of enterovirus meningitis should be based on testing of CSF specimens, and sepsis syndrome is best diagnosed in the neonate by testing serum, plasma, or CSF samples.

PERINATAL GROUP B STREPTOCOCCAL DISEASE

In the 1970s, group B streptococcal (GBS) disease was the leading infectious cause of neonatal morbidity and mortality, with case rates of two to three per 1000 live births and case-fatality rates as high as 50%.[24] In 1996, consensus guidelines from the Centers for Disease Control and Prevention, the American Academy of Pediatrics, and the American College of Obstetrics and Gynecology were issued in an effort to reduce the rate of GBS disease in newborns.[24] The guidelines called for administration of intrapartum prophylactic antibiotics for GBS using a risk-based or screening-based approach. In the risk-based approach, antibiotics were administered based on identification of one of the following risk factors: intrapartum fever, prolonged rupture of membranes, or imminent preterm delivery. For the screening-based approach, vaginal/rectal cultures were collected at 35 to 37 weeks' gestation, and those women with positive cultures received intrapartum antibiotics. Since the widespread implementation of these guidelines, the number of cases of GBS disease has decreased, but GBS remains a serious cause of neonatal infection. GBS disease in the newborn may be classified as early disease, which occurs within 1 week of life and usually presents as a sepsis syndrome or pneumonia, or late disease, which is defined as that presenting at greater than 1 week of life, and which presents most commonly as sepsis or meningitis.

GBS colonization of pregnant women is common, with a prevalence of 10 to 30%; colonization may be transient, chronic, or intermittent.[123] Those women who are colonized are 25 times more likely to deliver infants with early-onset GBS disease.[12] The effectiveness of the 1996 guidelines for the prevention of neonatal GBS was re-evaluated, and it was determined that the screening approach to GBS prevention was greater than 50% more effective than the risk-based approach.[136] Based on these findings, the Centers for Disease Control and Prevention (CDC) in 2002 issued updated guidelines recommending that vaginal/rectal GBS screening cultures be done on all pregnant women. Exceptions included women with a previous infant who had GBS disease and those with GBS bacteriuria during pregnancy, because these women require intrapartum antibiotics. The risk-based approach is to be used only for women with unknown GBS status at the time of labor and delivery. See the CDC guidelines[24] for a more detailed description, and refer to the CDC Website for; updated guidelines that were published in 2010.

Methods for GBS screening of cultures have been standardized and include collection of a vaginal/rectal swab and transport to the laboratory in Amies or Stuart media. The specimen is then inoculated into an enrichment broth (LIM broth), incubated for 18 to 24 hours, and subcultured onto a sheep-blood agar plate. GBS is identified according to colony morphology, hemolysis, and latex agglutination testing. This two-step method ensures maximal sensitivity for GBS detection. GBS cultures usually require 2 to 3 days to complete. Because GBS is universally susceptible to penicillin and ampicillin, antimicrobial susceptibility testing is not routinely performed, but it is needed for women with a serious allergy to penicillin.

Nucleic Acid Testing for GBS

The clinical utility of a real-time PCR assay (Light Cycler assay, Roche Diagnostics) for the detection of GBS in pregnant women[7] was compared with culture in 112 pregnant women and was found to have a sensitivity of 97%, a specificity of 100%, and negative and positive predictive values of 98.8% and 100%, respectively. Testing results were available within 45 minutes of the time the specimen arrived in the laboratory, which raised the possibility of offering real-time testing to women who present in labor. This could be especially useful for women who present with an unknown GBS status; based on current guidelines, these women would receive intrapartum antibiotics based on risk factors. Because women without risk factors are still at risk of delivering newborns with GBS disease,[136] PCR testing would undoubtedly offer a more sensitive method for GBS detection than one based on risk factors alone. In addition, intrapartum testing would be useful in identifying women whose GBS status changes in the interval between screening-culture (weeks 35 to 37 of gestation) and the time of delivery.

Currently, several real-time PCR tests for the detection of GBS directly from rectal/vaginal swabs from pregnant women have been cleared by the FDA: the IDI-Strept B Assay (BD Diagnostics-GeneOhm, San Diego, Calif), the BD Max™ GBS Assay (BD Diagnostics-GeneOhm, San Diego, Calif), Smart GBS (Cepheid), and Xpert GBS (Cepheid). In a multicenter clinical trial, the IDI-Strept B test demonstrated a sensitivity of 94% and a specificity of 96% compared with intrapartum culture (IDI-Strept B package insert). The assay requires a few simple hands-on steps to prepare the specimen, the testing cartridge is inserted into the Smart Cycler, and testing is complete within an hour. The test also includes an internal control to monitor for inhibition of amplification. The Xpert GBS test has a sensitivity of 92% and a specificity of 96% for intrapartum testing. The test is rapid, with results available

tahir99-VRG & vip.persianss.ir

within an hour; it is easy to use and is designed for use in the clinical laboratory, as well as by nonlaboratory professionals such as labor and delivery nurses. These real-time GBS tests offer a rapid and sensitive alternative to GBS culture. Advantages need to be balanced with the challenge of providing intrapartum test results to clinicians within 1 to 2 hours at any time of day or night; also, the cost of nucleic acid testing must be compared with the cost of culture. If intrapartum testing is done at the time of labor and delivery, there will not be adequate time for erythromycin and clindamycin susceptibility testing, so women with severe penicillin allergies will require therapy with vancomycin. An alternative approach is to replace antepartum culture at 35 to 37 weeks' gestation with the real-time PCR assay. With the availability of an FDA-cleared test, there will be more discussion on the use of GBS PCR testing of pregnant women. Readers are referred to the CDC Website for updated recommendations, which are in preparation (http://www.cdc.gov/groupbstrep/hospitals/hospitals_guidelines.htm).

CYTOMEGALOVIRUS

CMV, a member of the herpesvirus family, is a double-stranded enveloped DNA virus. CMV causes a clinically minor infection in immunocompetent individuals but remains an important pathogen in immunocompromised individuals, including persons with AIDS, transplant recipients, and those on immune-modulating drugs. Primary infection is usually asymptomatic in immunocompetent persons, although a small percentage of individuals with CMV infection may develop a mononucleosis type of syndrome. Following primary infection, a life-long latent infection is established that does not cause clinical symptoms. However, if an infected individual becomes immunocompromised, the virus can reactivate, leading to a wide variety of clinical syndromes.

The most severe CMV infections are seen in those individuals who acquire their primary infection while immunocompromised. In persons with AIDS, CMV disease rarely occurs when the CD4+ cell count is above 100 cells/mm^3; the most common clinical presentations are retinitis, esophagitis, and colitis. In transplant recipients, the occurrence and severity of CMV disease are related to the CMV serostatus of the organ donor and recipient, the type of organ transplanted, and the overall degree of immunosuppression. For example, CMV disease tends to be more severe in lung transplant recipients than in renal transplant recipients. For all types of organ recipients, the most severe disease occurs when CMV-seronegative recipients receive an organ from a CMV-seropositive donor, and the primary CMV infection occurs while the person is immunosuppressed. CMV disease can also occur in seropositive individuals, whether they receive an organ from a seropositive or seronegative donor. Clinical findings associated with CMV disease in transplant recipients are diverse and include interstitial pneumonitis, esophagitis and colitis, fever, leukopenia, and, less commonly, retinitis and encephalitis.

The diagnosis of CMV disease represents a challenge because of the presence of latent infection. Immunocompromised individuals can have an asymptomatic, clinically insignificant, low-level, persistent infection that must be distinguished from clinically important active CMV disease. The distinction can be challenging when sensitive molecular assays are used that can detect small amounts of CMV DNA in clinical specimens.

Traditionally, the diagnosis of CMV disease relied on the detection of CMV from clinical specimens by the use of cell culture techniques in human diploid fibroblasts. Although considered the gold standard, these conventional culture methods are labor-intensive and have a long turnaround time of 1 to 3 weeks.[94] In addition, the assays lack adequate sensitivity for detecting CMV present in blood specimens. The (relatively) rapid shell-vial culture method can provide results in 1 to 2 days and is useful for detection of CMV in tissue, respiratory, and urine specimens. However, this assay may also fail to detect CMV in blood. Many laboratories rely on the antigenemia assay, which detects the matrix protein pp65 in polymorphonuclear cells. This semiquantitative assay is rapid, and the number of CMV antigen-positive cells correlates with the likelihood of CMV disease, but the assay is labor-intensive, and CMV antigen is not stable in whole blood specimens for periods greater than 24 hours.

Nucleic Acid Testing for CMV

In light of the limitations of culture and antigen detection methods, there has been great interest in using nucleic acid testing for the detection and quantification of CMV DNA from plasma and blood specimens. Few assays have been cleared by the FDA, and those that were have been withdrawn from the market. Many commercially available analyte specific reagents (ASRs) were removed from the market in 2008 to fulfill FDA ASR regulations. Some of these assays may become available after obtaining clearance from the FDA. Quantitative molecular CMV assays that remain commercially available include the AMPLICOR CMV MONITOR test (Roche Diagnostics), a DNA PCR assay that is an RUO test, and the artus CMV ASR (owned and distributed by Qiagen, with a distribution agreement with Abbott Molecular). Many studies have reported on performance of these assays. These LDTs use various specimen types, nucleic acid extraction methods, target genes, calibrators, and detection methods. As a result, viral load values obtained with the different assays may be inconsistent. This makes it difficult to compare results among clinical studies that use these assays and to establish concentrations of CMV DNA that correlate with clinical disease.

The analytical performance of the AMPLICOR CMV MONITOR RUO and that of the Artus CMV ASR tests have been evaluated.[18,19] The PCR-based AMPLICOR CMV MONITOR was shown to have a limited range of quantification of approximately 2.7 to 4.7 $\log_{10}$ and a limit of detection of 3.0 $\log_{10}$ copies/mL,[19] while the Artus-based real-time PCR assay is linear from 2.0 to 6.0 $\log_{10}$ copies/mL, with a limit of detection of 2.3 $\log_{10}$ copies/mL. Comparison of quantitative

tahir99-VRG & vip.persianss.ir

results between the two assays showed a mean difference of 0.012 $\log_{10}$, varying from −0.869 to 0.845 $\log_{10}$ copies/mL.[18] The reproducibility of the Artus-based assay is such that changes in viral load (copies/mL) less than fivefold to sevenfold may represent assay variability rather than clinically relevant changes in viral replication.

An unsettled issue for CMV molecular assays is the appropriate specimen type for testing. Almost all assays use plasma or whole blood, with concentrations of CMV DNA measured in whole blood higher than those measured in plasma.[121] The AMPLICOR PCR assay and the Artus real-time PCR assay can accommodate blood or plasma specimens. CMV DNA may be detected in whole blood or leukocytes of individuals without active CMV disease. Some studies have shown a good association between high CMV DNA concentrations in plasma and active CMV disease[22] and suggest that detecting CMV DNA in plasma rather than in leukocytes may provide a better correlation with clinical disease, because the detection of CMV DNA in plasma suggests active viral replication.[121] However, it is clear that CMV DNA can also be detected in the plasma in patients without active CMV disease.[21,22] Others prefer to test whole blood because CMV DNA can be detected more frequently in blood samples than in plasma. With either sample type, the key requirement is to establish a concentration of CMV DNA that correlates with the likelihood of disease. The concentration of DNA that predicts disease will be higher in assays that use whole blood specimens than in those that test plasma specimens.

The clinical uses of CMV molecular assays are diverse and include assisting in decisions regarding (1) initiation of preemptive therapy, (2) diagnosis of active CMV disease, and (3) monitoring of response to therapy. *Preemptive therapy* refers to the use of a laboratory test to identify a group of individuals at higher risk for developing CMV disease. For example, all members of the group would be tested for the presence of CMV DNA in their blood or plasma, and only those testing positive would be treated. Therapy is administered before development of symptoms in an attempt to prevent the onset of active disease. By contrast, with *prophylactic therapy,* all patients in the group are treated, without further stratification of risk, thus involving treatment of a greater number of patients.

Molecular assays have utility for the diagnosis of active CMV disease, because CMV DNA concentrations are higher in patients with active CMV disease than in those with asymptomatic infection.[35,67] A study in liver transplant recipients using the AMPLICOR PCR assay showed that the median peak viral load in patients with asymptomatic infection was 1850 copies/mL compared with 55,000 copies/mL for those with active disease.[67] The viral load cutoff that was most predictive of the development of active disease was between 2000 and 5000 copies/mL of plasma. It is important to note that viral load cutoffs will differ in studies using different assays and different specimen types (plasma vs. whole blood).

Once active CMV disease has been diagnosed, molecular assays are useful in monitoring response to therapy. Viral load values decrease rapidly after appropriate antiviral therapy is begun, and several studies have reported that CMV DNA is cleared from the plasma within several weeks of initiation of therapy.[21,22,68] Failure of viral loads to decrease promptly should raise concerns of possible treatment failure, because persistently elevated concentrations of CMV DNA during therapy have been seen in patients with documented resistance of CMV to the therapy.[21] Molecular assays also have clinical utility in identifying patients at risk for relapsing CMV infection. In solid organ transplant recipients, patients with a detectable viral load after completing 14 days of ganciclovir therapy for CMV infection are at increased risk of relapse. Similarly, an increased risk of relapse has been shown for patients with persistent pp67 mRNA after completion of a course of therapy. The rate of decline in CMV DNA after initiation of therapy can be used to predict risk of relapse of CMV infection. In one study, CMV DNA was cleared from the plasma in 17 days for patients without recurrent CMV disease compared with 34 days for those with evidence of recurrent disease.[68] By following viral load concentrations weekly after initiating antiviral therapy, it may be possible to identify those at risk of recurrent disease and thus intensify therapy and possibly prevent recurrent disease.

CMV DNA concentrations are also useful in assessing the risk of developing CMV disease in persons with AIDS. Detection of CMV DNA in plasma has been associated with increased risk of developing CMV disease and increased risk of death. In addition, each $\log_{10}$ increase in viral load (i.e., each 10-fold increase in concentration) has been associated with a threefold increase in the risk of developing CMV disease.[143] The clinical importance of CMV viral load in patients was further established in patients with advanced AIDS, in whom the CMV DNA load was found to be more predictive of developing CMV disease or death than was HIV-1 viral load. Individuals with a CD4+ cell count lower than 50 cells/μL (50 cells/mm^3) and an HIV-1 viral load greater than 10,000 copies/mL of plasma are at greatest risk of developing end-organ CMV disease. In this group of individuals, an increase in CMV DNA to above the limit of detection of the AMPLICOR PCR assay was associated with the development of CMV end-organ disease. This study identifies a group of HIV-1–infected individuals who may benefit from monitoring of CMV viral load and preemptive therapy for the prevention of CMV end-organ disease.

A major challenge that remains for laboratories offering these assays is the difference in results among assays. The available international standard for CMV, should improve the agreement of viral load values between the different tests; this was certainly seen for hepatitis C virus (HCV) viral load testing once that international standard became available. The availability of commutable calibrators has also been shown to improve agreement between two viral load tests.[20] These types of well-characterized standards and calibrators will assist in achieving better agreement of viral load values among different tests and will facilitate the determination of CMV concentrations that predict or correspond to clinical events.

MYCOBACTERIUM TUBERCULOSIS

Mycobacterium tuberculosis (MTb) causes a wide range of clinical infections, including pulmonary disease, miliary tuberculosis, meningitis, pleurisy/pericarditis/peritonitis, gastrointestinal disease, genitourinary disease, and lymphadenitis. MTb infection was in steady decline in the United States until the late 1980s into the early 1990s. The infection rate had declined to an all-time low by the late 1990s,[26] when the number of reported cases began to increase. This resurgence in the number of infections was related to the AIDS epidemic, homelessness, and a decreased focus on tuberculosis control programs. The infection rate continues to rise in foreign-born persons as the result of immigration from countries with a high prevalence of MTb infection.[26] This increase in MTb infection has focused considerable attention on the development of assays for its rapid diagnosis; molecular methods were at the center of this effort. The goal was to design very sensitive assays that would enable the direct detection of MTb from clinical specimens. However, this goal has proved to be more difficult to reach than was originally anticipated.

Standard methods for detection of MTb include acid-fast bacilli (AFB) smear and conventional and liquid culture methods. The AFB smear is rapid but has poor sensitivity of 20 to 80%.[13] Another challenge with AFB smear is that it cannot distinguish MTb from nontuberculous mycobacteria (NTM), such as *Mycobacterium avium*-complex (MAC). This distinction is important because both disseminated MAC and MTb are common infections in persons with AIDS. Culture methods for the detection of MTb are sensitive, but growth detectable by standard methods may require 6 to 8 weeks in culture. Growth often occurs more quickly in liquid culture than with conventional methods but can still require weeks. With these limitations of culture methods, there was great enthusiasm for nucleic acid testing as a rapid, sensitive method for detection of MTb, especially given the need to rapidly isolate patients with active, untreated disease and to initiate prompt therapy, particularly in immunocompromised hosts.

Nucleic Acid Testing for MTb

The Amplified *Mycobacterium tuberculosis* Direct test [MTD test (Gen-Probe) is the only available FDA approved amplification test for the detection of MTb from clinical samples. The MTD test is based on transcription-mediated amplification of ribosomal RNA and can be used to test both AFB smear-positive and smear-negative respiratory specimens. The MTD test has not been approved for nonrespiratory specimens; this limits its clinical utility for diagnosis of extrapulmonary MTb infection. This is unfortunate because diagnosis of some of these infections is often difficult. In addition to these commercially available assays, LDTs are widely used, and a key advantage of these assays is their ability to test respiratory as well as nonrespiratory specimens.

The MTD test has a sensitivity of 95 to 98% when AFB smear-positive respiratory specimens are used, and the specificity ranges from 99 to 100%. However, early studies showed that sensitivity for AFB smear-negative specimens was ≈50%.[25] Based on these data, it was clear that the test could not be used to rule out MTb infection on smear-negative respiratory specimens. This further limited the clinical utility of these tests because it became clear that nucleic acid testing would be used to supplement AFB smear and culture, rather than replace these testing modalities. Another limitation of currently available nucleic acid assays is that they can be used only on specimens from patients who have not received antituberculosis therapy in the previous 12 months. This limitation was included because DNA can persist in respiratory secretions (and other body fluids) for months after the mycobacteria are no longer viable. The MTD test was subsequently reformulated and evaluated in a clinical trial that compared this test versus culture and versus the probability of MTb infection as determined by a panel of experts.[75] The sensitivity and specificity of the test were 86% and 98%, respectively. Positive and negative predictive values were 91% and 97%, respectively. Based on this study, the reformulated MTD test was approved by the FDA for use on both AFB smear-positive and AFB smear-negative specimens.

In spite of the limitations discussed previously, nucleic acid amplification tests do provide added value in managing patients with tuberculosis. Advantages include rapid turnaround time, greater positive predictive value (>95%) with AFB smear-positive specimens in settings where nontuberculous mycobacteria are common, and rapid confirmation of MTb in 50 to 80% of AFB smear-negative, culture-positive specimens.[27] Because of increasing use of nucleic acid amplification tests, the CDC has provided updated guidelines for the use of nucleic acid amplification tests in the diagnosis of tuberculosis.[27] It is now recommended that nucleic acid amplification testing be performed on at least one respiratory specimen from each patient with signs and symptoms of pulmonary MTb for whom a diagnosis of MTb is being considered but has not yet been established, and for whom the test result would alter case management or MTb control activities. Patients with a positive AFB smear and a positive nucleic acid testing result should be presumed to have MTb infection, and there is no need for additional nucleic acid testing. If the sputum smear is AFB-positive and two or three specimens are negative by nucleic acid testing, and inhibition of amplification has been ruled out, then the patient can be presumed to have nontuberculous mycobacterial infection. If the sputum specimen is AFB smear-negative and repeatedly positive by the MTD test, then the patient can be presumed to have MTb infection. For patients with an AFB-negative smear, a negative nucleic acid test does not rule out MTb infection.

A key consideration with molecular assays is controlling for inhibition of amplification. This is particularly critical for the detection of MTb nucleic acid from respiratory specimens, as these specimen types often contain blood or glycoprotein, which can inhibit amplification. The MTD test does not contain an inhibition control, although many laboratories

tahir99-VRG & vip.persianss.ir

include such a control by adding a positive control material to a second aliquot of the clinical specimen.

An important role for molecular assays is in the diagnosis of extrapulmonary MTb infection, such as meningitis, pleuritis, pericarditis, or peritonitis, as these infections can be very difficult to diagnose using traditional methods. Amplification assays have been used on CSF specimens for the diagnosis of MTb meningitis,[5,10,85] although the tests have not been approved by the FDA for this indication. In addition, LDTs have been developed with the flexibility needed to test a variety of clinical specimens. As mentioned for respiratory specimens, it is critical to remember that a negative nucleic acid test result does not rule out extrapulmonary MTb infection, and molecular assays using these complex body fluids should include an inhibition control.

Updated guidelines on the use of nucleic acid amplification tests have expanded their role in the diagnosis of MTb infection. However, culture remains the gold standard for laboratory confirmation of MTb infection, and an isolate of the organism is needed for susceptibility testing. Although nucleic acid testing is recommended, a portion of the clinical specimen should always be reserved for culture.

HEPATITIS C VIRUS

HCV, an RNA virus, is a major cause of chronic liver disease. According to the National Health and Nutrition Examination Survey (NHANES) of 1988-1994, approximately 4 million Americans were infected with HCV, and 2.7 million were estimated to have chronic infection. After acute infection, 80 to 85% of individuals develop a chronic infection, and 2 to 4% of these individuals develop cirrhosis and end-stage liver disease, making end-stage liver disease secondary to HCV the most common indication for liver transplantation in the United States. The development of molecular testing for HCV infection has been a major advance in the clinical care of infected individuals.

Detection and Quantification of HCV

Applications of HCV RNA testing include (1) assisting in the diagnosis of HCV infection, (2) excluding HCV infection as the etiologic agent of symptoms, (3) screening the blood supply, (4) monitoring response to therapy, and (5) determining the duration of therapy. Qualitative molecular assays can be used to confirm the diagnosis of HCV infection, although improvements in quantitative assays have made them just as sensitive. A low detection limit is particularly important in distinguishing seropositive individuals who have cleared the infection (undetectable HCV RNA) from seropositive persons who have chronic infection (persistent HCV RNA).

Data from the CDC have shown that 95% of positive results of screening ELISA that have a high signal-to-cutoff ratio can be confirmed as true positives. For these specimens, confirmation testing is not routinely needed. For specimens with a low signal-to-cutoff ratio, confirmation testing should be done with a recombinant immunoblot assay (RIBA) or by detection of HCV RNA. If HCV RNA detection is used as the confirmatory test, then RNA-negative specimens should be tested in the RIBA. This is done to distinguish a false-positive ELISA result from true infection. Alternatively, repeat testing for HCV RNA should be conducted, because viremia may be intermittent and HCV infection should not be ruled out on the basis of one negative HCV RNA test.

Qualitative molecular assays are also used to diagnose HCV infection in infants born to HCV-infected mothers. Because maternal IgG antibody can cross the placenta, these infants can be seropositive into the second year of life. Detection of HCV RNA in the plasma or serum of the newborn shortly after birth would be diagnostic of infection.

Detection of HCV RNA in plasma or serum can be a useful diagnostic test in immunocompromised individuals, such as those with end-stage HIV-1 infection, because they may not mount a normal immune response to the virus and may not be seropositive.

Qualitative HCV RNA testing is also used to define a treatment response to therapy for HCV infection because these assays are very sensitive, with lower limits of detection between 5 and 50 copies/mL plasma. Response to therapy is defined as an undetectable HCV RNA after completion of therapy; a sustained virologic response (SVR) is defined as an undetectable viral load 24 weeks after completion of therapy.

More recently, qualitative HCV RNA assays have been developed for screening the blood supply. HCV RNA is detectable in serum during the "window period" (when tests for HCV antibodies are negative) between infection and seroconversion. Because most individuals with recently acquired HCV infection are asymptomatic, testing of blood donors for HCV RNA allows identification of individuals at risk for transmitting HCV infection that would have been missed if testing were done with only serologic assays. Nucleic acid testing for HCV RNA has reduced the window period by an average of 26 days.[80] By screening the blood supply with HCV antibody testing alone, it was estimated that 1 in 100,000 transfused units contained HCV RNA, but with the addition of testing by nucleic acid amplification technology (often called NAT) for HCV, the risk is projected to be reduced to 1 in 367,000 units.[80]

Several large clinical trials have established the benefit of treatment of chronic HCV infection with ribavirin and pegylated interferon-α [interferon-α with addition of polyethylene glycol (PEG)].[44,55] Overall SVRs of approximately 55% are obtained; patients who have the common genotype 1 have SVRs of only 42 to 46%, compared with 76 to 82% for those with genotype 2 or 3 infection. In addition, no additional benefit was derived from treating genotype 2 and 3 infection for 48 weeks compared with 24 weeks, thus allowing for a shorter course of therapy for genotype 2 and 3 infections. New, specific antiviral agents offer additional therapeutic choices; the HCV NS3/4A protease inhibitor, telaprevir, is one that has shown significant improvement in SVR as high as 25% over standard of care using ribavirin and pegylated interferon-α.[61,97] Both telaprevir and boceprevir have been approved by the FDA for use in combination with ribavirin

and peginterferon to treat chronic HCV infection, both drugs have shown substantial increases in the rate of SVR compared to with ribavirin and peginterferon alone. Although genotype is a strong predictor of response to therapy, studies have shown the utility of determining the viral load during the course of therapy. Patients who fail to have a 2 $\log_{10}$ drop in HCV RNA concentrations at 12 weeks [defined as an early virologic response (EVR)] after initiating interferon and ribavirin have a 3% likelihood of responding to therapy compared with 65% for patients who do achieve a 2 $\log_{10}$ drop in viral load. More recently, achieving an undetectable HCV RNA result at 4 weeks [defined as a rapid virologic response (RVR)] has been associated with an 89% likelihood of responding to just 24 weeks of therapy with ribavirin and pegylated interferon-α and achieving an SVR.[73,118,168] By determining HCV viral load at baseline, at 4 weeks, and again after 12 weeks of therapy, patients who are unlikely to respond to therapy can be identified earlier in the course of therapy. This will allow for (a) discontinuation of potentially toxic drugs and a reduction in the cost of therapy, or (b) increasing doses of these drugs, or (c) the addition of new antiviral medications. On the other hand, individuals who attain an RVR or EVR will likely have a good response to treatment and will have therapy continued for 24 to 48 weeks, depending on the HCV genotype, other risk factors, and drug side effects.

Available Assays for Detection and Quantification

Several qualitative assays have been approved by the FDA for the detection of HCV RNA in plasma or serum specimens (Table 42-3). The AMPLICOR HCV test, the COBAS AMPLICOR HCV test, and the COBAS Ampliprep/COBAS AMPLICOR HCV test (Roche Diagnostics) are based on RT-PCR technology; the COBAS AMPLICOR test allows for automation of the amplification and detection steps, and the COBAS Ampliprep adds automation for the nucleic acid extraction step. The first two versions of the AMPLICOR test have a lower limit of detection of 50 international units (IU)/mL, and the COBAS Ampliprep/COBAS AMPLICOR is lower at 13.9 or 18.8 IU/L for plasma because of the larger specimen volume that is extracted. The VERSANT HCV RNA Qualitative Assay (Siemens Healthcare Diagnostics) uses transcription-mediated amplification (TMA) and can detect as few as 5 IU/mL. In addition to these tests, laboratories have developed their own reverse transcription PCR and real-time PCR assays. Two additional qualitative assays are available only for screening the blood supply: the Procleix HIV-1/HCV Assay (Novartis Vaccines and Diagnostics Inc., Emeryville, Calif, in partnership with Gen-Probe) based on TMA technology,[70] and the AMPLISCREEN HCV test (Roche Diagnostics), which uses the reverse transcription PCR method. Both assays report a lower limit of detection of less than 50 IU/mL. Next generation blood screening instruments are currently in development.

Various tests are available for the quantification of HCV RNA. The VERSANT HCV RNA assay (Siemens Healthcare Diagnostics) was the first FDA-approved assay for HCV viral load testing (see Table 42-3). The assay is based on bDNA

TABLE 42-3 HCV RNA Tests in Clinical Use[a]

Test	Assay Method	Comments
RealTime HCV assay ASR[b]	RT-PCR[c]	Qualitative, LOD[d] defined by the individual laboratory

signal amplification technology and has a reasonably broad dynamic range and a lower limit of quantification of 615 IU/mL. The COBAS AMPLICOR HCV MONITOR test (Roche Diagnostics) uses RT-PCR and has a similar limit of quantification (600 IU/mL), but a more limited linear range requiring dilution of the clinical specimen to measure viral loads greater than 500,000 IU/mL. The first FDA-approved real-time PCR assay, the COBAS Ampliprep/COBAS TaqMan HCV test (CAP/CTM; Roche Diagnostics), has a lower limit of quantification of 43 IU/mL with a broad linear range across 6 $\log_{10}$ and uses the Ampliprep nucleic acid extraction automation. A real-time PCR assay from Abbott Molecular is also FDA-approved and has a linear range of 12 IU/ml to 100 million IU/ml. With their improved sensitivity and broad linear range, real-time tests are now widely used for monitoring response to antiviral therapy.

Several studies have evaluated and compared the FDA-cleared assays and the laboratory-developed assays; most have demonstrated good correlation.[45,102,119,133,165] Genotype-specific variability in quantification for particular HCV assays has been reported. Earlier versions of the AMPLICOR RT-PCR and bDNA assays did not accurately quantify all genotypes of HCV and usually underestimated the concentrations of genotypes 2 and 3. However, current versions of the AMPLICOR RT-PCR (version 2.0) and the VERSANT bDNA (version 3.0) quantify all HCV genotypes. The CAP/CTM assay may overquantify genotype 1 and underquantify genotype 4 specimens in comparison with the other assays.[132,157] However, all assays appear to perform well in determining SVR in patients.[93] The availability of an established World Health Organization (WHO) international standard has allowed standardization of HCV assays with reporting of results as IU per milliliter.

The intra-assay imprecision (SDs) of the HCV VERSANT bDNA, the AMPLICOR RT-PCR, and the CAP/CTM real-time PCR assays ranges from 0.05 to 0.3 $\log_{10}$; the VERSANT bDNA assay is most precise. The biological variation of HCV viral load (as SD) ranges from 0.5 $\log_{10}$ to 0.75 $\log_{10}$. Changes in HCV viral load need to exceed 1 $\log_{10}$ (i.e., a 10-fold change in concentration) or more to represent statistically significant changes beyond those explained by analytical and biological variation.

HCV Genotyping

A hallmark of HCV infection is genetic heterogeneity resulting from the low fidelity of the RNA-dependent RNA polymerase, which frequently introduces random nucleotide errors during viral replication. These replication errors could yield 10 to 100 nucleotide changes per position per year, giving rise to many genetic variants (quasispecies) of the virus in a single patient. Based on identification of these genomic differences, HCV has been classified into six major genotypes and multiple subtypes within each genotype. Geographic differences in the distribution of HCV types have been noted. In the United States, approximately two thirds of the infections are type 1, with the remaining being predominantly types 2 and 3.

The HCV genome contains well-defined 5′ and 3′ untranslated regions (5′UTR and 3′UTR). The 5′UTR is the most conserved portion of the genome and is frequently used as the target for molecular assays, including genotyping assays. The HCV genome is divided into seven areas: the core region that encodes the capsid C protein, the E1 and E2 regions that encode the envelope proteins (gp33 and gp72), and several nonstructural protein regions (NS2, NS3, NS4, and NS5). The NS5B region shows less sequence conservation than the 5′UTR, and sequencing of NS5B has been successfully used for genotyping HCV.

HCV genotyping, along with pretreatment viral load, age, gender, and the presence of hepatic fibrosis, can be used to determine the duration of antiviral therapy, with genotype being a strong predictor of a sustained virologic response. Several methods have been developed for genotyping and/or subtyping HCV, but most clinical laboratories use the reverse hybridization-based line probe assay (INNO-LiPA HCV II, Siemens Healthcare Diagnostics) or direct DNA sequencing. The INNO-LiPA assay is based on reverse hybridization of 5′UTR and core amplified products with genotype-specific probes. The INNO-LiPA HCV II discriminates and identifies the 6 HCV genotypes and subtypes.

Automated sequencing assays, developed both commercially and in-laboratory, are available to genotype HCV; the genomic regions commonly used include 5′UTR, NS5B, and core. Sequencing methods require sequence alignment and comparison with reference sequences to determine the genotype and subtype. An HCV genotyping kit based on automated sequencing (Trugene HCV 5′NC, Siemens Healthcare Diagnostics) targets the 5′UTR region. Although this assay can accurately type HCV, sequence variation in this region is not adequate to accurately subtype the virus.[110] When more variable regions of the virus are sequenced, such as NS5B, it is possible to determine both viral type and subtype. Several methods using real-time PCR technology, with or without melting curve analysis, are in limited use, and others are under development.

CLOSTRIDIUM DIFFICILE

Clostridium difficile is a gram-positive spore-forming anaerobic bacillus that is frequently found in the stool flora of healthy infants, but is rarely found in the stool flora of healthy adults and children older than 12 months. The organism is acquired by ingesting spores, which survive the gastric acid barrier and germinate in the colon. Alteration of the intestinal flora with the use of antibiotics facilitates colonization of the intestinal tract. Once colonized, patients may develop symptoms of diarrhea and/or colitis. Most strains of *C. difficile* make two toxins: toxin A and toxin B; the regulatory protein TcdC represses expression of the toxin A and B genes. These toxins are responsible for symptomatic disease; strains that lack these toxins do not cause diarrhea or colitis. Detection of these toxins or of their activity is essential in diagnostic tests for *C. difficile*–associated disease. An additional toxin, the binary toxin, has been described in some strains of

C. difficile, and recent reports have suggested that strains encoding the binary toxin have a deletion in the *tcdC* gene, leading to overexpression of toxins A and B (BI/NAP1/027), and are causing outbreaks of more severe disease.[95,96]

C. difficile is a frequent cause of antibiotic-associated diarrhea and colitis. In hospitals, the risk of infection increases with the length of hospital stay, and use of antimicrobial therapy greatly increases the likelihood of acquiring *C. difficile* colitis. *C. difficile* causes a spectrum of disease ranging from asymptomatic carrier state, to fulminant, relapsing, and fatal colitis. Diarrhea may be mild to severe. Pseudomembranous colitis is a classic presentation of *C. difficile* disease, and toxic megacolon may also be seen. Although clindamycin, penicillins, and cephalosporins have commonly been associated with disease, almost all antibiotics have been associated with disease.

Various non–nucleic acid tests are available for the diagnosis of *C. difficile* infection. Culture of the organism alone is not helpful in the diagnosis, as there needs to be confirmation that the organism is producing toxin. The cell culture cytotoxicity test neutralization assay (CCNA), which detects the cytopathic effect of toxin B, is considered the gold standard for the diagnosis of clinically important *C. difficile* infection. The test is highly sensitive and specific but is labor-intensive and technically demanding. The turnaround time of 1 to 3 days limits its clinical utility.[164] The most commonly used tests are enzyme immunoassays (EIAs) and lateral flow devices that detect toxin A and/or toxin B. Overall these tests have lower sensitivities (45 to 95%) and specificities (75 to 100%) than the cytotoxicity test.[116,141] In general, EIAs that detect both toxins A and B are preferred because some strains may not produce toxin A.[3,164] An alternative testing approach is detection of the common antigen glutamate dehydrogenase (GDH). The test does not distinguish between toxigenic and nontoxigenic strains and cannot be used alone for the diagnosis of *C. difficile* disease. A positive result needs to be confirmed with the cytotoxicity test, an EIA, or PCR for the detection of toxin. The GDH test is a useful screening test because it has a high negative predictive value. One study evaluated a two-step approach using the GDH test as the initial screen followed by a CCNA for antigen-positive specimens to confirm the presence of toxin. A negative antigen test was more than 99% predictive of a negative CCNA.[153] A limitation of this approach is the delay in obtaining a result because of the long turnaround time of the CCNA test.

Nucleic Acid Tests for *C. difficile*

In view of the limitations of traditional methods, molecular tests have recently been investigated as an alternative for the diagnosis of *C. difficile* infection. Four tests have been cleared by the FDA for the detection of *C. difficile* directly from stool specimens: GeneOhm Cdiff Assay (BD Diagnostics-GeneOhm), ProGastro Cd Assay (Gen-Probe), and the Xpert *C. difficile* test (Cepheid), and the Illumigene™ *C. difficile* (Meridian Bioscience Cincinnati, OH). These tests are designed to detect the toxin B gene *(tcdB)* or toxin A and B. The Xpert™ *C. difficile/Epi* Test also detects the binary toxin and the deletion of *tcdC,* thus allowing specific identification of the hypervirulent strain of *C. difficile* (027/NAP1/BI), although this test is cleared for epidemiologic studies only. A study comparing the GeneOhm test versus a CCNA test using anaerobic toxigenic culture as the gold standard found the CCNA test to have a sensitivity of 67.2% and a specificity of 99.1% [positive predictive value (PPV) 93.2%, negative predictive value (NPV) 94.4%], while the GeneOhm test had a sensitivity of 83.6% and a specificity of 98.2% (PPV 89.5%, NPV 97.1%).[146] Peterson and associates[116] evaluated an EIA that detects toxins A and B, a laboratory-developed real-time PCR test targeting a conserved region of *tcdB,* a CCNA, and anaerobic toxigenic culture. Culture test results and clinical criteria were used to assess the performance of the four tests. The sensitivities of the EIA, PCR, CCNA, and toxigenic culture were 73.3%, 93.3%, 76.7%, and 100%, respectively. The PCR test had a turnaround time of less than 4 hours, which was equivalent to the EIA, and it had a much greater sensitivity. Overall, PCR tests appear to be more sensitive than EIAs that detect toxin and more sensitive than CCNA tests. Concerns have arisen about the possibility of *C. difficile* with variant *tcdB* and the emergence of *tcdB*-negative *C. difficile* strains, which will not be detected by some of these PCR tests.

METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS* (MRSA)

Staphylococcus aureus is an important human pathogen and a leading cause of hospital-acquired infection (HAI). Colonization of the nares and skin is common. Transmission occurs primarily through contact with those who are infected or are carriers of the organism. This gram-positive coccus is responsible for a wide clinical spectrum of infections from minor skin infections such as folliculitis (furuncles) or carbuncles (boils), to more severe sepsis and CNS infection, to death. HAIs have become a significant problem affecting the health of millions of patients, extending their stay in the hospital and contributing to mortality. The National Healthcare Safety Network estimates a rate of 2 million HAIs per year in the United States, with 90,000 deaths per year[41]; *S. aureus* contributes to a significant number of these cases.

Treatment of *S. aureus* infection has become more difficult with its acquisition of resistance to the antibiotics oxacillin and methicillin. These organisms, referred to as methicillin-resistant *S. aureus* (MRSA), most often are acquired in the hospital and then are termed *hospital-acquired (HA) MRSA*. MRSA infections of individuals who have not been hospitalized within the previous year and have not undergone an invasive medical procedure including catheterization are termed *community-acquired (CA) MRSA*. These two types of MRSA have been shown to be genetically and biologically different. In the past few years, the number of cases of CA-MRSA has dramatically increased; it often occurs in otherwise healthy individuals. MRSA is usually resistant to all β-lactam agents, including cephalosporins and carbapenems. Unlike CA-MRSA, HA-MRSA is usually multidrug resistant

and is resistant to erythromycin and clindamycin. Vancomycin has been the mainstay in the treatment of MRSA, and the emergence of vancomycin-intermediate MRSA (VISA) and vancomycin-resistant MRSA (VRSA) is particularly disturbing. Additionally, when patients with MRSA have been compared with patients with methicillin-susceptible *S. aureus* (MSSA), MRSA-colonized patients more frequently developed symptomatic infection and had a higher case fatality rate for certain MRSA infections, including bacteremia and surgical site infection.[38]

Prevention of nosocomial transmission has become an important concern for healthcare facilities. Use of rapid molecular diagnostic tests for the detection of MRSA has been studied as a component of an approach to decrease the rate of nosocomial transmission of MRSA. One observational study evaluated clinical disease during hospitalization before and after implementing a universal surveillance program. The program used (1) rapid PCR-based MRSA detection for all hospital admissions, (2) decolonization procedures, and (3) contact isolation of patients who tested positive. The interventions reduced MSRA by almost 70% [confidence interval (CI), 89.2 to 19.6%].[125] Other studies, however, found no decrease in hospital acquisition of MRSA infection, although some demonstrated a reduction in the time patients spent in preemptive contact isolation because molecular surveillance testing was more rapid than conventional culture-based MRSA detection.[58,74,108] Recommendations for MRSA surveillance testing have been published.[106,139]

Resistance to methicillin is conferred by activity of the *mecA* gene product, penicillin-binding protein (PBP) 2a. It has a lower affinity for binding by methicillin, allowing it to evade inhibition by methicillin and to complete the transglycosidation step in cell wall synthesis in the bacteria. The *mecA* gene is carried on a mobile genetic element 21 to 67 kilobase pairs in length, and is referred to as a staphylococcal chromosomal cassette *mec* (SCC*mec*). The SCC*mec* contains several other antibiotic resistance determinants: the gene complex that encodes the recombinases for excision and integration from the staphylococcal chromosome and terminal repeat sequences necessary for mobilizing the cassette. At least six identified types of SCC*mec* cassettes based on the DNA sequence and the combination of *mecA* and recombinase gene complexes have been identified: types I, II, III, IV, V, and VI. SCC*mec* types I, II, and III are associated with HA-MRSA, and types IV and V have been associated with CA-MRSA. Some coagulase-negative staphylococci (CoNS) also carry the SCC elements with the *mecA* gene, and it is clinically important to differentiate them from MRSA. The SCC*mec* insertion into *S. aureus* is seen at the 3′ end of the open reading frame *(orf) X attB* gene sequence, which is an *S. aureus*–specific sequence. This provides one means of differentiating MRSA from *mecA*-containing CoNS by targeting PCR primers to this junction so that amplification occurs only if MRSA is present. The limitation of this method is that a separate amplification is required to detect the *mecA* gene.

Traditional methods of culture and antibiotic susceptibility testing have been important in the detection and identification of MRSA, and in distinguishing it from CoNS, but the requirement for 48 to 72 hours of culture to obtain a definitive result is a major disadvantage. Test results often are available too late to inform treatment decisions. The development of selective media with chromogenic indicators has decreased the time to detection, but at least overnight incubation is still required. Because methicillin resistance is almost always induced in the presence of β-lactam antibiotics when the *mecA* gene is present, detection using molecular methods is considered indicative of the presence of the organism with antibiotic resistance. The move toward reducing nosocomial transmission has further propelled the development of molecular assays for detection of the *mecA* gene to reduce the time to obtaining a result.

Nucleic Acid Testing for MRSA

Molecular tests can identify MRSA in a few hours or in a day, rather than the 3 to 4 days currently needed for culture methods. Timeliness not only reduces healthcare costs for the patient but also reduces the risk of transmitting the MRSA to healthcare workers and to other patients—a crucial step for infection control. Molecular tests are also sensitive and thus can increase the detection rate of MRSA. The high sensitivity of molecular assays permits direct detection of MRSA from clinical samples such as nasal swabs without the need for culture. Molecular assays are also highly specific and thus are able to distinguish, for example, *mecA*-carrying CoNS from true MRSA. Finally, on rare occasions, phenotypic tests for *S. aureus* give equivocal results, creating the need for alternative methods. Testing for susceptibility to oxacillin also sometimes gives equivocal results, again highlighting the need for alternative methods.

Four manufacturers have molecular assays for the detection of MRSA from nasal swab specimens cleared by the FDA: the GeneOhm MRSA assay (Becton-Dickinson; previously IDI-MRSA from Infectio Diagnostic Inc.) for the Smartcycler (Cepheid), the Xpert MRSA assays for the GeneXpert (Cepheid), the LightCycler MRSA Advanced Test (Roche), and the NucliSENS EasyQ MRSA (bioMérieux). The GeneOhm, Xpert MRSA, and LightCycler MRSA Advanced assays are designed for the detection of unique sequences at the junction of the SCC*mec* cassette in *S. aureus* but not for *mecA* gene detection. Another version of the Xpert MRSA assay, the Cepheid Xpert MRSA/SA Blood Culture Assay, has been cleared for MRSA determination from positive blood cultures using BD BACTEC Plus Aerobic/F blood culture bottles; it detects the *mecA* gene and the *S. aureus* protein A *(spa)* gene, along with the SCC*mec*. The NucliSENS EasyQ MRSA detects the SCCmec cassette junction *(orf X)* and the *mecA* gene. All the assays except the LightCycler MRSA Advanced Test demonstrate detection of the six primary SCC*mec*. Reports of loss of the *mecA* gene from the SCC element have been described, and the assays that lack direct

mecA detection demonstrate false-positive results in these instances, requiring subsequent evaluation specifically for the *mecA* gene or antibiotic susceptibility.[66]

The BD GeneOhm MRSA Assay was the first assay cleared by the FDA for direct detection of nasal colonization by MRSA. It applies a manual lysis step before assembly of the real-time PCR reaction using fluorescently labeled hybridization probes in the Smartcycler reaction tube. In the clinical trial, it demonstrated sensitivity of 93% and specificity of 96% compared with culture-based methods, although analysis of the culture-negative/MRSA assay–positive discrepant results showed that most cases were true positives [FDA 510(k) number k033415]. The limit of detection is reported as 15 genome copies per reaction, or approximately 325 colony-forming units (cfu) per swab.

The Cepheid Xpert MRSA Assays (Xpert MRSA, Xpert MRSA/SA Blood Culture, Xpert MRSA/SA Nasal, and Xpert MRSA/SA SSTI [from skin and soft tissue] assays) are unique among FDA-cleared molecular-based diagnostics because of the rating as "moderate complexity" assays according to Clinical Laboratory Improvement Amendments (CLIA) categorization. This is because the assays are performed on the GeneXpert Dx System, which utilizes automated nucleic acid extraction and real-time PCR amplification in a self-contained cartridge. This advance in test design allows for use with the "moderate complexity" designation. The single-use cartridge contains chambers for holding the specimen and the extraction and real-time PCR reagents, a pump and valve system for controlling the movement of fluids between chambers, and an integrated PCR reaction tube with a high surface area for rapid amplification. The Xpert MRSA assay detects the presence of the SCC*mec* cassette at the *orfX attB* site, along with an internal control for amplification. The Xpert MRSA/SA Blood Culture, Nasal, and SSTI assays are similar in design to the Xpert MRSA assay, except for modification of the nucleic acid extraction procedure and inclusion of detection of the *mecA* and the *S. aureus* protein A *(spa)* genes.

The LightCycler® MRSA Advanced is another real-time PCR method for the detection of the presence of the SCC*mec* cassette at the *orfX attB* site, and includes an internal control for amplification. The NucliSENS EasyQ MRSA test uses nucleic acid sequence based amplification (NASBA), to detect two DNA targets for the presence of MRSA; the SCCmec cassette junction *(orfX)* and the *mecA* gene. Unlike the GeneXpert system, both require separate nucleic acid preparation before performing.

In a multisite study[166] involving nasal specimens with MRSA prevalence ranging from 5 to 44%, the Cepheid Xpert MRSA assay was compared with chromogenic agar with or without preceding broth enrichment. The assay showed (1) 100% sensitivity and specificity (after clerical errors were removed), (2) a limit of detection of approximately 80 cfu per reaction, and (3) linearity across six logs from 68 cfu to 6.8×10^7. Other ASRs for MRSA detection are commercially available from several other vendors.

RESPIRATORY VIRUSES

The viruses that infect the respiratory tract consist of diverse groups that cause disease in humans, and new ones continue to be discovered. The more common viruses that infect humans include influenza A and B, parainfluenza virus (PIV) types 1 to 4, respiratory syncytial virus (RSV), metapneumovirus, adenovirus (more than 50 different types), rhinovirus (more than 100 different types), and coronavirus. All of these viruses can be associated with symptoms of the common cold, including fever, myalgia, malaise, headache, pharyngitis, cough, and sore throat. Some virus types are associated with typical presentations in distinct populations, for instance, tracheolaryngobronchitis or croup in a 4- to 6-year-old is most frequently associated with PIV 1 infection, but bronchiolitis (infection and inflammation of the medium- to small-caliber airways) in toddlers is associated with RSV infection and can suffocate the child through closure of the airway from inflammation. The disease spectrum ranges from the common cold to severe life-threatening pneumonia. It can be difficult to differentiate the viral origin based on signs and symptoms alone, and treatment options vary depending on the viral etiology. Infection with these viruses has demonstrated the potential for a public health threat of epidemic and pandemic proportions. The history of pandemic influenza is well known, starting with the 1918 influenza A. More recently, presentations of the deadly avian influenza A [hemagglutinin (H) type 5 and neuraminidase (N) type 1 H5N1] in 1997[142] and the severe acute respiratory syndrome (SARS) coronavirus in 2003 have been reminders of the potential for human infection by new or reassorted viruses.[43] Neither of these viruses seemed to acquire significant human-to-human transmission. In 2009, however, a multiply reassorted novel (swine-like) influenza A H1N1 was easily transmitted between humans and was declared a pandemic, although it appeared to be less deadly than seasonal influenza infection. Detection of emerging respiratory viruses will require multiple modalities, and molecular methods will be critical in evaluating these new viruses.

Acute respiratory viral infection (1) is a leading cause of hospitalization and death in infants and young children[60,126,138]; (2) contributes to problems of asthma exacerbation, otitis media, and lower respiratory tract infection[9]; and (3) contributes to acute disease in immunocompromised and elderly patients. Rapid diagnosis aids in effective treatment (e.g., with antiviral medications such as oseltamivir for influenza A infection) and management (e.g., reduction in inappropriately prescribed antibiotics for viral infection). Rapid antigen-based EIAs provide short turnaround times (minutes) but are hampered by poor diagnostic sensitivity compared with culture methods or molecular assays, and low positive predictive values, especially when the prevalence is low.[28,50,51,69] Direct fluorescent antibody (DFA) detection assays for viral antigens on centrifuged cellular material (cytospun) from nasopharyngeal swabs, aspirates, or wash specimens demonstrate greater rates of detection than the

rapid antigen assays, and provide results in a relatively short time frame of 2 to 4 hours. Rates of detection, however, are lower for antigen detection methods than for PCR methods.[49,51,87]

Cell culture methods, although slower than antigen detection methods, have been considered the gold standard for detection of a wide range of viral pathogens. In recent years, culture methods have been optimized for detection by combining multiple cell lines and improving turnaround time from weeks to days through the use of shell-vial spin amplification cultures. Here, the patient's specimen is concentrated onto cells grown on a coverslip, and fluorescent antibody detection is performed after 16 to 24 hours of incubation, instead of waiting for the development of a cytopathic effect. Although this has hastened the time to detection, 1 to 2 days is still required for results, along with significant technologist labor, and this method is not quite as sensitive as molecular methods of detection.

Nucleic Acid Testing for Respiratory Viruses

Molecular detection of respiratory viruses offers several advantages over traditional virologic culture or antigen detection. Most important, analytical sensitivity of molecular assays, primarily using PCR or real-time PCR, is consistently found to be better than that of traditional methods.* Results from molecular testing are more accurate and thus the patient benefits from the most appropriate treatment decision; also, infection control practitioners can more effectively implement strategies to prevent or reduce nosocomial transmission. Molecular assays can be designed to detect a wide range of viral pathogens, including for detection of new viruses. Multianalyte testing in a single or a small number of reaction tubes decreases the cost of reagents and technologist time and allows robotic implementation of specimen handling and testing.

Two important considerations in the design of a molecular-based detection method are whether the genetic material is DNA or RNA, and which method is appropriate for detection. For PCR, which is used most commonly, a DNA template is required, so RNA viruses must be reverse transcribed into a complementary DNA product (cDNA) before PCR amplification can be performed. Furthermore, it must be determined which viruses should be included in the detection process. Many different laboratory-developed assays have been designed specifically for particular needs with any number of organisms detected, and several commercial vendors have developed analyte specific reagents (ASRs). PCR-based assays that have been cleared by the FDA, include the ProFlu+, ProFast+, ProParaFlu+, Pro hMPV+, PROAdeno+ from Gen-Probe, the xTAG Respiratory Viral Panel from Luminex Corporation (Austin, Tex), the Verigene Respiratory Virus and Respiratory Virus Plus Nucleic Acid tests from NanoSphere Inc. (Northbrook, Ill), the Simplexa FluA/B and RSV test from Focus Diagnostics, Inc. (Cypress, California), the Xpert Flu Assay (Cepheid), and the FilmArray Respiratory Panel from Idaho Technologies (Salt Lake City, UT) (Table 42-4). All assays are cleared for

*Compared with direct fluorescent antibody (DFA) and shell-vial culture as the gold standard.
†Compared with xTAG Respiratory Viral Panel as the predicate device.
‡hMPV comparator assays are two-step RT-PCR assays that target conserved regions of the hMPV nucleocapsid or fusion gene.
§Compared with ProFlu+ as the predicate device.

use on nasopharyngeal swabs, and all use internal controls for amplification. The ProFlu+, the Verigene Respiratory Virus Nucleic Acid, and the Simplexa FluA/B & RSV tests detect influenza A and B and respiratory syncytial viruses while the Verigene Respiratory Virus Plus Nucleic Acid test includes influenza A subtyping. The ProFast+ is only performed for influenza A subtyping. The xTAG Respiratory Viral Panel and the FilmArray Respiratory Panel detect the influenza types and subtypes, RSV, and many more viruses. The ProParaFlu+ assay detects parainfluenza types 1, 2, and 3 and the ProAdeno+ detects adenoviruses. All influenza assays are reported to be capable of detecting the 2009 H1N1 influenza A.[51]

ProFlu+, ProFast+, ProParaFlu+, ProhMPV+, and ProAdeno+ from Gen-Probe use real-time PCR with reverse transcription followed by multiplex amplification and then detection through the use of fluorescently labeled TaqMan probes. All four kits include an internal control added to the specimen before extraction of the nucleic acids to monitor extraction and amplification efficiencies. The limit of detection, defined as the lowest concentration at which 95% or more of replicates tested positive, ranged from 10^2 to 10^{-1} tissue culture infective dose $(TCID)_{50}$/mL, depending on the specific virus detected.

The Verigene Respiratory Virus and Respiratory Virus Plus Nucleic Acid tests from Nanosphere use a unique single-use microfluidics cartridge in which products of the multiplex RT-PCR are captured to a microarray format and are detected with the use of gold nanoparticle probes. The nanoprobes are illuminated using a fixed wavelength light source and are detected with a single-image sensor in the dedicated detection instrument, the Verigene System. The assays include two internal controls: a process control for sample isolation, and an inhibition control for amplification. The Verigene Respiratory Virus Nucleic Acid test has been cleared by the FDA for the detection of influenza A, influenza B, and RSV, and for nucleic acid extraction performed with the NucliSENS easyMAG System (bioMérieux). Sensitivity ranges from 89 to 99% in comparison with culture and DFA detection, and depending on the virus tested. The limit of detection is reported to range from 0.05 to 50.0 $TCID_{50}$/mL, depending on the viral strain.

The xTAG Respiratory Viral Panel (RVP) assay is a multiplexed RT-PCR–based assay with fluorescently color-coded microsphere (bead) hybridization for simultaneous detection and identification of 12 respiratory viruses and subtypes (see Table 42-4). The multiplexed RT-PCR primers amplify conserved regions of the viruses, and the products are labeled with biotin-containing deoxynucleotides (dNTPs) in a second target-specific primer extension reaction. The extension product has a proprietary tag sequence incorporated for hybridization to the virus-specific probe on the color-coded bead. After hybridization, phycoerythrin-conjugated streptavidin is bound by the biotin-labeled primer extension products, and the fluorescent signal is quantified on the Luminex xMAP instrument. The instrument contains two lasers: one for identification of the color-coded bead, and the other for detection of the phycoerythrin signal attached to the primer extension product. The data are recorded as mean fluorescent intensities, and the software analyzes the data and reports the positive results. The assay includes a separate lambda phage amplification control and an MS-2 bacteriophage internal control for extraction and amplification.

Clinical trials with the Luminex xMAP for FDA submission demonstrated sensitivities ranging from 78.3 to 100%, depending on the virus (see Table 42-4). The manufacturer reports that the assay cannot adequately detect adenovirus species C, or serotypes 7a and 41, and that the RVP primers for detection of rhinovirus cross-react with enterovirus. Analyses by investigators prior to FDA approval (when the assay existed with detection for 20 viruses and subtypes) demonstrated a detection rate for influenza 5 to 10% more sensitive than that of DFA and culture.[82] Specificity is also high, ranging from 91.3 to 100%.

The Film Array Respiratory Panel combines multiplex testing with ease of use. Nucleic acid extraction, a multiplex amplification, and second round of target specific amplifcation and detection occurs within a single pouch. Test set up is simple and requires two pipetting steps one to add buffer to the pouch to hydrate the reagents and another to add sample. The test includes an internal control and detects the adenoviruses, coronaviruses HKU1 and NL63, hMPV, human rhinovirus/enterovirus, influenza A (subtypes H1, H3, H1 2009), influenza B, PIV 1-4, and RSV. Results are completed in an hour, currently the instrumentis designed to test a single sample per run, though multiple instruments can be linked.

Molecular testing for respiratory viruses will likely continue to include tests designed to detect the most common pathogens (influenza A and B and RSV), as well as tests that detect a broad array of viruses, as there are clinical needs for both types of tests. Other assays will likely be cleared by the FDA in the coming years, as several other commercial analyte-specific reagents are available, and reports of laboratory-developed assays are abundant.

CHAPTER 43

Pharmacogenetics

*Gwendolyn A. McMillin, Ph.D., D.A.B.C.C.(C.C., T.C.)**

The term *pharmacogenetics* comes from merging the names of *pharmacology* (the study of drugs, particularly drug handling and drug response) and *genetics* (the study of how traits are inherited). Pharmacogenetic testing is intended to predict or explain how people will respond to medicines and other pharmacologically or toxicologically active compounds, based on discrete genetic characteristics. Pharmacogenetics is a rapidly evolving and expanding field and a critical component of personalized medicine. Related work associating drug handling and response with the entire genome is known as *pharmacogenomics,* although some use the terms interchangeably. Pharmacogenetics and pharmacogenomics could include human germline mutations, somatic mutations such as those observed in a malignant tumor, gene copy number, or nonhuman (e.g., viral genome) mutations. Pharmacogenetic or pharmacogenomic profiles hold the potential to improve prescribing practices for most if not all drugs.[64,213]

The goal of pharmacogenetics today is to relate a discrete aspect of a patient's genetic inheritance (genotype) to phenotype, specifically, one or more aspects of pharmacokinetics (drug handling) and/or pharmacodynamics (drug action). Pretreatment pharmacogenetic testing has the potential to predict a phenotype before a drug is ever administered. Predicted phenotype information can be used to select a specific drug(s) that a patient is likely to respond to or select the optimal dosing interval for that patient, while at the same time avoiding or minimizing the incidence of adverse drug reactions (ADRs), including drug hypersensitivity. ADRs are a leading cause of morbidity and mortality in the United States, and the likelihood of response for many drug classes is less than 50%.[26,76,97,165,170] Approximately 10% of all drug labels now include references to pharmacogenetic findings, and several pharmacogenetic tests are available clinically that are designed to identify patients that may be genetically predisposed to ADRs or therapeutic failure.[39] However, clinical use of pharmacogenetics in prescribing most drugs requires more specific dosing guidelines and algorithms based on pharmacogenetic information. Such tools are being considered, developed, and/or evaluated to assist with the use of pharmacogenetic data to inform drug and dose selection, and are likely to improve uptake and utility of pharmacogenetic testing in the coming years.

The goal of this chapter is to familiarize the clinical laboratorian with concepts and examples of pharmacogenetic testing involving human germline variants. The chapter includes descriptions of several polymorphic genes and their applications to drugs used in major areas of medicine in which pharmacogenetic testing is currently applied. For a more in-depth discussion of pharmacogenetics or pharmacogenomics, or regarding specific clinical applications, the reader is encouraged to consult the excellent review articles and websites cited here, as well as the contemporary peer-reviewed literature.

DEFINING PHARMACOGENETIC TARGETS

For simplicity, the term *drug(s)* will be used throughout this chapter to reflect any xenobiotic (foreign compound absorbed by the human body) that is capable of evoking a physiologic or behavioral response, whether desirable (therapeutic) or undesirable (toxic). Responses to drugs and drug handling depend on many variables such as drug formulation, route of administration, clinical status (e.g., kidney function, liver function, protein status), age, gender, comedications, and genetics. Many of the variables surrounding drug handling and drug response are measurable and could be considered relative to optimizing drug therapy choices. However, most drugs are historically dosed according to population-based dosage and dose frequency recommendations. Dosing is typically optimized through trial and error, based on how a patient handles and responds to a drug or combination of drugs. Minimizing this process of trial and error is one of several strategies proposed to reduce the incidence of ADRs and improve rates of efficacy. Pharmacogenetic testing can be used to understand and predict specific aspects of the two major processes upon which pharmacology is based: pharmacokinetics and pharmacodynamics.

Pharmacokinetics describes the processes through which the body acts on a drug: absorption, distribution, metabolism, and elimination. Pharmacokinetic targets may therefore represent genes that code for transport proteins, metabolic

**The author gratefully acknowledges the original contributions of Drs. Mark W. Linder and Bonny Lewis Bukaveckas on which portions of this chapter are based.*

enzymes, or drug-binding proteins. Pharmacokinetics is often evaluated by measuring drugs and/or drug metabolites in biological fluids that are collected at specific times relative to the time of last drug administration. From these results, time-versus-concentration curves can be generated, and parameters such as clearance calculated.

Pharmacodynamics deals with responses to drugs and describes the processes that mediate those responses, whether the response is desirable or undesirable. Pharmacodynamic targets may represent genes that code for enzymes, receptors, ion channels, or other signaling proteins. Response to a drug may or may not show a relationship to drug dose or to the concentration of drug in blood. Pharmacodynamics can be measured for some drugs based on biomarkers [e.g., the international normalized ratio (INR) for warfarin] or based on clinical measurements [e.g., blood pressure, for antihypertensive drugs].

Pharmacogenetic testing provides information about the predicted pharmacokinetics and pharmacodynamics of an individual patient that otherwise are not readily measured. Testing can be used to predict unique characteristics of drug handling and drug response that could minimize the traditional trial and error style of dose optimization, particularly when used in combination with biochemical and clinical (measurable) factors. See Chapter 34 of this book for further discussion of pharmacokinetic and pharmacodynamic processes.

The first recognized pharmacogenetic targets largely described variation in drug metabolism. The early focus on drug metabolism reflects the fact that measurements of drug and drug metabolite concentrations in biological fluids predate detailed understanding of genetics and development of most biomarkers that describe pharmacodynamics. Distinct metabolic phenotypes were characterized and were subsequently found to cluster within families. For example, the metabolic phenotype for *N*-acetyltransferase (NAT), attributed to an enzyme originally called *isoniazid transacetylase,* was recognized in the 1950s with isoniazid (L-isonicotinyl hydrazide), a drug used to treat tuberculosis.[11,199] Population studies revealed a bimodal distribution in plasma and urine concentrations of the *N*-acetylated isoniazid metabolite. The concentration of the parent drug was highly correlated with the prevalence of toxic symptoms, including hepatotoxicity and a painful and progressive peripheral neuropathy that affected up to one third of Caucasian and African American patients. From this initial work, patients were phenotypically described as "fast acetylators" or "slow acetylators." Slow acetylators excrete large amounts of the parent drug relative to the acetylated metabolite when compared with fast acetylators. Family studies identified a strong genetic linkage of this phenotype and suggested that the phenotype was inherited as an autosomal recessive trait. However, details of the genetics, which are described later in this chapter, were not elucidated until several years later.

Clinical use of pharmacogenetic testing requires an understanding of how genetic variation of a metabolic enzyme affects drug response or drug dosing. Drug metabolism can effectively inactivate a substrate or increase water solubility of the substrate to promote its excretion. Conversely, metabolism can activate a substrate or prodrug (e.g., codeine, clopidogrel, tamoxifen). Less commonly, metabolism serves to extend the elimination half-life of a pharmacologically active or potentially toxic metabolite.[131]

Reactions catalyzed by metabolic enzymes are often categorized as Phase I and Phase II. Phase I reactions convert the parent compound into a more polar metabolite by introducing or removing a single functional group. Examples include (1) oxidation, (2) reduction, and (3) hydrolysis. The metabolites may or may not be pharmacologically or toxicologically active. Most Phase I reactions are oxidative and are mediated by cytochrome P450 isoenzymes (CYPs). Genetic variants of CYPs have been associated with changes in enzyme activity, stability, and/or substrate affinity that can lead to clinically significant phenotypes. In addition to genetic variability, many CYP isoenzymes are susceptible to dramatic differences in expression (>1000-fold) and drug-drug interactions that can change the phenotype from that which might be predicted based on genetics alone. This concept is known as *phenocopying.* A drug that can inhibit its own metabolism is known to exhibit autophenocopying.[134,144]

A relatively common fate of Phase I metabolic products is additional modification, such as through Phase II reactions. Phase II reactions may also occur independent of, or before, Phase I reactions. Phase II enzymes are generally transferases that conjugate drugs with acetyl, glucuronyl, amino acyl, or sulfate groups. Many Phase II enzymes exhibit genetic variation that has been associated with clinically significant phenotypical differences caused by changes in enzyme activity, stability, and/or substrate affinity.[187] For example, thiopurine *S*-methyl transferase *(*TPMT*),* *N*-acetyltransferase *(*NAT1, NAT2*),* and uridine diphosphate glucuronosyl transferase (UGT1A1) exhibit genetic variation and are discussed later in this chapter primarily relative to metabolism of drugs used in oncology and infectious disease.

Through genome-wide association studies and improved definition of response phenotypes, pharmacogenetic targets associated with several aspects of pharmacokinetics and pharmacodynamics are frequently proposed and described in the peer-reviewed literature, considerably increasing the breadth and complexity of drug-gene relationships. Thus far, most drug-gene associations are not sufficiently well studied clinically to be used to direct therapy. Therefore, it is not now practical, medically indicated, nor cost-effective to provide pharmacogenetic profiles for every drug. Based on successful applications to date, pharmacogenetic targets are most likely to be successful clinically when they:

1. Define a major pathway for metabolism of, or response to, a specific drug, thereby providing clear guidance for drug selection or avoidance.
2. Are associated with a clinically significant and actionable effect on the relationship between dose and plasma drug concentration or a measurable biomarker.
3. Predict dosing for a drug that has a narrow therapeutic index or limited temporal opportunity to exert efficacy, or

TABLE 43-1 Overview of Drugs for Which Revised Labeling Includes Pharmacogenetic Information

Drug	Relevant Area of Medicine	Year FDA Approved Revised Labeling	Approximate Rate of ADRs or Resistance	Gene or Allele	Other Drugs With Pharmacogenetic Relationship to Gene or Allele
6-Mercaptopurine	Oncology	2003	1 to 10% ADRs	*TPMT*	Azathioprine, 6-thioguanine
Irinotecan	Oncology	2004	30 to 40% ADRs	*UGT1A1*	Topotecan, nilotinib, protease inhibitors
Tamoxifen	Oncology	Proposed 2006	30% resistant	*CYP2D6*	Codeine
5-Fluorouracil	Oncology	2003	20% ADRs	*DYPD*	Capecitabine
Atomoxetine	Psychiatry	2004	5 to 10% ADRs	*CYP2D6*	Antidepressants, amphetamine
Carbamazepine	Psychiatry, Neurology	2007	10% ADRs	*HLA-B*1502*	Phenytoin, lamotrigine
Abacavir	Infectious Disease	2007	5 to 8% ADRs	*HLA-B*5701*	
Isoniazid	Infectious Disease	Not Available		*NAT*	Rifampin, hydralazine
Warfarin	Cardiology	2007	5 to 40% ADRs	*CYP2C9, VKORC1*	
Clopidogrel	Cardiology	2009	30% resistant	*CYP2C19*	Voriconazole, omeprazole, diazepam, nelfinavir, antidepressants, tamoxifen

ADRs, Adverse drug reactions.

for a drug that requires a long period of time to establish efficacy.

The utility of pharmacogenetic testing may be compromised when (1) no alternative drugs are available for an indication, (2) incorporation of pharmacogenetic testing does not clearly improve patient care, (3) less sophisticated or less expensive tools or tests are sufficient for making prescribing decisions, or (4) accommodations to specific dose or dosing strategies are not available. Some specific gene-drug relationships for which the labeling has been revised to include pharmacogenetic information are shown in Table 43-1. Although these gene-drug examples apply primarily to oncology, psychiatry, neurology, infectious disease, and cardiology, other areas of medicine are likely to benefit from pharmacogenetic testing as well. The examples are intended to provide a foundation of concepts that the reader can translate to future applications as they emerge and develop.

APPROACHES TO PHARMACOGENETIC TESTING

Pharmacogenetic testing can predict that a patient is likely to (1) fail therapy, (2) suffer an ADR, or (3) exhibit altered pharmacokinetics. This knowledge then assists in selection of drug, drug dosage, and dosing frequency, thus promoting successful therapy and avoiding undesirable outcomes such as an ADR. Pharmacogenetic testing is designed to detect a phenotype (phenotyping) or a genetic sequence that has been associated with a phenotype (genotyping). Examples of both approaches (phenotyping and genotyping) will be provided; however, more emphasis is given to the genetic approaches, which are currently more common. Neither phenotyping nor genotyping is intended to replace the need for clinical assessments of drug response, or to replace the need for therapeutic drug monitoring. Several considerations of these two testing approaches are summarized in Table 43-2 and are described in greater detail later.

Phenotyping defines the "state" rather than the "trait." Phenotyping has been applied most frequently to detecting pharmacokinetic variation, particularly in drug metabolism and clearance. Measurement of the drug metabolism phenotype, under highly controlled circumstances, can provide extremely meaningful information.

A common approach to phenotyping is to administer a probe drug, that is, a drug that is known to be metabolized by the same enzyme or pathway as the intended therapeutic drug. Biological fluid, typically urine and/or blood, is collected at specific times after administration of the probe drug. The concentrations of parent drug and one or more drug metabolites are then determined. The ratios of parent to metabolite or of two metabolite concentrations (e.g., metabolite A/metabolite B) are compared, and a metabolic ratio is calculated. The phenotype associated with *CYP2D6* has historically been determined through the use of probe drugs. For this particular enzyme, a continuum of metabolic phenotypes is described, varying from poor (little to no activity) to intermediate, to extensive (normal), to ultra-rapid. Urine collected at a specified time after administration of the probe drug (e.g., 8 hours) is analyzed for the parent drug and a metabolite that is generated primarily via CYP2D6. Example

TABLE 43-2 Comparing Phenotype and Genotype Testing Strategies

	Phenotype	Genotype
Represents	"State" represents current response; may not represent inheritance	"Trait" represents inheritance; may not be consistent with the phenotype
Sensitive to gene expression	Yes	No
Sensitive to protein function	Yes	No
Requires collection of multiple specimens	Commonly	No
Requires administration of a probe drug	Possibly	No
Other limitations	• Specimen instability for enzyme or other protein of interest may lead to inaccurate results • May have to be repeated for patients who recently received a blood transfusion • May be influenced by comedications (drug-drug interactions)	• May not include all clinically relevant genes and/or alleles • Genotype-phenotype relationship (interpretation) may not be known

parent-metabolite pairs used to calculate a metabolic ratio for phenotyping of CYP2D6 include dextromethorphan/dextrorphan, debrisoquine/4-hydroxydebrisoquine, sparteine/dehydrosparteine, and nortriptyline/10-hydroxynortriptyline.[38] An example of phenotype results generated with the probe drug debrisoquine is shown in Figure 43-1. A "cutoff" metabolic ratio is used to distinguish a normal, extensive metabolizer (EM) from a poor metabolizer (PM). Although the metabolic ratio is theoretically a good indicator of enzyme expression and function at the time of the test, marked variation in metabolic ratio has been demonstrated among the phenotypes.[20] Similar variation in metabolic ratio is commonly observed with other probe drugs as well.

Another example of a probe drug is caffeine, which is used to determine acetylator phenotype mediated by NAT.[21,72,121] To determine the NAT phenotype with this probe drug, the patient is given 200 mg caffeine after an overnight fast. Urine is collected 4 and 5 hours later. The 4-hour specimen is discarded, and the 5-hour specimen is analyzed for caffeine metabolites 5-acetylamino-6-formylamino-3-methyluracil (AFMU) and 1-methylxanthine (1X). See Figure 43-2 for sample data. Cutoffs for acetylator phenotypes are based on the ratio of AFMU/1X. Considering a bimodal distribution of acetylators, a ratio of less than 0.66 is used to define slow acetylators. Because a trimodal distribution has now been described and may be of interest, a ratio higher than 3.0 could define "ultrarapid" acetylators; a ratio between 0.66 and 3.0 would define an "intermediate" acetylator phenotype.[57]

Phenotype testing based on probe drug administration requires that the probe compound be (1) safe, (2) easy to administer in the target population, (3) relatively inexpensive, and (4) it must exhibit pharmacokinetics that support convenient collection of specimens from the patient. The need to administer a probe drug and to collect urine over several hours has always limited the practical utility of patient phenotyping with a probe drug. Even with the logistics managed, phenotyping may be difficult to accomplish because of limited availability and appreciable costs of laboratory testing. Phenotype results based on a probe drug may be difficult to interpret as a result of potentially unrecognized or unrecorded confounding factors, such as diet, comedications, consumption of alcohol or over-the-counter medications, disease status, gender, and age.

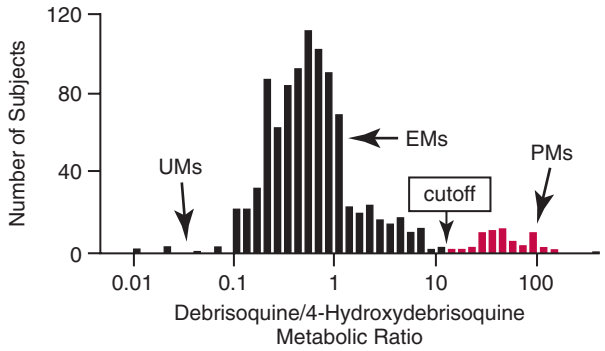

Figure 43-1 Histogram of the "debrisoquine metabolic ratio" in a typical Caucasian population. Metabolic ratios were determined from the concentrations of debrisoquine and 4-hydroxydebrisoquine (metabolite) in a urine specimen collected 8 hours after a 10 mg dose of debrisoquine was given. The data demonstrate a clear distinction between poor metabolizer (PM), extensive metabolizer (EM), and ultra-rapid metabolizer (UM) phenotypes. *(From Caldwell J. Pharmacogenetics and individual variation in the range of amino acid adequacy: the biological aspects. J Nutr 2004;134:1600S-4S; discussion 30S-2S, 67S-72S. Reproduced by permission from the American Society for Nutritional Sciences.)*

Phenotyping is also performed in vitro by measuring the activity of a particular metabolic enzyme using peripheral blood cells as a surrogate to metabolism by the whole patient. For example, a common method of phenotyping TPMT activity is to isolate red blood cells, lyse the cells, and incubate

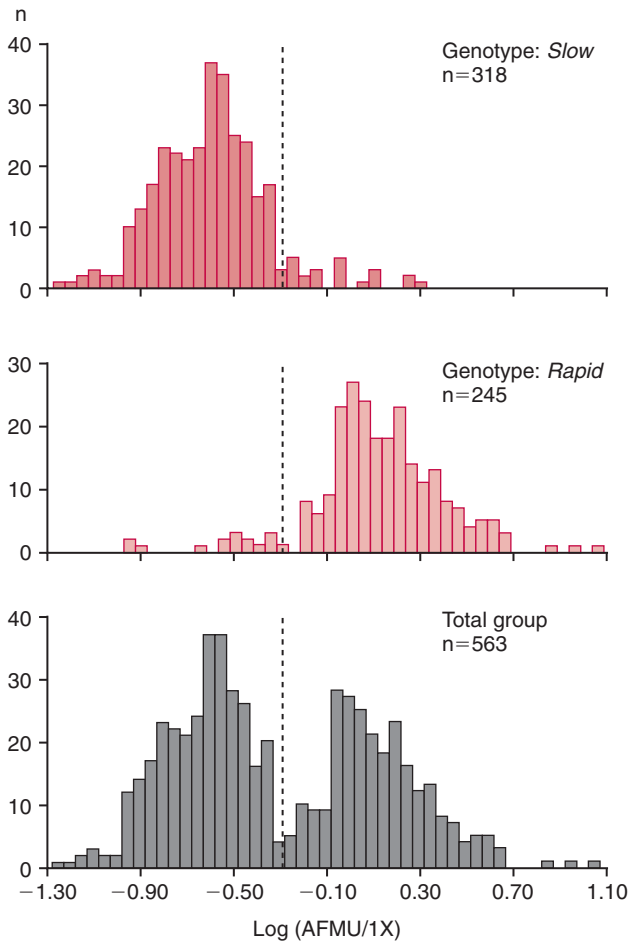

Figure 43-2 Histogram of *N*-acetyltransferase (NAT2) phenotypical activities as obtained by the caffeine test: 5 hour urine collection obtained after administration of caffeine and analyzed for caffeine metabolite concentrations. Values represent the logarithmically transformed ratio of metabolites 5-acetylamino-6-formylamino-3-methyl-uracil (AFMU) and 1-methylxanthine (1X). From the distinct bimodal distribution, an antimode of log(0.50) = –0.30 was obtained *(dotted line).* *(From Cascorbi I, Drakoulis N, Brockmoller J, Maurer A, Sperling K, Roots I. Arylamine N-acetyltransferase (NAT2) mutations and their allelic linkage in unrelated Caucasian individuals: correlation with phenotypical activity. Am J Hum Genet 1995;57:581-92. Reproduced by permission from the University of Chicago Press.)*

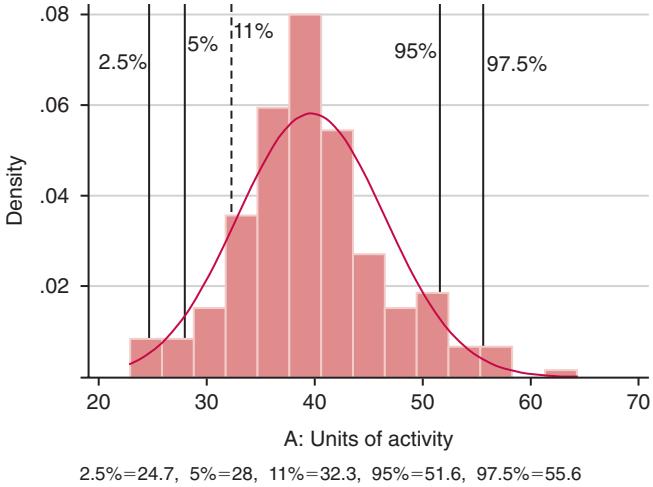

Figure 43-3 Histogram of thiopurine *S*-methyltransferase (TPMT) phenotypical activity obtained with blood samples from 199 healthy Caucasian adult volunteers. Blood lysate was incubated with *S*-adenosyl-L-methionine and 6-mercaptopurine at 37 °C for 60 minutes. The reaction was stopped, and concentrations of 6-methyl-mercaptopurine were determined by ultraviolet high-performance liquid chromatography (HPLC-UV). Data indicate that the activity of TPMT is variable, and that the definition of enzyme impairment is challenging based on phenotype studies alone. Percentiles could be used to phenotype patients, with the 11% mark (corresponding to published incidence of TPMT impairment in Caucasians) used as a cutoff to identify patients who might require a dose adjustment.

the lysate with substrate 6-mercaptopurine (6-MP) and a methyl donor such as *S*-adenosyl-L-methionine for 1.5 hours at 37 °C.[74,201] The concentration of methylated product, 6-methyl mercaptopurine (6-MMP), is measured and compared with a reference interval. An example of TPMT phenotype data generated in a healthy adult population is shown in Figure 43-3. Reduced or deficient TPMT activity is detected when low 6-MMP concentrations are measured. The clinical significance of low TPMT activity is high risk of myelosuppression due to an accumulation of 6-thioguanines (6-TGNs) when patients are treated with 6-MP or azathioprine (AZA), a related prodrug that is metabolized to 6-MP. Patients with impaired TPMT activity require lower doses of these drugs and close clinical monitoring to minimize the risk of toxicity and ensure efficacy of the drug.[7,36] This application is discussed in greater detail in the following section on TPMT genetics. Other examples of enzymes that have been successfully evaluated for in vitro phenotypes include (1) pseudocholinesterase, for detecting individuals with susceptibility to prolonged apnea when treated with succinylcholine or other similar medications; (2) glucose-6-phosphate dehydrogenase (G6PD), for detecting susceptibility to hemolysis in response to drugs such as primaquine, sulfonamides, chloramphenicol, and vitamin K; and (3) NAT, for detecting poor metabolism of drugs such as sulfonamides, isoniazid, and clonazepam.[33,50] With each, a substrate for the enzyme is incubated with the isolated cells under conditions (temperature, time, cofactors, pH, etc.) optimal for the enzyme of interest. The reaction is stopped and the product is measured with an analytical technique such as spectrophotometry or liquid chromatography with ultraviolet or mass spectrometric detection.

The in vitro phenotype approach has several limitations, for example, data are not valid if the patient from whom cells are collected is receiving the same drug used by the laboratory as a substrate in the phenotyping assay for that drug, at the time of specimen collection. Factors such as (1) recent blood transfusions, (2) hormonal fluctuations, (3) handling of the blood before and after isolation of cells, and (4) inadequate

environmental control during the assay also introduce variability.[81] In addition, many enzymes are expressed in variable quantities with age, leading to the need for age- or population-specific reference intervals to accurately interpret results. For example, a study of 60 full-term newborns demonstrated that TPMT activity was higher in the newborns than in race-matched healthy adults, but displayed the same tri-modal distribution observed in adults. This observation may lead to inappropriate interpretation of newborn phenotype results, if results are compared with an adult reference interval.[118] Finally, unrecognized or unrecorded confounding factors, such as diet, comedications, and consumption of alcohol or over-the-counter medications, may compromise interpretation of in vitro phenotype results as well.[165]

The second major approach to detecting and evaluating pharmacogenetic variability is through genotyping. Genetic testing may be useful for predicting specific pharmacokinetic and/or pharmacodynamic variables that are well characterized. The value of genotyping depends very much on a strong genotype-phenotype correlation. In the simplest scenario, a genotype result will account for 100% of the anticipated phenotype. Completely definitive genotype-phenotype relationships (100% certainty) are rare—a fact that creates controversy surrounding the value of a single-gene association. It is estimated, for example, that genotyping of *TPMT* can reliably predict the phenotype 80 to 90% of the time.[151] However, the complexity of the metabolism surrounding thiopurine drugs (see TPMT discussion later) raises questions regarding other potentially important genes that contribute to the overall pharmacokinetics of these drugs. For example, variants in three other genes have recently been demonstrated to influence metabolism of azathioprine, and a polymorphism in the inosine trisphosphatase gene *(ITPA)* appears to be responsible for ADRs experienced by some patients treated with AZA.[168,193]

When a good genotype-phenotype relationship exists, genotyping assays have advantages over phenotyping because they (1) can be less expensive than phenotyping, (2) are more reproducible between laboratories, and (3) are not subject to intraindividual variability caused by a specific set of clinical conditions or expected biological variations that complicate phenotyping assays. Genotyping assays are also less invasive and less time-consuming for the patient. Thus, the single sample required for genotyping may be collected anytime, anywhere. Saliva-based testing, which generates an adequate quantity and quality of DNA for most genetic testing, would make at-home collections particularly convenient.[66]

Despite advantages of genotyping over phenotyping, genotyping has limitations that must be recognized. For example, some of the assays using target amplification are prone to false negatives because they rely on the presence or absence of a polymerase chain reaction (PCR) product. The specific allelic variants detected by a given analytical method vary, and, short of sequencing the entire gene, currently available genotyping techniques cannot detect all possible variants. Because of the large amount of variation in many genes, suites of variants are screened, potentially missing some important genetic variations because the patient possesses a rare or novel polymorphism that is not detected by the screen. Further, polymorphisms with unknown clinical significance may be identified by some techniques. Extreme care must be taken to ensure that these data are not misinterpreted, and that the laboratory test employed provides sufficient coverage of genetic variants common to the ethnic population of interest. Another disadvantage of genotyping is that it may not accurately predict function of the expressed protein. Using *CYP2D6* as an example, it has been shown that patients of a single common genotype have metabolic ratios (with probe drug dextromethorphan or debrisoquine) that span a 1000- to 10,000-fold range. The exact reason for this broad range is unknown, but it is probably related to (1) individual differences in expression of the *CYP2D6* gene, (2) inherent alternative metabolic pathways, (3) significant interlaboratory and intraindividual variability in phenotype measurements, and (4) possible combinations of other minor undetected genetic polymorphisms in the *CYP2D6* gene. Finally, specific interactions between the target enzyme or protein and other drugs, chemicals, or some foods can change the phenotype, such as by converting a "normal" or extensive metabolizer phenotype to a poor metabolizer phenotype. This type of phenocopying is observed with grapefruit juice, which has been shown to inhibit CYP3A4, and many antidepressant medications (e.g., fluoxetine), which are known to act as both substrates and inhibitors of CYP2D6.[63,135,144] Such drug and food interactions can have extremely important consequences for the phenotype and can be difficult to both recognize and monitor.

CLINICAL APPLICATION OF PHARMACOGENETIC TESTING

Pharmacogenetic testing is clinically useful only when information is sufficient to allow interpretation of the results. This information must be derived from in vivo human studies. Many examples of this type of information can be found in the peer-reviewed literature. One limitation of existing literature, however, is that most data are based on retrospective studies, and there is no single printed source in which all of this information has been collated. The Pharmacogenetics and Pharmacogenomics Knowledge Base is a publicly available Internet research tool developed by Stanford University with funding from the National Institutes of Health (NIH) and is part of the NIH Pharmacogenetics Research Network (PGRN), a nationwide collaborative research consortium. Its aim is to aid researchers in understanding how genetic variation among individuals contributes to differences in reactions to drugs. This regularly updated database is an excellent source of genetic and clinical information derived from research studies at various medical centers in the PGRN (www.pharmgkb.org, accessed June 28, 2011). Several of the figures illustrating pharmacogenetically important drug metabolism pathways are found in this chapter, with permission from PharmGKB and Stanford University.[91]

Many ongoing clinical trials designed to study the efficacy and toxicity of new pharmaceutical products or new indications for previously developed pharmaceuticals have employed pharmacogenetic testing, or have incorporated pharmacogenetic testing into the study protocol (for a current listing, see www.clinicaltrials.gov, accessed June 28, 2011). Thus it is anticipated that pharmacogenetic guidelines, and possibly new companion diagnostics that would be simultaneously released to market with the pharmaceutical, will be available in the coming years. In addition, drugs that were previously removed from development because of ADRs may be reconsidered if a genetic test can be demonstrated to identify individuals at high risk for ADRs, that would then avoid use of that drug. A discussion of pharmacogenetic testing of clinical relevance to the areas of oncology, psychiatry and neurology, cardiology, and infectious disease is provided in the next section. For each of the major genes discussed in this chapter, Table 43-1 provides a list of common drugs for which pharmacogenetic associations with these genes have been made and drug labels revised. Because many other drug-gene combinations are recognized that may lead to additional drug label revisions, the discussion provided here is in no way comprehensive. In addition, many of the specific genes discussed later have applications to other areas of medicine, some of which are mentioned briefly. The purpose of the discussion in this chapter is to provide examples against which additional pharmacogenetic tests and applications can be compared, critiqued, and understood, and to guide involvement of the clinical laboratorian in this emerging new field of laboratory medicine.

Pharmacogenetics in Oncology

Oncology is an area of medicine in which correct or incorrect choice of therapy can lead to a life or death situation. The temporal opportunity for a therapy to exert effect is narrow, the incidence of ADRs with many available drugs is high, and the overall rates of efficacy are low. It is estimated that as many as 40% of oncology patients receive the wrong drug.[27,198] Many of the tests routinely used to characterize tumor tissue are based on detecting overexpression of specific proteins (e.g., HER2/neu) or the presence of somatic gene variants in a tumor (e.g., *K-ras*). Tumor profiling tests, which evaluate the expression of many genes (e.g., Oncotype DX), can be used to assess the prognosis of certain cancers. Results of these tests certainly guide therapeutic decisions but are not discussed here. The germline pharmacogenetics that is the focus of this chapter is complementary to these tumor-based tests. Some pharmacogenetic tests that predict metabolism are potentially applicable to cancer chemotherapy because metabolic enzymes are required to activate many drugs used in oncology (e.g., tamoxifen, cyclophosphamide). Metabolic enzymes are also required to inactivate some drugs commonly used in oncology (e.g., irinotecan, 6-MP, 5-fluorouracil). Impairment or altered expression of a key metabolic enzyme could make the difference between therapeutic success and ADRs.[70] In theory, optimal dose could be determined for these and all other drugs, based on understanding and coordinated application of pretherapeutic pharmacogenetics with post-therapeutic pharmacokinetic and pharmacodynamic monitoring. Table 43-3 lists examples of genes that are potentially important in selecting and dosing cancer therapies.

Pharmacogenetics has also been applied to risk stratification; this is particularly relevant for cancers that could be triggered by environmental or dietary exposure to a wide variety of xenobiotics.[15,164] Also shown in Table 43-3 are some of the genetic targets and known substrates that have been studied with regard to risk of various cancers. Genes that encode drug-metabolizing enzymes are of greatest interest for this application because it is through these enzymes that xenobiotics become activated or inactivated. For example, several substrates of NAT1 and NAT2 are potentially cancer-causing. In addition to NAT1 and NAT2, the glutathione *S*-transferases (GSTs) are important contributors in establishing the risk of cancer triggered by xenobiotic exposures. At least 16 GSTs have been identified, and these are divided into eight classes. The key members are listed in Table 43-3: alpha (GSTA1, GSTA2), mu (GSTM1), pi (GSTP1) and theta (GSTT1). Additional classes are called kappa, sigma, zeta, and omega. The *GSTM1*-deficient trait has, for example, been associated with higher risks of lung and bladder cancer, although the specific trigger or substrate is not known.[60] With additional study and validation of these and other genetic markers, testing to identify individuals with high susceptibility to chemicals may become important, particularly in high-risk occupational settings such as agriculture and manufacturing.

Three thoroughly-characterized gene-drug associations used to direct therapy in oncology are discussed in detail later in this chapter: *TPMT* for 6-mercaptopurine (6-MP), *UGT1A1* for irinotecan, and *CYP2D6* for tamoxifen.

Pharmacogenetics in Psychiatry and Neurology

Pharmacogenetics testing has shown promise in selecting or optimizing drug therapy for depression, schizophrenia, pain, and addictive behaviors. Many drugs used in psychiatry and neurology have low (<50%) efficacy rates, high interindividual variation in pharmacokinetics, and life-threatening ADRs. In addition, the response to drugs used for depression and schizophrenia cannot be adequately assessed for weeks to months after initiation. Standard-of-care practices today are based on the traditional trial-and-error approach. Pharmacogenetic tests could contribute to drug and dose selection by evaluating patient candidacy for specific drugs, and by allowing pretherapeutic identification of individual differences in pharmacokinetics or pharmacodynamics, particularly for drugs with a narrow therapeutic index.[28,112] It is no surprise that initial applications of pharmacogenetics in these clinical areas were related to thoroughly-characterized metabolic phenotypes. Of particular interest have been drug substrates of CYP2D6, CYP2C19, and CYP2C9. Dosing guidelines for many antidepressant and antipsychotic medications based on predicted metabolic phenotypes have been published.[88,89] A more conservative recommended strategy is to avoid drugs

TABLE 43-3 Pharmacogenetic Targets Potentially Important to Risk of Cancer, Selection of Therapeutic Cancer Drugs, and Optimization of Drug Dose

Gene or Protein Target	Chemotherapeutic Drug	Carcinogen Substrates
CD117 (C-KIT)	Imatinib	
CYP2B6	Cyclophosphamide, ifosfamide	
CYP2C9	Cyclophosphamide, ifosfamide	
CYP2C19	Tamoxifen	
CYP2D6	Tamoxifen	
CYP3A4	Cyclophosphamide, etoposide Ifosfamide, teniposide, vindesine, vinblastine, vincristine	Aflatoxin B1 6-Aminochrysene
DPYD	5-Fluorouracil, capecitabine	
EGFR	Erlotinib, cetuximab, gefitinib	
GSTA1, GSTA2	Cyclophosphamide	Cumene hydroperoxides
GSTM1		Aflatoxin B1 epoxides Benzo(a)pyrene 4,5 oxide Trans-stilbene oxide
GSTP1	Thiotepa, cyclophosphamide, ethacrynic acid	4-Nitrochinolone 1-oxide
GSTT1		Ethylene oxide, methyl chloride, dichloromethane
Her2/neu	Trastuzumab, lapatinib	
KRAS	Cetuximab, panitumumab	
MTHFR	Methotrexate, 5-fluorouracil	
NAT2	Amonafide	*p*-Aminobenzoic acid, 4-aminobiphenyl, 2-aminofluorene, *p*-aminosalicylic acid, benzidine, toluidine
Philadelphia chromosome	Busulfan, dasatinib, nilotinib	
PML/RAR (alpha) fusion	Tretinoin, arsenic oxide	
TPMT	6-Mercaptopurine, azathioprine, 6-thioguanine	
TYMS	5-Fluorouracil, capecitabine	
UGT1A1	Irinotecan, nilotinib	
UGT2B15	Tamoxifen	

that are associated with extreme phenotypes (e.g., UM, PM) or high risk of ADRs, unless alternative therapies are not available.[29]

Risk of ADRs may be associated with inappropriate drug concentrations, as a result of impaired metabolism, or may be unrelated to concentration and dose. For example, severe cutaneous reaction syndromes (SCARS), such as Stevens-Johnson syndrome and toxic epidermal necrolysis, lead to life-threatening and extremely painful rashes. Approximately one third of all drug-induced SCARS are associated with the antiepileptic drug carbamazepine. The occurrence of SCARS in patients treated with carbamazepine has been associated with a specific allele of human leukocyte antigen (HLA), *HLA-B*1502*.[207] This allele occurs most commonly in patients of Asian ancestry. In the Han Chinese population, the odds ratio for carbamazepine-induced SCARS is 2504 when the *HLA-B*1502* allele is present. Associations of this allele with SCARS induced by phenytoin and lamotrigine have also been reported.[111] Detection of HLA alleles associated with drug-induced SCARS before therapy is initiated could allow drug avoidance and substantially reduced risk of the associated ADR.

Resistance to drugs used in psychiatry and neurology is common and is not necessarily related to drug concentration or dose of drug. Genes related to pharmacodynamics of these drugs primarily code for various components within the neurotransmitter systems on which the drugs act. Genes associated with the serotoninergic (e.g., *SLC6A4*), noradrenergic *(SLC6A2)*, and dopaminergic (e.g., *DRD2*) neurotransmitter systems are best characterized. Serotonin-receptor variants have been correlated with response to antidepressants such as escitalopram, fluoxetine, and paroxetine. In addition, the S allele of the serotonin transporter gene *(SLC6A4),* also known as the short form of the long/short polymorphism, predicts poor response and increased risk of ADRs with fluvoxamine, mirtazapine, and paroxetine. Variants in the glucocorticoid receptor gene *(NR3C1)* have also been proposed to predict response to nortriptyline and escitalopram. Time to response to the antipsychotics risperidone and olanzapine has been associated with variants in the promoter region of

the dopamine D2 receptor gene *(DRD2)*. Genes associated with the biosynthesis and disposition of neurotransmitters *(MAOA*, *TPH)* may be important as well.[100,129,159,189]

Optimal dosing of the anticonvulsant drug phenytoin can be predicted by testing for variation in *CYP2C9, CYP2C19,* and *MDR1;* the latter encodes the p-glycoprotein. CYP2C9 is estimated to contribute to 90% of phenytoin metabolism, and CYP2C19 is thought to contribute to 10% of phenytoin metabolism, in persons with EM phenotypes for both enzymes. In patients who are CYP2C9 PM (poor metabolizers), CYP2C19 is the primary route of phenytoin elimination, and hence the importance of testing for CYP2C19 increases.[46,84,110] However, pharmacogenetics has not been helpful in elucidating resistance mechanisms in epilepsy.[82,166]

Three thoroughly-characterized gene-drug associations used to direct therapy in psychiatry and neurology are discussed in detail here: *CYP2D6* and *CYP2C19* for antidepressants, *CYP2D6* for codeine, and *HLA-B*1501* for carbamazepine.

Pharmacogenetics in Cardiology

Clinical management of acute cardiovascular events, such as myocardial infarction, pulmonary embolism, and a major bleed, cannot wait for genetic testing results to guide therapeutic decisions, at least based on the technologies and methods for genetic testing that are used today. However, preventive cardiovascular medicines are among the most widely prescribed of all drugs. Prominent examples include (1) prophylactic warfarin to prevent thromboses, (2) statins and antiplatelet therapies to minimize the risk of future coronary events, and (3) therapies used to treat hypertension. Each provides opportunities for pharmacogenetics to improve therapy in cardiology.

Procainamide is a classic antiarrhythmic, the metabolism of which is primarily mediated by *N*-acetylation. The rate of acetylation is genetically determined, based on NAT, and shows a bimodal (possibly trimodal) distribution of slow and fast acetylators that correlates to genetic variants in *NAT1* or *NAT2*. The *N*-acetylated metabolite, known commonly as NAPA, is routinely monitored with parent drug to optimize dose. Many CYP substrates have cardiovascular applications as well. For example, clopidogrel is a commonly prescribed CYP2C19 substrate. Clopidogrel is a prodrug and, much like tamoxifen and codeine, will exert little to no benefit unless metabolically activated. Indeed, approximately one third of patients are classified as resistant to clopidogrel, in part because of this pharmacokinetic variation. Pharmacodynamic variability can also explain drug resistance and toxicity. For example, drug transporters that facilitate uptake and elimination of statins may have pharmacogenetic implications. Variants of the OATP1B1, encoded by *SLCO1B1,* and the ABCB1, encoded by the *ABCB1,* are associated with pharmacokinetic variability and statin-induced myopathy.[103,138] In the PROSPER study, Iakoubova and colleagues[73] have reported that elderly carriers of the *KIF6 719Arg* variant with prior vascular disease receive significant benefit from pravastatin therapy; however, no benefit was observed in noncarriers with prior disease or in those without prior disease (carriers or noncarriers).

Ideally, pharmacogenetic testing predicts key aspects of pharmacokinetic and pharmacodynamic variability to guide therapeutic decisions. Combining testing for a key pharmacokinetic gene and a key pharmacodynamic gene is best exemplified by the association of warfarin dose with variants in *CYP2C9,* which is responsible for inactivation of warfarin, and *VKORC1,* the gene that codes for the primary target for the anticoagulant action of warfarin. Another gene, *CYP4F2,* is associated with increased dose requirements of warfarin.

Three thoroughly-characterized gene-drug associations used to direct therapy in cardiology are discussed in detail here: *CYP2C19* for clopidogrel, *CYP2C9* for warfarin, and *VKORC1* for warfarin.

Pharmacogenetics in Infectious Disease

Pharmacogenomics has been applied to infectious disease, primarily to understand organism susceptibility, to study comparative genomics, and to target drug development efforts. This growing area of research will be complementary to host pharmacogenetics, the focus of this chapter. In patients treated with interferon, overlap in the relationship between organism and host has been exemplified by the association of clearance of hepatitis C virus and variants of the gene for interleukin 28B *(IL28B)*.[44]

Regarding more traditional host pharmacogenetics of infectious disease, several targets related to pharmacokinetics are substrates of NAT: isoniazid, dapsone, and the sulfonamides. Although pharmacogenetic testing for *NAT1* and *NAT2* is not routine, variation in these genes has the potential to influence metabolism and steady-state concentrations of these drugs. Concentrations of proguanil are affected by variant *CYP2C19,* and *CYP2C8* is associated with risk of toxicity from amodiaquine. Other pharmacogenetic associations include (1) *CYP2B6* alleles and risk of central nervous system ADRs from efavirenz,[19] (2) *UGT1A* gene variants and severe hyperbilirubinemia associated with protease inhibitors,[95] and (3) variants of the CYP3A family and rates of clarithromycin clearance.[140]

Pharmacodynamic targets that are unrelated to the desirable response of the drug represent a unique opportunity for pharmacogenetic testing. An example of a very successful pharmacogenetic test for predicting risk of ADRs is detection of *HLA-B*5701,* which predicts abacavir-induced hypersensitivity reaction. Genotyping for *HLA-B*5701* before an abacavir-containing regimen is prescribed was recommended in the 2008 guidelines on the use of antiretroviral agents in HIV-1–infected adults and adolescents, which were developed through the Office of AIDS Research Advisory Council and have now become routine clinical practice.[109,147,188]

Three thoroughly-characterized gene-drug associations used to direct infectious disease therapies are discussed in detail here: *CYP2C19* for omeprazole and proguanil, *HLA-B*5701* for abacavir, and *UGT1A1* for protease inhibitors.

The following sections of this chapter provide information on selected key pharmacogenetic targets, the relationship

between genotype and phenotype for each, and clinical applications of testing.

PHASE I METABOLIC ENZYMES: CYTOCHROME P450 ISOZYMES

As stated earlier, most Phase I reactions are oxidative and are mediated by cytochrome P450 enzymes (CYPs). CYPs are heme-containing enzymes that are synthesized from a superfamily of CYP genes and are classified into families, and further into subfamilies, based on amino acid homology. The major CYPs that are believed to contribute to drug metabolism are CYP1A2, CYP2B6, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and the CYP3A family. Examples of drug substrates, inhibitors, and inducers are shown in Table 43-4. Although the pharmacogenetics of only CYP2C9, CYP2C19, and CYP2D6 are specifically discussed here, all the CYP families exhibit genetic variation that could influence optimal prescribing practices for drug substrates.[187] Alleles for all CYP genes are described according to international consensus.[77] In brief, the *1 ("star 1") allele is the normal (EM) allele that codes for a protein predicted to function with full enzymatic activity and to be expressed in typical quantities. Often *1 describes a scenario wherein no variant alleles are detected. Therefore, the true accuracy of a *1 allele designation is dependent on whether the assay used to make that call is comprehensive. All alleles are described with a star followed by a number, and possibly a letter to describe an allele subtype. Subtypes have not been shown to influence the phenotype, and identification of them probably is not important clinically but could be important for haplotype assignment or to support research studies. Numerical assignments of other alleles are based largely on chronology of identification, wherein alleles identified earliest in time have the lowest numbers. Some alleles are associated with normal protein function and expression, others with impaired function, altered expression, or no predicted enzyme activity at all (e.g., truncated protein, complete gene deletion). Common alleles for *CYP2C9, CYP2C19,* and *CYP2D6* are shown in Table 43-5. A common single-nucleotide polymorphism (SNP) used to detect each allele is bolded, but in many cases detection of other SNPs is required to accurately classify a genotype. The assignment of phenotype predictions from genotype is described in detail for CYP2D6 (Figure 43-4) but applies generally to other CYPs as well.

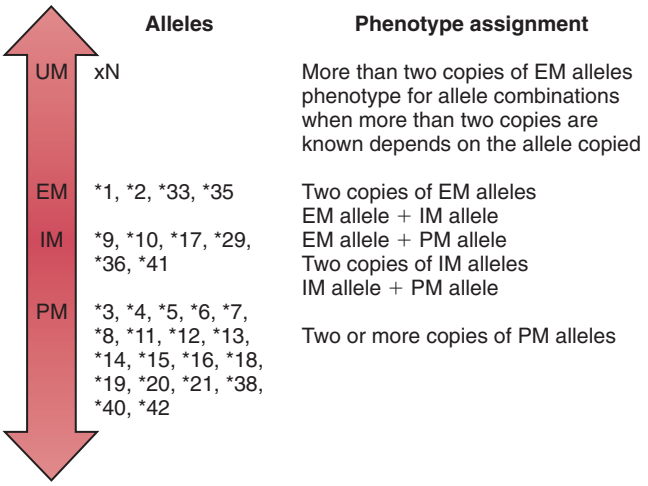

Figure 43-4 CYP2D6 phenotype can be estimated based on the combination of alleles detected. Shown here is a continuum of metabolic phenotypes: poor (PM), extensive (normal, EM), intermediate (IM), and ultra-rapid (UM). The alleles that correspond to enzyme activity are also listed, adjacent to the formulas for establishing a clinical phenotype, based on the combination of two or more alleles.

CYTOCHROME P450 2D6 (CYP2D6)

Cytochrome P450 2D6 (CYP2D6), originally named debrisoquine hydroxylase, is a Phase I enzyme known to metabolize more than 100 drugs and environmental toxins.[8,51,144] As shown in Table 43-4, CYP2D6 is inhibited by several compounds, some of which are substrates. When a CYP2D6 inhibitor is administered along with a CYP2D6 substrate, the phenotype for the patient may appear impaired. This concept, known as *phenocopying,* is of significant concern with CYP2D6. Also, CYP2D6 is frequently implicated in ADRs and has been the subject of many U.S. Food and Drug Administration (FDA)-issued public health advisories. Metabolic phenotypes of CYP2D6 are best described as a continuum that varies from no activity to very high activity. For ease of characterization, a tetra-modal distribution of CYP2D6 activity is described containing the four groups of people called ultra-rapid metabolizers (UMs), extensive (normal) metabolizers (EMs), intermediate metabolizers (IMs), and poor metabolizers (PMs). Translation of a phenotype to a clinical application can be somewhat difficult, as the actual phenotype is dependent not only on the genetic makeup of CYP2D6, but also on (1) expression of CYP2D6, (2) whether drug-drug interactions affect the phenotype, and (3) whether CYP2D6 activates or inactivates the drug of interest.[34] The pharmacogenetics of CYP2D6 and/or phenotype testing can potentially be applied to improve prescribing of any medications known to be transformed by this enzyme. Two clinical applications for CYP2D6 pharmacogenetics include tamoxifen (described later), neuroleptics (some described in the psychiatry section of this chapter), and codeine.

Genotype to Phenotype

The relationship between the CYP2D6 enzyme metabolic rate (phenotype) and the *CYP2D6* genotype has been extensively characterized.[3,98,127,132,149] The *CYP2D6* gene contains 4408 bases and is located on chromosome 22q13.2, near two pseudogenes with greater than 90% homology. More than 90 allelic variants have been described in the *CYP2D6* gene. Alleles, listed with associated nucleotide changes and known effects on enzyme activity for *CYP2D6,* are shown in Table 43-5. Effects on enzyme activity are used to group the alleles according to the predicted phenotype, assuming that two

Modified from the Human Cytochrome P450 (CYP) Allele Nomenclature Committee. Available at: http://www.imm.ki.se/CYPalleles (accessed on June 28, 2011). Reproduced with permission of Sarah C. Sim, Webmaster. No information regarding enzyme activity is listed in the above table when none was present at this reference.

copies of that allele were inherited: PM, IM, EM, and UM. However, the actual phenotype will reflect a sum of the alleles. A summary of *CYP2D6* alleles and assignment of phenotypes are shown in Figure 43-4. Among Caucasians, approximately 1 to 10% are genetically UM, and 5 to 10% are PM. Only 1 to 3% of African Americans and Asians are PM, but many are IM.[75]

The CYP2D6 phenotype that is most simple to characterize is the PM phenotype, for which essentially no CYP2D6 activity is anticipated. The PM phenotype is expected when two or more copies of PM alleles are inherited. The sensitivity and specificity of the genotype to predict the PM phenotype are estimated to be 100%, but are far less for the other phenotypes. Other phenotype assignments are based largely on the highest functioning phenotype prediction. For example, at least one functional EM allele is thought to generate a phenotype that falls within the limits of normal. The UM phenotype is assigned when more than two copies of functional EM alleles are identified; this is often referred to as a *gene duplication.* Duplication of PM alleles has no effect on

the phenotype, and duplication of IM alleles may or may not affect the phenotype.[210] An *activity score* has been proposed to help translate genotype to phenotype.[41]

Based on the AmpliChip CYP2D6 test (Roche Molecular Diagnostics, Pleasanton, California), which is an FDA-cleared in vitro diagnostic test that detects 33 allelic variants, the EM genotype predicts an EM phenotype with 95% sensitivity and 47% specificity. For the IM phenotype, the sensitivity of genotyping is estimated at 42% and specificity at 97%. For the UM phenotype, the sensitivity of genotyping is estimated at 6% and specificity at 99%.[142] These results illustrate that difficulties exist in detection and in incorporation of nongenetic factors when CYP2D6 phenotypes are assigned for all but the PM, based on genotype data alone.

Testing

The *CYP2D6* gene is challenging to genotype because of (1) the presence of the pseudogenes, (2) the sheer number of genetic variants, (3) the complexity of the genetic variants, and (4) the need for identification of gene dose, specifically, duplications and deletions of the gene. *CYP2D6* pharmacogenetic screening protocols vary tremendously in ability to accurately detect gene dose and to detect many versus only a few of the most common variants.

To separate *CYP2D6* from structurally similar pseudogenes, *CYP2D6* genotyping protocols often employ long PCR or nested PCR strategies with a first PCR step designed to amplify a large *CYP2D6*-specific region.[61] Small nucleotide changes within this region, including SNPs and smaller insertions/deletions of one or a few bases, are then detected in a second amplification step designed as a PCR restriction fragment length polymorphism (RFLP) assay or as an allele-specific PCR without subsequent digestion. By evaluating the entire gene, such as through use of the single-strand conformation polymorphism technique described by Broly and colleagues, both known and unknown variants in the *CYP2D6* gene can be detected.[16] Other technologies used for genotyping *CYP2D6* include real-time PCR methods and microarrays.[22,62,130,142] It is important that an assay identify a sufficient number of variants to accurately classify an allele. For example, both the *CYP2D6*10* and *CYP2D6*4* alleles contain the 100C→T variant. Because the phenotype predictions differ for the two, it is clinically relevant to determine which allele is present. The pattern of additional SNPs unique to each allele helps distinguish the two and suggests the likelihood that both alleles could be present. Because complete gene deletion *(CYP2D6*5)* and duplication events *(CYP2D6*1XN)* occur relatively commonly and have significant effect on the phenotype, analytical techniques that can detect and quantify these events are preferred. Successful published methods have utilized RFLP, long-product PCR assays, microarrays, or real-time quantitative PCR of *CYP2D6,* sometimes in relation to an internal reference gene.[69,104,152]

Tamoxifen Application

Tamoxifen is an antiestrogenic prodrug widely used to treat and prevent breast cancer; it is a good example of a drug for which pharmacogenetic testing of CYP2D6 is applied clinically.[67] Tamoxifen mediates its therapeutic effects through modulation of estrogen receptors (ERs), leading to suppression of estrogen-mediated cell proliferation. Therefore, hormone-sensitive breast tumors (ER-positive) are most likely to respond to tamoxifen. A meta-analysis of the Early Breast Cancer Trialist Collaborative Group (EBCTCG) study at the 15-year follow-up period for ER-positive breast cancer showed that 5 years of tamoxifen reduced the recurrence rate by 50% and the mortality rate by a third.[1] However, the success of tamoxifen therapy is variable, and 30 to 45% of patients on tamoxifen relapse or die from recurrent cancer.[133]

Tamoxifen is extensively metabolized by many Phase I and Phase II enzymes (Figure 43-5). The lack of efficacy with tamoxifen can be explained, in part, by interindividual differences in the metabolic activation of tamoxifen. Tamoxifen is a prodrug and must be metabolized to the active principles to elicit the desired therapeutic effect. The most potent antiestrogenic metabolites are 4-hydroxy tamoxifen and endoxifen, each shown to exhibit approximately 100-fold greater affinity for the ER than the parent drug tamoxifen. The concentrations of these metabolites compared with the concentrations of *N*-desmethyl tamoxifen, an inactive metabolite, and tamoxifen itself, are shown in Table 43-6. Because the amounts of endoxifen are greater than the amounts of 4-hydroxy tamoxifen, endoxifen is largely credited with producing antiestrogenic effects of tamoxifen.[14] Considerable

TABLE 43-6 Involvement of CYP2D6 in Steady-State Concentrations of Tamoxifen and Major Tamoxifen Metabolites

	Expected Plasma Concentration Range, nmol/L	Involvement of CYP2D6	Estrogen Receptor Effect
Tamoxifen	190 to 420		Weak antagonist
N-Desmethyltamoxifen	280 to 800	Minor	Weak antagonist
N,N-Didesmethyltamoxifen	90 to 120	Minor	Weak antagonist
Endoxifen	14 to 130	Major	Strong antagonist
4-Hydroxytamoxifen	3 to 17	Among others	Strong antagonist

Modified from Brauch H, Mürdter TE, Eichelbaum M, Schwab M. Pharmacogenomics of tamoxifen therapy. Clin Chem 2009;55:1770-82.

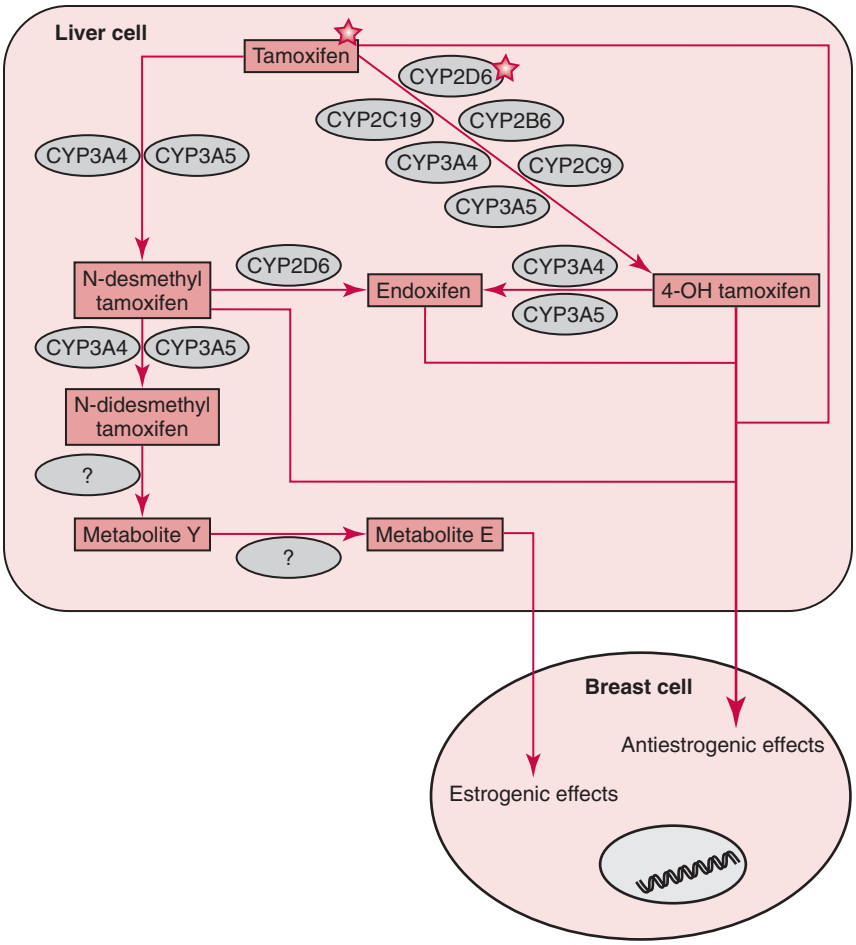

Figure 43-5 Illustrated pharmacokinetic and pharmacodynamic pathways for tamoxifen. Cytochrome P450 (CYP) isozymes are involved in the activation and inactivation of tamoxifen, and CYP2D6 is key to production of the active metabolite endoxifen. Most of the antiestrogenic effects of tamoxifen are attributed to endoxifen. Many additional factors in the pharmacokinetics and pharmacodynamics of tamoxifen are not known. *(Reproduced by permission from PharmGKB and Stanford University.[91])*

evidence suggests that CYP2D6 is a major route for production of endoxifen. Thus, patients with impaired CYP2D6 have been shown to produce less endoxifen than patients with a CYP2D6 EM phenotype. In addition, a PM phenotype and lower endoxifen concentrations are observed in patients with EM genotype, who are coprescribed known strong inhibitors of CYP2D6, such as fluoxetine or paroxetine. It is interesting to note that patients treated with CYP2D6 strong inhibitors and patients who are known CYP2D6 PMs have been shown to exhibit fewer of the common antiestrogenic ADRs such as hot flashes.[14,49,128]

One way in which pharmacogenetic testing of CYP2D6 is used clinically is to qualify patients as good metabolic candidates for tamoxifen pretherapeutically. In this scenario, patients with a PM genotype are not expected to respond appropriately to standard doses of tamoxifen and might be considered for alternative antiestrogenic therapy, such as an aromatase inhibitor. Thus a CYP2D6 PM may be best served clinically by selecting a different agent. An IM is likely to require higher doses of tamoxifen than an EM, and a UM may require lower doses of tamoxifen than an EM. However, appropriate dose optimization studies and determination of a target therapeutic range for tamoxifen are currently lacking. In any case, the best drug must be considered relative to side effect profiles, cost to the patient, and the specific clinical scenario. If tamoxifen is prescribed, the patient should be counseled regarding the phenocopying effects that occur through drug-drug interactions, particularly with the use of CYP2D6 strong inhibitors that are likely to compromise the efficacy of tamoxifen by inhibiting tamoxifen activation.

Other genes are likely to play an important role in the pharmacogenetics of tamoxifen. For example, the *CYP2C19*17* allele, which confers a rapid metabolizer phenotype, is associated with improved response to tamoxifen. The roles of CYP3A4 and CYP3A5 have not been clearly defined.[31,200] The active metabolites endoxifen and 4-hydroxy tamoxifen are inactivated by several enzyme-mediated Phase II (conjugation) reactions (see Figure 43-5). In theory,

impairment in Phase II enzymes would lead to accumulation of endoxifen and exaggerated response. The sulfotransferase isoform 1A1 *(SULT1A1)* and UDP-glucuronosyltransferase isoform 2B15 *(UGT2B15)* genes encode for the most common conjugative enzymes associated with inactivation and elimination of the active tamoxifen metabolites. The *SULT1A1*2* allele (reduced activity) has been associated with improved response to tamoxifen.[47,200] However, the distinct role of these and other genes is not well studied or understood. Also of interest would be genes associated with the pharmacodynamics of tamoxifen, such as estrogen receptors and genes associated with estrogen-mediated cell proliferation. Correlation of metabolites with ADRs, particularly risk of endometrial cancer, a rare but significant ADR of tamoxifen, would be useful as well.

Codeine Application

Codeine, an alkaloid obtained from opium or prepared from morphine by methylation, is a widely used analgesic medication. Codeine must be activated by conversion to morphine, through a demethylation reaction mediated primarily by CYP2D6, to produce analgesia. Therefore, a CYP2D6 PM would not be predicted to activate codeine as an EM would, and analgesia may not be experienced with standard doses. A PM may be best served clinically by selecting a different analgesic agent. An IM is likely to require higher doses of codeine than an EM, and a UM may require lower doses of codeine than an EM. In a typical EM scenario, only about 10% of the codeine is converted to morphine. Administration of codeine to a person with the UM phenotype is a significant safety concern because higher than expected concentrations of morphine can be produced, leading to risk of unintentional overdose and opioid toxicity. In an example case report, respiratory depression and coma were observed in a 62-year-old man with the UM phenotype who was given a moderate dose of codeine. Concentrations of morphine were 80 times higher than expected.[43] Of particular concern clinically is administration of codeine to a woman who exhibits a CYP2D6 UM phenotype and is breast-feeding.[108,202] After clinical reports of opioid toxicity in breast-fed newborns of UM mothers, the FDA issued a public health advisory in 2007 warning that codeine administration to mothers with a CYP2D6 UM phenotype could lead to higher than expected morphine concentrations in the breast milk.

Antidepressant Application

Antidepressant dosing is challenging because several weeks is required to assess efficacy, and optimizing dose may require many months of trial and error.[112] Most of the antidepressants available today are substrates of CYP2D6, and many are also inhibitors. Case reports of CYP2D6-related toxicity and death have been published. The first of these involved a child with a PM genotype who was prescribed the antidepressant fluoxetine.[150] Fluoxetine is a selective serotonin reuptake inhibitor (SSRI) that is demethylated to form the only active metabolite, norfluoxetine. Fluoxetine is a racemic mixture of two enantiomers, S and R. S-fluoxetine and S-norfluoxetine are much more potent in the inhibition of serotonin reuptake than the R-enantiomers. Although several CYP isozymes are involved in the metabolism of fluoxetine, metabolism by CYP2D6 is considered the major route. CYP2D6 is also inhibited by both fluoxetine and norfluoxetine, leading to prolongation in the half-life of the drug and the metabolite within the first weeks of therapy. A CYP2D6 PM would require lower doses of fluoxetine and might be best managed with another drug, one that does not require CYP2D6.[29,89]

Tricyclic antidepressants such as nortriptyline are also metabolized by CYP2D6. The relationship between drug concentrations and toxicity for CYP2D6 phenotypes and genotypes has been extensively characterized for nortriptyline. As shown in Figure 43-6, a CYP2D6 PM requires lower doses of nortriptyline than an EM to produce similar serum concentrations of active drug. Nortriptyline, which is also an active metabolite of amitriptyline, is hydroxylated by CYP2D6 to form an inactive metabolite (10-hydroxynortriptyline). Clearance of amitriptyline, nortriptyline, and other tricyclic antidepressants is reduced by at least 50% in PMs of CYP2D6.[187] Tricyclic antidepressants have a narrow

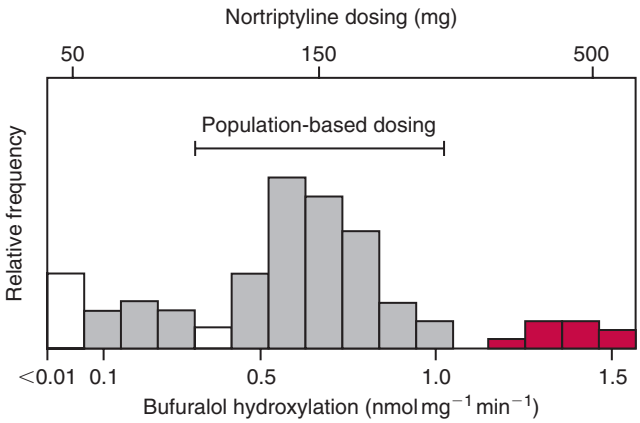

Figure 43-6 Variation in drug metabolism and nortriptyline dosing in the European population, based on cytochrome P450 CYP2D6 activity (hydroxylation of bufuralol). Within the population, four phenotypes can be identified: poor metabolizers (PMs), who lack the functional enzyme; intermediary metabolizers (IMs), who are heterozygous for one functional allele or have two partially defective alleles encoding the enzyme; extensive metabolizers (EMs), who have two normal alleles; and ultra-rapid metabolizers (UMs), who carry duplicated or multiduplicated functional *CYP2D6* genes. The relative frequency of these phenotypes refers to the European population as a whole. The doses of nortriptyline that are required to achieve therapeutic concentrations in all phenotypes are given. Despite this variation in metabolizing capability, population-based dosing is used today and is based on the average plasma concentrations obtained in a given population for a given dose. *(From Ingelman-Sundberg M. Pharmacogenetics of cytochrome P450 and its applications in drug therapy: the past, present and future. Trends Pharmacol Sci 2004;25:193-200. Reproduced by permission from Elsevier.)*

therapeutic index and are associated with severe anticholinergic ADRs that may be life-threatening. Despite these concerns, the drugs are attractive because response rates are higher than for many other classes of antidepressants, and they are available in generic (cost-effective) formulations. The *CYP2D6* genotype has been used to pretherapeutically triage patients as high-risk or low-risk relative to ADRs and response to amitriptyline and nortriptyline. For example, the proportion of patients with ADRs during treatment with these drugs was 12.1% in carriers of two functioning CYP2D6 alleles versus 76.5% in carriers of only one functional allele, in one study.[171,172] Such predictions of pharmacokinetics can be clinically useful and may include multiple relevant genes. The only in vitro diagnostic test currently cleared by the FDA for CYP2D6, the Roche Amplichip, also includes CYP2C19.[142]

Average recommended adjustments for these and other antidepressants vary from 20% of the usual dose for the CYP2D6 PM phenotype to 300% of the usual dose for the CYP2D6 UM. However, some studies have shown no relationship between drugs and CYP2D6 genotype, and the Evaluation of Genomic Applications in Practice and Prevention (EGAPP) Working Group recommends against genetic testing for SSRIs in particular.[2] This may be a result of the fact that most drugs can be metabolized through alternative minor pathways and may act through multiple mechanisms that may or may not relate to the concentration of parent and/or metabolites. In addition, the relationship between circulating concentrations of SSRIs and response is poor. This may reflect unrecognized risks associated with drug metabolites generated by routes considered to be minor. For example, potentially toxic metabolites may accumulate as a result of UM status, possibly leading to ADRs. Thus individuals with the PM or the UM genotype-phenotype may be best served by selecting medications that are metabolized by an alternative (non-CYP2D6) route.[29]

Cytochrome P450 2C9 (CYP2C9)

CYP2C9 is a member of the CYP2C family, which includes CYP2C8, CYP2C9, CYP2C18, and CYP2C19. CYP2C9 is primarily expressed in the liver, at substantially higher quantities than the other CYP isozymes. Concentrations of CYP2C9 are exceeded only by those of CYP3A4.[145,169] CYP2C9 is associated with the metabolism of 15 to 20% of all drugs. Examples of drugs metabolized by CYP2C9 include warfarin, anticonvulsants, nonsteroidal anti-inflammatory drugs (NSAIDs), antidiabetic agents, cholesterol-lowering drugs, and drugs used to treat infection (see Table 43-4). Genotype-based dosing guidelines have been proposed for CYP2C9 substrates and are the subject of intense clinical study for the anticoagulant drug warfarin.[144,154] Similar to CYP2D6, CYP2C9 is subject to induction and inhibition through drug-drug interactions, which will affect the phenotype. For example, CYP2C9 is induced by rifampicin, which will significantly increase the clearance of drugs eliminated by CYP2C9. Common inhibitors of CYP2C9 that reduce clearance of drugs include amiodarone and fluconazole.[80,126,194] Coadministration of CYP2C9 substrates and inducers or inhibitors can lead to life-threatening ADRs, based on whether CYP2C9 activates or inactivates a drug.[105,161]

Genotype to Phenotype

The *CYP2C9* gene is clustered in a 500 kb region on chromosome 10q24 containing CYP genes in the order *CYP2C8-CYP2C9-CYP2C19-CYP2C18*. At least 34 allelic variants have been described in this gene.[55,91] However, two variant alleles, *CYP2C9*2* and *CYP2C9*3,* account for most impaired CYP2C9 PM phenotypes.[127] These alleles are defined by nonsynonymous variants that are relatively common in Caucasians, but have significantly lower allele frequencies in African and Asian populations.[99,167] The *2 allele is identified by R144C (430C→T), and the *3 allele is identified by I359L (1075A→C). The allelic frequency of *CYP2C9*2* has been reported as 8 to 19% in Caucasians, and as 1 to 4% in African Americans and Canadian Native Indians. This allele has not been detected in Asians. The allelic frequency of *CYP2C9*3* has been reported as 6 to 10% in Caucasians, 1.7 to 5% in Asians, and 0.5 to 1.5% in African Americans. Homozygosity for the *CYP2C9*3* allele is relatively rare in Caucasians (1 to 2%).[157] Studies in vitro have shown that the protein produced by the *CYP2C9*3* variant is less than 5% as efficient as the *CYP2C9*1*; *CYP2C9*2* shows about 12% of *CYP2C9*1* activity in most assays. Both variant alleles result in PM in the homozygous state and IM phenotypes when heterozygous. However, the clinical impact of a *CYP2C9*3* variant is more significant than that of a *CYP2C9*2* variant. Additional alleles of interest include *CYP2C9*4, CYP2C9*6,* and *CYP2C9*8.* The *CYP2C9*4* (I359T, 1076T→C) is also more common in Caucasians (6%) than in African Americans (0.5%).[86,175] In contrast, *CYP2C9*6* (frame shift, 818delA), a null allele with lack of activity due to a splicing mutation that causes a frame shift resulting in a truncated protein, has a high prevalence in African Americans. The *CYP2C9*6* in a homozygous individual was shown to contribute to an extremely long phenytoin elimination, with a half-life approximately 5.8 times longer than that of *CYP2C9* extensive metabolizers.[85] The *CYP2C9*8* allele (R150H, 449G→A) has been shown in vitro to have greater activity than the wild-type enzyme, demonstrating 175% tolbutamide hydroxylase activity of recombinant wild type, suggesting that a UM phenotype for CYP2C9 may exist.[9] Many promoter variants are known as well, but their clinical significance has yet to be determined.[92]

Testing

Several protocols have been published for detecting variants in this gene. Most focus on detection of only the *2 and *3 alleles, although multiplexed assays have been described that screen the entire gene for variants.[139,174] Genetic tests have been cleared by the FDA as in vitro diagnostic tests and are available clinically with intent to identify patients at risk for impaired S-warfarin metabolism. These tests include genotyping of *CYP2C9, VKORC1,* and, in at least one test, *CYP4F2*.[87,106]

Warfarin Application

Warfarin is the most widely used anticoagulant drug in the world. Individual response to warfarin is highly variable, and the drug is implicated in life-threatening adverse events, especially when dosed inappropriately. Too much warfarin leads to bleeding, and too little warfarin fails to prevent blood clots. The dose for individual patients is routinely adjusted to achieve a target therapeutic INR (international normalized ratio), usually between 2 and 3. INR is calculated from the prothrombin (clotting) time (PT) of blood samples (see Chapter 59). Factors known to affect warfarin dose requirements include age, gender, clinical status, body size, dietary factors, concomitant medications, and the presence of genetic variation in genes associated with drug metabolism (primarily *CYP2C9*) and response (primarily *VKORC1*). CYP2C9 is the enzyme responsible for inactivating the S-isomer of warfarin that is principally responsible for the anticoagulant effect of the drug. As illustrated in Figure 43-7, standard 5 mg/d maintenance dosing of warfarin in subjects with *CYP2C9* genetic variants can lead to excessive warfarin exposure, resulting in an exaggerated anticoagulant response. Some drug-drug interactions produce a similar result. The clinical impact of a *CYP2C9* polymorphism includes increased risk of ADRs and increased time to achieve a stable INR. Individuals with these variants are at risk of prolonged bleeding time and increased incidence of severe bleeding in warfarin therapy. It is now known that CYP2C9 genotype accounts for only part of the variability in warfarin sensitivity because VKORC1 genotype, age, and weight are also key factors in predicting the therapeutic dose for warfarin.[4,177,179,180] The *VKORC1* gene is discussed in greater detail below.

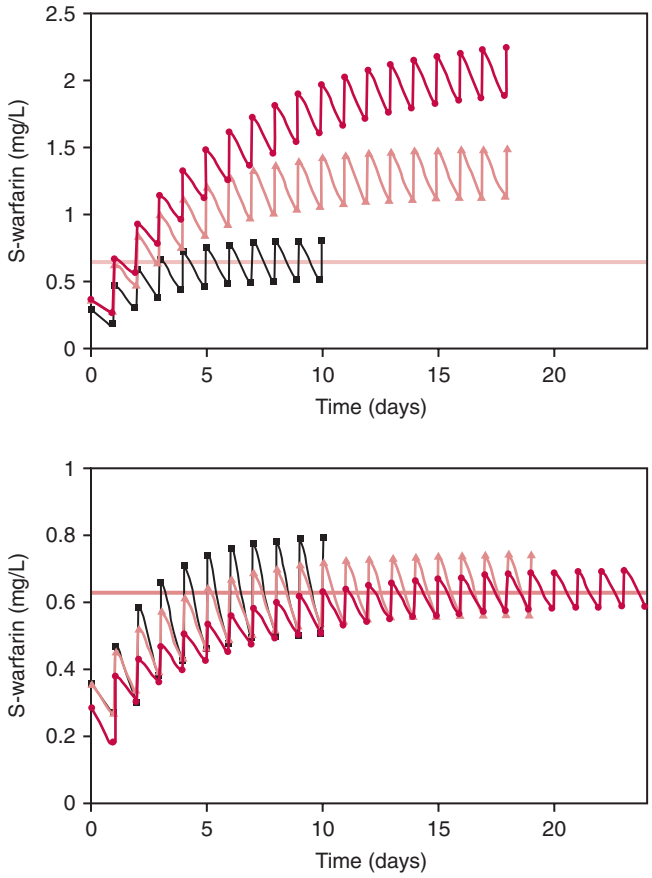

Figure 43-7 Model of warfarin dosing based on *CYP2C9* genetics. In both panels, the conventional therapeutic *S*-warfarin target concentration is shown *(horizontal line)* for reference. The *top panel* depicts a model for warfarin therapy in patients using the standard 5 mg/d dose with all genotypes. *CYP2C9*1/*1* individuals ( ) on 5 mg twice per day would attain stable and therapeutic serum *S*-warfarin concentrations (0.68 μg/mL) in approximately 4 days. *CYP2C9*1/*2* ( ) and *CYP2C9*1/*3* (•) individuals on the same 5 mg dose are modeled to attain *S*-warfarin serum concentrations that are too high by the second day and if not adjusted would lead to overanticoagulation. *CYP2C9*1/*2* patients would stabilize at twice therapeutic serum concentrations after 10 to 12 days, but *CYP2C9*1/*3,* if not adjusted, would continue to rise. The *bottom panel* depicts serum *S*-warfarin concentration outcomes for a dosing regimen modified for genotype. All patients would be given the standard 5 mg dose twice, then would be switched to a *CYP2C9* genotype adjusted dose for maintenance, with *CYP2C9*1/*2* receiving 3 mg and *CYP2C9*1/*3* receiving 1.5 mg. This genotype adjusted dosing could result in *CYP2C9*1/*2* and *CYP2C9*1/*3* achieving stable, therapeutic *S*-warfarin concentrations in 10 days, thereby avoiding overanticoagulation in these individuals. *(Adapted from Linder MW, Looney S, Adams JE III, Johnson N, Antonino-Green D, Lacefield N, et al. Warfarin dose adjustments based on CYP2C9 genetic polymorphisms. J Thromb Thrombolysis 2002;14:227-32. Reproduced by permission from Springer.)*

Cytochrome P450 2C19 (CYP2C19)

CYP2C19 is a member of the CYP2C family, which includes CYP2C8, CYP2C9, CYP2C18, and CYP2C19, of which *CYP2C9* and *CYP2C19* exhibit substantial genetic and clinically significant variability. CYP2C19 is involved in the metabolism of a number of other therapeutic drugs, including citalopram, diazepam, omeprazole, propranolol, and proguanil (see Table 43-4).[144] Of particular relevance to defining phenotypes of CYP2C19 metabolism is the anticonvulsant mephenytoin. CYP2C19 specifically mediates 4-hydroxylation of the S-enantiomer of mephenytoin, and variation in this reaction led to the characterization of CYP2C19, which was originally called *mephenytoin hydroxylase.*[25] Poor, intermediate, extensive, and ultra-rapid metabolizer phenotypes (PM, IM, EM, UM) are described.

Genotype to Phenotype

Genetic variation in CYP2C19 correlates with the IM and PM phenotype. Although at least 25 allelic variants of *CYP2C19* have been described, CYP2C19*2 and CYP2C19*3 account for 99% of PM in Asians and approximately 87% in Caucasians.[17,30,37,91] The PM phenotype occurs in 2 to 5% of Caucasian and Black Zimbabwean Shona populations, and 10 to 23% of Asian populations.[212] The *CYP2C19*2* arises from a 681G→A, which results in a splicing defect and essentially

no enzyme activity. The second most common *CYP2C19* allele *(CYP2C19*3)* associated with the PM phenotype results from a single nucleotide substitution, 636G→A, which produces a premature stop codon and no active enzyme product.[30,127] The allele frequency of *CYP2C19*2* is reported to be 32% in East Asians and 71% in Polynesians (Vanuatu), and is approximately 15% in Caucasians and African Americans. The allele frequency of *CYP2C19*3* is reported as 6 to 10% in East Asians, 13.3% in Polynesians, and less than 1% among Caucasians. The *CYP2C19*17* arises from a promoter variant in the gene (-806C→T), is present in nearly 40% of Caucasians, Blacks, and Asians, and is associated with a UM phenotype for CYP2C19. However, the *CYP2C19*4* allele, a relatively rare loss of function (PM) allele, that affects the initiation codon for the gene (1A→G), has been demononstrated to occur in cis linkage disequilibrium with the *CYP2C19*17*. The presence of both alleles must be evaluated based on haplotype, and when present, is called the *CYP2C19*4B* haplotype, observed thus far in only Ashkenazi and Sephardi Jewish populations. The clinical phenotoype of this new haplotype is not yet understood.[157A]

Testing

Several protocols have been published for detecting variants in CYP2C19. Most focus on detection of only the *2 and *3 alleles, although multiplexed assays have been described that detect an expanded panel of alleles (including *4 and *17 alleles), and/or screen the entire gene for variants. The only genetic test for *CYP2C19* that is currently cleared by the FDA as an in vitro diagnostic test is the Roche Amplichip, which also includes *CYP2D6*.[142] Other assay reagents are sold in the United States through research-use-only (RUO) labeling.

Clopidogrel Application

Clopidogrel is a second-generation thienopyridine that inhibits platelet aggregation. This drug is widely used in combination with aspirin to reduce the incidence of thrombotic and ischemic events in patients with coronary artery disease, with acute coronary syndrome (ACS), and/or after percutaneous coronary intervention (PCI) with stenting. Yet, a significant proportion of patients realize insufficient clopidogrel-induced platelet inhibition, and rates of drug resistance are estimated at 30%.[59] One explanation for drug resistance is based on the fact that clopidogrel is an inactive prodrug that requires metabolism to generate the active metabolite. The active metabolite irreversibly inhibits the platelet adenosine diphosphate (ADP) receptor, P2Y12. Carriers of the *CYP2C19*2 and *3* alleles have reduced formation of the active metabolite of clopidogrel, demonstrate reduction in clopidogrel-induced platelet inhibition, and have a higher incidence of major thrombotic events.[13,120,163] Two potential treatment strategies for carriers of *CYP2C19*2 and *3* are to use higher doses of clopidogrel or alternative P2Y12 inhibitors. Higher loading and maintenance doses (e.g., 1200 mg loading and 150 mg maintenance) appear, in part, to overcome the genetic deficiency of the *2 allele, although maintenance doses of up to 300 mg/d might be required to achieve adequate platelet inhibition.[48,136] For carriers of two impaired alleles (e.g., homozygous for *2), an alternative therapy may be preferred, such as the newly approved prasugrel, which does not require CYP-mediated activation.[13,120] The impact of the *CYP2C19*17* genotype, other variant genotypes, and *CYP2C19*4B* haploytpe remain to be defined.

Antidepressant Application

A common reason for genotyping *CYP2C19* is to explain inappropriate response to antidepressant medications. For example, CYP2C19 is the primary enzyme responsible for converting amitriptyline to its active metabolite nortriptyline. Monitoring serum or plasma concentrations of both amitriptyline and nortriptyline as a sum is used to guide amitriptyline therapy.[102,137] The utility of *CYP2C19* genotyping is somewhat controversial. Using a quantitative gene-dose model, it was found that *CYP2D6* but not *CYP2C19* genotyping is most useful in amitriptyline therapy based on the fact that *CYP2C19* polymorphisms alter the ratio of amitriptyline to nortriptyline, but not the sum of the two.[171] The model was derived in a Caucasian population, whereas *CYP2C19* PMs are much more common in Asian populations.[160] CYP2D6 is also thought to be more important than CYP2C19 for newer antidepressants.[54] However, CYP2C19 becomes very important for a drug that is a substrate of both CYP2D6 and CYP2C19 when CYP2D6 is impaired or deficient.

Omeprazole and Proguanil Applications

Omeprazole, a proton pump inhibitor, is primarily inactivated by the CYP2C19 enzyme. It has been reported that homozygous variant subjects had 100% cure of upper gastrointestinal (GI) ulcers after omeprazole-based therapy versus 65% and 25% for heterozygous and homozygous wild-type patients, respectively. Studies have also demonstrated greater effectiveness of single-dose omeprazole for management of *Helicobacter pylori* infection and peptic ulcer in subjects with one or more *CYP2C19* PM alleles. This is thought to be the result of greater exposure to a therapeutic compound in PMs and IMs. This difference in exposure is illustrated in Figure 43-8, wherein the area under the time-versus-concentration curve after a single dose of omeprazole was dramatically larger for *CYP2C219* PMs. However, using triple therapy with rabeprazole, amoxicillin, and clarithromycin, *H. pylori* antimicrobial susceptibility was shown to be a more important factor than *CYP2C19* genotype.[123] No dose adjustments have been proposed to adjust for *CYP2C19* genotype. Gene-gene interactions may indicate a need to test for genetic variation in more than one gene to guide therapy. Multigene studies have shown that interleukin-1β genetic polymorphisms *(IL-1B),* although not an independent factor in treatment outcome, influence the impact of the *CYP2C19* genotype on the cure rate of 1-week triple therapy for *H. pylori* infection.[181]

The antimalarial prodrugs proguanil and chlorproguanil require CYP2C19-dependent bioactivation for therapeutic

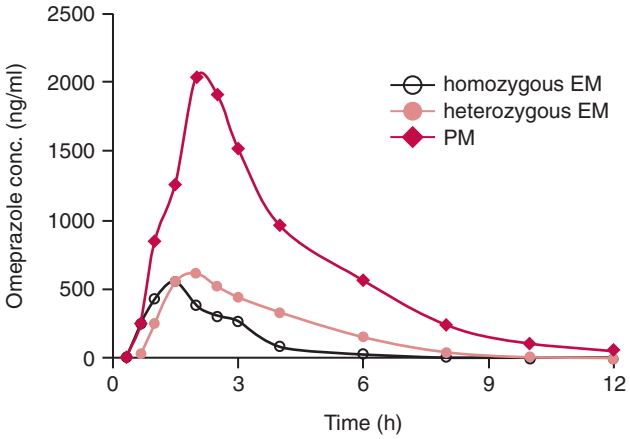

Figure 43-8 Mean plasma concentration-time profile of omeprazole after oral administration of 40 mg omeprazole (in the form of 2 × 20 mg Losec capsules) to 27 male Chinese subjects phenotyped for CYP2C19 activity with mephenytoin. Plasma concentrations of omeprazole were significantly higher in poor metabolizers (PMs) (♦) than in homozygous extensive metabolizers (EMs) (•) or heterozygous EMs (○). In addition, the elimination half-life for omeprazole was 2.3-fold greater in PMs than in EMs ($P < 0.001$). *(From Yin OQ, Tomlinson B, Chow AH, Waye MM, Chow MS. Omeprazole as a CYP2C19 marker in Chinese subjects: assessment of its gene-dose effect and intrasubject variability. J Clin Pharmacol 2004;44:582-9. Reproduced by permission from Sage Publications Inc.)*

efficacy. A clear gene-dose effect has been observed for the oxidation of proguanil to cycloguanil and 4-chlorophenylbiguanide. Clinical response has been shown to be affected in CYP2C19 PM individuals.[68,205]

Other Cytochrome P450 Genes

Additional CYPs including *CYP2B6, CYP3A4,* and *CYP3A5* have been proposed as important pharmacogenetic targets. CYP3A4 and CYP3A5 have been the subject of extensive study, as they are believed to be the predominant CYP expressed in adult human liver and are responsible for the metabolism of at least 50% of all currently used drugs, as well as many endogenous steroid hormones. Linkage results from a Japanese population demonstrate that CYP3A4 and CYP3A5 are closely linked, and that the two genes are in close proximity, so some effects originally thought to be due to a *CYP3A4* allele are probably actually due to a *CYP3A5* allele in linkage disequilibrium.[40] The most common and clinically significant nonfunctional variant of *CYP3A5* is an A→G change at position 6986 that leads to mis-splicing, and is known as *CYP3A5*3*.[93] CYP3A5 is expressed in about 50% of African Americans and only 10 to 30% of Caucasians and Asians. This expression level correlates with allele frequencies of the *3 allele of approximately 50% in African Americans, and 70 to 90% in Caucasians. Because of the allele frequency of the *3, *CYP3A4* is most common in Caucasians, and *CYP3A5* in African Americans. As in the CYP3A subfamily, high interindividual variation is seen in CYP2B6 expression, estimated at 20- to 250-fold, which may be due to differences in transcriptional regulation, as well as genetic variation.[94,186] Many alleles have been reported that correlate with increased or decreased expression, and are present in high frequencies, yet their clinical significance is not well defined. Like for CYP2D6, defining the phenotype is complicated by the fact that many of the drugs that are metabolized by CYP2B6 are also inducers or inhibitors of this enzyme; examples of such drugs include cyclophosphamide, phenobarbital, rifampicin, phenytoin, artemisinin, carbamazepine, efavirenz, and nevirapine.[209]

PHASE II METABOLIC ENZYMES

As described earlier, Phase II enzymes are generally transferases that conjugate drugs with acetyl, glucuronyl, amino acyl, or sulfate groups. Phase II reactions may occur before or after Phase I reactions or independent of them. The enzymes are not typically induced or inhibited to the same degree as CYPs. However, exhausting the substrates or cofactors for transfer, such as glutathione or acetyl-CoA, will prevent the corresponding transferase reactions from occurring. Similar to Phase I enzymes, Phase II enzymes are synthesized from genes that are classified into families and further into subfamilies based on homology.

N-Acetyltransferases (NAT1 and NAT2)

The *N*-acetyltransferase (NAT) polymorphism is one of the earliest pharmacogenetic targets recognized and characterized. NATs are Phase II enzymes that catalyze the transfer of an acetyl moiety from acetyl-CoA to homocyclic and heterocyclic arylamines and hydrazines. Substrates include drugs, carcinogens, toxicants, and possibly endogenous compounds. Slow metabolizer phenotypes, which may affect up to 90% of some populations, are manifested by changes in protein expression, protein stability, and/or enzyme kinetics.

Genotype to Phenotype

Studies with additional substrates for NAT have demonstrated that the phenotype was not relevant to all substrates. For example, the NAT phenotype was clearly recognized for arylamines such as isoniazid, some sulfonamides, amrinone, dapsone, procainamide, caffeine, and clonazepam. The phenotype was not observed with other arylamine substrates such as *p*-aminobenzoate (PABA) and *p*-aminosalicylate (PAS). A folate catabolite, *p*-aminobenzoylglutamate, is the only endogenous NAT substrate proposed.[125] However, *NAT2* knock-out and *NAT1* and *NAT2* double knock-out mice do not express phenotypical abnormalities, suggesting that these enzymes are not required for development or function.[176]

In 1965 it was proposed that two isoforms of NAT, later named *NAT1* and *NAT2,* were responsible for the differences in phenotypes observed previously. Of the two proposed isoforms, NAT2 correlated best with the isoniazid (polymorphic) phenotype.[78] It was also suggested that the fast and

slow acetylator phenotypes were caused by differences in expression rather than in enzyme kinetics. Subsequently, it was found that although most substrates exhibit higher specificity for NAT1 or NAT2, most substrates have affinity for both NAT1 and NAT2. Nonetheless, substrates were commonly classified as monomorphic (substrates of NAT1) or polymorphic (substrates of NAT2) until the mid 1990s.

NAT1, which is now recognized to be polymorphic, is extremely unstable and therefore more difficult to study than NAT2. Because of stability differences and overlapping substrate specificity, tissue localization studies for the NATs have been challenging. It is now recognized that both NAT1 and NAT2 are expressed throughout the GI tract, and in the lung, bladder, ureter, and liver.[52,203]

Three human NAT genes are mapped to chromosome 8p22 and were first cloned in 1990. The *NAT1* and *NAT2* genes share 87% nucleotide sequence identity and 81% amino acid sequence identity. The third gene, *NATP,* is thought to be a noncoding pseudogene. Each of the NAT genes has an intronless open reading frame exon of 870 bp and codes for 290 amino acids. Many variant alleles have been described for both NAT1 and NAT2. A consensus nomenclature was published in 1995 and updated in 2000.[10,12,191] *NAT1*3* and *NAT2*4* are considered the wild-type alleles, although the designation is somewhat arbitrary in view of the high frequencies of multiple alleles in the population. For *NAT2,* the former common nomenclature included M1 for *NAT2*5A,* M2 for *NAT2*6A,* and M3 for *NAT2*7A.* The *NAT2*5, *6, *7, *13,* and *14* alleles are thought to account for more than 99% of slow acetylator phenotypes. The *NAT1*10* is the most common variant *NAT1* allele in many human populations, but the phenotype-genotype relationship is not well defined. Other *NAT1* alleles that are rare in humans and produce enzymes with definitively reduced activity and potential clinical implications include *NAT1*14, *15, *17, *19,* and *22.*

The three-dimensional crystal structures of the two NAT isoenzymes have been determined. Structural studies suggest that the active catalytic site of the NATs involves three amino acids: a cysteine residue juxtaposed with histidine, and aspartate residues. The C-terminus is responsible for substrate specificity.[162] The acetylation reaction occurs through a classical two-step mechanism, whereby an acetyl moiety is transferred from acetyl CoA to NAT, and then from NAT to the arylamine to form an arylamide. As shown in Figure 43-9, *N*-acetylation, thought to primarily generate nontoxic stable products, is mediated by both NAT1 and NAT2. *O*-Acetylation of cytochrome P450 *N*-hydroxylated products is also mediated by both NAT1 and NAT2 and is thought to generate reactive products that may spontaneously decompose to form nitrenium ions. Nitrenium ions are electrophiles that may subsequently bind covalently to intracellular nucleophiles such as DNA or proteins and be responsible for cell death, mutagenesis, or other toxicities. An intramolecular *N,O*-acetyltransfer reaction is mediated primarily by NAT1 and may lead to reactive products. Other enzymes that may interrupt or contribute to these reactions include CYP1A2, prostaglandin H synthase, UDP-glucuronosyltransferase, and sulfotransferase.[53,204]

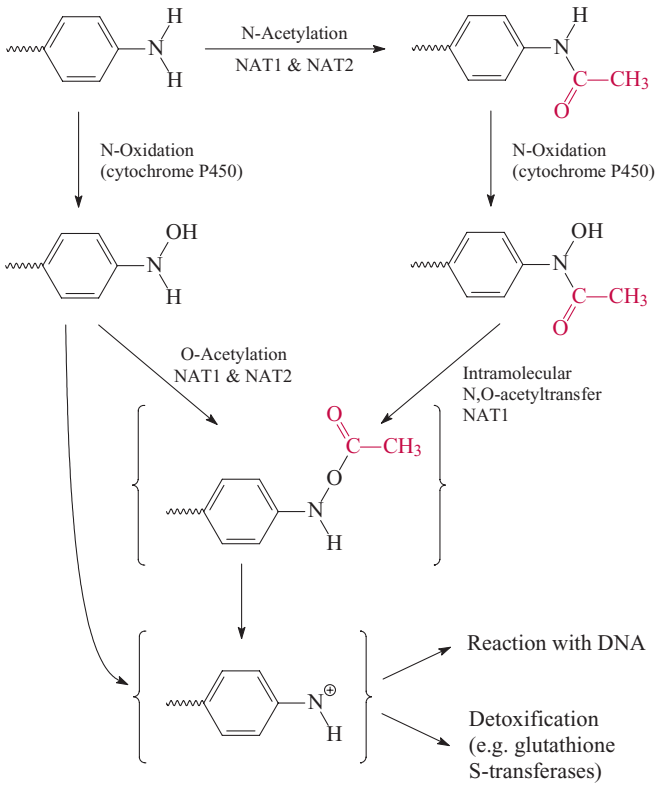

Figure 43-9 Schematic view of the role of *N*-acetyltransferase (NAT) enzymes in the metabolism of aromatic amines. *N*-acetylation might be a detoxification reaction in a number of cases; however, after *N*-hydroxylation of aromatic amines [e.g., by cytochrome P450 (CYP) enzymes], NAT enzymes can bioactivate these intermediates by *O*-acetylation or by intramolecular *N,O*-acetyltransfer, leading to the formation of nitrenium ions, which might react with DNA or alternatively be detoxified by, for example, GST enzymes. It is shown that a number of other biotransformation enzymes are involved in the metabolism of aromatic amines as well. *(Redrawn from Wormhoudt LW, Commandeur JNM, Vermeulen NPE. Genetic polymorphisms of human N-acetyltransferase, cytochrome P450, glutathione-S-transferase, and epoxide hydrolase enzymes: relevance to xenobiotic metabolism and toxicity. Crit Rev Toxicol 1999;29:59-124. Reproduced by permission from Taylor and Francis, Inc.)*

Testing

NAT2 slow acetylators are common in many populations, including approximately 83% of Egyptians; 40 to 60% of Caucasians, Europeans, and African Americans; 10 to 30% of Asians; and 5% of Canadian Eskimos.[57,122] *NAT1*10* allele frequency is reported to be high in a Japanese population (62.3%) compared with a European population (29%), but additional efforts are required to fully elucidate the population frequencies of the various *NAT1* alleles currently

identified.[83] Variables that affect NAT phenotyping include the substrate or probe drug used, the age and disease status of the individual, medications, dietary factors such as ingestion of well-cooked meat, and lifestyle factors such as cigarette smoking or occupational exposure to NAT substrates.

Genotyping can predict NAT phenotype quite well, with concordance of 90 to 100% for *NAT2*. Methods have primarily employed PCR-RFLP, but real-time PCR and other allele-specific detection methods have been described.

Clinical Applications

NAT status has been implicated in propensity for experiencing ADRs and, unlike the CYPs and TPMT, has been associated with risk of disease, including immunologic disorders, such as rheumatoid arthritis and systemic lupus erythematosus, and several cancers, particularly bladder, lung, gastric, and colorectal. NAT substrate exposure can be related to cigarette smoking, some medications, occupational exposure (cooking, dye, and rubber industries), and several environmental toxicants (see Table 43-3). NAT testing may be important for individuals at high risk of exposure to NAT substrates or in whom adverse reactions to probable NAT substrates have been experienced.

Neither genotyping nor phenotyping methods are widely available for clinical testing. However, research involving the genotyping or phenotyping of NAT polymorphisms has significantly impacted pharmacotherapy with NAT substrates and drug development. With isoniazid, recognition of distinct phenotypical differences that led to ADRs resulted in further research into the pathologic mechanisms. For example, the neuropathic consequences are linked to pyridoxine deficiency, which can be avoided by coadministration of pyridoxine to all patients. Because rapid acetylators are less likely to respond to the conventionally administered dose, isoniazid dosing intervals are changed from once a week to twice per week. For procainamide, determining the acetylator status is accomplished through routine therapeutic drug monitoring of the parent and the metabolite, *N*-acetylprocainamide (NAPA). The dose of procainamide is adjusted based on the parent/metabolite ratio. In the development of amonafide, a chemotherapeutic agent inactivated by NAT conjugation, acetylator-based dosing was defined through clinical trials. Although the drug is no longer in development, it is an example of how pharmacogenetic phenomena can support individualized therapy.

Thiopurine S-Methyltransferase

TPMT is a Phase II metabolic enzyme that catalyzes the inactivation of 6-MP by S-methylation, thus preventing it from forming thioguanine nucleotides (TGNs). TPMT also affects AZA, which is another prodrug that is metabolized to 6-MP, as illustrated in Figure 43-10. Endogenous substrates for TPMT are currently unknown. AZA and 6-MP are used in the therapeutic management of leukemias, particularly acute lymphoblastic leukemia (ALL) in children, but are also used to treat a diverse range of conditions, including rheumatic disease, inflammatory bowel disease, and solid organ transplantation. These agents are cytotoxic, acting via incorporation of TGN into DNA. Outside the bone marrow, these agents can be oxidatively inactivated by xanthine oxidase or methylated by TPMT. In hematopoietic tissue, however, the effect of xanthine oxidase is negligible, leaving TPMT as the only significant inactivation pathway. Thus hematopoietic tissues are susceptible to damage in cases in which TPMT activity is very low. TPMT activity is highly variable in all large populations studied to date; approximately 90% of individuals have high activity, 10% have immediate activity, and 0.3% have low or undetectable enzyme activity. This trimodal activity is a direct result of enhanced proteasomal degradation of TPMT.[178] Numerous studies have shown that TPMT-deficient patients are at high risk for severe, and sometimes fatal, hematologic toxicity.

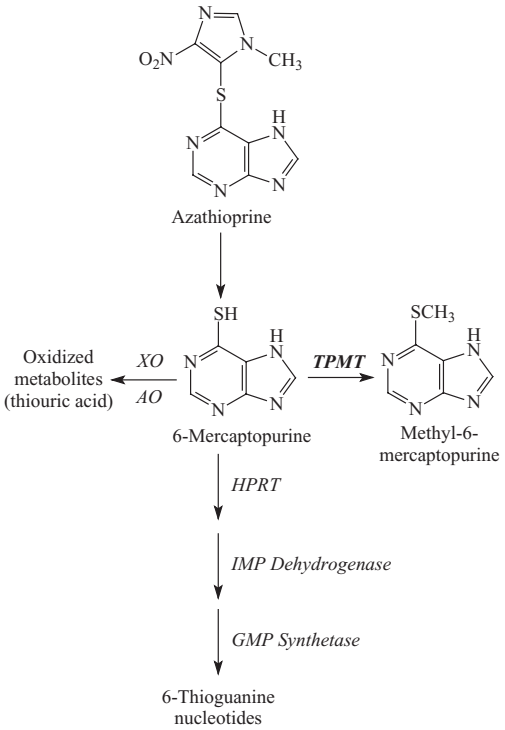

Figure 43-10 Simplified metabolic pathway for prodrug thiopurines azathioprine and 6-mercaptopurine. *AO,* Aldehyde oxidase; *GMP,* guanine monophosphate; *HPRT,* hypoxanthine phosphoribosyltransferase; *IMP,* inositol monophosphate; *TPMT,* thiopurine *S*-methyltransferase; *XO,* xanthine oxidase.

Genotype to Phenotype

TPMT was the first widely used pharmacogenetic marker for individualizing drug therapy based on a patient's biochemical phenotype (erythrocyte enzyme activity) or genotype. Patients with a "low methylator" status are at significantly greater risk of toxicity, often necessitating a lower dose of these medications (as low as 5% of standard doses) because of accumulation of active drug. Prospective determination of functional TPMT status is useful for preventing mercaptopurine toxicity.[24,158] Whether TPMT testing is based on

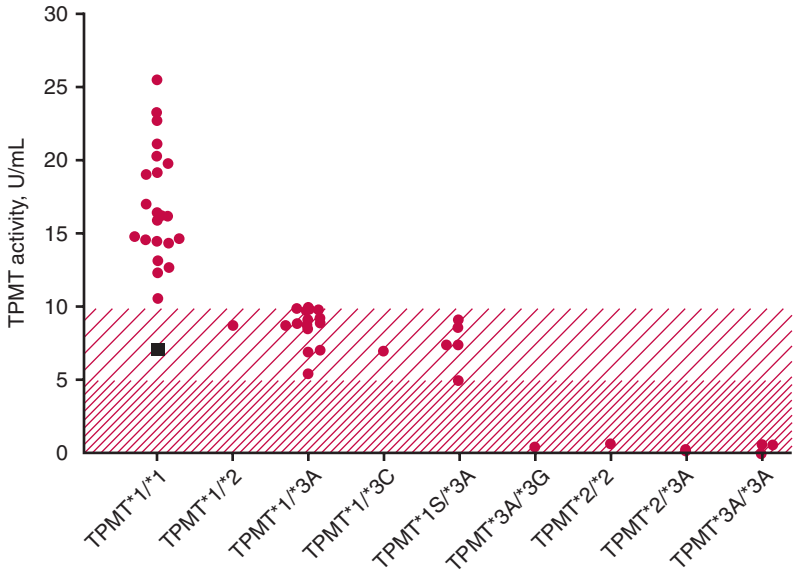

Figure 43-11 Thiopurine *S*-methyltransferase (TPMT) activity as related to genotypes determined by mutation-specific polymerase chain reaction methods. The *heavily shaded area* depicts the range of TPMT activity in erythrocytes that defines TPMT deficiency (<5 U/mL of packed red blood cells); the *lightly shaded area* depicts intermediate activity that defines TPMT heterozygous phenotypes (5 to 10 U/mL of packed red blood cells); and the *nonshaded area* depicts the range of TPMT activity in patients who have homozygous wild-type phenotypes. *Black circles* indicate patients with concordant genotype and phenotype; the *black square* indicates one patient with discordant genotype and phenotype (*TPMT*1/*1*). *(From Yates CR, Krynetski EY, Loennechen T, Fessing MY, Tai HL, Pui CH, et al. Molecular diagnosis of thiopurine* **S***-methyltransferase deficiency: genetic basis for azathioprine and mercaptopurine intolerance. Ann Intern Med 1997;126:608-14. Reproduced by permission from the American College of Physicians.)*

phenotype or genotype, the goal is individualized dosing with controlled systemic exposure.[35]

The molecular basis for variable TPMT activity has now been defined for the majority of patients.[119] The *TPMT* gene is located on chromosome 6p22.3 and is 26,833 bases long, exhibiting genetic polymorphism in all populations studied to date. At least 28 *TPMT* alleles have been identified, including single-nucleotide polymorphisms (SNPs) that lead to amino acid substitutions, formation of a stop codon, or a change that destroys a splice site. Four alleles, *TPMT*2, *3A, *3B,* and **3C,* account for 80 to 95% of intermediate or low enzyme activity cases in most ethnic groups. The **3A* allele is most common in Caucasians, whereas **3C* is most common in African American and Asian populations. The *TPMT *2* and **3B* alleles are rare in comparison with *TPMT*3A* or **3C. TPMT*3A* contains two nonsynonymous SNPs, one in exon 7 and another in exon 10, that result in Ala154Thr and Tyr240Cys alterations in encoded amino acids. *TPMT*3B* occurs rarely and contains only the exon 7 SNP; *TPMT*3C* contains only the exon 10 SNP. Thus a heterozygote **3B/*3C* could be mistaken for a **3A,* which would adversely impact assignment of phenotype. *TPMT*3C* is the most common variant allele in East Asian and African American populations (frequency approximately 2%). Patients with one wild-type allele and one of these variant alleles (i.e., heterozygous) have intermediate activity, and patients inheriting two variant alleles are TPMT deficient.[151] The relationship between phenotype and genotype is very good for most patients, as illustrated in Figure 43-11.

Trinucleotide repeat variants in the promoter region have been described that may explain the 1 to 2% of Caucasians who demonstrate ultra-metabolizer phenotype. A promoter region VNTR (variable number tandem repeat) that may have functional significance has also been investigated.

Testing

TPMT testing may occur via at least three routes: (1) biochemical phenotyping by determination of TPMT activity within erythrocytes from the patient; (2) metabolic phenotyping by determination of concentrations of 6-MP and thioguanine in the patient; or (3) genotyping. Biochemical phenotyping depends on stable enzyme activity between the times of blood collection and analytical testing. This approach therefore is challenged by storage and stability concerns and is limited to patients who have not received a blood transfusion over the weeks previous to TPMT testing, and who have healthy red blood cells at the time of testing (often not the case at the time ALL is diagnosed). When these or other limitations of biochemical phenotyping apply, *TPMT* genotyping is the preferred pretherapeutic testing approach. Metabolic phenotyping requires that AZA or 6-MP be administered before testing. This approach is therefore most useful for

optimizing dose once steady-state concentrations have been achieved, or for troubleshooting for patients who have experienced toxicity or an ADR. *TPMT* genotype correlates well with TPMT activity in leukemia cells, as would be expected for germline mutations. By using PCR-based assays to detect the three signature mutations in these alleles, a rapid and relatively inexpensive assay identifies ≈90% of all variant alleles. In Caucasian populations, *TPMT*3A* is the most common variant *TPMT* allele (3.2 to 5.7% of *TPMT* alleles), although *TPMT*3C* has an allele frequency of 0.2 to 0.8%, and *TPMT*2* represents 0.2 to 0.5% of *TPMT* alleles.[2,24,104] Studies in Caucasian, African, and Asian populations have revealed that the frequency of these variant *TPMT* alleles differs among various ethnic populations. East and West African populations have a frequency of variant alleles similar to Caucasians, but the variant alleles in the African populations were predominantly *TPMT*3C*.[5] Among African Americans, *TPMT*3C* is the most prevalent allele, but *TPMT*2* and *TPMT*3A* are also found, reflecting the integration of Caucasian and African American genes in the U.S. population.[65] In Japanese and Chinese populations, *TPMT*3C* is almost exclusively the causative variant allele. In other Asian populations, *TPMT*3C* is also predominant.[115]

Many common genotyping tests do not detect TPMT deficiency in all patients, particularly those with a rare or unknown but clinically significant variant. Compound heterozygotes also present a challenge to PCR-based genetic testing in this gene. For example, patients with the heterozygous genotype *TPMT*1/*3A* have a 35% risk of hematopoietic toxicity versus a 7% risk for patients with a homozygous wild-type genotype. Alternatively, patients with the *TPMT*3B/*3C* genotype are TPMT-deficient and are at very high risk for thiopurine toxicity. These two genotypes are impossible to distinguish when conventional PCR genotyping is used.[18,115] The *TPMT*3B* allele is rare (≈1% of variant alleles), but its presence can have grave clinical consequences. A haplotyping method and a matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometric method, both using genomic DNA, discriminate *TPMT*1/*3A* from *TPMT*3B/*3C*.[151,153]

6-Mercaptopurine and Azathioprine Applications

An analysis of mercaptopurine therapy for childhood ALL found that TPMT-deficient patients tolerated full doses of mercaptopurines for only a brief period (7% of the scheduled weeks of therapy), whereas heterozygous and homozygous wild-type patients tolerated full doses for 65% and 84% of scheduled weeks of therapy during the 2½ years of treatment, respectively. The percentage of weeks in which mercaptopurine dosage had to be decreased to prevent toxicity was 2%, 16%, and 76% in wild-type, heterozygous, and homozygous variant individuals. Collectively, these studies demonstrate that the influence of *TPMT* genotype on hematopoietic toxicity is most dramatic for homozygous variant patients, but is also of clinical relevance for heterozygous individuals, who represent about 10% of patients treated with these medications. The labeling for 6-MP was revised in 2004 to include TPMT testing options. It is advised that patients who are TPMT PMs seek alternative therapies. In the absence of alternative therapy, 5 to 10% of the conventional dose, with careful monitoring, has been recommended. For patients who are predicted to be TPMT IMs, a dose reduction of 30 to 70% has been recommended, based on the specific clinical scenario. This testing is routinely performed pretherapeutically at many children's oncology centers for ALL patients.[70]

A growing and potentially valuable use of TPMT status testing is before intravenous AZA loading, a strategy used in the management of Crohn's disease. Dose-related toxicities resulted in AZA discontinuation in 10 to 20% of cases, and it has been estimated that over 6 months, 20% of patients would need TPMT analysis to avoid one serious ADR. TPMT status testing before taking AZA has been modeled to be cost-effective in a variety of theoretical situations. Analysis of some recent studies suggests that by optimizing the maximum AZA dose between 0.75 and 3 mg/kg/d, depending on TPMT status testing (with a drastic reduction in dosage for patients homozygous for variant *TPMT* alleles), considerable cost savings can be made by avoiding hospitalization and rescue therapy for leukopenic events.[116,184,192] Furthermore, one study reported that the median dose reduction required for TPMT-deficient patients was 90.8% (range, 50 to 94%) and the median dose reduction in *TPMT* for heterozygotes was 67% (range, 0 to 93%).[36] This study included only patients referred for hematopoietic toxicity. However, previous studies have reported that heterozygous patients needed only 15 to 30% dose reduction to avoid ADRs. TPMT phenotyping or genotyping is performed by approximately half of gastroenterologists surveyed.[208]

Although detection of *TPMT* polymorphisms is thought to prospectively identify approximately 10% of patients likely to experience dose-limiting toxicity from AZA and 6-MP therapy, toxicity is estimated to occur in 15 to 28% of patients. Thus, toxicity related to thiopurine therapeutics cannot be explained by known *TPMT* polymorphisms alone. Cao and Hegele described an inosine triphosphatase (ITPA)-deficient phenotype that may provide an additional mechanism for thiopurine-related toxicity.[143] This phenotype, similar to TPMT deficiency, is clinically benign until a patient is exposed to a thiopurine therapeutic such as 6-MP or AZA. The ITPA deficiency phenotype is associated with a 94C→A polymorphism of *ITPA* and approximately 25% residual red cell ITPA activity. Consequently, the metabolite 6-thio-ITP accumulates and may contribute to toxicities previously associated only with TPMT deficiency. Variants in xanthine oxidase/dehydrogenase (XDH) and aldehyde oxidase (AO) and molybdenum cofactor sulfurase (MOCOS) have also been reported to affect treatment outcome with azathioprine.[208] Therefore, other indicators of 6-MP and AZA phenotype may become important for predicting risk of ADRs in the future.

UDP-Glucuronosyltransferase 1A1 (UGT1A1)

The mammalian uridine diphosphate (UDP) glucuronosyl transferase (UGT) family comprises 117 members that can be divided among UGT1, UGT2, UGT3, and UGT4. The

UGT1 and UGT2 families are most efficient at glucuronidation in humans, and the UGT1 family is of most interest clinically. Hepatic isoforms include UGT1A1, 1A3, 1A4, 1A6, and 1A9; UGT1A7, 1A8, and 1A10 have been localized to extrahepatic tissues such as mouth, esophagus, intestine, pancreas, and colon. Of these, the clinical consequences of genetic and clinical variations have been best studied for UGT1A1. The primary goal of glucuronidation is to increase the water solubility of a compound, which typically inactivates that compound and promotes its elimination. An important endogenous substrate for UGT1A1 is bilirubin. Impairment of UGT1A1 leads to accumulation of bilirubin. UGT1A1 is also involved in the glucuronidation of drugs. Impairment of UGT1A1-mediated glucuronidation of drugs was first recognized in patients with Gilbert disease (also known as Gilbert-Meulengracht disease) who were administered irinotecan. An inverse relationship between expression of UGT1A1 and bilirubin concentration was recognized in patients with Gilbert disease and ultimately led to recognition of variation in the promoter region of the gene. These Gilbert patients experienced grade 4 neutropenia when irinotecan was administered—a consequence of reduced glucuronidation of the active irinotecan metabolite, a UGT1A1 substrate.[107,114,141,173]

Genotype to Phenotype

The *UGT1A1* gene is located on chromosome 2q37.1, along with other *UGT* genes, and is 155,596 bases long. The 5-exon genes of the UGT1 family each contain a unique first exon plus four exons that are shared between the genes; the exons may have evolved by a process of duplication, leading to the synthesis of proteins with identical carboxyl-terminal and variable amino-terminal domains. UGT1A1 is the most 3′ of the UGT1A isoform genes. More than 30 SNPs that lead to nonfunctional UGT1A1 have been identified in the promoter and unique exon 1 for this gene. Mutations in the *UGT1A1* gene that lead to complete absence of UGT1A1 activity have been associated with the severe hyperbilirubinemia seen with Crigler-Najjar syndrome. Variations in the number of TA repeats within the TATA box region of the UGT1A1 promoter have been associated with Gilbert disease, a clinically benign, mild hyperbilirubinemia.[15]

The most common number of TA repeats found in the TATA sequence of the *UGT1A1* promoter region in Caucasians is 6. This allele is known as $(TA)_6$ or *UGT1A1*1.* The most common variant of this sequence is the presence of seven repeats, known as $(TA)_7$ or *UGT1A1*28,* and leads to a 30% reduction in promoter activity of the UGT1A1and a reduction in transcription.[96] Tests for detection of *UGT1A1*28* are commercially available. Both $(TA)_5$ and $(TA)_8$ variants of this sequence, although relatively rare, are recognized to exist and correlate with higher and lower expression than the $(TA)_6$, respectively, thus preserving the anticipated inverse relationship between *UGT1A1* expression and the number of dinucleotide repeats. Genotypes are typically referred to as 6/6 for no variants, or 7/7 for homozygosity of *UGT1A1*28.* A nonsynonymous coding variant G71R *(UGT1A1*6)* is also known. The *UGT1A1*28* allele is common in Caucasian populations and populations of African origin (0.26 to 0.56). The *UGT1A1*6* variant is found almost exclusively in Asian populations, with a frequency of 0.13 to 0.25, and is also associated with hyperbilirubinemia.

Irinotecan Application

A well studied example of a pharmacogenetic application for *UGT1A1*28* genotyping is seen with irinotecan. Irinotecan is widely used in metastatic colorectal cancer and in other tumors such as lung and liver. Irinotecan is a prodrug, converted by carboxylesterases to produce the active, cytotoxic metabolite SN-38. This metabolite is a topoisomerase 1 inhibitor and the active agent against malignant cells. Approximately 20 to 35% of patients experience dose-limiting and potentially life-threatening (grade 3 or 4) diarrhea and/or neutropenia when treated with irinotecan.

The toxicity of irinotecan (and of the similar camptothecin analog, topotecan) is related to the accumulation of SN-38. A major route for inactivation of SN-38 is formation of the glucuronide conjugate (SN-38G), a reaction mediated by UGT1A1. Individuals possessing variant TA repeats in UGT1A1 are susceptible to dose-limiting toxicity with irinotecan. It is proposed that the risk of toxicity is near 0% for patients with the TA6/6 genotype, approximately 12.5% for patients with the TA6/7 genotype, and approximately 50% for patients with the TA7/7 genotype. It is generally recommended that patients with the TA7/7 genotype receive a reduced dose of irinotecan as compared with the dose given to patients with a TA6/6 genotype, although specific dosing guidelines are lacking, and the effect is probably most relevant only in "high dose" irinotecan regimens.

UGTs are known to be induced by aryl hydrocarbons and phenobarbital. The flavonoid chrysin has been studied for its ability to induce UGT1A1 specifically in the gastrointestinal tract, because it is not well absorbed and therefore would stay within the gastrointestinal tract, potentially minimizing the opportunity for drug-induced diarrhea. Coadministration of other drugs, such as loperamide, may prevent or alleviate the diarrhea associated with irinotecan. Similarly, coadministration of erythropoietin, granulocyte-colony stimulating factor, or other agents may minimize or shorten the duration of the neutropenic effects of irinotecan.[21] Because the disposition of irinotecan involves other UGTs, as well as the CYP3A family and drug transporters such as ABCB1, ABCC2, and ABCG2, additional study will be required to determine the most effective strategy for identification and management of individuals susceptible to the toxicity of irinotecan. As data accumulate, the utility of genotype-based dose optimization versus coadministration of compounds that counteract or relieve the associated toxicities will be better characterized.

Protease Inhibitors Application

Hyperbilirubinemia with clinically apparent jaundice is frequently observed in patients with human immunodeficiency virus (HIV) who are receiving protease inhibitors such as indinavir and atazanavir. Both of these drugs are

glucuronidated by and are potent inhibitors of UGT1A1.[211] Thus patients who are carriers for *UGT1A1*28* would be at high risk of jaundice, because the consequences of indinavir inhibition would be more pronounced in people with *UGT1A1*28,* who are predisposed to reduced bilirubin glucuronidation activity. Indeed, the presence of *UGT1A1*28* is highly predictive of elevated post-therapeutic bilirubin concentrations in patients treated with indinavir.[214] Case reports of grade 4 hyperbilirubinemia related to *UGT1A1*28* resulting in hepatotoxicity have been published.[58] In addition, a genotype-phenotype association study of *UGT1A1, UGT1A3,* and *UGT1A7* genotypes and hyperbilirubinemia have identified combinations of four *UGT1A* SNPs spanning these three different genes and have associated these variants with grades 3 and 4 hyperbilirubinemia after treatment with atazanavir.[95,96] Patients who were homozygous for all four SNPs expressed the highest incidence of severe hyperbilirubinemia, suggesting a strong association between genetics and response. Genotyping for the combination of these SNPs may be useful in predicting susceptibility to severe hyperbilirubinemia and, in view of the high allele frequency of *UGT1A1*28,* could theoretically reduce drug-induced jaundice by 75%.[148]

Other Phase II Metabolism Enzymes

Other Phase II enzymes that exhibit marked genetic variability among individuals may be clinically important. For example, genetic variations in glutathione *S*-transferases, alcohol dehydrogenase, catechol-*O*-methyltransferase, and dihydropyrimidine dehydrogenase have been studied. Dihydropyrimidine dehydrogenase (coded from *DPYD*) is the initial and rate-limiting enzyme in the three-step pathway of uracil and thymidine catabolism and in the pathway leading to formation of β-alanine. It is also responsible for degrading fluoropyrimidines, such as the commonly used cancer chemotherapeutic drugs 5-fluorouracil and capecitabine. Decreased enzyme activity is associated with a higher risk of severe or fatal toxicity from standard doses of 5-fluorouracil.[117,182,190]

PHARMACODYNAMIC GENES

Vitamin K Epoxide Reductase Complex 1 *(VKORC1)*

Vitamin K epoxide reductase (VKOR), a 163 amino acid protein encoded by the subunit complex 1 gene *(VKORC1),* is a key enzyme in the vitamin K cycle, and is the primary site of action for the commonly used oral anticoagulant warfarin. VKOR converts vitamin K epoxide to vitamin K, which is the rate-limiting step in vitamin K recycling. Several coagulation factors are vitamin K dependent. Impairment of VKOR therefore limits activation of the vitamin K–dependent coagulation factors and explains the anticoagulation effect of warfarin.[42] Further, the amount of VKOR expressed, which may be genetically controlled, will dictate a person's sensitivity to warfarin. Although the activity of VKOR has been recognized since the 1970s, the gene was not cloned and characterized until 2004-2005.[101,197]

Genotype to Phenotype

The *VKORC1* gene is located on chromosome 16 and contains 5126 base pairs arranged in three exons. More than 30 variants have been described that originally were grouped and defined on the basis of haplotypes. *VKORC1* variants are associated most commonly with warfarin sensitivity, but also with warfarin resistance, and are implicated in multiple coagulation factor deficiency disorders. In 2005, two independent laboratories defined a haplotype indicative of warfarin sensitivity (*2 and Group A), based on low dose requirements. The allele frequency of the low-dose or "sensitive" haplotypes was approximately 15% for African Americans, 40% for Caucasians, and 90% for Asian populations.[45,146] It was later recognized that a promoter variant is in very strong linkage disequilibrium with the warfarin-sensitive haplotypes. Because this variant was shown to directly affect expression of the VKOR protein, it is thought to be causative for the warfarin sensitivity phenotype.[79] Most clinical testing currently available detects only the promoter variant of *VKORC1* (–1639G→A). Typically, this variant is tested along with the two common variants of CYP2C9: *CYP2C9*2* (430C→T) and *CYP2C9*3* (1075A→C). Other variants in these and other genes that have been studied to date would appear to have little importance for warfarin dosing.[155,196]

Warfarin Sensitivity Application

As discussed previously, warfarin is a commonly prescribed oral anticoagulant used to prevent thromboembolic disease after surgery and on a long-term basis for patients with deep vein thrombosis, atrial fibrillation, recurrent stroke, or heart valve prosthesis. Warfarin acts through inhibition of Vitamin K epoxide reductase (VKOR), which leads to a reduced amount of vitamin K available to serve as a cofactor for active clotting proteins. Warfarin is a very difficult drug to dose correctly because it has a narrow therapeutic range and wide interindividual and intraindividual variability in response. The dose of warfarin is typically adjusted based on a target range for the INR, for example, 2.0 to 3.0. Inappropriate dosing of warfarin has been associated with substantial risk of major and minor hemorrhage or thomboemboli. Genetic variants of *VKORC1,* representing sensitivity in response to warfarin, and of *CYP2C9,* representing pharmacokinetics of warfarin, are thought to account for approximately one third of the variability among patients. When the genetic variants are combined with common clinical factors and early INR data, up to 70% of the variability seen among patients is thought to be explained. These sources of variability are discussed in detail in the 2008 practice guidelines published by the American College of Chest Physicians, as well as in the product labeling for the popular formulation of warfarin sold as Coumadin.[6]

Among the many mathematical algorithms published for predicting warfarin dose, consistently included covariates include age, gender, an index of body size, and the three common genetic variants: *CYP2C9*2, CYP2C9*3,* and a promoter variant of *VKORC1* (–1639G→A). Some algorithms account for factors such as smoking status, interfering

TABLE 43-7 Example Doses of Warfarin Predicted by the Scone Algorithm[156] for a 6 Foot Tall, 55-Year-Old Person

	CALCULATED DAILY MAINTENANCE DOSE (MG) OF WARFARIN PER GENOTYPE AND PERCENT DIFFERENCE FROM THE NO VARIANT DETECTED DOSE PREDICTION		
***CYP2C9* Variants**	***VKORC1 GG* (No Variants)**	***VKORC1 AG***	***VKORC1 AA***
*1/*1 (no variants)	6.8 mg/d	5.6 (−18%)	4.5 (−34%)
*1/*2	5.6 (−18%)	4.5 (−34%)	3.6 (−47%)
*1/*3	5.0 (−26%)	4.0 (−41%)	3.1 (−54%)
*2/*2	4.5 (−34%)	3.6 (−47%)	2.7 (−60%)
*2/*3	4.0 (−41%)	3.0 (−56%)	2.3 (−66%)
*3/*3	3.5 (−49%)	2.6 (−62%)	1.9 (−72%)

concomitant medications (e.g., amiodarone), liver disease, and existing INR data.[124] An example of doses predicted with one of the first published algorithms[156] for a patient that is 6 feet tall and 55 years of age is shown in Table 43-7. Comparisons of several published algorithms demonstrate good agreement in predicting maintenance dose requirements for populations studied.[56,206] The overall goals of algorithm-guided dosing include reducing the risk of bleeding events, achieving a stable and therapeutic dose sooner, and maintaining therapeutic INRs more consistently. The International Warfarin Pharmacogenetics Consortium has demonstrated some improvement in pharmacogenetics-guided management over fixed dose or clinical monitoring alone, particularly for people who require low doses.[90] However, specific guidelines for application of pharmacogenetic data and related dosing algorithms to clinical practice are lacking, and prospective clinical studies are few in number. Moreover, clinical studies have not consistently demonstrated improved outcomes for patients who receive gene-based dosing of warfarin. Several multisite international studies are currently under way to gather more information as to how and whether pharmacogenetic testing should be routinely applied to warfarin initiation.[32,113,185,195]

Human Leukocyte Antigen (HLA) Complex, Class I, B

The human leukocyte antigen (HLA) complex is a cornerstone for the immune system because of its involvement in identification of foreign proteins. HLA is the human version of the major histocompatibility complex (MHC), a gene family common to many species. The HLA proteins produced from these genes are expressed on the surface of nearly all cells, where they bind to peptides that are exported from the cell. These peptides are thereby captured and displayed to the circulating cells of the immune system. If the immune system recognizes the peptides as foreign (e.g., viral or bacterial peptides), it responds by triggering the infected cell to self-destruct.

Genotype to Phenotype

The MHC in humans consists of more than 200 genes, clustered on chromosome 6. Genes in this complex are categorized into three groups: class I, class II, and class III. Humans have three major class I genes, known as *HLA-A, HLA-B,* and *HLA-C*. It is the *HLA-B* gene that has been best characterized from the perspective of pharmacogenetics, based on a high degree of polymorphism and association of variants with drug hypersensitivity reactions. Some HLA genes have hundreds of variant alleles, classified by a number (such as *HLA-B27*); closely related alleles are categorized together. For example, more than 40 very similar alleles are subtypes of *HLA-B27*. These subtypes are designated as *HLA-B*2701* to *HLA-B*2743*. *HLA-B* gene variants are also associated with risk of disease, particularly immune-mediated inflammatory disease.

Risk of SCARS and Related Drug Hypersensitivity Applications

Severe cutaneous reaction syndromes (SCARS), such as Stevens-Johnson syndrome and toxic epidermal necrolysis, lead to extremely painful rashes that sometimes are life-threatening. The diagnosis of Stevens-Johnson syndrome versus toxic epidermal necrolysis is based on the amount of skin affected, whereas toxic epidermal necrolysis affects more than 30% of the body surface area and therefore is more serious. Overall, drug-induced SCARS occur rarely (1 to 6 per 10,000), but the incidence is approximately 10-fold greater in Asian populations, and reactions are characteristically observed with certain drugs. For example, drug-induced hypersensitivity reactions like SCARS are associated with the antiepileptic drugs carbamazepine, phenytoin, and lamotrigine; drugs used in the management of infectious disease, including abacavir, nevirapine, and sulfamethoxazole; the antiplatelet drug ticlopidine; and the antigout agent allopurinol. The best characterized HLA-drug associations today are *HLA-B*1502* and carbamazepine, *HLA-B*5801* and allopurinol, and *HLA-B*5701* with abacavir. Although not common in most populations, the mortality rates are 5 to 10% for Stevens-Johnson syndrome and up to 40% for toxic epidermal necrolysis.[23,183] Therefore, detection of a high-risk allele before therapy is initiated could allow drug avoidance and substantially reduced risk of the associated ADR.

Genetic testing for HLA variants is highly variable among laboratories, ranging from complete gene sequencing, to identification of single SNPs that are in linkage disequilibrium with high-risk haplotypes. Phenotyping for abacavir is also available. Pretherapeutic testing to identify patients at risk for abacavir hypersensitivity was incorporated into the 2008 guidelines for the use of antiretroviral agents in HIV-1–infected adults and adolescents, published by the Office of AIDS Research Advisory Council, and has been shown to be cost-effective.[71,109]

FUTURE DIRECTIONS

As discussed previously in this chapter, any protein for which the related gene exhibits polymorphism has potential pharmacogenetic implications. The future success of pharmacogenetics depends on understanding (1) the interrelationship of the various proteins involved in pharmacokinetics and pharmacodynamics, (2) the balance between major versus minor pathways, and (3) the mechanisms of action of specific drugs. Also important is an understanding of haplotype relationships, the possible implications of heterozygote variants, and gene dose, for single genes and for combinations of genes. Genome-wide association studies are anticipated to increase the complexity of pharmacogenetics, but they also improve our understanding and utility of genotype-phenotype relationships. Additional clinical studies, particularly prospective and outcome-related studies, are needed to guide implementation of pharmacogenetic findings in the clinic. Finally, closer integration of pharmacy professionals with clinical laboratories and clinicians and increased availability of cost-effective commercial testing will improve the success of pharmacogenetic applications.

CHAPTER 44

Hematopoietic Malignancies

Kojo S. J. Elenitoba-Johnson, M.D.

The hematologic malignancies include leukemias, lymphomas, myeloproliferative disorders, and plasma cell neoplasia. The leukemias are primarily bone marrow and peripheral blood–based processes, whereas the lymphomas are tissue based. The plasma cell dyscrasias are predominantly bone marrow–based diseases. The genetic aberrations that occur in hematopoietic neoplasia may be point mutations, deletions or amplifications of genetic material, chromosomal gains or losses, or translocations. These genetic abnormalities generally lead to deregulation of the function of proto-oncogenes, tumor suppressor genes, or genes involved in the regulation of apoptosis. Identification of genetic abnormalities that underlie the pathogenesis of various hematopoietic malignancies has permitted the development of tumor classification schemes based on nonrandom genetic alterations, the creation of tumor-specific therapeutic interventions, and the use of molecular tests that serve as important adjuncts in the monitoring, prognostics, and overall management of patients with hematopoietic malignancies.

This chapter reviews the molecular basis for the development of human hematopoietic malignancies and includes a discussion of the diagnostic techniques that are used routinely in molecular diagnostic laboratories for the detection and quantification of the distinctive molecular genetic abnormalities that are characteristic of different human leukemias and lymphomas. Where relevant, some detail is provided on the pathogenesis of specific neoplasms that provide insights into the molecular basis for the particular assay design. Additionally, somatic mutations in "karyotypically normal" leukemias that carry important prognostic implications are discussed. Finally, the ability to profile mutations that confer resistance to tyrosine kinase inhibitors ushers in the era of personalized medicine such that specific treatment options can be offered, depending on the known resistance properties conferred by specific mutations.

ANTIGEN RECEPTOR REARRANGEMENTS FOR DETERMINATION OF CLONALITY

The histologic features that distinguish benign reactive lymphocytic proliferations from malignant populations can be subtle and somewhat subjective. The introduction of molecular biological techniques into diagnostic pathology has refined lymphoma diagnostics and classification. B and T lymphocytes exhibit the unique property of rearrangement of the immunoglobulin (Ig) and T-cell receptor (TCR) genes, respectively. Immunoglobulin and T-cell receptor genes encode the amino acid sequences of polypeptides that constitute the corresponding antigen receptor. Antigen receptor molecules mediate antigen recognition and are responsible for the specificity of the normal immune response. B lymphocytes are the mediators of humoral response and produce immunoglobulins, and T lymphocytes mediate the cellular response. Each reactive lymphocyte carries a unique antigen receptor gene sequence; therefore, identification of clonal populations arising from a parent malignant lymphocyte becomes feasible because the malignant population is characteristically monoclonal. Tests for monoclonality were originally developed using the Southern blotting hybridization (SBH) method, which remains the gold standard for specificity for detection of clonality throughout a broad range of lymphoid malignancies (Table 44-1). More recently, SBH has been complemented by polymerase chain reaction (PCR)-based strategies.

Molecular Genetic Basis for Immunoglobulin Gene Rearrangements

Humoral immunity is achieved by the cognitive and effector functions provided by B lymphocytes. Immunoglobulins are produced exclusively by B lymphocytes and constitute the hallmark of the humoral response. Ig molecules are heterodimeric polypeptides composed of two identical 50 to 70 kDa

TABLE 44-1 Detection Frequency of Antigen Receptor Gene Rearrangements by Southern Blot Analysis

	Cases With Antigen Receptor Gene Rearrangement, %					
	Immunoglobulin Genes			T-Cell Receptor Genes		
	IgH	Igκ	Igλ	TCRβ	TCRγ	TCRδ
B-Cell Neoplasms						
Precursor B-cell acute lymphoblastic leukemia/lymphoma	100	40-50	20-25	20-30	50-60	70-80

Ig, Immunoglobulin; *NA,* not applicable; *NK,* natural killer cell; *TCR,* T-cell receptor.

heavy chains, associated with two identical light chains, kappa (κ) or lambda (λ) of approximately 23 kDa. The Ig chains are linked by noncovalent forces and interchain disulfide bridges, and together form a bilaterally symmetric structure. The heavy and light chain proteins encoded by their corresponding genes are composed of a tandem series of homologous segments consisting of approximately 110 amino acid residues. These segments undergo folding into 12 kDa domains with single intrachain disulfide bridges. Heavy chains contain one variable (V) and three constant (C) domains; light chains contain one N-terminal V and one C domain. In both heavy and light chains, the V domain consists of four relatively invariable framework regions of 15 to 30 amino acids separated by three 9 to 12 amino acid–long hypervariable or complementarity determining regions (CDRs). In both heavy and light chains, the CDR3 region is the farthest away from the N-terminus, and it exhibits the greatest sequence variability among the three CDRs. The

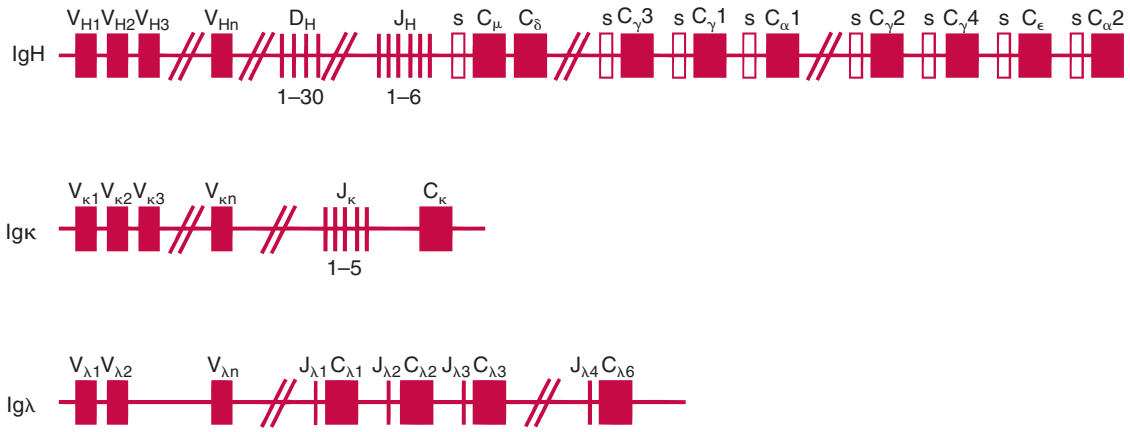

Figure 44-1 Schematic representation of germline configurations of the antigen receptor gene loci. Immunoglobulin heavy chain (IgH), immunoglobulin kappa (Igκ), and immunoglobulin lambda (Igλ) light chains. Each gene comprises several variable (V), joining (J), and constant (C) segments. Note that the IgH gene contains diversity (D) gene segments. Switch regions are indicated by *S*.

C-terminal region of secreted Ig molecules binds to complement components and Fc receptors. The genes encoding the Ig proteins are the target of DNA-based studies for clonality assessment.

The organization of Ig genes in the germline is fundamentally similar in all species studied. Genes encoding the two light chains, (κ and λ), and the single locus containing the various heavy chain genes are located on different chromosomes. To generate the large number of antibody molecules needed, B cells have evolved a unique strategy that involves recombination of germline-encoded immunoglobulin gene segments and a somatic hypermutation mechanism that further diversifies the reactivities of the rearranged antigen receptor molecules.[140] The immunoglobulin heavy and light chain gene loci—IgH, Igκ, and Igλ—are located at chromosomes 14q32, 2p12, and 22q11, respectively. In the germline configuration, all antigen receptor genes are composed of discontinuous DNA segments that are referred to as variable (V), diversity (D), joining (J), and constant (C) regions. Although both Ig heavy and light chain genes contain V, J, and C regions, only the IgH genes contain D regions (Figure 44-1). The IgH gene contains approximately 87 VH, 30 DH, and 6 JH segments. The IgH VH segment genes can be categorized into seven families, based on relatedness of the DNA sequences. The ability of Ig genes to undergo recombination in a manner analogous to shuffling of cards affords the capacity to generate an enormous primary repertoire of 10^9 Ig molecules (Figure 44-2). The human Ig C region contains 11 C region segments, which define nine functional immunoglobulin classes and subclasses (IgM, IgD, IgG1, IgG2, IgG3, IgG4, IgA1, IgA2, and IgE). The C region genes are initially uninvolved in the rearrangement process, but are subsequently juxtaposed to the VDJ complex during RNA splicing. Incorporation of C regions into the rearranged VDJ recombination permits class switching. Thus, the specific V(D)J rearrangement can be expressed as IgG, IgA, or other Ig

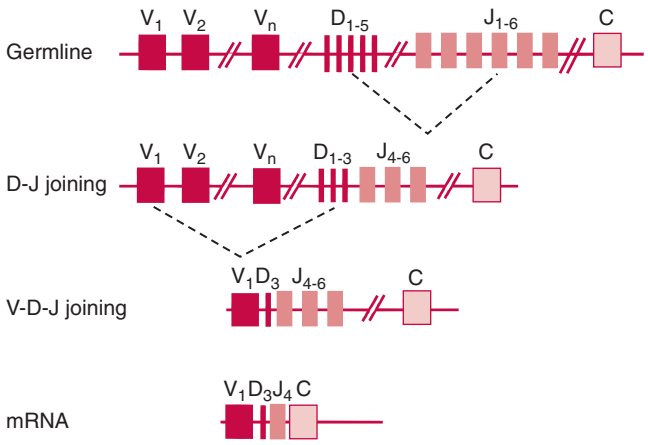

Figure 44-2 Schematic representation of antigen receptor gene rearrangement mechanism using the immunoglobulin heavy chain (IgH) locus as a model. An initial DJ joins in a partial/incomplete recombination, followed by a VDJ joining to complete the rearrangement. The C regions are included at the mRNA level via RNA splicing to form a V(D)JC transcript.

classes. Following the formation of a productive IgH rearrangement, the light chain loci undergo a similar recombination process involving the joining of V to J segments, because no D segments are present in the light chain loci.[28]

The Igκ light chain gene is located on chromosome 2p11-13 and contains up to 1000 Vκ genes, five Jκ segments, and one Cκ gene. A κ-deleting sequence (element) is present 3′ to the Cκ region. In Igλ-expressing B cells in which the Igκ genes are not productively rearranged, the κ-deleting element undergoes rearrangement such that the Cκ locus is deleted. The Igλ light chain is situated on chromosome 22q11 and is composed of several Vλ segments with Jλ and Cλ segments arranged in tandem. The Cλ locus is polymorphic and

may be present in one to nine copies per allele in different individuals. The hierarchy of the rearrangement events is such that both alleles of the heavy chain rearrange prior to the light chain genes, and the kappa (κ) light chain locus is productively rearranged before (in most cases, but not always) the λ light chain genes. Thus, the immunoglobulin lambda (λ) light chain gene is not favored for clonality analysis because it frequently rearranges after the κ light chain gene. In addition, because most clonal rearrangements of the immunoglobulin heavy chain gene can be detected in up to 95% of clonal processes, it has become customary to perform only Southern blot analysis for the IgH locus in many laboratories.

Molecular Genetic Basis for T-Cell Receptor Gene Rearrangements

A similar process as described for the Ig genes occurs in the T-cell receptor (TCR) genes, with the notable exception of the absence of a somatic hypermutation mechanism in T-cell receptor gene rearrangements. The developmental hierarchy of T-cell receptor genes is such that the TCR-δ gene is the first to rearrange, followed by the TCRγ, TCRβ, and then the TCRα genes.[26] The TCR-δ gene is located on chromosome 14q11 and contains six or fewer Vδ segments, only two or three Dδ segments, and three Jδ segments (Figure 44-3). It is located within the TCR-α gene, immediately 3′ to the last TCR-Vα gene and 5′ to the TCR-Jα segments. This location is important in that productive rearrangements of the TCRδ gene lead to expression of the γ/δ TCR. In the event that the TCRδ rearrangement is nonproductive, Vα to Jα rearrangements obligatorily require that the TCRδ be deleted. The TCRα gene is located on band 14q11 and flanks the TCRδ gene on either side; it contains several Vα segments, an extensive J region composed of up to 50 Jα genes, and one Cα locus. By virtue of the architecture of the TCRα and δ loci, rearrangement of a Vα segment to a Jα segment typically leads to deletion of the intervening TCRδ loci. T cells undergoing such rearrangements may go on to express the TCR-α/β protein. The TCRβ gene is located on band 7q34 and contains 75 to 100 Vβ segments, flanked at the 3′ end by two Dβ, Jβ, and Cβ regions. Each region consists of one Dβ segment, with six or seven Jβ segments and one Cβ segment. Rearrangements may occur within or between segments (e.g., Vβ1 to Jβ1, Vβ2 to Jβ1). Extensive sequence homology is noted between the Cβ1 and Cβ2 segments. This phenomenon is exploited in the utilization of a consensus Cβ probe in the Southern blotting–based clonality assessment of TCR genes. The TCRγ gene is located on band 7q15 and contains about 11 Vγ segments and two Jγ genes.[24] The simple structure of the architecture of this gene favors its utilization as a target for TCR receptor PCR, where consensus primers are designed to encompass the relatively few Vγ and the Jγ genes.

Southern Blot Hybridization Analysis for Antigen Receptor Gene Rearrangements

In this procedure, high-quality total cellular DNA extracted from a fresh or fresh-frozen specimen is subjected to digestion using different bacterial restriction endonucleases, which produce DNA fragments of different sizes encompassing the Ig or TCR gene region segments to be interrogated (Figures 44-4 and 44-5). Enzyme-restricted DNA from each enzyme is subjected to gel electrophoresis and is transferred by blotting and immobilized on a membrane. A labeled probe complementary to the Ig J region segment is hybridized to the membrane. Clonal rearrangements are recognized by the identification of one or two novel rearranged bands that are distinct from the germline pattern obtained with a benign sample or placental DNA. One or two novel rearranged

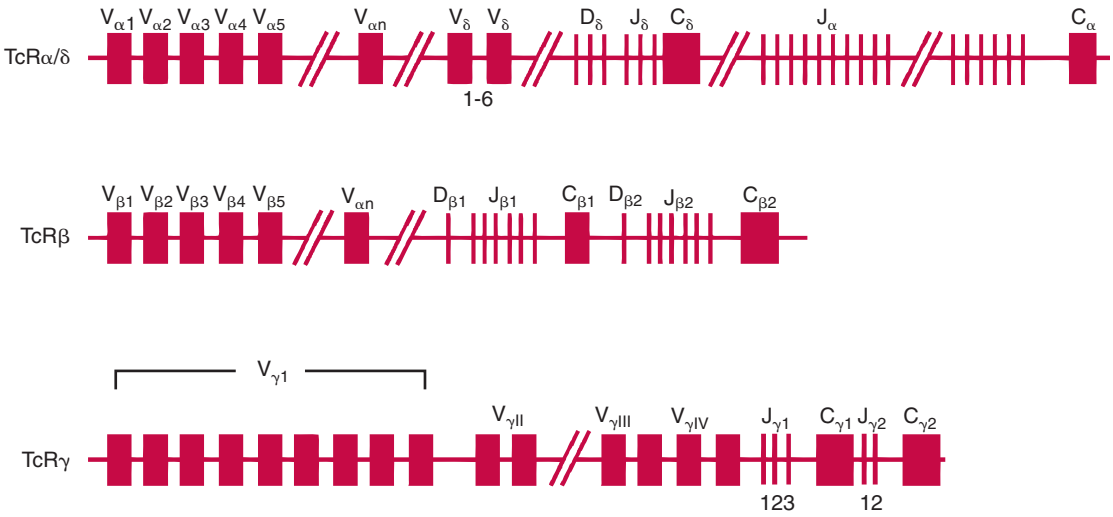

Figure 44-3 T-cell receptor (TCR) genes consist of α/δ-, β-, and γ-chain genes. The architectural configurations are similar to those of the immunoglobulin (Ig) loci. Note that only the TCRβ- and δ-chain genes contain diversity (D) regions.

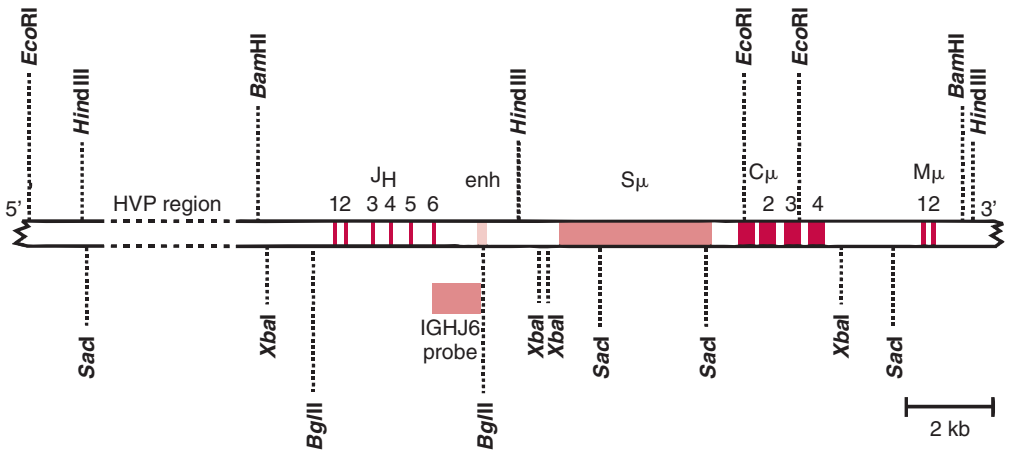

Figure 44-4 Restriction map of the immunoglobulin heavy chain (IgH) locus. The sites of the enzyme restriction sites determine the sizes of the fragments that are visualized using the IgH J6 probe as illustrated (e.g., BamHI, XbaI, and BglII enzymes yield 16 kb, 6.2 kb, and 3.8 kb fragments, respectively). Restriction patterns different from the germline patterns are indicative of a novel rearrangement event.

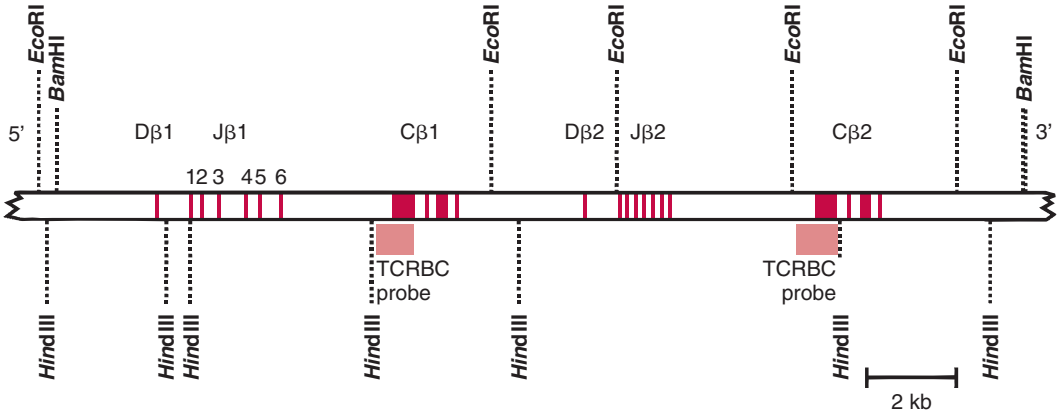

Figure 44-5 Restriction map of the T-cell receptor (TCR)β chain locus. The probe is complementary to the TCRβ constant region. Extensive sequence homology is noted between the Cβ1 and Cβ2 segments. Thus the Cβ probe hybridizes to both the Cβ1 and Cβ2 segments, thereby resulting in two germline band signals for all enzymes depicted, except BamHI. The EcoRI site located between the Cβ1 and Jβ2 segments is notoriously resistant to digestion and may yield a partial digest with a band of 8.0 kb.

(nongermline) bands may be identifiable, depending on whether a clonal monoallelic or biallelic rearrangement is present (Figure 44-6).

Material suitable for Southern blot analysis includes fresh tissue or aspiration biopsy material, as long as sufficient cellular material can be obtained from the specimen of interest. Ethanol-fixed tissue can also be successfully utilized. However, formalin-fixed tissue yields DNA of insufficient quality to permit reliable Southern blotting because of cross-linking of proteins to DNA. A Southern blot hybridization assay using three enzymes requires approximately 1.5×10^7 cells (approximately 15 μg of intact total cellular DNA). Hypothetically, all of the antigen receptor genes could be utilized as potential targets for assessment of clonality status. However, only the immunoglobulin heavy and light chains and the T-cell receptor β-chain loci have gained widespread use for clonality testing. With regard to the other T-cell loci, the TCR-α locus is impractical because it is composed of several J segments that are distributed widely apart, and it would pose practical challenges in the optimization of assays for multiple probes. Evaluation of TCRγ and δ loci is not favored because they have only a limited number of V segments, such that even reactive T-cell populations may yield confusing nongermline bands.

The diagnostic hallmark of a clonal population is the presence a nongermline novel rearranged band (see Figure 44-6). However, it is important to recognize that under certain circumstances, nongermline bands do not indicate

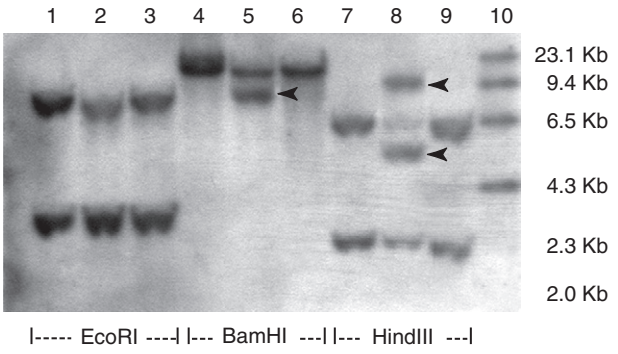

Figure 44-6 Southern blot hybridization analysis for clonal rearrangements of the T-cell receptor (TCR)β chain locus. DNA samples extracted from two different patients with a suspected diagnosis of T-cell lymphoma are assessed. *Lanes 1 to 3* represent the EcoRI digests. *Lanes 4 to 6* show the BamHI digests, and *lanes 7 to 9* demonstrate the HindIII digests from both samples run side by side. *Lane 10* shows the DNA size marker. *Lanes 1, 4,* and *7* show the restriction patterns in the germline control (placenta) using the EcoRI, BamHI, and HindIII enzymes, respectively. DNA from patient 1 *(lanes 2, 5,* and *8)* shows a germline pattern using EcoRI, but novel rearrangements *(arrowheads)* using BamHI and HindIII. Patient 2 *(lanes 3, 6,* and *9)* shows a germline pattern in all three enzyme digests. Accordingly, sample 1 is scored as showing evidence for a monoclonal T-cell population, and sample 2 is scored as showing evidence for a polyclonal T-cell population.

monoclonality. For example, single-nucleotide polymorphisms (SNPs) may create or abolish restriction enzyme recognition sites, thus yielding fragments with novel restriction banding patterns. In this scenario, utilization of a different enzyme would yield a germline configuration. The potential of these SNPs to confound the interpretation of Southern blot studies justifies the utilization of up to three or more enzymes for the unequivocal assignment of monoclonality. A second situation in which a nongermline band may occur and yet not indicate monoclonality is partial digestion. This is typically evident in the control sample (placental DNA) and invalidates the significance of any such band in the test sample. Clonal rearrangements of the Ig or TCR genes have been used to ascertain the lineage of hematologic neoplasms that do not express B- or T-cell specific markers. Intuitively, clonal rearrangements of Ig genes would indicate B-cell processes, and clonal rearrangements of TCR genes would indicate T-cell processes. However, some malignant lymphomas and leukemias may demonstrate both Ig and TCR rearrangements. In particular, acute leukemias and lymphoblastic lymphomas may demonstrate both Ig and TCR gene rearrangements. Further, up to 20% of acute myeloid leukemias may demonstrate rearrangements of Ig or TCR genes.[20,59,73] Hence, lineage is best assigned using a combination of immunophenotypical and molecular studies.

Polymerase Chain Reaction Analysis of Antigen Receptor Gene Rearrangements

Although Southern blot hybridization analysis for detection of antigen receptor gene rearrangements is recognized as the "gold standard" for assessment of clonality, PCR-based assays have become the mainstay for the detection of rearrangements of Ig and TCR genes in many molecular diagnostic laboratories. This is because SBH is more labor-intensive and takes longer to complete. Additionally, SBH requires a substantial quantity of intact DNA and hence is less amenable to specimens with suboptimal DNA quality (as is the case with fixed paraffin-embedded tissue samples). PCR on the other hand is well suited for the utilization of such specimens, which constitute the majority of samples analyzed in the clinical laboratory.

Application of PCR for the identification of clonality entails the utilization of consensus V region and J region primers and in vitro amplification of DNA across the V(D)J junction, followed by gel electrophoresis or other methods to determine the size distribution of PCR-generated fragments. In the germline configuration, V and J region segments are located several kilobases apart and are not amplifiable. However, the V(D)J recombination brings the VDJ segments into close proximity, thereby permitting amplification of products that, based on primer location, are usually 80 to 350 bases in length. The V region primers typically are designed to be complementary to the conserved framework (I, II, or III), and the J region primer is typically complementary to consensus sequences present across all six J regions in the immunoglobulin heavy chain gene. Similar strategies may be used for light chain genes as well, but the yield is lower; hence, IgH-PCR is favored. Utilization of framework III consensus primers offers the highest yield but can be complemented by increased diagnostic sensitivity afforded by the inclusion of framework II and/or framework I primer-mediated IgH-PCR for clonality. With regard to T-cell assays, the TCRγ-PCR is the most informative. In these assays, monoclonal populations yield one or two dominant bands (Figure 44-7), while polyclonal cells, each of which carries a unique rearrangement with slightly different band sizes, demonstrate a ladder or smear pattern on gel electrophoresis.[81,130] Thus the specificity of each rearrangement identified by PCR is determined by the junctional sequence; hence the marker of clonality in PCR differs from that in SBH analysis, wherein the marker is the configuration of rearranged antigen receptor genes.

Following PCR, the amplification products are analyzed by agarose or polyacrylamide gel electrophoresis and are visualized by ethidium bromide staining.[38,138] Agarose gels, although less expensive, do not provide resolution of polyacrylamide, which can be configured to reliably discriminate bands differing in size by as few as three bases. This is often very useful in the assessment of PCR products for antigen receptor gene rearrangement assays. Further resolution may be achieved by evaluating sequence-specific and melting characteristics of double-stranded DNA using denaturation gradient gel electrophoresis or temperature gradient gel electrophoresis.[55] More recently, capillary gel electrophoresis has

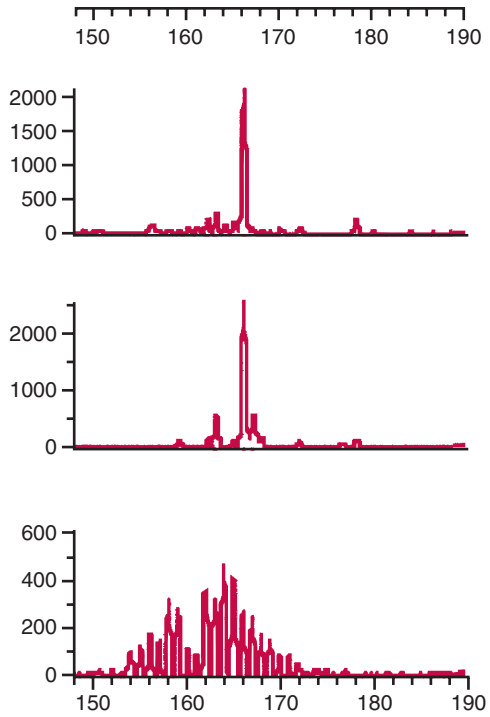

Figure 44-7 Polymerase chain reaction (PCR) analysis for clonal rearrangements of the antigen receptor gene loci. PCR analysis of the T-cell receptor (TCR) γ-chain locus is shown. The *upper and middle panels* show duplicate assays with monoclonal capillary electrophoretic peaks of identical size (≈166 bp) in the two replicates. The *bottom panel* shows a polyclonal pattern.

become a preferred method for analysis of antigen receptor gene rearrangement. A successful study would exhibit PCR products in the expected size range, appropriate results in positive and negative controls, and absence of bands in the template-free (H_2O) control.

PCR-based clonality assays are less sensitive in detecting all possible clonal rearrangements when compared with SBH analysis, which approaches 100% if sufficient restriction enzymes and a variety of probes are used. Depending on the assay and the lymphoid neoplasm tested, PCR-based clonality studies may show false-negative rates from 10 to 40% when compared with SBH. False negatives occur for several reasons. First, in contrast to SBH, PCR does not detect partial DJ rearrangements, wherein V and J region genes are not approximated to one another and are too distant for conventional PCR to generate an amplification product. Second, the consensus primers are incapable of hybridizing to all of the different V regions, any one of which could be potentially present in any single neoplasm. Of particular importance to the Ig genes, somatic mutations occurring within the Ig V region genes result in decreased ability for the consensus V region primers to anneal optimally to the V region genes in the template DNA. Thus lymphoid neoplasias with a high somatic hypermutation rate, such as follicular lymphoma, yield lower positive rates by PCR-based Ig clonality tests.[125,126] Most of the difficulties described previously can be overcome by the utilization of multiple primer sets. In the event of a negative PCR result, SBH analysis may be performed if sufficient high-quality genomic DNA is available. The main drawback for PCR is the propensity for contamination. Various strategies for contamination control such as maintaining separate DNA extraction and amplification rooms, utilization of laminar flow hoods, and incorporation of uracil DNA glycosylase into PCR should be employed as a rule to prevent contamination problems.

The ability to detect rare DNA species carrying a specific molecular aberration (sensitivity) of PCR is dependent on the particular application. For antigen receptor gene rearrangement studies, PCR can detect a monoclonal population in a background of 10^2 to 10^3 polyclonal cells of the same phenotype (B or T cells). By comparison, PCR can detect one cell harboring a chromosomal translocation within a background of 10^5 to 10^6cells negative for the translocation.[92]

MOLECULAR GENETICS OF MALIGNANT LYMPHOMAS

Antigen receptor gene rearrangements, which are integral to normal B- and T-cell development, and the elaboration of an appropriate immune response are fraught with susceptibility for abnormal translocation of foreign genes, deregulation of which contributes to the development of lymphoid neoplasia. A translocation typically involves the transfer of chromosomal material from one chromosome to a different chromosome. Indeed, nonrandom chromosomal translocations are frequently observed in hematologic neoplasia, and in many cases are characteristic of specific types of tumors. Translocations typically occur in one of two structural configurations, each with distinctive genetic consequences. In the first scenario, the translocation results in the juxtaposition of the intact coding sequence of an oncogene in close proximity with an antigen receptor gene, leading to dysregulated expression and increased production of the structurally normal oncoprotein. This mechanism is most frequently seen in malignant lymphomas, as exemplified by the t(14;18)(q32;q21) characteristic of follicular lymphoma. This translocation juxtaposes the *BCL2* gene on 18q21 adjacent to the IgH gene on 14q32, leading to overexpression of BCL2 mRNA and protein.[142] In the second scenario, chromosomal translocation leads to an in-frame juxtaposition of two different genes, with resultant creation of a novel chimeric gene. This mechanism is most commonly observed in the leukemias, and less commonly in malignant lymphomas. The t(2;5)(2p23;q35) seen in anaplastic large cell lymphoma is one example wherein an abnormal fusion gene *(NPM-ALK)* is formed and is central to pathogenesis.[96] As another example, the t(11;18)(q21;q21) seen in a subset of extranodal marginal zone B-cell lymphomas of mucosa-associated lymphoid tissue leads to formation of an abnormal *API-MALT1* chimeric gene fusion.[29] Reverse transcription PCR is a well-suited strategy for the diagnostic detection of such chimeric fusions, because the fusion product is often within the size range of amplifiability of conventional PCR. Many of the translocation

breakpoints are widely dispersed and are not clustered. If DNA were to be considered as the template for such PCR, it would best be performed as a long-distance (LD) PCR protocol. However, LD PCR protocols are not applicable to many clinical sample types. A list of common chromosomal translocations, participating genes, and associated lymphomas is provided in Table 44-2.

Southern Blot Hybridization Analysis for the Detection of Chromosomal Translocations

Southern blot hybridization analysis is an excellent method for the detection of chromosomal translocations. A sequence-specific probe to the gene of interest is utilized for SBH analysis, as described for the antigen receptor genes. Detection of a pattern of bands of different sizes from those seen in the germline configuration of the gene suggests the presence of a translocation. This approach method does not, however, identify the translocation partner of the gene of interest. As with the antigen receptor gene rearrangement studies by SBH, SNPs at enzyme restriction sites may result in nongermline patterns that may be misinterpreted as translocations. In this scenario, utilization of a different restriction enzyme will correctly show the gene locus to be of germline size. The labor-intensive nature of SBH and the requirement for high-quality DNA have diminished its popularity for routine detection of chromosomal translocations in the clinical laboratory. In this regard, PCR continues to gain in utilization for detection of recurrent chromosomal translocations.

Polymerase Chain Reaction Analysis for Detection of Chromosomal Translocations

PCR is well suited for analysis of chromosomal translocations, particularly when the translocation breakpoints are clustered and the sequences flanking the translocation breakpoints are well characterized.

t(14;18)(q32;21)—*BCL2/JH* Aberration

The translocation t(14;18)(q32;21), characteristic of follicular lymphoma, exemplifies the utility of PCR in the detection of a chromosomal translocation characteristic of a specific form

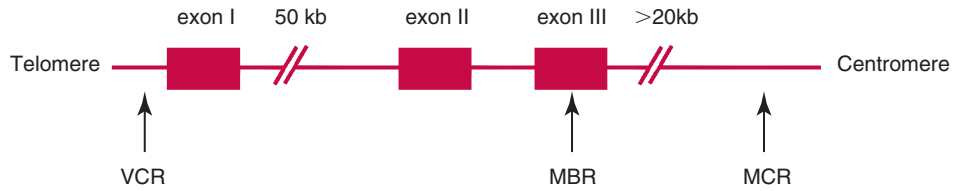

Figure 44-8 Schematic representation of the organization of the *BCL2 gene* and the most frequent breakpoints on chromosome 18q21 involved in the t(14;18). The *BCL2*exons are represented as rectangles. MBR represents the major breakpoint cluster region, where approximately 50 to 60% of breakpoints occur. MCR represents the minor breakpoint cluster region, where 20 to 25% of breakpoints may be found. VCR represents the variant cluster region, where 5 to 20% of breakpoints may be found.

of non-Hodgkin lymphoma. The t(14;18) is a balanced reciprocal translocation involving the *BCL2 gene* (18q21) and the IgH locus (14q32) (Figure 44-8). The *BCL2* gene is composed of three exons and two introns.[128] At up to four different regions on 18q21, breakpoints are frequently found. The 18q21 breakpoints in most translocations are clustered in the *major breakpoint cluster* region (MBR). The MBR is a 150 bp sequence located within the 3′ untranslated region of exon 3 of the *BCL2 gene,* and harbors approximately 60% of the breakpoints found in follicular lymphoma.[141,152] Another 20% of follicular lymphomas harbor t(14;18) aberrations in which the breakpoint is located at the *minor cluster* region, which is located 30 kb further 3′ to the *BCL2 gene*. An additional cluster of breakpoints occur within the *variant cluster region* located 5′ upstream to the *BCL2* gene, accounting for approximately 5% of the breakpoints found in follicular lymphoma (see Figure 44-8).[112] More recently, an intermediate cluster region (ICR) has been described with additional 18q21 breakpoints associated with follicular lymphoma.[1] Although initial studies comparing conventional cytogenetics, Southern blot, and PCR-based methods for detection of the t(14;18) (not including the ICR) showed that 86% of cases were identified by Southern blotting and 75% by PCR,[66] the inclusion of PCR assays targeting the ICR improves the PCR detection rate for the t(14;18).[1] Figure 44-9 shows fluorescence in situ hybridization (FISH) analysis demonstrating the t(14;18) in a sample that tested negative by PCR. An important caveat to note is that the t(14;18) has been detected in benign tonsils and reactive lymph nodes,[4,87] and in the peripheral blood of normal blood donors.

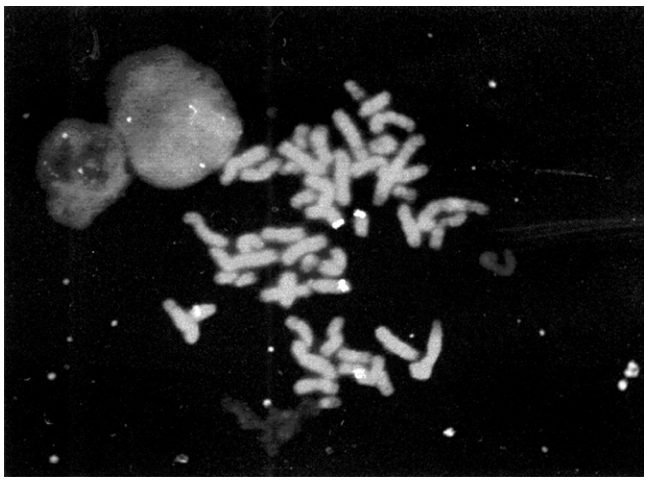

Figure 44-9 Fluorescence in situ hybridization for the t(14;18) anomaly on metaphase spreads of a case of follicular lymphoma. The immunoglobulin heavy chain sequences on 14q32 when juxtaposed to the *BCL2* sequences on 18q21 yield a fusion signal indicative of the presence of the t(14;18).

t(11;14)(q13;32)—*CCND1/JH* Aberration*

The t(11;14)(q13;32) abnormality is characteristic of mantle cell lymphoma,[85,151] but is rare in other types of malignant lymphoma. This translocation juxtaposes the *CCND1* locus on 11q13 with the immunoglobulin heavy chain gene enhancer locus at 14q32.[143] This leads to deregulation of the cyclin D1 gene with a quantitative increase in the production of normal cyclin D1 transcripts. Structurally, multiple breakpoints are found on chromosome 11. The most frequently involved location on 11q13 is the major translocation cluster (MTC) region, located 110 kb 5′ to the *CCND1* locus.[143] Other breakpoints occurring within minor translocation cluster regions have been described 3′ to the major translocation cluster but 5′ to the *CCND1* locus (Figure 44-10).[111] The *CCND1* gene is composed of five exons covering a genomic distance of approximately 15 kb.[97] The gene encodes cyclin D1, which regulates cellular transition from G1 to S phase. Despite the diversity of breakpoints flanking the *CCND1* gene, the t(11;14) does not lead to disruption of the coding region of the *CCND1* gene. Consequently, the expression of cyclin D1 is qualitatively normal but quantitatively increased. One of the practical consequences of the multiple breakpoints in mantle cell lymphoma is that approximately 70% of cases of mantle cell lymphoma can be demonstrated to harbor the t(11;14) by Southern blotting analysis using multiple probes for detection of the various breakpoints.[155] By comparison,

*Accepted gene names and symbols can be found at http://www.genenames.org/accessed July 15, 2011.

most published PCR protocols detect only approximately 40% of the t(11;14) anomalies in mantle cell lymphoma, and most of these are clustered in the MTC.[155] This is in marked contrast to DNA fiber FISH, which reportedly may detect up to 95% of the t(11;14) aberrations, making FISH the most sensitive method for detection of this abnormality.[145]

MOLECULAR GENETICS OF LEUKEMIAS

Human leukemias are characterized by recurrent genetic abnormalities that can be utilized as genetic markers of the specific leukemia. The genetic abnormalities are most often recurrent chromosomal translocations that result in chimeric fusions with dysregulated cellular functions, leading to differentiation block or enhancement of proliferation. The chronic leukemias of myeloid-derived cells are characterized by constitutive activation of tyrosine kinases, which primarily confer an excessive proliferative signal and an increased survival advantage. An example of this is the t(9;22), which results in the *BCR-ABL* chimeric fusion characteristic of chronic myelogenous leukemia (CML). Inhibition of activated tyrosine kinases is a bonafide therapeutic option, as in the case of imatinib mesylate (Gleevec) in CML. By comparison, the chromosomal translocations in acute myeloid leukemias typically result in loss-of-function aberrations within transcription factors that lead to maturational arrest or differentiation blocks at early stages of hematopoietic development. The preponderance of evidence suggests that genetic aberrations leading to maturational arrest in the acute myeloid leukemias are by themselves insufficient to cause leukemia. The concomitant occurrence of cooperating mutations in the *RAS* and tyrosine kinase genes *FLT3* and *C-KIT* permits progression to a frank leukemia. In either case, the presence of genetic aberrations provides a target for disease detection and monitoring, and for potential gene-specific therapy. A comprehensive list of translocations and fusions thereby arising in acute leukemias is provided in Table 44-3. The most frequently employed technique for the detection of chimeric transcripts in the molecular laboratory is reverse transcriptase–polymerase chain reaction (RT-PCR). Although it is recognized that the definitive method for detection of point mutations is sequencing, a variety of techniques may be used to screen for the presence of point mutations (e.g., single-strand conformation polymorphism analysis,[102,134] denaturation gradient gel electrophoresis,[12] fluorescence real-time PCR-based melting curve analysis).[39]

Recurrent Chromosomal Translocations in Acute Myeloid Leukemias

The translocations that occur in the acute myeloid leukemias target transcription factors or transcriptional coactivators. The transcription factors are involved in the differentiation of hematopoietic cells, and disruption of their normal function by the translocation leads to developmental arrest and maturational block at immature stages of differentiation. Targeted transcription factors include the retinoic acid receptor alpha (RARα) in acute promyelocytic leukemia (APL) and several members of the core binding factor (CBF) complex. Core binding factor is a transcription factor composed of heterodimers including a DNA-binding component known as *AML1 (RUNX1/CBFA2/PEBP2A)* and a subunit CBFβ that activates the transcription of *AML1*. CBF is targeted in the t(8;21)[43] aberration, which results in the AML/*ETO* fusion characteristic of acute myelogenous

leukemia (AML) with differentiation (AML FAB-M2). CBF is similarly targeted in the inv(16), which leads to generation of a fusion gene *(CBFβ/SMMHC)* comprised of *CBFβ* and the smooth muscle myosin heavy chain gene *(SMMHC)* found in a subset of AML4Eo.[88] The multilineage importance of CBF is manifest in a subset of precursor B-cell acute lymphoblastic leukemias, where it is targeted in the t(12;21), which leads to the TEL/*AML1* fusion.[54] All chimeric proteins that result from chimeric fusions are dominant negative inhibitors of CBF-mediated transcription.[49,62] The transcriptional repression of CBF target genes caused by CBF-chimeric proteins partially involves recruitment of the histone deacetylase complex.

By comparison, APL is characterized by translocations involving the RARα gene (see Table 44-3). These translocations result in a block of myeloid differentiation at the promyelocytic stage. It has been shown that maturational arrest is due in part to recruitment of the nuclear corepressor–histone deacetylase complex. The ability of all-*trans* retinoic acid (ATRA) to bind to *PML/RARα,* resulting in release of the nuclear corepressor complex, explains in part the ability of ATRA to relieve the maturational block in promyelocytes central to the development of APL.

t(8;21)(q22;q22)—AML1-ETO

The t(8;21)(q22;q22) was originally described in a case of acute leukemia by Janet Rowley in 1973.[113] The translocation is found in approximately 7% of cases of de novo AML and is more common in young individuals. The translocation is found in 20 to 40% of AMLs of the FAB-M2 subtype.[3] It has been reported infrequently in AML FAB-M1, AML FAB-M4, and rare cases of therapy-associated AML. The translocation leads to fusion of the *AML1* gene (acute myeloid leukemia 1 gene), also known as *CBFA2* (core binding factor subunit A2) or *PEBP2α* (polyoma enhancer binding protein 2 subunit α), to the *ETO* gene (8;21), also known as *MTG8* (myeloid translocation gene on chromosome 8).

The t(8;21) portends a good prognosis in cases of de novo AML, with a favorable response to treatment with cytosine arabinoside.[98] The *AML1-ETO* chimeric fusion is detectable by RT-PCR in the vast majority of t(8;21)-positive AMLs, thus making RT-PCR a good choice for detection of the t(8;21) in clinical samples. The *AML1-ETO* fusions join exon 5 of *AML1* to exon 2 of *ETO* (Figure 44-11), and the fusion transcript can be detected in complex translocations in a significant proportion of cases that are t(8;21) negative by conventional cytogenetics.[3,94] Specifically, RT-PCR has been reported to detect *AML1-ETO* fusions in 8 to 12% of AML.[3,79,94] It is interesting to note that the *AML1-ETO* fusion transcript may be detected using sensitive end point PCR assays several years after chemotherapy or bone marrow transplant (BMT), thus limiting its predictive value for relapse in affected patients.[70] Quantitative studies using recently developed real-time PCR protocols (Figure 44-12) provide a better indication of increasing transcript copies and hence disease recurrence.

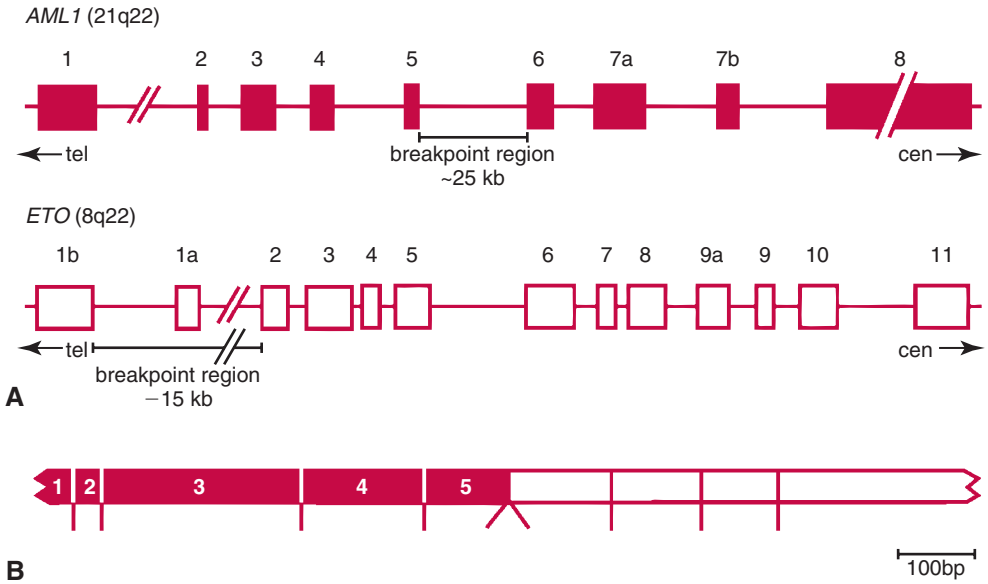

Figure 44-11 Schematic representation of the organization of the *AML1* (21q22) and *ETO* genes (8q22) involved in the t(8;21) anomaly that is characteristic of FAB AML-M2. The centromeric *(cen)* and telomeric (tel) directions are indicated. In A, the exons of the *AML1* gene are depicted in *red rectangles;* the exons of the *ETO* gene are depicted in *white rectangles.* In B, the configuration of the *AML1/ETO* chimeric fusion is shown. The numbers below the fusion transcript indicate the position of the first nucleotide in the exon involved, or the last nucleotide of the exon immediately 5′ to the fusion.

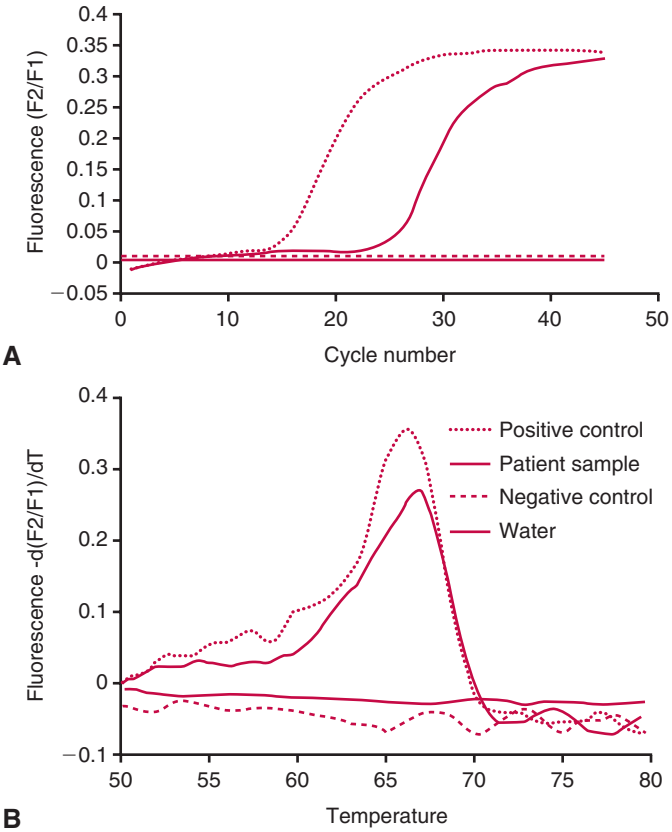

Figure 44-12 Real-time polymerase chain reaction (PCR) detection of *AML1/ETO* fusion transcript. Real-time PCR detection was performed using a sequence-specific hybridization probe format with oligonucleotide probes labeled with fluorescein as the donor fluorophore and LCRed640 as the acceptor. Postamplification melting analysis was performed to provide confirmation of amplicon identity through the probe melting temperature. A shows the fluorescence (F) versus cycle number (C) on the LightCycler (Roche Diagnostics, Indianapolis, Ind). The characteristic three-phase profiles of amplification curves are recognizable (i.e., initial lag, exponential or log/linear, and the final plateau phase). The *red dotted curve* represents the positive amplification signal for the t(8;21) in the Kasumi cell line positive control. The *red solid curve* represents the patient sample, also showing the presence of the *AML1/ETO* fusion. The *red dashed line* represents a negative control (placental cDNA), and the *red flat line* is the no-template (H_2O) control. B shows the derivative melting curves with positive melting peaks at ≈65 °C in both the Kasumi cell line positive control and the patient sample. Both negative and water controls show flat lines indicating the absence of the t(8;21) *AML1/ETO* product.

t(15;17)(q22;q21)—*PRAM1* (also known as PML-RARA)

The t(15;17) is the characteristic molecular abnormality in APL, which is classified as AML FAB-M3. This abnormality is present in virtually all cases of APL, which accounts for 5 to 10% of all AMLs. The t(15;17) results in juxtaposition of the putative transcription factor *PML* on 15q22[13,90] to the retinoic acid receptor-α gene on 17q21.[107] The breakpoints on chromosome 17 are confined to a 15 kB fragment within intron 2 of the *RARα* locus. The breakpoints on chromosome 15 are more varied with involvement of three or more distinct regions (Figure 44-13, *A*). These include intron 6 *(BCR 1),* which is involved in approximately 55% of cases, exon 6 *(BCR 2),* which is involved in 5% of cases, and intron 3 *(BCR 3),* which is involved in 40% of cases. Similar to the scenario seen in the t(9;22) leading to *BCR-ABL* fusion, the different breakpoints on *PML,* the alternatively spliced transcripts, and usage of two different polyadenylation sites further give rise to a greater variety of *PML-RARα* fusion transcripts of different sizes (Figure 44-13, *B*).[10] Recognition of these varied transcripts is important in the design of diagnostic RT-PCR assays that are capable of detecting the majority of t(15;17) fusions. In this regard, most assays have been directed at the *PML-RARAα* fusion, because the reciprocal *(RARα-PML)* fusion is not detectable in some cases of APL. The PML-RARA chimeric protein contributes to leukemogenesis by blocking the differentiation of myeloid cells at the level of promyelocytes. The persistent detection of *PML-RARA* transcripts in treated patients is an ominous indicator of a tendency for relapse. Quantitative real-time PCR provides an opportunity for sensitive and specific monitoring of consecutive samples at appropriate intervals.

Recurrent Chromosomal Translocations in Chronic Leukemias of Myeloid/Monocytic Lineage

The chronic myeloid leukemias are characterized by translocations that lead to constitutive activation of tyrosine kinases. The most frequent is the t(9;22)(q34;q11), resulting in the *BCR/ABL* fusion characteristic of CML. Up to seven different chromosomal translocations are associated with the chronic leukemias of myeloid/monocytic lineage, and all are characterized by the formation of a chimeric fusion with a carboxy-terminal tyrosine kinase domain and an oligomerization motif in the amino-terminus of the fusion protein. The oligomerization motif is important for the constitutive activation of tyrosine kinase, which transforms hematopoietic cells and confers them with ligand-independent growth potential.

t(9;22)(q34;q11)—*BCR-ABL* Aberration

The t(9;22) Philadelphia chromosome is the diagnostic hallmark of CML and is found in virtually 100% of cases. The translocation is also found in up to 20 to 50% of acute lymphoblastic leukemias (ALLs) in adults, in 2 to 10% of childhood ALLs, and in rare cases of malignant lymphoma and myeloma.[11,75-77,91] The t(9;22) results in the juxtaposition of 3′ sequences on the *c-ABL* tyrosine kinase proto-oncogene (9q34) to the 5′ sequences of the breakpoint cluster region *BCR* gene (22q11). The t(9;22) results in the formation of two hybrid genes: *BCR-ABL* on the derivative chromosome 22, and *ABL-BCR* on the derivative chromosome 9.[27] The *BCR-ABL* fusion encodes a chimeric protein with constitutively activated tyrosine kinase activity. Although the breakpoints on chromosome 9 are relatively constant and 5′ to exon 2 of

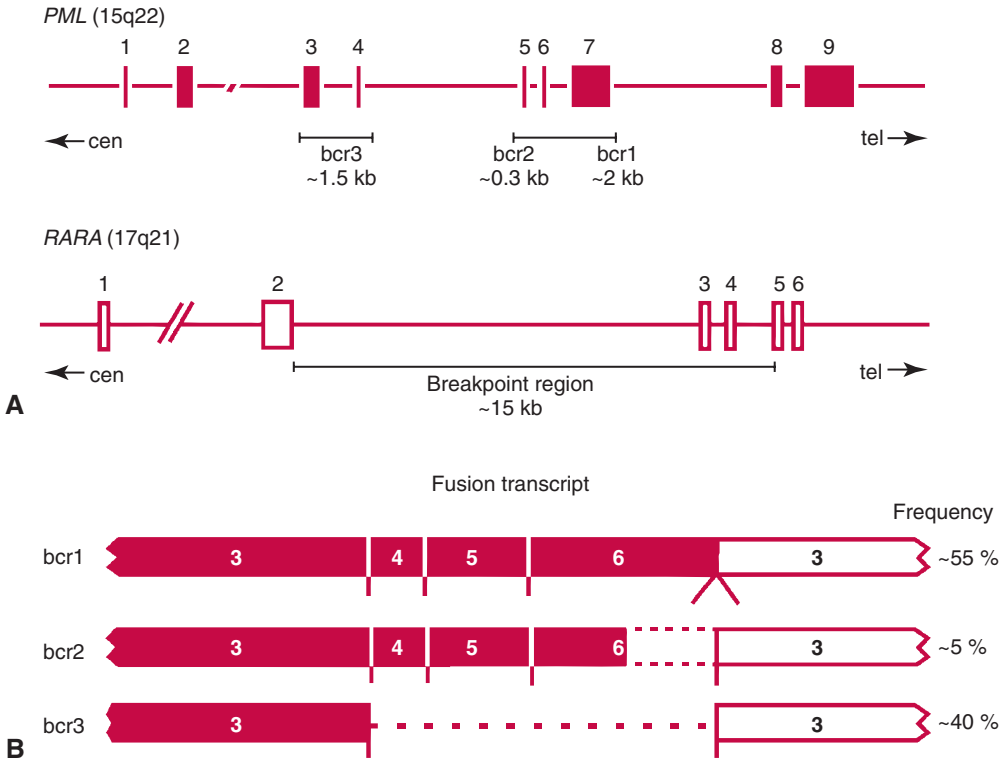

Figure 44-13 Schematic representation of the organization of the *PML* (15q22) and *RARα* (17q11) genes involved in the t(15;17) anomaly, which is characteristic of FAB AML-M3. The centromeric *(cen)* and telomeric (tel) directions are indicated. In A, the exons of the *PML* gene are depicted in *red rectangles,* and the exons of the *RARα* gene are depicted in *white rectangles.* In *B,* the configuration of the *PML-RARα* chimeric fusions is shown.

c-*ABL*, the breakpoints on chromosome 22 are quite variable and within the *BCR* gene (Figure 44-14).[61,75] Depending on the location of the breakpoint, the fusion protein resulting from *BCR-ABL* fusion can vary in size from 190 to 230 kDa. Up to 95% of CMLs, 30 to 50% of adult t(9;22)-positive ALLs, and 20 to 30% of childhood t(9;22)-positive ALLs harbor breakpoints in the M-*BCR* region of the *BCR* gene.[56,104,109,119] The *BCR* breakpoints in virtually all CML cases occur in the 9.0 kb region between exons 13 and 15 (also known as b2 and b4, respectively). Fusion occurs to a breakpoint located in the large intron between exons 1b and 2 of the *ABL* gene.[21] The resulting *BCR-ABL* transcript measures 8.5 kb and contains *BCR* exon b2 or b3 and ABL exon 2 (exon a2). This transcript encodes the 210 kDa BCR-ABL chimeric protein ($p210^{BCR/ABL}$). The most frequent fusions found in CML are b3-a2 fusions, which account for 55% of *BCR-ABL* junctions, and the b2-a2 transcript (40%).[129] Less frequently (5%), both b3-a2 and b2-a2 fusions may occur as a result of alternative splicing.[129] Thus far, no significant prognostic differences between p210-positive CMLs with different transcripts are apparent.[129]

In rare cases of CML, the breakpoint in the *BCR* gene occurs at the ALL-associated m-*BCR*, which leads to generation of the $p190^{BCR/ABL}$ fusion protein.[127] p190-positive CML patients characteristically exhibit relative and absolute monocytosis in peripheral blood reminiscent of chronic myelomonocytic leukemia.[93] Another distinct but rare fusion that has been described in t(9;22)-positive CML is one that results in the formation of a large 230 kDa fusion protein as a consequence of a fusion between exon 19 (c3) of *BCR* and exon 2 (a2) or ABL. The *BCR* breakpoints for this fusion are located in the micro breakpoint cluster region (μ-*BCR*) located between exons 19 and 20 (see Figure 44-14). The p230 fusion is characteristic of a peculiar form of chronic myelogenous leukemia with prominent neutrophilic proliferation. The clinical course of p230-positive CML is reportedly indolent in most cases.[105]

Another distinct breakpoint cluster region in the *BCR* gene has been uniquely associated with t(9;22)-positive ALLs.[61] Up to 60% of t(9;22)-positive ALLs carry translocations in which the *BCR* breakpoint genes are located in a distinct region known as the *minor breakpoint cluster region* (m-*BCR*). m-*BCR* is located between the two alternative exons and exon 2. The ABL breakpoints are located in the large intron between exon 1b and exon 2 of the ABL gene. The resulting e1-a2 fusion encodes a 190 kDa *BCR-ABL* chimeric protein[22] that is expressed mostly in ALLs, and rather infrequently as the exclusive *BCR-ABL* transcript in CML.[114,127] On the other hand, the remaining 40% of t(9;22)-positive ALLs may express the p210 *BCR-ABL* fusion, thus indicating

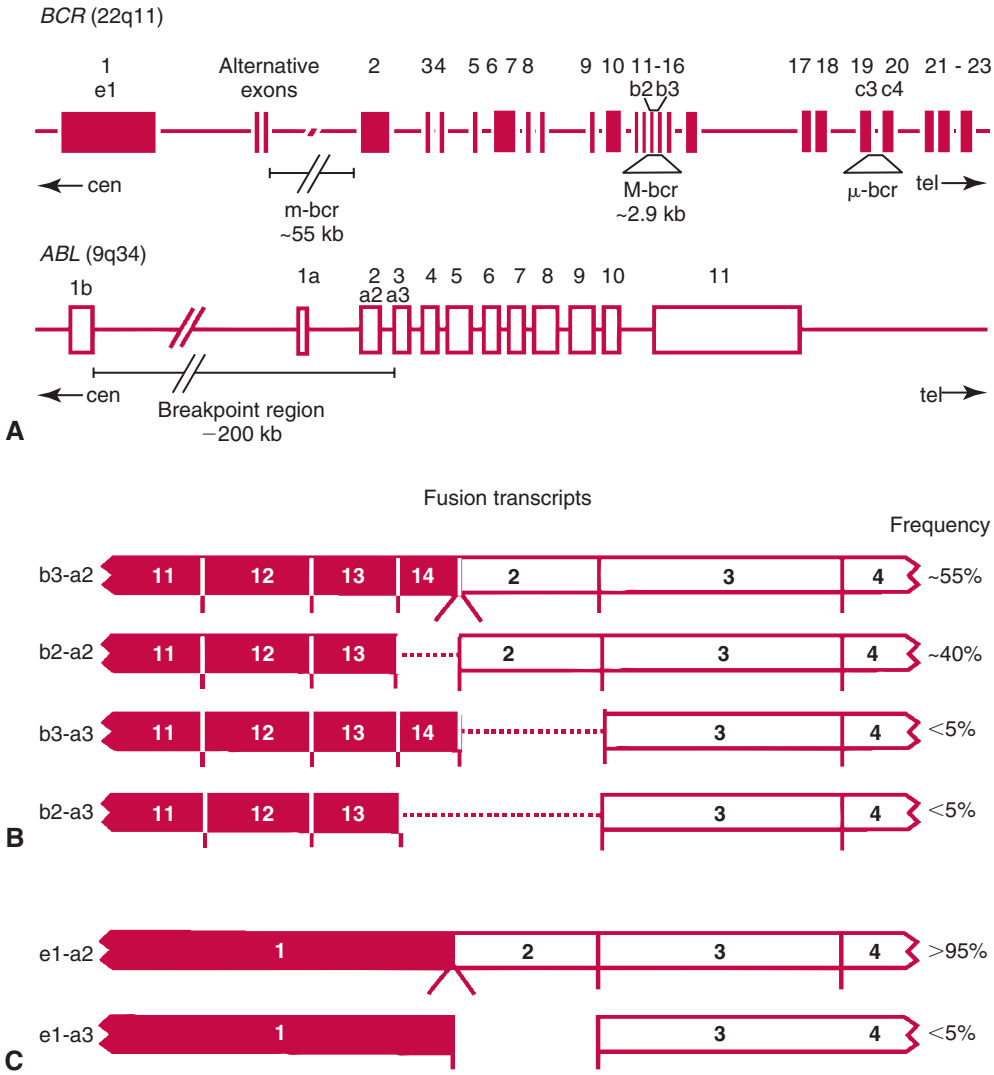

Figure 44-14 Schematic representation of the *BCR* (22q11) and *ABL* (9q34) genes involved in the t(9;22), which is characteristic of all chronic myelogenous leukemias (CMLs) and a subset of acute lymphoblastic leukemias (ALLs). The centromeric (cen) and telomeric (tel) directions are indicated. The relative positions of the major breakpoint cluster (M-*BCR*), the minor breakpoint cluster (m-*BCR*), and the micro breakpoint cluster regions (μ-*BCR*) are shown. The previously used alternative nomenclature for the *BCR* and *ABL* exons is included where relevant. In A, the exons of the *BCR* genes are depicted in *red rectangles,* and those of the *ABL* genes are depicted in *white rectangles.* In B, the configuration and varieties of the *BCR-ABL* chimeric fusions seen in CML are shown. In the *lower part* of B, the configuration and varieties of the *BCR-ABL* fusions seen in *ALL* are shown. The e1-a2 transcript is most commonly detected in t(9;22)-positive *ALL,* but the b3-a2 and b2-a2 fusions are most commonly detected in CML.

its relative lack of specificity. A significant number of CML cases express the low levels of e1-a2 transcripts, in addition to p210, via an alternative splicing mechanism.[25,64,114,146]

Conventional cytogenetics, FISH, and RT-PCR have been reliably utilized for the laboratory detection of the t(9;22). RT-PCR detection is possible in up to 95% of cases and may detect up to 10% of cases missed by conventional cytogenetics[25]; it is an important modality for minimal residual disease detection. Quantitative real-time PCR-based approaches have improved our ability to detect and quantitate *BCR-ABL* transcripts in CML patients[37,74] (Figure 44-15, *A*). The availability of the tyrosine kinase inhibitor imatinib mesylate for CML is an important development in the treatment of CML[36-37]; it underscores the importance of methods for sensitive and specific identification and quantification of *BCR-ABL* fusions in patients with a clinical suspicion for CML.

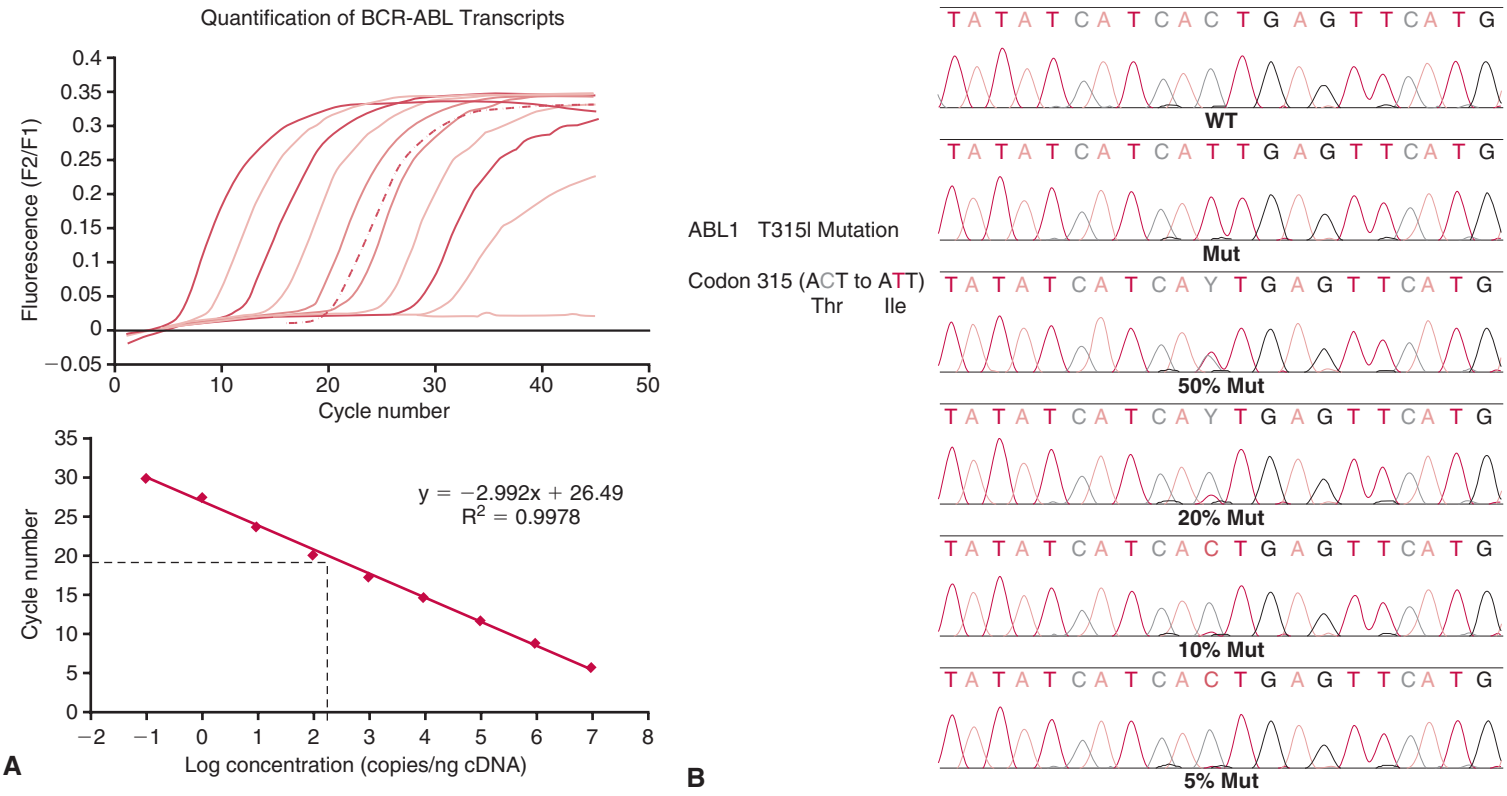

Figure 44-15 **A, Real-time quantitative polymerase chain reaction (PCR) of *BCR-ABL* transcripts. Serial log dilutions of the plasmids containing the *BCR-ABL* transcripts. Real-time PCR provides a remarkable dynamic range of quantification (10^9 to 10^0 template copies) in this example. The *upper panel* shows the amplification curves obtained using the *BCR-ABL*–containing plasmids and an unknown patient sample depicted as a *dotted line*. Note the regular ≈3.3-cycle interval between log dilutions. The *lower panel* shows a standard curve (linear regression of cycle number vs. log template concentration). As indicated by the *dotted line* in the *lower panel,* the cycle threshold (onset of the log-linear phase of the amplification curve) can be used to quantitate the copy number of the target in the tested sample. B, Detection of *ABL1* kinase mutation by direct sequencing. The ACT→ATT transition at codon 315 results in a threonine→isoleucine substitution at the amino acid level: the *T315I* mutation. The *T315I* mutation confers resistance to imatinib, nilotinib, and dasatinib and is an important cause of resistance to tyrosine kinase inhibitors in Ph+ leukemias (CML and ALL). The mutated peak is clearly visible even to a dilution of tumor concentration of 10%.**

t(9:22) in ALL

The t(9;22) has emerged as a sine qua non for the diagnosis of CML, and the recent development of novel tyrosine kinase inhibitor therapy portends a favorable prognosis. By contrast, the presence of the t(9;22) is an independent poor prognostic factor in ALLs.[45,124,154]

Reverse Transcription Polymerase Chain Reaction

Reverse transcription polymerase chain reaction (RT-PCR) involves the initial synthesis of complementary DNA (cDNA) from messenger RNA (mRNA) using a reverse transcriptase enzyme. Reverse transcription can be performed using oligo-dT priming, random hexamers, or gene-specific primers. The cDNA generated is utilized as the template for PCR. This strategy is indicated for the detection of chromosomal translocations wherein breakpoints are widely separated by large intervening introns between juxtaposed fragments that limit the practicality of conventional PCR.

Real-Time Polymerase Chain Reaction

PCR assays have traditionally entailed a two-step procedure comprising an initial amplification reaction, followed by analysis of PCR products in a separate process. PCR product analysis has generally entailed size fractionation by gel electrophoresis and product visualization by ultraviolet (UV) transillumination of ethidium bromide–stained gels or chemiluminescent or radioisotopic detection. The advent of real-time PCR techniques led to PCR amplification with simultaneous monitoring of product accumulation.[63]

Real-time PCR methods employ variations of three fundamental fluorescence chemistries to monitor product accumulation. Higuchi and associates introduced the incorporation of a double-stranded DNA (dsDNA) binding dye (ethidium bromide) into amplification reactions, with fluorescence monitoring at each cycle for quantitative analysis.[63] Real-time PCR using dsDNA-binding dyes such as ethidium bromide and SYBR Green I (Invitrogen Ltd, Paisley, United Kingdom) is relatively inexpensive and easy to use, but does not offer specificity beyond that inherent within the PCR. In poorly optimized reactions, nonspecific dsDNA binding dye- or intercalator-based assays may be prone to yielding false-positive results. It is thus important to carefully optimize primer design to minimize primer dimer and nonspecific product formation.[17] By comparison, sequence-specific fluorescence probe-based systems provide definitive identification of the sequence of interest by virtue of hybridization of fluorescently labeled internal probes to the amplified target sequence.[156]

The most commonly utilized sequence-specific chemistries include exonuclease (TaqMan, Applied Biosystems, Carlsbad, Calif), linear hybridization probe, and hairpin-based (molecular beacon) systems. The TaqMan chemistry takes advantage of the 5→3 exonucleolytic activity of the *Taq* polymerase. In this system, an oligonucleotide probe is dually labeled with a donor fluorophore at the 5′ end, and then with a fluorescence quencher at the 3′ end. The proximity of the quencher to the fluorescent effectively quenches the fluorescence of the donor fluorophore. The labeled probe hybridizes to the amplicon during PCR, but the exonuclease activity of Taq leads to probe hydrolysis and release of the donor fluorophore from the effect of the quencher. Hence, the generation of signals using the TaqMan system requires both hybridization and cleavage of the probe to separate the donor fluorophore and the quencher. The ensuing increase in fluorescence is indicative of new strand synthesis and can be used to monitor PCR progress. Another variation on the dual-labeled sequence-specific probe theme is the hairpin (molecular beacon) system.[144] In this system, a single-stranded molecule is configured in such a way that it possesses a stem-and-loop structure. The sequence of the loop segment of the molecule is complementary to a specific sequence within the target of interest. The stem is composed of two complementary arm sequences that flank the loop sequence. The arm sequences when annealed form the stem and are dissimilar to those of the target sequences. The 5′ end of the probe is labeled with a fluorescent donor (e.g., EDANS), and the 3′ end is labeled with a quencher (e.g., DABCYL). Hybridization of the probe to the target leads to the formation of a hybrid that is longer and more stable than that formed with the arm sequences in the stem configuration (in the absence of target). In a nonhybridized state, the molecular beacon fluorescence is quenched. When linearized by hybridized to target, quenching is removed and fluorescence emission occurs.

The adjacent hybridization probe-based systems employ two oligonucleotide probes. One of the probes is labeled at its 3′ end with fluorescein, and the other is labeled at its 5′ end with a fluorescent acceptor (e.g., Cy5). Hybridization of both probes to the template leads to juxtaposition of the fluorophores to within a distance of one nucleotide base. An accompanying increase in fluorescence is the result of fluorescence resonance energy transfer (FRET) between the excited donor fluorophore and the acceptor. The specificity of oligonucleotide probe hybridization–based schemes ensures that no signal is generated when a nonspecific product is amplified. In sequence-specific probe formats, the probes are included in the amplification reaction in marked excess compared with the template.

Quantification

Real-time PCR is particularly advantageous for the quantitative analysis of nucleic acid sequences. Previously, quantitative PCR was based on end point or competitive assays, which measured band intensities in ethidium bromide–stained gels or via radioisotopic labeling.[148] Fluorescence-based real-time PCR assays characteristically demonstrate three time succession phases: an initial background phase, an exponential or logarithmic phase, and a plateau phase. Onset of the exponential phase is inversely related to the abundance of the target of interest at the beginning of the PCR. By using controls with known quantities of a specific target, a standard curve can be plotted with a crossing threshold (*y*-axis) against log concentration (*x*-axis) for the target of interest. The crossing threshold for a control and specific gene targets in unknown samples can be derived from their PCRs and read off the standard curve to yield a copy number for the target transcript.

ABL-1 Drug Resistance Mutations in Ph+ Chromosome–Positive Leukemias

Philadelphia choromosome–positive chronic myeloid leukemia represents a prototypical disease for targeted cancer therapeutics with the advent of tyrosine kinase inhibitors (TKIs) such as imatinib mesylate (Gleevec). Although imatinib is associated with durable responses in most patients, TKI-resistant clones carrying mutations in the ABL kinase domain have emerged as a frequent mechanism for disease recurrence. Disease remission may be achieved by changing to a different TKI with different kinase inhibitory characteristics, which retains activity against the particular ABL-1 kinase mutation. In this regard, molecular diagnostics testing involving sequencing of the ABL-1 kinase gene plays a role in the selection of appropriate TKIs and the identification of resistance mutations (Figure 44-15, *B*).[16,68]

Mutations of Oncogenes and Tumor Suppressor Genes in Hematopoietic Malignancies

Malignant Lymphomas

Mutations involving several oncogenes and tumor suppressor genes have been identified as important in the pathogenesis of malignant lymphomas. These include mutations targeting *p53* and *p16* tumor suppressor genes.[40,116] It is significant that mutations occurring in genes encoding components of the

nuclear factor–kappaB (NF-κB) signaling pathway have been identified in several histologic subtypes of lymphoma. These include *CARD11,*[82] *A20/TNFAIP3, TRAF2,* and *TRAF5* genes.[23] *A20/TNFAIP3* is targeted most frequently across diverse histologic subtypes of malignant lymphoma[71] and is discussed briefly in the following section.

A20/TNFAIP3

Tumor necrosis factor-α–induced protein 3 *(TNFAIP3)* is induced by TNF-α and is a negative regulator of NF-κB. TNFAIP3 is a ubiquitin ligase with deubiquitinating activity,[153] and is capable of inhibiting TNF-induced apoptosis. The gene that encodes TNFAIP3/A20 maps to chromosome 6q23, a locus that is frequently deleted in non-Hodgkin lymphoma. Studies have demonstrated that TNFAIP3/A20 is frequently inactivated by deletions involving 6q23, or by mutations[23,71] or by promoter hypermethylation[65] in diverse forms of malignant lymphoma.

Acute Myeloid Leukemias

Various somatic mutations occur in AMLs and have been demonstrated to carry important implications for prognosis. Among these are mutations involving *RAS, FLT3, NPM1, CEBP-α,* and *c-KIT.* Many of these are routinely tested in molecular diagnostics reference laboratories and are discussed in the sections that follow here.

RAS Mutations

The concomitant occurrence of genetic aberrations and chromosomal translocations is common in hematologic malignancies. The *RAS* oncogene, one of the most frequently mutated genes in cancer,[14] is mutated in up to 25 to 44% of hematopoietic malignancies and myelodysplastic syndromes (MDSs).[7] The presence of *RAS* mutations has been reported to confer a worse prognosis on patients with AML and MDS.[100,101] The mutations are clustered in "hot spots" that occur in codon 12, 13, or 61, rendering them fairly straightforward to detect with the use of different technical strategies.

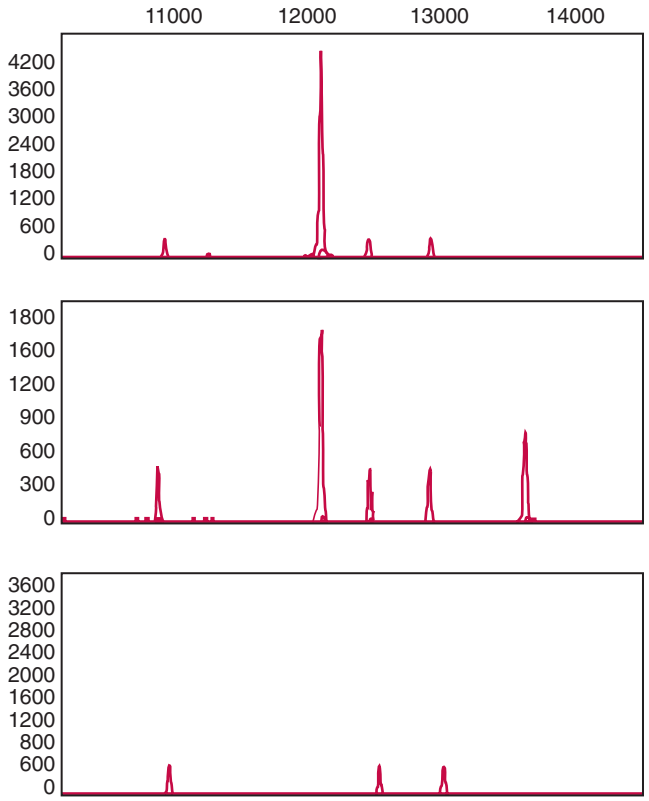

Figure 44-16 Detection of internal tandem duplications of the *FLT3* gene by polymerase chain reaction (PCR) and capillary gel electrophoresis of PCR products. Capillary electropherograms show clear resolution of PCR products. The *x*-axis represents the sizes of PCR products, and the *y*-axis shows the fluorescence intensity, which correlates with the abundance of the PCR product. The *upper panel* shows a wild type of pattern *(red peak).* The *middle panel* shows an additional peak of greater size than the wild-type peak *(red peak on the left).* The *red peak on the right* represents an *FLT3* internal tandem duplication. The *lower panel* shows the size markers *(red peaks)* also present in the upper and middle panels.

FMS-like Tyrosine Kinase 3

Mutations of the tyrosine kinase gene, *FLT3,* have been described in acute myeloid leukemias.[99,157] Most mutations are internal tandem duplications (ITDs) within the juxtamembrane domain (JMD) of the gene, and are present in up to 24% of AML cases. ITDs have been identified in all FAB subtypes of AML, most frequently in acute promyelocytic leukemia (AML FAB-M3). Figure 44-16 shows an example of an *FLT3* ITD detected by PCR and capillary electrophoresis in a case of acute myeloid leukemia, which also demonstrated the presence of the *PML-RARα* fusion transcript. The presence of the ITD was inferred by the larger PCR product size and was subsequently confirmed by sequencing. Additional mutations distinct from ITDs occurring in the JMD have been described in a subset of AMLs. The most frequent of these is a base substitution occurring at aspartic acid residue 835 in the activation loop of *FLT3. D835* mutations have been identified in 7% of AML, 3% of MDS, and 3% of ALL.[157] In considering *FLT3* ITDs and activation mutations combined, *FLT3* may be the most frequently mutated gene in acute myeloid leukemia. Mutations in the activation loop of another receptor tyrosine kinase, *c-KIT,* have been reported in mast cell proliferations[89] and in a small proportion of AMLs.[18]

Nucleophosmin 1 *(NPM1)* Gene Mutations

The nucleophosmin *(NPM1)* gene encodes a nucleolar phosphoprotein that shuttles between the nucleus and the cytoplasm. Mutations in exon 12 of the gene were found to result in abnormal cytoplasmic localization of *NPM1.*[46] The most common of these is a four-base pair insertion, TCTG, which leads to the loss of critical tryptophan residues required for *NPM1* nucleolar localization, and to the generation of an additional nuclear export signal in the C-terminus of *NPM1.*[47] *NPM1* gene mutations are the most prevalent genetic

aberration in AML in adults, and are detectable in 24 to 35% of all cases.[46,133,139] The prevalence of *NPM1* mutations is even greater in karyotypically normal AMLs with detection in 43 to 62% of cases. By comparison, *NPM1* mutations are found at much lower frequencies in AMLs occurring in children (8% of childhood AML).[24] *NPM1* mutations appear to associate with distinct clinical features such as female sex, high total white blood cell count (WBC) and bone marrow blast counts, high CD33, and low to absent CD34 expression. *NPM1* mutations are preferentially associated with the AMLs with monocytic differentiation. It is important to note that *NPM1* mutations are associated with a favorable prognosis after intensive induction therapy.[52,117,122] However, this association with a favorable prognosis is lost when *NPM1* mutations are detected concomitantly with ITDs of the *FLT3* gene,[33,139] or with partial tandem duplications of the *MLL* gene.[118]

CCAAT Enhancer–Binding Protein Alpha (CEBPα) Gene Mutations

The CCAAT enhancer–binding protein alpha (CEBPα) is an important transcriptional regulator of differentiation of pluripotent myeloid progenitors into mature granulocytes.[50,103] As with *NPM1,* CEBPα mutations are found predominantly in AMLs with normal karyotype. CEBPα mutations can be divided into two major categories. The first category of mutations consists of nonsense mutations located in the N-terminal region of the protein that result in a truncated protein with dominant negative properties. In the second variety, the mutations are distributed mainly in the leucine zipper domain in the C-terminal basic region, resulting in CEBPα proteins with decreased DNA binding and dimerization activity. It is interesting to note that N- and C-terminal mutations may be detectable in the same AML case, and mutations may coexist on the same (monoallelic) or on different alleles (biallelic). Clinically, karyotypically normal AMLs with CEBPα mutations exhibit distinct clinical features such as high peripheral blood blast counts, lower platelets, and lower likelihood of extramedullary disease.[118]

Partial Tandem Duplications (PTDs) of the Myeloid/Lymphoid or Mixed Lineage Leukemia *(MLL)* Gene

MLL-PTD is detectable in 5 to 11% of karyotypically normal AMLs. In comparison with *NPM1*-mutation positive AMLs, the clinical features of MLL-PTD–positive AMLs are not distinctive. Although concurrent existence of *NPM1* and CEBPα mutations is infrequent in cases with MLL-PTD, MLL-PTD–positive AMLs may harbor *FLT3* ITD mutations in up to 40% of cases.[50,103] MLL-PTD is associated with inferior relapse-free survival in some studies, without significant effect on overall survival.[34,118,132]

Wilms' Tumor Suppressor 1 Gene *(WT1)*

The Wilms' tumor suppressor gene, *WT1,* located on chromosome 11p13, encodes a 45 kDa protein that appears to function in transcriptional regulation by suppressing the expression of growth-inducing genes, such as early growth response, insulin-like growth factor 2, and platelet-derived growth factor A chain genes.[84] Other chromosomal changes in Wilms' tumors indicate that mutations of *WT1* may be only one step in the process of carcinogenesis. Mutations involving the *WT1* gene are detectable in up to 12.6% of karyotypically normal AMLs.[51,72] Although initial studies indicated that *WT1* mutations by themselves conferred an adverse impact on AML prognosis, these findings have not been confirmed by other studies.[51] More recent studies show data to support that it is the *WT1*^{mut}/*FLT*-ITD–positive genotype that confers a worse clinical outcome.

The *p53* gene is a tumor suppressor gene that encodes a nuclear phosphoprotein/transcription factor, which regulates diverse cellular processes, including DNA repair, cell cycle arrest, and apoptosis. *p53* inactivation is associated with genomic instability and deregulated cell cycle entry and progression. The *p53* gene is the most commonly mutated tumor suppressor gene in cancer, and *p53* mutations are commonly present in a variety of hematologic disorders, including blast crisis in CML, AML, MDS,[83,150] and adult T-cell leukemia/lymphoma.[115] *p53* mutations are implicated in the histologic transformation of follicular lymphoma into diffuse large B-cell lymphoma,[116] and have been described in a small subset of cases of Hodgkin disease.[41] *p53* mutations correlate with resistance to chemotherapy and portend a worse prognosis.[150] The *p53* mutations are localized mainly to mutational "hot spots" in exons 5 through 8, and may be single base substitutions, deletions, or insertions. Dominant negative inactivation of critical p53 protein function can be achieved by a mutation on one allele, because the wild-type protein can dimerize with mutated proteins and consequent functional impairment.[53] denaturing gradient gel electrophoresis (DGGE),[57] constant gradient gel electrophoresis,[12] and single strand confirmation polymorphism (SSCP)[41] have been used with success in screening for *p53* mutations.

Myeloproliferative Disorders

Janus Kinase (JAK) 2 Gene Mutations

The myeloproliferaative disorders include polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF). In 2005, an activating mutation in exon 14 of the Janus kinase 2 gene was discovered in patients with PV, ET, and PMF by independent researchers.[6,69,86] This mutation, *JAK2V617F,* occurs as a result of a nucleotide change at position 1849, leading to the substitution of a phenyl alanine for a valine at codon 617. *JAK2V617F* is detectable in approximately 95% of cases of PV, 50% of ET, and 30% of PMF. It is interesting to note that the burden of the mutant allele in patients with PV and PMF is higher than that seen in patients with ET.[136] In PV, the higher mutant allele burden is attributed to *JAK2V617F* homozygosity, which occurs by mitotic recombination.[6,86] This mutation develops in an early-stage hematopoietic progenitor with stem cell characteristics. Aside from the *JAK2V617F* mutation, other mutations have been reported in exon 14 of JAK2 and include *D620E* (PV, unclassifiable myeloproliferative neoplasm) and *E627E* (unclassifiable myeloproliferative neoplasm). Other exon 14 mutations have

been described in rare AMLs *(K607N)*. The importance of detection of the *JAK2* mutation is underscored by the fact that it is considered a major criterion for the diagnosis of PV in the 2008 revision of the World Health Organization (WHO) classification of myeloid neoplasms and acute leukemia.[137,147]

Rare patients with PV with a dominant clinical picture of erythrocytosis have been shown to carry mutations in exon 12 of the *JAK2* gene [N542-E543del (most common), F537-K539delinsL, and K539L]. These mutant alleles have been demonstrated to induce cytokine-independent proliferation and constitutive activation of JAK-STAT signaling, as is the case with the *V617F* allele.[123]

Myeloproliferative Leukemia Virus Oncogene Homology (MPL) Gene Mutations

The hematopoietic receptor superfamily includes the myeloproliferative leukemia virus oncogene, which encodes the thrombopoietin (TPO) receptor. The *MPL* gene maps to band 1p34.[80] Codon 515 is affected in a number of somatic mutations associated with *MPL (W515L, W515K, W515S, W515A, W515R).*[120,121] Additionally, a subset of patients with familial thrombocytosis have been demonstrated to harbor germline *MPL* mutations *(MPLS505N).*[30] Somatic *S505N* mutations have been identified in cases of sporadic ET and PMF.[106] Mutations involving the *MPL* gene are estimated to be present in as many as 4% of cases of ET (9% of *JAK2V17F*-negative cases) and in 10% of cases of PMF.[121]

MINIMAL RESIDUAL DISEASE DETECTION AND MONITORING

The occurrence of characteristic genetic aberrations and the uniqueness of antigen receptor gene rearrangements in lymphoid neoplasia provide an attractive opportunity for the exploitation of the high sensitivity and specificity of molecular techniques for the detection of minimal residual disease and for therapeutic monitoring. The sensitivity and specificity of molecular techniques capable of detecting one aberrant cell in a background of 10^3 to 10^6 are superior to those provided solely by clinical or microscopic examination. In this regard, PCR-based studies have enjoyed the greatest usefulness for the detection of clonal antigen receptor rearrangements and recurrent chromosomal translocations. With regard to antigen receptor gene rearrangements, clonal identity may be established by designing sequence-specific primers for the unique antigen receptor rearrangement, or by sequencing the PCR product. The ideal scenario for analysis of antigen receptor rearrangements for monitoring of minimal residual disease (MRD) requires previous identification of the specific clonal antigen receptor gene rearrangement in the tumor of interest by PCR and DNA sequencing, followed by clonality analysis and sequencing of initial and subsequent samples. The antigen receptor gene rearrangement sequences of initial and subsequent biopsies are compared for sequence homology. Alternatively, tumor-specific antigen receptor primers may be designed for amplification of the subsequent sample, with successful amplification considered evidence of clonal identity.

Minimal residual disease monitoring using antigen receptor PCR based–monitoring is especially significant in the pediatric population among patients with acute lymphoblastic leukemia/lymphoma.[95] Detection of clonal rearrangements of the antigen receptor genes at the end of induction therapy has been shown to be predictive of patients with high relapse potential.[44,149] In addition, the demonstration of persistent positivity in successive analyses is an indicator of future clinical relapse, although persistent negativity is indicative of a durable remission.[131]

The detection of chromosomal aberrations by PCR-based methods continues to evolve as a tool for MRD detection. Indeed, the clinical significance of the qualitative detection of chromosomal translocations has been the subject of intense study with varying implications, depending on the natural biology of the hematologic disorder (if present), the specific clinical context, the translocation detected, or the method employed. For instance, the t(14;18) has been detected in the peripheral blood and reactive lymphoid tissues of healthy individuals, leading to uncertainty about the significance of qualitative detection of the t(14;18).[35,87] Similarly, highly sensitive PCR assays have detected the t(9;22) in the peripheral blood of otherwise healthy elderly individuals.[9,15]

The implications of qualitative detection of translocations vary with the translocation detected. For instance, a very high risk of relapse is associated with the detection of residual *PML-RARα* transcripts after therapy.[31,32] By contrast, the t(8;21) *AML1-ETO* fusion may be detected in patients who have sustained and durable clinical remissions following treatment. The *AML1-ETO* fusion may also be detected in patients who have undergone chemotherapy or bone marrow transplantation.[70,78] On the other hand, detection of the t(9;22) *BCR-ABL* fusion transcript is prognostically significant for relapse, if conversion to positivity occurs within 6 to 12 months of treatment. The predictive value of the presence of chimeric transcripts can be affected by therapy-associated factors such as graft-versus-host disease or the type of transplant.[110] Nevertheless, persistent molecular negativity for the *BCR-ABL* transcript is indicative of good response to therapy and favors a durable remission.

The recent availability of quantitative real-time PCR-based assays for the quantitative detection of specific genetic alterations holds great promise in the quantification of tumor burden, response to therapy, and relapse potential. Appropriately done, the tests should be performed at a series of regular and successive time points during management of the disease. This approach is more apt to identify increasing, decreasing, or stabilizing trends in the abundance of the translocation product in tested samples. Figure 44-15 shows a quantitative RT-PCR study for the *BCR-ABL* transcript that incorporates several quantification standards for determination of the number of copies of the fusion transcript present in the sample. An alternative approach involves expression of

the ratio of expression levels of the fusion transcript being tested against those of a stably expressed housekeeping gene, and monitoring the changes that ensue over time.

DETECTION OF VIRAL GENOMES

Viruses involved in the pathogenesis of abnormal proliferations of hematopoietic cells include the human T-cell leukemia virus type I, found in adult T-cell leukemia/lymphoma, and Kaposi sarcoma herpesvirus/human herpesvirus-8 (KSHV/HHV8), seen in primary effusion lymphoma and multicentric Castleman disease.[19] These viruses can be detected using the standard molecular biology techniques described in this chapter. Primer design should take into consideration the propensity for shared sequences within related viruses. Optimal specificity can be obtained by assigning primers to unique portions of the genome of the virus of interest. Because of its well-established role in the pathogenesis of a variety of lymphoproliferative disorders, Epstein-Barr virus (EBV) and its detection are discussed in the following section as an example of a virus that may be detected by in situ hybridization.

Epstein-Barr Virus

Epstein-Barr virus (EBV) was identified in 1964 by Epstein, Achong, and Barr in cultured cells obtained from a malignant lymphoma described by Dennis Burkitt.[42] EBV was subsequently identified by Werner Henle and colleagues as the cause of infectious mononucleosis.[60] EBV is a lymphotropic virus that has been associated with different malignant neoplasms, including endemic Burkitt lymphoma, nasopharyngeal carcinoma, nasal natural killer cell (NK)/T cell or NK-/T- type lymphoma, and some subtypes of Hodgkin lymphoma. EBV is also implicated in the pathogenesis of most post-transplant lymphoproliferative disorders.[67] Figure 44-17 shows an example of positive EBV signals (EBER in situ hybridization) in a case of post-transplant lymphoproliferative disease.

EBV is an enveloped icosahedral virus containing a double-stranded DNA genome of 172 kb with more than 100 open reading frames, potentially encoding an equivalent number of proteins.[5] The precise size of each virion varies from particle to particle because of the presence of tandemly repeated sequences, each 500 bp long and present in the virus termini. Viral tropism is mediated via attachment of the gp350/220 viral envelope protein to the complement receptor type 2 C3d (CR2) or CD21.[48,135] The virus exhibits tropism for B cells, some T cells, dendritic cells, and epithelial cells. After infection, typically via the oropharyngeal mucosa, EBV undergoes lytic replication in vivo. In the lytic replication, the linear genome is duplicated and assembled into viral capsid, and it exits the cell by budding or lysis. By contrast, B cells are efficiently immortalized by EBV in vitro. In immortalized cells, the viral genome is circularized by fusion of the termini (episomal), and the viral infection is latent with lack of production of viral particles. In the latent phase, viral replication occurs coordinately with host cell division. During latent infection, 11 genes are actively transcribed, including six nuclear antigens (EBNA-1, -2, -3A, -3B, -3C, and -LP), 3 membrane proteins (latent membrane proteins LMP-1, -2A, and -2B), and 2 EBV-encoded, small, nonpolyadenylated RNAs (EBER-1/-2).[2] The EBERs are present at very high copy numbers in the nuclei of latently infected cells.[84] The abundance of this transcript makes it very attractive for detection of latent EBV infection in cells and tissue specimens by in situ hybridization (see Figure 44-17).

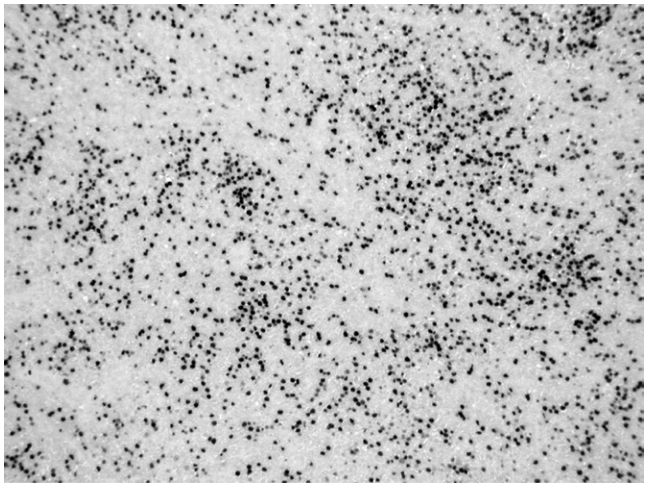

Figure 44-17 In situ hybridization (ISH) for the Epstein-Barr virus (EBV). ISH hybridization for EBV shows numerous positive signals *(dark-black spots)* for EBV using the EBER-1 probe. The tissue sample was obtained from a solid organ transplant patient who developed widespread nodal and extranodal masses. The positive reaction for EBV in this assay supports a diagnosis of post-transplant lymphoproliferative disease.

Three latency patterns of expression have been described that relate to the expression of latency gene products. In latency pattern I, exemplified by Burkitt lymphoma cells, EBNA-1 is the only antigen that is expressed. In latency pattern II (exemplified by Hodgkin lymphoma), EBNA-1 and LMP-1 are expressed, and in latency pattern III (exemplified by post-transplant lymphoproliferative disease), all nuclear and latent membrane antigens are expressed. Based on the premise that one virion infects one host cell, and each virion has a unique number of terminal repeats with each episome being exactly replicated in all of its progeny, the clonality status of different cell populations has been assessed using probes complementary to the EBV termini by Southern blotting hybridization analysis.[58] Genomic probes that are complementary to sequences adjacent to the EBV termini, so-called terminal repeat region probes, are utilized. In this assay, a specimen yielding a single size of episomal EBV DNA is considered monoclonal. This is based on the premise that all cells arose from a parent cell containing the same EBV DNA episome that was replicated in the progeny. By contrast, a sample yielding episomes of various sizes, with a ladder

pattern in which fragments differ by 500 bp, is indicative of a polyclonal population wherein each different progenitor cell harbored a different EBV DNA episome.[108]

An obvious advantage of using EBV terminal repeat probes for assessment of clonality is that they can also be used for assessment of clonality in EBV-positive nonhematopoietic neoplasms (e.g., nasopharyngeal carcinoma) in which antigen receptor gene rearrangements are not informative.[108] EBV in situ hybridization using probes targeting the EBER-1 transcript has contributed significantly to the identification of EBV in several hematopoietic and nonhematopoietic disorders.

IN SITU HYBRIDIZATION

The ability to visualize the cellular localization of different gene products is an important aspect of molecular biology and pathology. In situ hybridization (ISH) is a method that permits identification of the exact cellular location of target DNA or RNA in cytologic preparations or microscopic sections. In situ hybridization entails the synthesis of a nucleic acid (DNA or RNA) probe that is complementary to the gene sequence of interest. The probe may be labeled by nonisotopic or radioisotopic methods. ISH hybridization of fixed paraffin-embedded tissue sections entails initial dissolution of paraffin in xylene and serial dehydration in graded ethanols. For DNA targets, the tissue section is subjected to denaturation, followed by application of the probe for hybridization. Several washing steps with modulation of stringency (temperature, ionic/salt concentration) are necessary to ensure specificity of the hybridization. Development of signals indicative of specific hybridization depends on the system used. Colorimetric detection using avidin-biotin and peroxidase chemistry with a substrate yielding a visible precipitate (e.g., diaminobenzidine) is currently favored for light microscopic applications. In situ hybridization is versatile and is not limited to the detection of viral targets; it has found utility in a number of diagnostic settings, including the assessment of B-cell clonality by light chain restriction. Developments that have led to widespread utility of ISH include nonfluorescent chromophore in situ hybridization protocols that permit ISH analysis of a variety of targets using the light microscope.[8]

CONCLUSIONS

Hematopoietic neoplasms are associated with distinctive molecular aberrations that are amenable to diagnostic detection. In addition, identification of the molecular abnormality in many cases also carries important prognostic and disease-specific treatment implications. The method chosen depends on the nature of the aberration being evaluated, the nature of available samples, and the level of sensitivity afforded by available methods. Technical issues aside, the clinical significance of each test has to be determined on an individual basis. Most important, molecular tests should be utilized as adjunctive parameters in evaluation of the patient, and they should never be used in isolation without consideration of clinical findings. Ideally, the management of a patient should incorporate the entire complement of clinical and diagnostic information pertinent to the individual and his or her disorder.

CHAPTER 45

Plasma Nucleic Acids

Y. M. Dennis Lo, M.A., D.M., D.Phil., F.R.C.P.(Lond. & Edin.), F.R.C.Path., F.R.S.,, and Rossa W. K. Chiu, M.B.B.S., Ph.D., F.H.K.A.M.(Pathology), F.R.C.P.A.

With the notable exception of virology, much of molecular diagnostics has been built on the detection of nucleic acids from cellular materials. However, over the past 15 years or so, much interest has developed in the molecular diagnostic applications of cell-free nucleic acids in plasma and serum. This chapter reviews the remarkable developments in this emerging area.

DISCOVERY AND EARLY WORK

It is generally agreed that cell-free nucleic acids in plasma were first discovered by Mandel and Metais in 1948.[136] It was especially remarkable that this work preceded the discovery of the double-helical structure of DNA in 1953.[204] However, the significance of the work by Mandel and Métais was not recognized for many years. It was not until 1966 that interest in the area re-emerged with the finding of DNA in the serum of patients with systemic lupus erythematosus.[187] Similar findings in other autoimmune diseases were subsequently reported.[101] In the 1970s, it was reported that increased concentrations of cell-free DNA were found in the serum of cancer patients, when compared with controls.[102] Furthermore, it was shown that the reduction in concentrations of serum DNA correlated with treatment response. However, the origin of such serum DNA remained unclear.

CIRCULATING DNA AS A TUMOR MARKER

In 1989, Stroun and associates proposed that such DNA might have originated from cancer cells.[182] However, definitive proof of this hypothesis had to wait until 1994, when two groups used polymerase chain reaction (PCR)-based technologies to show that oncogene mutations were indeed detectable in the plasma of patients with pancreatic cancer,[179] myelodysplastic syndrome, and acute myelogenous leukemia.[197] Two years later, two groups confirmed these observations by showing that tumor-derived microsatellite alterations could be found in the plasma and serum of patients with small cell lung cancer[25] and head and neck cancer,[146] respectively. These results laid the foundation for rapid developments in the field over the following decade (Table 45-1).

Measurement of Total Plasma DNA Concentrations

Several groups have replicated the previously mentioned pioneering work on plasma and serum DNA. On the simplest level, the total concentrations of DNA in plasma are measured. Thus, some groups have demonstrated that the total concentrations of DNA in the plasma of cancer patients are generally higher than those in controls.[5,8,171,174,180] For example, Sozzi and colleagues showed that the median concentration of plasma DNA in lung cancer patients is almost eight times higher than that in controls.[180] Similar results have been reported by Paci and coworkers.[154] However, it is important to note that the total concentration of plasma/serum DNA is relatively nonspecific and could be influenced by pathologies other than cancer (e.g., tissue injury, as discussed later). Thus, most workers in the field have focused on a variety of tumor-derived genetic and other molecular alterations.

Plasma DNA Size as a Tumor Marker

Circulating DNA in plasma consists of short fragments of DNA.[87] In 2003, it was shown that the DNA molecules in the plasma of gynecologic and breast cancer patients were shorter than those in the plasma of control subjects.[200] In this study, the length of plasma DNA molecules was assessed by measuring the relative abundance of a longer versus a shorter fragment of DNA using quantitative PCR.[200] Results were expressed as a *DNA integrity index*. This approach was similar to the method used to analyze the length of Epstein-Barr virus (EBV) DNA in the plasma of patients with nasopharyngeal carcinoma (NPC).[20] Wang and associates attributed the success of plasma DNA size as a tumor marker to the fact that necrosis might be a relatively commonly phenomenon in tumor tissues and might be associated with the liberation of relatively longer fragments of DNA into the plasma. It was also suggested that cell death in normal tissues might be more related to apoptosis, which might be associated with the release of shorter DNA fragments into the circulation. Various groups have confirmed the potential usefulness of plasma DNA integrity analysis for cancer patients.[18,73,89,196] For example, Chan and colleagues reported that the plasma DNA integrity of NPC patients was higher than that of controls.[18] Furthermore, radiotherapy was associated with a reduction

TABLE 45-1 Plasma Nucleic Acid Features Associated With Tumors

Features	Examples
Total plasma DNA concentration	Elevated in cancer patients over controls
Plasma DNA size	Plasma DNA molecules are longer (higher integrity) in cancer patients than in controls
Loss of heterozygosity	Microsatellite and single-nucleotide polymorphism analysis
Gene mutations	*KRAS, APC, TP53, EGFR*
Aberrant DNA methylation	P16, *SEPT9* (septin 9), *APC, GSTP1, RASSF1, rarB2*
Tumor-associated viral DNA	HBV, HPV, EBV
Plasma RNA	Tyrosinase, VEGF, thymidylate synthase, *BMI1,* laminin B1
Plasma RNA integrity	Plasma RNA molecules are more fragmented (reduced integrity) in cancer patients than in controls
Plasma microRNA	Aberrant concentrations of certain microRNA species in a number of malignancies

EBV, Epstein-Barr virus; *HBV,* hepatitis B virus; *HPV,* human papillomavirus; *VEGF,* vascular endothelial growth factor.

in the plasma DNA integrity index in 70% of patients. Most important, patients who did not demonstrate this reduction had a worse prognosis than those who had normalization in the DNA integrity index. However, Holdenrieder and coworkers and Boddy and associates were unable to reproduce the value of DNA integrity analysis for the plasma and serum of cancer patients.[9,77] Chan and colleagues studied preanalytical factors associated with the measurement of DNA integrity.[19] These workers showed that clotting and delayed separation of plasma from blood cells for 24 hours would significantly increase the concentration and observed size of cell-free DNA in blood samples. They also showed that repeated freezing and thawing of plasma samples, but not extracted DNA, leads to fragmentation of DNA. These factors should be taken into consideration if DNA integrity should become a clinical molecular test.

Detection of Loss of Heterozygosity in Plasma

Numerous groups have reported the detection of tumor-associated loss of heterozygosity (LOH) in the plasma/serum of cancer patients. As examples, this has been reported in lung cancer,[68] prostate cancer,[143,172] breast cancer,[173] melanoma,[185,186] renal cancer,[69] and transitional cell carcinoma of the urinary bladder.[199] Most workers have used microsatellites as the targets for such analysis. However, debate regarding the robustness of this approach is ongoing, as it has been demonstrated that PCR artifacts might occasionally result in the false identification of LOH when in fact none is present.[40] It has been suggested that fractionation of plasma DNA and specific targeting of lower-molecular-weight DNA might improve the detection of LOH in plasma.[143] Targeting of single-nucleotide polymorphisms (SNPs), instead of microsatellites, is an alternative method for the detection of LOH.[22]

Detection of Somatic Gene Mutations in Plasma

Another approach for the detection of tumor-derived DNA in plasma is to target mutant gene sequences. Examples of genes that have been studied in this fashion include the *KRAS* oncogene in colorectal carcinoma[94,166,167,183] and pancreatic carcinoma,[12,58,210] the adenomatosis polyposis coli *(APC)* gene in colorectal carcinoma,[97] and the *TP53* gene (coding for the p53 protein) in lung cancer,[72] ovarian cancer,[152] and hepatocellular carcinoma (HCC).[79,90,92] Much interest has been expressed in mutations in the epidermal growth factor receptor *(EGFR)* gene in non–small-cell lung cancer and its relation to response to tyrosine kinase inhibitors.[133,155] It has been shown that the mutational status of the *EGFR* gene can be predicted from plasma/serum DNA analysis and is strongly correlated with response to tyrosine kinase inhibitor treatment.[91,134,213]

The main challenge faced by investigators working with the detection of tumor-derived gene mutations is that the minority mutant DNA molecules are surrounded by a "sea" of nonmutant molecules. Thus, detection methods should allow the sensitive and specific detection of such mutant sequences from the background. Many workers initially used allele-specific PCR amplification.[40,91]

Much promise has been shown with the use of techniques that allow analysis of single DNA molecules. One such method is single-molecule PCR or digital PCR (see Chapter 17), in which the DNA template is diluted and then amplified in a series of PCRs.[198] The degree of dilution is such that each PCR will contain approximately 0.5 copy of the template. In such a situation, distribution of the template DNA molecule among the PCRs will follow the Poisson distribution,[125] with some reactions containing no target molecule and other reactions containing a single target molecule. The Poisson distribution also predicts that some reactions will contain more than a single target molecule. However, the latter will be the minority at the template concentration of 0.5 copy of target per reaction. Reactions containing a single target molecule, mutant or wild-type, can be analyzed without the interference of closely related sequences. Another advantage of the digital PCR approach lies in its quantitative applications. In this regard, the number of positive reactions will reflect the number of starting template molecules. The number of reactions containing more than one template molecule can be mathematically "corrected" by using the Poisson distribution.[125] The main disadvantage of digital PCR is the need to carry out numerous parallel PCRs. However, the development of several platforms for high-throughput implementation of digital PCR has offered the hope that this method

might eventually be used in routine molecular diagnostics. One such method employs microfluidics to distribute the reaction mixture to hundreds or thousands of nanoliter chambers.[203] This method has been used for the detection and measurement of the concentration of *EGFR* mutations in the plasma of non–small-cell lung cancer patients.[213] Another method involves the performance of PCR in emulsions, following the capture of PCR products on beads.[48] This method, which is referred to as *BEAMing (beads, emulsion, amplification, and magnetics),* has been used to detect and measure the concentration of mutant DNA molecules in the plasma of colorectal cancer patients.[44,45]

Detection of Aberrant DNA Methylation in Plasma

Much interest has arisen in the study of epigenetic alterations in tumors. *Epigenetics* is the study of molecular changes that influence gene expression, but that do not involve a change in DNA sequence.[175] One of the best studied epigenetic mechanisms is DNA methylation, which typically involves the methylation of the cytosine residue of the CpG dinucleotide. DNA methylation in the promoter region of genes is associated with gene silencing.[85] This is one of the mechanisms for the inactivation of tumor suppressor genes in cancer.[139] In 1999, two groups first demonstrated the presence of tumor-associated DNA methylation in the plasma and serum of cancer patients.[51,208] Both groups used a method known as methylation-specific PCR (MSP).[75] DNA for MSP analysis is first treated with bisulfite, a process that converts unmethylated cytosine to uracil, while leaving methylated cytosine unchanged.[62] Hence, methylated and unmethylated sequences can then be amplified using different primers. The versatility of MSP has since been enhanced by the development of quantitative MSP, in which the concentration of targets with different methylation status can be measured.[49,117]

Tumor-associated DNA methylation changes have since been detected for many tumor suppressor genes and for many types of cancer. Examples include the gene for p16 in non–small-cell lung cancer,[51] colorectal cancer,[145] and HCC[208] patients; the *SEPT9* gene (septin 9) in colorectal cancer[71]; the *APC* and several other genes in breast cancer[78]; and the *GSTP1* gene in prostate cancer.[4] The main advantage of the methylation-based approach is that one methylation assay can typically be used for several tumor types. This is different from the previously mentioned approach of targeting tumor-specific gene mutations in which multiple assays are often needed to target the many possible mutations of a gene.

The main disadvantage of the MSP-based approach is that the bisulfite conversion step is known to degrade the input of DNA significantly, with certain workers estimating that in some cases, the degree of degradation might be greater than 90%.[70] In addition, many workers have reported that the sensitivity of detecting a single aberrantly methylated marker might be quite low. Possible explanations for this observation include the fact that a particular tumor suppressor gene may be aberrantly methylated in only a proportion of tumors, and the fact that bisulfite-related DNA degradation might reduce the target DNA available for analysis. Thus, many researchers have used a combination of methylated markers for cancer detection purposes.[78]

In an attempt to bypass the use of the bisulfite conversion step, Chan and associates investigated the use of methylation-sensitive restriction enzyme digestion followed by real-time PCR detection of the *RASSF1 (RASSF1A)* gene, which is hypermethylated in a significant proportion of HCC.[17] The methylation-sensitive restriction enzyme will not cleave the hypermethylated, tumor-derived *RASSF1* sequences while digesting the background nonmethylated sequences of non-tumoral origin. This assay shows that hypermethylated *RASSF1* sequences are detectable in 93% of the plasma of patients with HCC, in only 58% of chronic carriers of the hepatitis B virus (HBV), and in 8% of healthy controls. Furthermore, for the former two groups, the median plasma concentration of hypermethylated *RASSF1A* sequences in the cancer group is some 6.5 times higher than that in the HBV carrier group. A possible disadvantage of this approach is the possibility that incomplete digestion by the restriction enzyme will lead to false-positive results. In this regard, quality control steps for assessing the enzyme digestion step are essential. Future studies are needed to investigate the robustness of this approach in a large-scale clinical setting.

Another exciting development in plasma-based methylation analysis is the use of BEAMing for methylation analysis, so-called methyl-BEAMing.[108] This technology allows the digital analysis of individual bisulfite-converted DNA molecules through emulsion PCR, bead capture, and magnetic separation. This technology allows the detection of one methylated DNA molecule in a background of approximately 5000 unmethylated molecules. Clinical utility of this approach has been demonstrated through detection of the hypermethylated vimentin gene in the plasma of colorectal cancer patients.

Viral DNA in Plasma

Several tumor types are associated with viral infection. Examples include the association of HBV infection with HCC, human papillomavirus (HPV) with cervical carcinoma, and EBV infection with NPC. Numerous workers have looked for tumor-associated viral sequences in the plasma or serum of cancer patients. The most convincing data have been reported for detection of EBV DNA in the plasma or serum of NPC patients.[119,144] With the use of real-time PCR technology, EBV DNA has been detected in NPC patients with a sensitivity of 96% and a specificity of 93%.[119] The plasma concentrations appear to be positively correlated with tumor load and stage, and can serve as a prognosticator.[15,104,113,118] Furthermore, measurement of circulating EBV DNA concentrations can allow one to monitor treatment response and to predict tumor relapse.[14,115] Preliminary data suggest that detection of circulating EBV DNA is a marker for the screening of NPC.[103] It has been shown that circulating EBV DNA in NPC patients consists of short DNA fragments, instead of complete virions.[20] EBV has also been associated with certain lymphomas and a small proportion of gastric carcinomas; plasma/

serum EBV DNA has been detected in the plasma of a proportion of such patients.[99,100,120]

A similar approach has been applied to the detection of HPV DNA in the plasma/serum of patients with cervical cancer.* However, the sensitivity of this approach varies greatly from group to group, with several groups reporting very low values. For example, Dong and colleagues reported that only 6.9% of plasma samples obtained from patients with invasive cervical cancer were HPV DNA positive.[47] Similarly, Sathish and coworkers reported a plasma positivity rate of only 11.8% in cervical cancer patients.[169] Thus, the clinical role, if any, of detecting HPV DNA in the plasma of cervical cancer patients remains unclear at the present time.

CIRCULATING RNA AS A TUMOR MARKER

With the success of detecting tumor-derived DNA molecules in the plasma of cancer patients, some workers have started to explore the detection of tumor-derived RNA in plasma. This was first achieved in 1999 by two groups: through the detection of tyrosinase mRNA in the serum of melanoma patients, and through EBV RNA in the plasma of NPC patients.[93,114] These observations were initially rather intriguing, because RNA has been generally regarded as a highly unstable class of molecules. Subsequent work has demonstrated that plasma RNA is particle associated—a configuration that might protect the RNA molecules from degradation in plasma.[64,74,149] Indeed, endogenous plasma RNA has been demonstrated to be stable enough to be processed with several hours' delay from sample collection to preparation. Consistent with its particle-associated nature, plasma RNA has been shown to be degraded rapidly if subjected to detergent treatment (which would disrupt the particles),[50] filtration with submicron-size filters,[50,149] and high-speed centrifugation.[149] Although plasma RNA is stable enough to be detectable by sensitive molecular techniques such as PCR, such molecules nonetheless are fragmented and partially degraded, instead of existing as intact mRNA molecules.[13] Indeed, many species of tumor-derived mRNA have now been successfully detected in the plasma and serum of cancer patients. Examples include vascular endothelial growth factor (VEGF) and thymidylate synthase mRNA in the plasma of patients with colorectal carcinoma,[65,66] Bmi-1 mRNA and RNA subunits of the telomerase complex in the plasma of breast cancer patients,[24,178] and lamin B1 mRNA in the plasma of HCC patients.[184]

Analogous to plasma DNA, investigators have studied the integrity of plasma RNA in cancer patients. However, the observation is reversed, namely, that cancer patients appear to have lower plasma RNA integrity than do controls.[207] A possible explanation of this observation is that the concentration of RNase in the plasma/serum of cancer patients is increased.[163,176]

Much interest has been focused on micro RNAs (miRNAs), a class of short (19 to 25 nucleotides), single-stranded, non–protein-coding RNA that plays an important role in the regulation of gene expression.[86] Chim and associates first reported that cell-free miRNA is detectable in human plasma, using placental miRNA in the plasma of pregnant women as a model system.[26] Following this publication, a flurry of reports were published confirming the presence of miRNA in plasma and serum.* These reports further show that plasma/serum miRNA can be used as a biomarker for various types of cancer, including lymphoma,[98] prostate cancer,[141] ovarian cancer,[164] lung cancer,[23] and colorectal cancer.[147] Chim and colleagues showed that miRNA appeared to be very stable in plasma, indeed even more stable than mRNA in plasma.[26] Furthermore, it was shown by these workers that most of the detected plasma miRNA passed through a 0.22 μm filter. This finding suggests that plasma miRNAs are predominantly non–particle associated, or that they are associated with particles smaller than 0.22 μm. This issue requires continued investigation because other workers have reported the presence of miRNA in plasma in microparticles referred to as *exosomes* or *microvesicles.*[81,160]

FETAL NUCLEIC ACIDS IN MATERNAL PLASMA

Demonstration of the presence of tumor-derived DNA in the plasma of cancer patients prompted Lo and coworkers in 1997 to explore whether an analogous phenomenon might also be present in pregnancy (i.e., whether the fetus would release its DNA into the plasma of its mother).[122] This analogy is particularly intriguing because there are similarities between the placenta of the fetus and a tumor, with the former being referred to as a *pseudomalignant tissue.*[181]

Discovery and Basic Biology of Fetal DNA in Maternal Plasma

Using a sequence on the Y chromosome as a marker for a male fetus, Lo and associates demonstrated that this DNA was detectable in the plasma and serum of a woman bearing a male fetus, thus demonstrating the existence of fetal DNA in maternal plasma.[122] This group of investigators went on to develop a real-time PCR-based assay for measuring the fractional and absolute concentrations of fetal DNA in maternal plasma.[126] It has since been reported that fetal DNA represents a mean of 3 to 6% of the DNA that is present in maternal plasma, as measured by PCR-based techniques. With the use of more precise digital PCR-based techniques, the median fractional concentration of fetal DNA in maternal plasma has been found to be some two times higher, with a median value around 10% in the first and second trimesters, and 20% during the third trimester.[131] The absolute concentration of circulating fetal DNA increases with gestational age, probably as a consequence of the increase in fetal tissue mass. Following delivery, fetal DNA is cleared very rapidly, with a half-life on the order of 16 minutes.[129]

The tissue of origin of fetal DNA in maternal plasma has been generally agreed to be the placenta. This conclusion is supported by various findings. First, fetal DNA has been found in maternal plasma even in anembryonic pregnancies, in which no embryo was found, but in which the placenta was present.[2] Second, it has been shown that fetal DNA in maternal serum carries the placental karyotype in cases in which the fetus proper and the placenta contain different cytogenetic signatures.[60] Finally, fetal DNA in maternal plasma has been shown to carry the DNA methylation signature of the placenta.[16,27,28,151]

Through the use of a series of quantitative PCR assays with different amplicon lengths, Chan and colleagues showed that circulating fetal DNA in maternal plasma consisted of short DNA fragments.[21] These observations are consistent with the suggestion that fetal DNA is released from the placenta into the maternal plasma as a result of apoptosis or necrosis.[188] Furthermore, it was shown that circulating fetal DNA was generally shorter in length than the maternally derived DNA in maternal plasma.[21] This observation has opened up the possibility of preferentially enriching for fetal DNA by targeting short DNA fragments. One way of doing this is by electrophoresis of plasma DNA fragments.[109,112] Another method consists of digital PCR analysis of plasma DNA from maternal plasma using a nested set of PCR primers.[132] The nested set of primers would produce amplicons of different sizes. A digital PCR well containing a long (e.g., maternal) template DNA molecule would be predicted to produce both a long and a short amplicon. Conversely, a digital PCR well containing a short (e.g., fetal) DNA molecule would produce only the short amplicon. This has been referred to as *digital size selection.*[132] One advantage of this system is that the size cutoff can be readily changed by designing PCR primers with different amplicon sizes.

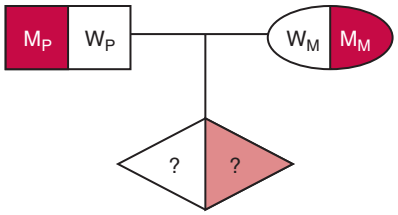
Rapid clearance of circulating fetal DNA following delivery has prompted some investigators to study the mechanisms of clearance. Botezatu and associates postulated that a proportion of fetal DNA in maternal plasma might be cleared via the urinary system, with some fetal DNA still detectable in maternal urine.[10] However, several other groups have been unable to detect fetal DNA in maternal urine, or they did so only at a relatively low proportion, even during the third trimester, or in pathologies associated with increased concentrations of fetal DNA in maternal plasma (e.g., preeclampsia).[83,111,135] One possible explanation for the difficulties experienced by these latter groups is that fetal DNA in maternal urine, if present, would be even more fragmented than its counterpart in maternal plasma. Thus, very short amplicons or special methods for urine DNA extraction might be required for such analysis.[177]

Applications to Sex-Linked Diseases, RhD Genotyping, and Monogenic Disease

The first diagnostic applications of cell-free fetal DNA in maternal plasma have centered on those that could be achieved through the detection of fetal-derived paternally inherited sequences that are not present in the genome of the pregnant woman (Figure 45-1). One example of such an application is fetal sex determination by the detection of Y chromosomal sequences from a male fetus in maternal plasma. This strategy is useful for the noninvasive prenatal diagnosis of sex-linked disorders.[38,82] This approach is also useful for the prenatal investigation of congenital adrenal hyperplasia, because if the fetus can be shown to be male, then prenatal steroid treatment to avoid virilization could be avoided.[82,165] Another example of such an application is the prenatal determination of fetal RhD status in pregnancies involving an RhD-negative pregnant woman.[52,59,123] The robustness of the fetal sex and RhD applications is high, and these applications have been utilized for clinical purposes in a number of centers in Europe and the United States.

Several groups have reported the detection of paternally inherited fetal gene mutations in maternal plasma. Examples include mutations causing achondroplasia,[110,168] myotonic dystrophy,[3] α-thalassemia,[34] β-thalassemia,[76] and cystic fibrosis.[11,67] For autosomal dominant disorders, such as achondroplasia, the detection of a fetal-derived mutation from the plasma of a woman who does not carry the mutation is indicative of an at-risk fetus (see Figure 45-1). However, for autosomal recessive disorders, early work in this area was focused on families in which the father and mother carried different mutations (see Figure 45-1). Thus, detection of the mutation that the father has passed on to the fetus would only increase the fetal risk of being a compound heterozygous victim of the disease from 25 to 50%. Conversely, if the paternal mutation is shown to be undetectable in maternal plasma, an affected fetus can be excluded (see Figure 45-1).[34] Diagnostically, the latter scenario is more useful for patient management than the former scenario. An alternative way is to examine genetic polymorphisms linked to the wild-type (i.e., nonmutant) gene in the father and demonstrate that the fetus has inherited the wild-type paternal marker combination.[31,46]

A technical challenge for these applications is the need to detect a minority sequence (i.e., the fetal target) that might differ from the majority background (i.e., the maternal background) by as little as a single base pair (e.g., for the detection of a single point mutation, or an SNP allele). Examples of methods that have been developed for this purpose include single-allele base extension[46] or allele-specific base extension,[191] followed by mass spectrometry or peptide nucleic acid clamping.[109] Investigators have combined (1) the previously mentioned size selection strategy for enriching shorter fetal DNA molecules, and (2) such assays for detecting fetal-derived gene mutations or polymorphisms in maternal plasma.[109] Another very promising approach for the sensitive and specific detection of fetal-derived gene mutations and polymorphisms is through the use of digital PCR.[125,131,132] Thus, by the use of highly diluted DNA samples and multiple digital PCRs, in which each reaction contains a mean of some 0.5 target molecule, most reactions would contain just a single target template molecule or no target molecule. In other words, fetal and maternal DNA molecules derived from the same locus would be distributed into separate PCR wells, and thus would not interfere with each other during the



Condition	Approach
Autosomal dominant traits or mutations	
Paternally inherited	Qualitative detection of M_P
Maternally inherited	Quantitative comparison between M_M and W. **If M_M = W, fetus has inherited M_M.** If M_M < W, fetus has not inherited M_M.
Autosomal recessive conditions or diseases	
When M_P and M_M are identical	Quantitative comparison between M and W. If M = W, fetus is heterozygous. If M > W, fetus is homozygous for the mutation. If M < W, fetus has not inherited the mutation.
When M_P and M_M are different	Assess which paternal allele has been transmitted to the fetus by qualitative detection of M_P or W_P by a polymorphism that distinguishes W_P from M_P, M_M and W_M. Assess which maternal allele has been transmitted to the fetus by quantitative comparison between M_M and W. If M_M = W, fetus has inherited M_M. If M_M < W, fetus has not inherited M_M.

Figure 45-1 Approaches to the noninvasive prenatal diagnosis of monogenic disease by maternal plasma DNA analysis. *M,* Mutant allele; *MM,* maternally inherited mutant allele; *MP,* paternally inherited mutant allele; *W,* wild-type allele; *WM,* maternally inherited wild-type allele; *WP,* paternally inherited wild-type allele.

amplification process. This is analogous to the detection of tumor-derived gene mutations using the digital PCR-based approach described earlier in this chapter. The advent of refinements to the digital PCR process, including microfluidics[131] and BEAMing,[44,45,48] potentially makes this approach more suited to routine clinical application.

Another challenge in this field is to extend the application of plasma DNA-based fetal diagnostics beyond the detection of paternally inherited gene mutations or polymorphic alleles that are absent in the maternal genome. For autosomal recessive disease, such a development would allow a complete diagnosis to be made, instead of just limiting the approach to the exclusion of an affected compound heterozygous fetus.[31,34] This goal has been achieved through the development of the concept of relative mutation detection (RMD) (see Figure 45-1).[132] Thus, for an autosomal recessive disease in which the mother and the father are carriers of the same mutation, the ratio of mutant and wild-type alleles in the parental genomes would be 1:1. If the fetus has inherited a mutant allele from both of its parents, then the ratio of the mutant to the wild-type allele in its genome would be 2:0. When this fetus then releases its DNA into the maternal plasma, a slight excess of mutant over wild-type alleles in the mixture of genomes is seen in the maternal circulation. This allelic imbalance will be small and correlated with the fractional fetal DNA concentration in maternal plasma. With the use of the superior quantitative precision of digital PCR techniques, such an allele imbalance has been detected successfully in maternal plasma.[132] Conversely, if the fetus has inherited one mutant allele from one of its parents and a wild-type allele from the other parent, then the ratio of mutant to wild-type alleles in its genome would also be 1:1. Thus, when this fetus then releases its DNA into the maternal plasma, no allelic imbalance would be observed. With future developments in digital PCR technologies and other digital counting techniques (e.g., massively parallel DNA sequencing described later), it is hoped that this approach will enter clinical practice.

Detection of Chromosomal Aneuploidies

The detection of fetal chromosomal aneuploidies, such as trisomy 21, using cell-free fetal nucleic acids in maternal plasma is challenging because the cell-free nature of such nucleic acids obviates the use of cell-based methods such as fluorescence in situ hybridization (FISH) for counting the number of the target chromosome in a fetal cell. The second

Total (maternal + fetal) amount or proportion of plasma DNA molecules derived from the potentially aneuploid chromosome is increased in pregnancies involving an aneuploid fetus rather than a euploid fetus.** ***Red lines*** **represent fetal DNA molecules from the aneuploid chromosome.** ***Black lines*** **represent maternal DNA molecules from the aneuploid chromosome.**

challenge reflects the fact that fetal DNA represents only a small fraction of the total DNA in maternal plasma.[126,131]

Several approaches have been developed to address the challenges of detecting aneuploidies (Figure 45-2). One approach is to target a fetal-specific subset of plasma nucleic acids. One family of such markers consists of loci that demonstrate different DNA methylation patterns between fetal and maternal DNA in maternal plasma.[158] The *SERPINB5* gene, coding for maspin, is the first fetal DNA methylation marker that can be used as a generic indicator of the presence of fetal DNA in maternal plasma.[28] The fetal-derived subset of *SERPINB5* promoter sequences in maternal plasma is characterized by a hypomethylated nature, when compared with maternally derived ones. In other words, when one analyzes hypomethylated *SERPINB5* promoter sequences in maternal plasma, one is essentially just analyzing the fetal-derived sequences. This feature allows one to overcome the challenge concerning low fractional concentrations of fetal DNA in maternal plasma. It is therefore fortunate that the *SERPINB5* gene is present on chromosome 18, the chromosome that is involved in trisomy 18. One would still have to develop a technology to measure the dosage of chromosome 18 through analysis of hypomethylated *SERPINB5* sequences in maternal plasma.

In 2006, Tong and associates achieved this goal through development of the epigenetic allelic ratio (EAR) approach (see Figure 45-2).[189] With this method, one targets fetuses that are heterozygous for an SNP within the region of the *SERPINB5* gene that is hypomethylated in the placenta when compared with maternal blood cells. The latter requirement exists because most of the fetal DNA in maternal plasma is released by the placenta,[2,7,60] while the background maternal DNA has been postulated to be derived from maternal blood cells.[130] For a fetus that has two copies of chromosome 18, the ratio of the two SNP alleles should be 1:1. However, for a fetus that has three copies of chromosome 18, the ratio would be changed to 2:1 or 1:2. The main limitation of the EAR approach is that it requires markers with both usable

DNA methylation characteristics and informative SNPs within a close (e.g., amplifiable by PCR) distance from one another.

Another variant of the epigenetic theme is the so-called epigenetic-genetic (EGG) chromosome dosage approach (see Figure 45-2).[190] With this method, one determines the ratio between a fetal DNA methylation marker on the target chromosome (e.g., chromosome 21) and a fetal-specific genetic marker (e.g., a marker on the Y chromosome for a male fetus). As an illustration, for a euploid fetus, the ratio of a fetal DNA methylation marker on chromosome 21 and a Y chromosomal marker will be 2:1. For a trisomy 21 fetus, the ratio will be 3:1. The main advantage of the EGG method over the EAR method is that it would be much easier to find markers with the required epigenetic characteristics for the EGG approach than to find markers with both the epigenetic characteristics and the requirement of having an SNP marker in the same region for the EAR approach. In this regard, many groups have reported candidate fetal DNA methylation markers on the chromosomes commonly involved in chromosomal aneuploidies of importance for prenatal diagnosis.[27,151,156,190]

Another family of fetal-specific nucleic acid markers in maternal plasma is the group of mRNA molecules produced in placenta.[150] For fetal trisomy detection, one has to identify placental mRNA transcribed from genes located on the target chromosomes (e.g., chromosome 21).[153] The discovery of such markers has been facilitated by the development of a microarray-based approach in which thousands of such genes could be interrogated in a single experiment.[195] One of the most promising of such genes is the *PLAC4* gene (placenta-specific 4) located on chromosome 21.[128,193] The mRNA coded by *PLAC4* is detectable in maternal plasma from the first trimester onward and is cleared rapidly following delivery.[128] For the detection of trisomy 21, one could use the RNA-SNP allelic ratio approach,[128] which is analogous to the EAR approach for fetal DNA methylation markers (see Figure 45-2). Thus, one would be detecting a 2:1 or 1:2 ratio for a trisomy 21 fetus versus the 1:1 ratio for a euploid fetus. The RNA-SNP allelic ratio approach has also been demonstrated for the prenatal detection of trisomy 18.[194] The main limitation of the RNA-SNP allelic ratio approach is that one could cover only a proportion of the population (i.e., individuals informative for the SNP marker) with a single RNA-SNP marker. Thus, to obtain high population coverage, one would require multiple RNA-SNP markers, and this would increase the complexity of development and eventual applications. Apart from the use of placental mRNA for RNA-SNP allelic ratio analysis, the absolute concentration of *PLAC4* can be used as a risk indicator for trisomy 21.[193] Although this approach is not as sensitive and specific as the RNA-SNP allelic ratio approach, it does offer the advantage of having broad population coverage.

Another approach reported in the literature and using fetal DNA in maternal plasma for aneuploidy detection is the use of formaldehyde treatment.[42,43] It has been postulated by Dhallan and associates that treatment by formaldehyde of a maternal blood sample stabilizes maternal blood cells, thus leading to a reduction in the liberation of DNA from these cells. The latter process, if not prevented, would potentially lead to the dilution of fetal DNA in maternal plasma.[42] Unfortunately, several groups have not been able to replicate these data, and the diagnostic impact of this approach remains uncertain.[29,37,80,121]

Yet another alternative strategy for detecting fetal-specific DNA and RNA aneuploidy involves the detection of fetal chromosomal aneuploidy, despite the fact that fetal DNA represents only a minor fraction of DNA in maternal plasma. Such methods attempt to detect the slight quantitative sequence imbalance that would exist in maternal plasma if an aneuploid fetus were present. For example, if the fetus has trisomy 21, then there should be a slight increase in sequences derived from chromosome 21 in maternal plasma, when compared with those derived from the other chromosomes. In other words, one is attempting to measure the relative chromosome dosage (RCD) (see Figure 45-2). For a maternal plasma sample containing 10% fetal DNA, one would need to detect a 5% increase in the sequences derived from chromosome 21 if one wishes to detect the presence of a trisomy 21 fetus.[54,125] Two groups have outlined strategies for using digital PCR for RCD analysis.[54,125] Indeed, this concept can be generalized to other single-molecule counting methods.[30] The discrimination power of such methods increases with the increase in the number of molecules analyzed. With the advent of massively parallel DNA sequencing,[6,137,170] millions or even billions of molecules are readily analyzed in a single run. Thus, it has been shown that fetal trisomy 21 can be detected with high accuracy using the sequencing-by-synthesis[33,53] and sequencing-by-ligation[32] platforms. With the rapid reduction in the costs of sequencing and the increase in throughput and in the amount of sequencing per run, this technology is expected to impact clinical practice in the near future, subject to large-scale validation trials.

Pregnancy-Associated Disorders

Several groups have shown that the concentration of fetal DNA in maternal plasma is increased in a variety of pregnancy-associated disorders, including preeclampsia[124,215] and preterm labor.[56,106] In particular, the relationship between circulating fetal DNA concentrations and preeclampsia has been studied by a number of groups.[124,215] Following the onset of preeclampsia, both fetal and total cell-free DNA concentrations are increased in maternal plasma,[215] and fetal DNA clearance appears to be impaired in preeclamptic pregnancies.[96] In addition, several workers have reported that circulating cell-free fetal DNA is already elevated before the onset of clinical features of preeclampsia.[39,84,105,107,214] These latter observations thus open up the possibility that circulating fetal DNA measurement might identify pregnant women at increased risk of developing preeclampsia.

Most of the previously mentioned data on preeclampsia were generated using Y chromosomal markers that could be used only in pregnancies involving male fetuses. Two approaches have been used to generate fetal sex-independent

and genetic polymorphism-independent nucleic acid markers. The first involves the use of fetal DNA methylation markers. Hypomethylated *SERPINB5* and hypermethylated *RASSF1* sequences, both markers for fetal DNA in maternal plasma, have been shown to be elevated in the plasma of pregnant women with preeclampsia.[28,192] Hypermethylated *RASSF1,* in particular, has the advantage that it is detected with relatively simple methylation-sensitive restriction enzyme digestion, followed by real-time PCR.[16]

The second approach involves the detection of placental mRNA in maternal plasma.[150] Various groups have demonstrated that a number of such mRNA markers are increased in the plasma of women suffering from preeclampsia.[55,148,159]

The final word has not been said concerning the relative merit of using fetal DNA versus RNA in the prediction, detection, and monitoring of preeclamptic pregnancies. Both approaches require extra steps specific to the marker chosen. For example, when one uses DNA methylation markers, one has to use steps that allow analysis of DNA methylation status (e.g., methylation-sensitive restriction enzyme digestion,[16] methylation-specific PCR).[28,75] Plasma RNA analysis, however, has the disadvantage that a number of groups have advocated the use of potentially hazardous reagents (e.g., Trizol) in preserving the integrity of RNA.[149,209] Plasma RNA markers, on the other hand, offer the advantage that each copy of a fetal gene can theoretically transcribe multiple copies of mRNA, thus providing a biological amplification system.

An emerging class of plasma RNA markers for pregnancy-associated disorders consists of plasma miRNA. In 2008, it was first demonstrated that placental miRNA could be detected in the plasma of pregnant women.[26] Plasma miRNA appears to be more stable than plasma mRNA. Because miRNA expression has been reported to be aberrant in preeclampsia,[157,216] it is possible that some of such plasma miRNA markers might be used to detect and monitor pregnancy-associated disorders.

OTHER APPLICATIONS OF PLASMA NUCLEIC ACIDS

The finding of circulating tumor-derived and fetal-derived DNA in the plasma of cancer patients and pregnant women has prompted researchers to look for other nonhost nucleic acid species in plasma. In 1998, Lo and colleagues reported that donor-derived DNA can be detected in the plasma of patients who have received liver and kidney transplantation.[127] This phenomenon was first observed using sex-mismatched transplantations in which the donor was a male subject and the recipient was a female subject. This observation has been replicated by a number of independent groups in both human subjects[63,140,142] and a rat model.[138] Cell death has generally been regarded as the mechanism through which DNA is released by cells into the plasma. Because graft rejection is a cause of cell death following transplantation, it has been proposed that the measurement of donor-derived DNA concentration in the plasma of transplant recipients might serve as a marker for graft rejection.[127] This hypothesis has been shown to be correct.[63,142] Furthermore, it has been shown that the total concentration of plasma DNA can serve as a rejection marker.[142] This would significantly facilitate the ease with which this technology could be used clinically, as one does not have to use genetic polymorphisms that are informative for only a proportion of donor-recipient pairs.

Plasma nucleic acid technology has been studied as a tool to detect a variety of pathologies associated with tissue damage. Examples include trauma,[116] stroke,[162] myocardial infarction,[41,161] exercise-induced injury,[57] and burns.[36] Furthermore, persistent elevation of plasma DNA has been associated with poor prognosis in trauma patients.[95]

Plasma RNA markers have also been used in monitoring tissue damage. Plasma RNA markers offer the advantage that different tissues have their own RNA expression profiles. For example, plasma albumin mRNA is increased in multiple liver pathologies, including liver cancer, cirrhosis, and chronic hepatitis B.[35] When used in this fashion, plasma albumin mRNA appears to be more sensitive than conventional markers such as alanine aminotransferase. As another example, plasma endothelial-specific mRNA has been shown to be elevated in patients with burn injuries and to correlate with the severity of the injury.[61] With the emergence of plasma miRNA markers, these molecules have also been used for assessment of tissue injury. One example is the use of plasma miR-122 and miR-192 in assessment of drug-induced liver injury.[202] Another example is the use of miR-208[88,201] and miR-1[1] in the detection of acute myocardial infarction.

CONCLUDING REMARKS

Over the past 15 years or so, the field of circulating nucleic acids has developed very rapidly. This development has coincided with a number of important technological advances in nucleic acid detection, such as real-time PCR, mass spectrometry, and massively parallel DNA sequencing. It is likely that some of these developments will have a significant impact on the clinical practice of molecular diagnostics in the near future.

Diabetes Mellitus

David B. Sacks, M.B., Ch.B., F.R.C.Path.

Diabetes mellitus is a group of metabolic disorders of carbohydrate metabolism in which glucose is underused, producing hyperglycemia. Some patients may experience acute life-threatening hyperglycemic episodes, such as ketoacidosis or hyperosmolar coma. As the disease progresses, patients are at increased risk for the development of specific complications, including *retinopathy* leading to blindness, *nephropathy* leading to renal failure, and *neuropathy* (nerve damage), collectively known as microvascular complications, as well as *atherosclerosis,* which is considered a *macrovascular complication.*[169,218] The last may result in stroke, gangrene, or coronary artery disease.

Diabetes is a common disease, although the exact prevalence is unknown. It is estimated that ≈250 million people currently have diabetes, and by 2025 this number will reach 280 million, 80% of whom will live in developing countries. In the United States, the number of people with diabetes has increased dramatically. The prevalence in 1999-2002 was 9.3%, 30% of whom were undiagnosed.[57] Analysis of the 2005-2006 National Health and Nutritional Examination Survey (NHANES) using both fasting glucose and oral glucose tolerance testing (OGTT) shows a prevalence of diabetes in the United States in persons 20 years of age and older of 12.9% (equivalent to ≈40 million people).[58] Of these, ≈40% are undiagnosed. Similarly, the prevalence of diabetes in Asian populations has increased rapidly in recent decades, reaching more than 110 million in 2007.[50] These statistics led to a description of diabetes as "one of the main threats to human health in the twenty-first century."[267] The prevalence of diabetes mellitus increases with age, and approximately half of all cases occur in people older than 55 years. In the United States, more than 20% of the population older than 65 years have diabetes.[99] A racial predilection has been noted, and by the age of 65, 33%, 25%, and 17% of Hispanics, blacks, and whites, respectively, in the United States have diabetes. In 2007, diabetes mellitus was estimated to be responsible for $174 billion in healthcare expenditures in the United States.[17] The direct costs were $116 billion, with 56% of that total incurred by those 65 years and older. An estimated 3.8 million people worldwide died from diabetes-related causes in 2007.[115] Diabetes is the fourth most common cause of death in the developed world.

CLASSIFICATION

Diabetes was initially diagnosed by OGTT. Values greater than two standard deviations above the mean of the value found in a selected population of healthy volunteers without a family history of diabetes mellitus were accepted as diagnostic. This criterion led to the identification of large numbers of asymptomatic people with abnormally high 1 to 2 hour postload glucose values, but normal fasting blood glucose. They were presumed to have early or mild diabetes mellitus. In 1975 it was estimated that more than half the population older than 60 years was abnormal. Follow-up on these individuals indicated that most of them with lesser degrees of glucose intolerance did not manifest definite evidence of diabetes mellitus in the next 10 years, and a large percentage returned to normal glucose tolerance.

Most populations have plasma glucose values that exhibit a unimodal, log-normal distribution (a distribution curve that is skewed to the high end but becomes bell shaped on a logarithmic axis). Ethnic groups with a high prevalence of diabetes, such as the Pima Indians and Nauruans, exhibit bimodal blood glucose distributions.[80] Optimal distinction between normal and diabetic individuals in these groups occurs at a fasting glucose around 140 mg/dL and glucose concentrations greater than 200 mg/dL 2 hours after an oral glucose load. Furthermore, the specific microvascular complications of diabetes were believed to be rare in patients with fasting or 2 hour postprandial glucose concentrations less than 140 or 200 mg/dL, respectively. These observations formed the basis for the criteria proposed in 1979 by a workgroup of the National Diabetes Data Group[174] and later endorsed by the World Health Organization (WHO) Committee on Diabetes.

The 1979 classification scheme recognized two major forms of diabetes: type I (insulin-dependent) diabetes mellitus (IDDM) and type II (non–insulin-dependent) diabetes mellitus (NIDDM).[174] The terms *juvenile-onset* and *adult-onset diabetes* were abolished. To base the classification on cause rather than on treatment, the American Diabetes Association (ADA) established a workgroup in 1995 to re-examine the classification and diagnosis of diabetes mellitus. The revised classification, published in 1997,[9] eliminates the terms *insulin-dependent diabetes mellitus* and *non–insulin-dependent diabetes mellitus,* which now are termed *type 1*

BOX 46-1 Classification of Diabetes Mellitus

Type 1 diabetes
  Immune-mediated
  Idiopathic
Type 2 diabetes
Other specific types of diabetes
  Gestational diabetes mellitus (GDM)
  Impaired glucose tolerance (IGT)
  Impaired fasting glucose (IFG)

and *type 2 diabetes,* respectively (Box 46-1). Furthermore, the categories of previous abnormality of glucose tolerance and potential abnormality of glucose tolerance have been eliminated.

Type 1 Diabetes Mellitus

Approximately 5 to 10% of all cases of diabetes mellitus are included in this category. Patients usually have abrupt onset of symptoms (e.g., polyuria, polydipsia, rapid weight loss). They have insulinopenia (a deficiency of insulin) caused by loss of pancreatic islet β-cells and are dependent on insulin to sustain life and prevent ketosis. Most patients have antibodies that identify an autoimmune process (see later discussion); some have no evidence of autoimmunity and are classified as type 1 idiopathic. The peak incidence occurs in childhood and adolescence. Approximately 75% acquire the disease before the age of 18, but onset in the remainder may occur at any age. Age at presentation is not a criterion for classification.

Type 2 Diabetes Mellitus

This group accounts for approximately 90% of all cases of diabetes. Patients have minimal symptoms, are not prone to ketosis, and *are not dependent on insulin* to prevent ketonuria. *Insulin concentrations may be normal, decreased, or increased,* and most people with this form of diabetes have impaired insulin action. *Obesity* is commonly associated, and weight loss alone usually improves hyperglycemia in these persons. However, many individuals with type 2 diabetes may require dietary manipulation, oral hypoglycemic agents, or insulin to control hyperglycemia. Most patients acquire the disease after age 40, but it may occur in younger people. Type 2 diabetes in children and adolescents is an emerging, significant problem.[12,59,267] Among children in Japan, type 2 diabetes is now more common than type 1.[267]

Other Specific Types of Diabetes Mellitus

This subclass includes uncommon patients in whom hyperglycemia is due to a specific underlying disorder, such as genetic defects of β-cell function; genetic defects in insulin action; disease of the exocrine pancreas; endocrinopathies (e.g., Cushing's syndrome, acromegaly, glucagonoma); administration of hormones or drugs known to induce β-cell dysfunction (e.g., dilantin, pentamidine) or to impair insulin action (e.g., glucocorticoids, thiazides, β-adrenergics); infection; uncommon forms of immune-mediated diabetes; or other genetic conditions (e.g., Down syndrome, Klinefelter syndrome, porphyria; see Reference 18 for a detailed list). This was formerly termed *secondary diabetes.*

Gestational Diabetes Mellitus

This is defined as any degree of glucose intolerance *with onset or first recognition during pregnancy*[157] (i.e., diabetic women who become pregnant are not included in this category). Estimates of the frequency of abnormal glucose tolerance during pregnancy range from 1 to 14%, depending on the population studied and the diagnostic tests employed.[131] In the United States, gestational diabetes mellitus (GDM) occurs in 6 to 8% of pregnancies (≈200,000 cases annually). Women with GDM are at significantly increased risk for the subsequent development of type 2 diabetes mellitus, which occurs in 6 to 62%.[130] The risk is particularly high in women who have marked hyperglycemia during or soon after pregnancy, women who are obese, and those whose GDM was diagnosed before 24 weeks' gestation.[135] At 6 to 12 weeks postpartum, all patients who had GDM should be evaluated for diabetes using nonpregnant OGTT criteria. If diabetes is not present, patients should be re-evaluated for diabetes at least every 3 years.[19]

Impaired Glucose Tolerance

Impaired glucose tolerance (IGT) is diagnosed in people who have fasting blood glucose concentrations less than those required for a diagnosis of diabetes mellitus, but have a plasma glucose response during the OGTT between normal and diabetic states. The 2 hour postload plasma glucose following an OGTT is 140 to 199 mg/dL for this classification. An OGTT is required to assign a patient to this class. Development of overt diabetes occurs at a rate of 1 to 5% per year, but a large proportion of cases spontaneously revert to normal glucose tolerance. Microvascular disease is rare in this group, and patients usually do not experience the renal or retinal complications of diabetes. Patients have an increased prevalence of atherosclerosis and mortality from cardiovascular disease.[65]

Impaired Fasting Glucose

This category is analogous to IGT, but it is diagnosed by a *fasting* glucose value between those of normal and diabetic individuals, namely, fasting plasma glucose (FPG) between 100 and 125 mg/dL. It is a metabolic stage between normal glucose homeostasis and diabetes. As with IGT, persons with impaired fasting glucose (IFG) are at increased risk for the development of diabetes and cardiovascular disease. IFG and IGT are not clinical entities, but rather are risk factors for diabetes and cardiovascular disease.

HORMONES THAT REGULATE BLOOD GLUCOSE CONCENTRATION

During a brief fast, a precipitous decline in the concentration of blood glucose is prevented by breakdown of glycogen

stored in the liver and synthesis of glucose in the liver. Some glucose is derived from gluconeogenesis in the kidneys.[84] These organs contain glucose-6-phosphatase, which is necessary to convert glucose-6-phosphate (derived from gluconeogenesis or glycogenolysis) to glucose. Skeletal muscle lacks this enzyme; muscle glycogen therefore cannot contribute directly to blood glucose. With more prolonged fasting (>42 hours), gluconeogenesis accounts for essentially all glucose production. In contrast, after a meal, the absorbed glucose is converted to glycogen (for storage in the liver and skeletal muscle) or fat (for storage in adipose tissue). Despite large fluctuations in the supply and demand of carbohydrates, the concentration of glucose in the blood is normally maintained within a fairly narrow range by hormones that modulate the movement of glucose into and out of the circulation. These include insulin, which decreases blood glucose, and the counter-regulatory hormones (glucagon, epinephrine, cortisol, and growth hormone), which increase blood glucose concentrations (Figure 46-1).[84] Normal glucose disposal depends on (1) the ability of the pancreas to secrete insulin, (2) the ability of insulin to promote uptake of glucose into peripheral tissue, and (3) the ability of insulin to suppress hepatic glucose production. The major insulin target organs are liver, skeletal muscle, and adipose tissue. These organs exhibit some differences in their responses to insulin. For example, the hormone stimulates glucose uptake through a specific glucose transporter—GLUT4—into muscle and fat cells, but not into liver cells.

Insulin

Insulin is a protein hormone produced by the β-cells of the islets of Langerhans in the pancreas. Insulin was the first protein hormone to be sequenced, the first substance to be measured by radioimmunoassay (RIA), and the first compound produced by recombinant DNA technology for clinical use. It is an anabolic hormone that stimulates the uptake of glucose into fat and muscle, promotes the conversion of glucose to glycogen or fat for storage, inhibits glucose production by the liver, stimulates protein synthesis, and inhibits protein breakdown.

Chemistry

Human insulin [molecular weight (MW) 5808 Da] consists of 51 amino acids in two chains (A and B) joined by two disulfide bridges, with a third disulfide bridge within the A chain. The amino acid sequence of human insulin differs slightly from insulin of other species, but the carboxyl terminal region of the B chain (B23 to B26), which appears crucial for the biological actions of insulin, is highly conserved among species. Insulin from most animals is immunologically and biologically similar to human insulin, and in the past, patients were treated with insulin purified from beef or pig pancreas. The most commonly used forms now are recombinant human insulins.

Synthesis

Preproinsulin, a protein of about 100 amino acids (MW 12,000 Da), is formed by ribosomes in the rough endoplasmic reticulum of the pancreatic β-cells (Figure 46-2). Preproinsulin is not detectable in the circulation under normal conditions because it is rapidly converted by cleaving enzymes to proinsulin (MW 9000 Da), an 86 amino acid polypeptide. This is stored in secretory granules in the Golgi complex of the β-cells, where *proteolytic cleavage to insulin and connecting peptide (C-peptide) occurs.*[179] Cleavage of proinsulin is catalyzed by two Ca^{2+}-regulated endopeptidases: prohormone convertases 1 and 2 (PC1 and PC2).[195] PC1 (sometimes designated PC3) hydrolyzes the molecule on the *C*-terminal

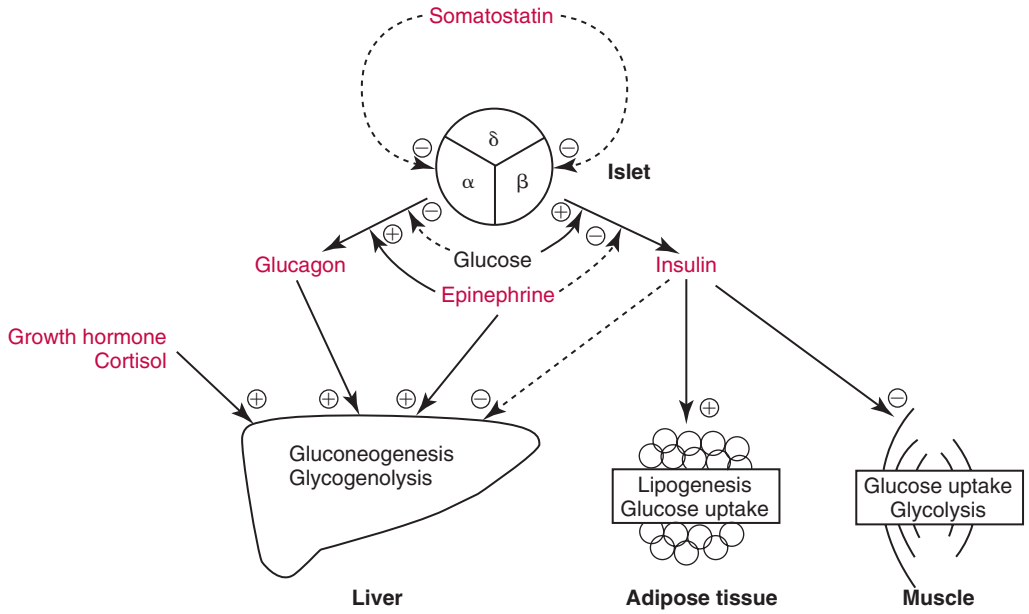

Figure 46-1 Hormonal regulation of blood glucose. Key: +, stimulation; –, inhibition. Cortisol, growth hormone, and epinephrine antagonize the effects of insulin.

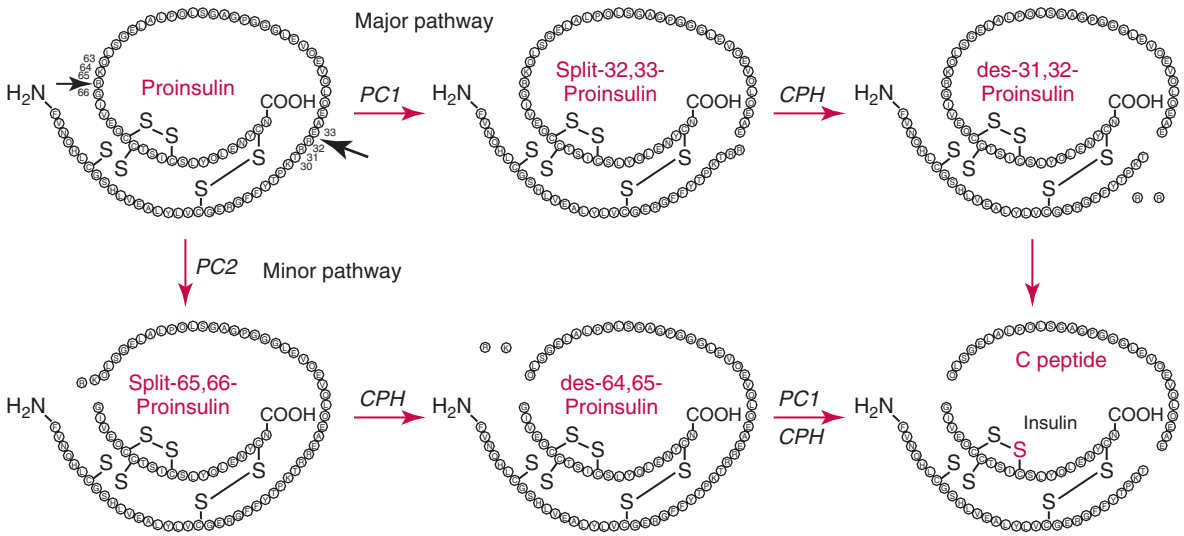

Figure 46-3 Processing of proinsulin. The enzymes prohormone convertase 1 and 2 (PC1 and PC2) act on proinsulin to form the appropriate split proinsulins. Carboxypeptidase-H (CPH) removes the two exposed basic amino acid residues *(circles)*.

end of Arg-31 and Arg-32 (at the BC junction) to yield split-32, 33-proinsulin (Figure 46-3). PC2 cleaves proinsulin on the *C*-terminal side of dibasic residues Lys-64 and Arg-65 (at the AC junction) to generate split-65,66-proinsulin. Each enzymatic hydrolysis is rapidly followed by the removal of two newly exposed *C*-terminal basic amino acids by carboxypeptidase-H to produce insulin and C-peptide.

The split proinsulin intermediates are rarely detected in patient samples because of the relatively high quantity of carboxypeptidase-H. This enzyme produces the more commonly observed proinsulin intermediates, des-31,32-proinsulin and des-64,65-proinsulin (see Figure 46-3). Most proinsulin processing is sequential. Intact proinsulin is initially hydrolyzed by PC1 or carboxypeptidase-H. The resultant des-31,32-proinsulin is converted by PC2 and carboxypeptidase-H to insulin and C-peptide. Less than 10% of proinsulin is metabolized via des-(64-65)-proinsulin, which is present in negligible amounts in humans. Des-31,32-proinsulin is the major proinsulin conversion intermediate.[223] Glucose regulates biosynthesis of both proinsulin and PC1, but has no effect on PC2 or carboxypeptidase-H. At the cell membrane, insulin and C-peptide are released into the portal circulation in equimolar amounts. In addition, small amounts of proinsulin and intermediate cleavage forms enter the circulation.

Release

Glucose, amino acids, pancreatic and gastrointestinal hormones (e.g., glucagon, gastrin, secretin, pancreozymin, gastrointestinal polypeptide), and some medications (e.g., sulfonylureas, β-adrenergic agonists) stimulate insulin secretion. Insulin release is inhibited by hypoglycemia, somatostatin (produced in the pancreatic δ-cells), and various drugs (e.g., α-adrenergic agonists, β-adrenergic blockers, diazoxide, phenytoin, phenothiazines, nicotinic acid).[184] In healthy individuals, insulin is secreted in a pulsatile fashion, with glucose and insulin the main signals in the feedback loop. Glucose elicits the release of insulin from the pancreas in two phases. The first phase begins 1 to 2 minutes after intravenous injection of glucose and ends within 10 minutes. This phase, illustrated by the sharp spike in Figure 46-4, *A*, represents the rapid release of stored insulin. The second phase, beginning at the point where the first phase ends, depends on continuing insulin synthesis and release and lasts until normoglycemia has been restored, usually within 60 to 120 minutes. With progressive failure of β-cell function, the first-phase insulin response to glucose is lost, but other stimuli such as glucagon or amino acids may be able to elicit this response. Although the second-phase insulin response is preserved in most patients with type 2 diabetes mellitus, both the first-phase response (Figure 46-4, *B*) and normal pulsatile insulin secretion[174] are lost. In contrast, patients with type 1 diabetes mellitus exhibit minimal or no insulin response (Figure 46-4, *C*).

Degradation

On the first pass through the portal circulation, approximately 50% of insulin is extracted by the liver, where it is degraded. Because the amount extracted is variable, plasma insulin concentrations may not accurately reflect the rate of insulin secretion. Additional insulin degradation occurs in the kidneys. Insulin is filtered through the glomeruli, reabsorbed, and degraded in the proximal tubule. The basal insulin secretory rate is about 1 U (43 μg)/h, with total daily secretion of about 40 U. The half-life of insulin in the circulation is between 4 and 5 minutes.

Proinsulin

Proinsulin, which has relatively low biological activity (approximately 10% of insulin potency), is the major storage form of insulin.[198] Normally, only small amounts (about 3% of the amount of insulin, on a molar basis) of proinsulin enter the circulation. However, the hepatic clearance rate for proinsulin is only 25% of that for insulin, and the half-life of proinsulin is ≈30 minutes. Therefore in the fasting state, circulating proinsulin concentrations are approximately 10 to 15% of insulin concentrations.

C-Peptide

Proinsulin is cleaved to a 31 amino acid connecting (C) peptide (MW 3600 Da) and insulin (see Figure 46-3). C-peptide is devoid of biological activity but appears necessary to ensure the correct structure of insulin.[104] Although insulin and C-peptide are secreted into the portal circulation in equimolar amounts, fasting C-peptide concentrations are fivefold to 10-fold higher than those of insulin owing to the longer half-life of C-peptide (≈35 minutes). The liver does not extract C-peptide, which is removed from the circulation by the kidneys and degraded, with a fraction excreted unchanged in the urine.

Antibodies to Insulin

Antibodies to insulin develop in almost all patients who are treated with exogenous insulin.[197] These antibodies are usually present at low titer and produce no adverse effects. On rare occasions (usually in patients with type 2 diabetes), high titers of insulin antibodies may cause insulin resistance. Improvement in the purity of animal insulins and the widespread use of human insulin have reduced, but not totally eliminated, antibody production. Recent advances in insulin delivery systems, namely, continuous subcutaneous insulin infusion and inhaled insulin, have significantly increased concentrations of insulin antibodies.[189] Antibodies to insulin rarely develop in patients who have not received exogenous insulin.

Although rare, patients with antibodies to the insulin receptor have been described.[79] On binding the receptor, these antibodies act as antagonists, producing hyperglycemia (e.g., in patients with acanthosis nigricans), or agonists, resulting in hypoglycemia.

The Mechanism of Insulin Action

Although the metabolic effects produced by insulin are well known, the molecular mechanism of insulin action remains incompletely understood.[40,231] It is generally accepted that the initial event is the binding of insulin to specific receptors in the plasma membrane (Figure 46-5). The human insulin receptor, which is well characterized, is a heterotetramer, comprising two α- and two β-subunits. The α-subunit (MW 135,000 Da) is located on the outer surface of the plasma membrane and contains the site where insulin binds. The β-subunit (MW 95,000 Da) extends intracellularly through the plasma membrane and contains an intrinsic tyrosine kinase. Binding of insulin to the α-subunits induces a conformational change in the receptor, resulting in activation of tyrosine kinase, which catalyzes the phosphorylation of tyrosine residues on several proteins. One of the major substrates for this tyrosine kinase is the receptor itself.

In addition to phosphorylating itself, the insulin receptor catalyzes the tyrosine phosphorylation of various specific intracellular proteins (see Figure 46-5). These include the four members of the family of insulin-receptor substrate (IRS) proteins (termed IRS-1, IRS-2, IRS-3, and IRS-4), Shc, and Gab-1. The phosphorylated tyrosines on these target proteins act as docking sites for selected intracellular signal transducer

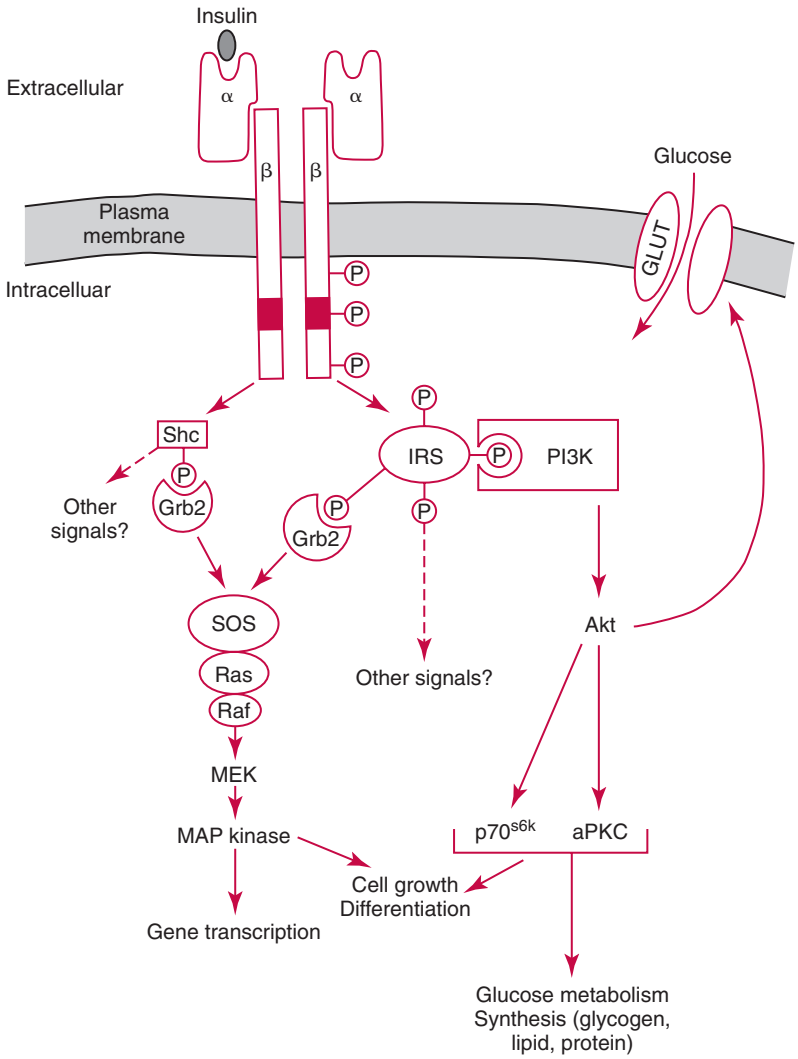

Figure 46-5 Mechanism of insulin action. Binding of insulin to the extracellular α-subunit of the insulin receptor induces autophosphorylation of the β-subunit of the receptor and phosphorylation of selected intracellular proteins, such as Shc and the insulin-receptor substrate (IRS) family. These latter phosphoproteins interact with other targets, thereby activating phosphorylation cascades, which result in glucose uptake (in adipose tissue and skeletal muscle), glucose metabolism, synthesis (of glycogen, lipid, and proteins), enhanced gene expression, cell growth, and differentiation. *aPKC,* Atypical protein kinase C; *p,* protein phosphorylation. See text for details.

proteins.[231] Most of these transducer proteins contain one or more Src homology 2 (SH2) domains. The SH2 domain is a sequence of approximately 100 amino acids that recognizes phosphotyrosine.[183] Sequence differences in the SH2 domain dictate the specificity of binding. SH2-containing proteins depicted in Figure 46-5 include those labeled phosphatidylinositol 3-kinase (PI3K) and growth factor receptor–bound protein 2 (Grb2), both of which mediate downstream signal transduction events. Similar to other growth factors, insulin stimulates the mitogen-activated protein (MAP) kinase cascade via Ras. In addition, phosphatidylinositol 3′-kinase activates atypical protein kinase C (aPKC) via Akt. The latter enzymes regulate glucose transport by modulating translocation of GLUT4 (the insulin-sensitive glucose transporter) to the plasma membrane. Akt also phosphorylates and inactivates GSK-3, thereby enhancing glycogen synthesis. Some of these events are listed in Figure 46-5. The pathways are elaborate, and although several components have been identified, there remain considerable gaps in our knowledge and understanding. Recent studies have clarified a fundamental concept—that insulin-mediated signaling events are highly redundant. For example, when two key insulin-signaling molecules, IRS-1 and GLUT4, were knocked out in transgenic mouse experiments, the resulting animals had

minor metabolic defects rather than overt diabetes.[196] Similarly, mice with knockout of insulin receptors from skeletal muscle or liver do not develop diabetes.

Glucose Transport

The transport of glucose into cells is modulated by two families of proteins.[263] The sodium-dependent glucose transporters (SGLTs) use the electrochemical sodium gradient to transport glucose against its concentration gradient. SGLTs promote the uptake of glucose and galactose from the lumen of the small bowel and their reabsorption from urine in the kidney. Members of the second family of glucose carriers are called *facilitative glucose transporters* (GLUT) (Table 46-1).

TABLE 46-1 Facilitative Human Glucose Transporters

Name	Class	Tissue	Function
GLUT1	I	Wide distribution, especially brain, kidney, colon, and fetal tissues	Basal glucose transport
GLUT2	I	Liver, β-cells of pancreas, small intestine, and kidney	Non–rate-limiting glucose transport
GLUT3	I	Wide distribution, especially neurons, placenta, and testis	Glucose transport in neurons
GLUT4	I	Skeletal muscle, cardiac muscle, adipose tissue	Insulin-stimulated glucose transport
GLUT5	II	Small intestine, kidney, skeletal muscle, brain, and adipose tissue	Transports fructose (not glucose)
GLUT6	III	Brain, spleen, leukocytes	
GLUT7	II	Intestine, testis, prostate	
GLUT8	III	Testis, heart, brain	
GLUT9	II	Kidney, liver	
GLUT10	III	Liver, pancreas	
GLUT11	II	Pancreas, kidney, placenta, skeletal muscle	
GLUT12	III	Heart, prostate	
HMIT		Brain	Transports *myo*-inositol (not glucose)
GLUT14	III	Testis	

These transporters are designated GLUT1 to GLUT14, based on the order in which they were identified.[209] Eleven have been shown to catalyze sugar transport. They can be divided into three classes, based on sequence similarities and characteristics. The best characterized are class I. Less is known about those in classes II and III. GLUT1 is widely expressed and provides many cells with their basal glucose requirement. GLUT1 in the blood-brain barrier and GLUT3 in neuronal cells provide the constant high concentrations of glucose required by the brain. GLUT2 is expressed in hepatocytes, β-cells of the pancreas, and basolateral membranes of intestinal and renal epithelial cells. It is a low-affinity, high-capacity transport system that allows non–rate-limiting movement of glucose into and out of these cells. GLUT4 catalyzes the rate-limiting step for glucose uptake and metabolism in skeletal muscle, the major organ of glucose consumption. GLUT4 is also present in adipose tissue.

When circulating insulin concentrations are low, most of the GLUT4 is localized in intracellular compartments and is inactive. After eating, the pancreas releases insulin, which stimulates the translocation of GLUT4 to the plasma membrane, thereby promoting glucose uptake into skeletal muscle and fat. Insulin-stimulated glucose transport into skeletal muscle is defective in type 2 diabetes mellitus, but the mechanism has not been established.

Insulin-like Growth Factors

Insulin-like growth factors 1 and 2 (IGF-1 and IGF-2) are polypeptides structurally related to insulin.[190] These hormones (previously referred to as *nonsuppressible insulin-like activity* or *somatomedin*) exhibit metabolic and growth-promoting effects similar to those of insulin. Accumulating evidence implicates the IGF axis in the development of several common cancers.[207] IGF-1 (previously known as somatomedin C) is an important mediator of growth hormone action and is one of the major regulators of cell growth and differentiation. The physiologic role of IGF-2 is not known. Synthesis of IGF-1 depends on growth hormone and occurs predominantly in the liver. In addition, many other cells produce IGF-1 that does not enter the circulation but acts locally. Circulating IGF concentrations are approximately 1000-fold higher than insulin concentrations, and the hormone is kept inactive by binding to a family of at least six specific binding proteins.[113] These proteins regulate IGF by protecting the ligands in the circulation and delivering them to their target tissue. In contrast to insulin, which is unbound in the circulation, less than 10% of total serum IGF-1 is free. The biological actions of IGF are exerted through specific IGF receptors or the insulin receptor. The IGF-1 receptor is closely related to the insulin receptor in structure and biochemical properties. In contrast, the IGF-2 receptor is quite different; it lacks tyrosine kinase activity, and its physiologic relevance is not understood. The IGF-1 receptor has a high affinity for both IGF-1 and IGF-2, but a low affinity for insulin. The IGF-2 receptor has high, low, and no affinity for IGF-2, IGF-1, and insulin, respectively. The insulin receptor binds insulin with high affinity and IGF-1 and IGF-2 with low affinity.

The significance of IGFs in normal carbohydrate metabolism is not known. Exogenous administration produces hypoglycemia, whereas a deficiency of IGF-1 results in dwarfism (pygmies and Laron dwarfs). IGFs, particularly IGF-2, may be produced in excess by extrapancreatic neoplasms, and patients may have fasting hypoglycemia.[60] The high concentrations of both IGF-2 protein in the blood and IGF-2 messenger RNA (mRNA) in tumor extracts have led to the proposal that IGF-2 is the humoral mediator of non–islet cell tumor–induced hypoglycemia.[217] Measurement of plasma IGF-1 concentration may be useful in evaluating growth hormone deficiency and excess (acromegaly), and in monitoring response to nutritional support.

Counter-Regulatory Hormones

Several hormones have actions opposite to those of insulin. These counter-regulatory hormones are catabolic and increase hepatic glucose production initially by enhancing the breakdown of glycogen to glucose (glycogenolysis), and later by stimulating the synthesis of glucose (gluconeogenesis).[83,84] The initial response (within minutes) to low blood glucose is an increase in glucose production, stimulated by glucagon and epinephrine. Over time (3 to 4 hours), growth hormone and cortisol increase glucose mobilization and decrease glucose use (see Figure 46-1). Evidence also suggests that glucose production by the liver is an inverse function of ambient glucose concentration, independent of hormonal factors *(glucose autoregulation)*. The role of other hormones or neurotransmitters is not clear but appears relatively unimportant. Multiple counter-regulatory hormones exhibit both redundancy and hierarchy. Glucagon is the most important, and epinephrine becomes critical when glucagon is deficient. The other factors have lesser roles. These hormones, briefly described here, are discussed further in Chapters 30, 51, 53, and 54.

Glucagon

Glucagon is a 29 amino acid polypeptide secreted by α-cells of the pancreas. The major target organ for glucagon is the liver, where it binds to specific receptors and increases both intracellular adenosine-5′-monophosphate and calcium. Glucagon stimulates the production of glucose in the liver by glycogenolysis and gluconeogenesis.[144] In addition, glucagon enhances ketogenesis in the liver. A minor target organ for glucagon is adipose tissue, where the hormone increases lipolysis. Glucagon secretion is regulated primarily by plasma glucose concentrations, with low and high plasma glucose being stimulatory and inhibitory, respectively. Long-standing diabetes mellitus impairs the glucagon response to hypoglycemia, resulting in an increased incidence of hypoglycemic episodes. Stress, exercise, and amino acids induce glucagon release. Insulin inhibits glucagon release from the pancreas and decreases glucagon gene expression, thereby attenuating its biosynthesis. Increased glucagon concentrations, secondary to insulin deficiency, are believed to contribute to the hyperglycemia and ketosis of diabetes.

Proglucagon is also produced in the distal gut by L-cells, which process it into glucagon, glucagon-like peptide-1 (GLP-1), and GLP-2. Food ingestion stimulates release of GLP-1, which acts on β-cells of the pancreas to stimulate insulin gene transcription and potentiate glucose-induced insulin secretion. GLP-1 and glucose-dependent insulinotropic polypeptide (GIP) are incretin hormones that are responsible for 70% of postprandial insulin secretion.[55] GLP-1 reduces hyperglycemia by regulating insulin and glucagon secretion, thus providing gastric emptying and satiety. For these reasons, GLP-1 analogs are generating interest in the treatment of type 2 diabetes,[55] and two (exenatide and liraglutide) have received Food and Drug Administration (FDA) approval.

Epinephrine

Epinephrine, a catecholamine secreted by the adrenal medulla, stimulates glucose production (glycogenolysis) and decreases glucose use, thereby increasing blood glucose concentrations. It also stimulates glucagon secretion and inhibits insulin secretion by the pancreas (see Figure 46-1). Epinephrine appears to have *a key role in glucose counter-regulation when glucagon secretion is impaired* (e.g., in type 1 diabetes mellitus). Physical or emotional stress increases epinephrine production, releasing glucose for energy. Tumors of the adrenal medulla, known as *pheochromocytomas,* secrete excess epinephrine or norepinephrine and produce moderate hyperglycemia as long as glycogen stores are available in the liver.

Growth Hormone

Growth hormone is a polypeptide secreted by the anterior pituitary gland. It stimulates gluconeogenesis, enhances lipolysis, and antagonizes insulin-stimulated glucose uptake.

Cortisol

Cortisol, secreted by the adrenal cortex in response to adrenocorticotropic hormone (ACTH), stimulates gluconeogenesis and increases the breakdown of protein and fat. Patients with Cushing's syndrome have *increased cortisol* owing to tumor or hyperplasia of the adrenal cortex and may become hyperglycemic. In contrast, people with Addison's disease have *adrenocortical insufficiency* caused by destruction or atrophy of the adrenal cortex and may exhibit hypoglycemia.

Other Hormones Influencing Glucose Metabolism

Thyroxine

Thyroxine, secreted by the thyroid gland, is not directly involved in glucose homeostasis, but it stimulates glycogenolysis and increases the rates of gastric emptying and intestinal glucose absorption. These factors may produce glucose intolerance in thyrotoxic individuals, but patients usually have a fasting plasma glucose concentration in the reference interval.

Somatostatin

Somatostatin, also called *growth hormone–inhibiting hormone,* is a 14 amino acid peptide found in the gastrointestinal tract, the hypothalamus, and the δ-cells of the pancreatic islets.

Although somatostatin does not appear to have a direct effect on carbohydrate metabolism, it inhibits the release of growth hormone from the pituitary. In addition, *somatostatin inhibits secretion of glucagon and insulin by the pancreas,* thus modulating the reciprocal relationship between these two hormones.

CLINICAL UTILITY OF MEASURING INSULIN, PROINSULIN, C-PEPTIDE, AND GLUCAGON

Box 46-2 lists the clinical conditions in which hormones that regulate glucose, namely, insulin, proinsulin, C-peptide, and glucagon, have been measured. Although there is interest in the possible clinical value of measurement of the concentrations of insulin and its precursors, the assays are useful primarily for research purposes. There is no role for routine testing for insulin, proinsulin, or C-peptide in most patients with diabetes mellitus.[204] Measurement of C-peptide is sometimes necessary in the United States for patients to obtain insurance coverage for continuous subcutaneous insulin infusion pumps. It must be emphasized that the diagnostic criteria for diabetes mellitus do not include measurements of hormones, which remain predominantly research tools.

BOX 46-2 Clinical Utility of Insulin, Proinsulin, C-Peptide, and Glucagon Assays

Insulin
- Evaluation of fasting hypoglycemia
- Evaluation of the polycystic ovary syndrome
- Classification of diabetes mellitus
- Prediction of diabetes mellitus
- Assessment of β-cell activity
- Selection of optimal therapy for diabetes
- Investigation of insulin resistance
- Prediction of the development of coronary artery disease

Proinsulin
- Diagnosis of β-cell tumors
- Familial hyperproinsulinemia
- Cross-reactivity of insulin assays

C-Peptide
- Evaluation of fasting hypoglycemia
  - β-Cell tumors
  - Factitious
- Classification of diabetes mellitus
- Assessment of β-cell activity
- Obtaining insurance coverage for insulin pump
- Monitoring therapy
  - Pancreatectomy
  - Transplant (pancreas-islet cell)
  - Immunomodulation of type 1 diabetes

Glucagon
- Diagnosis of α-cell tumors

Insulin

The primary clinical application of insulin measurement is in the evaluation of patients with fasting hypoglycemia (discussed in more detail in Chapter 26). Measurement of circulating insulin could be helpful in evaluating insulin resistance and insulin secretion. Insulin determination has also been proposed to be of value in selecting the optimal initial therapy for patients with type 2 diabetes mellitus. In theory, the lower the pretreatment insulin concentration, the more appropriate might be insulin or an insulin secretagogue as the treatment of choice. Although intellectually appealing, no evidence suggests that knowledge of the insulin concentration leads to more efficacious treatment. Evidence indicates that increased concentrations of insulin in nondiabetic individuals predict the development of coronary artery disease.[96] Nevertheless, it is not clear whether the increased insulin is responsible for the risk of coronary disease, and the clinical value is questionable.[204] In the past, measurement of insulin was advocated in the evaluation and management of patients with polycystic ovary syndrome.[204] Women with this condition have insulin resistance and abnormal carbohydrate metabolism that may respond to oral hypoglycemic agents. However, it is not clear whether assessing insulin resistance by measuring insulin concentrations affords any advantage over clinical signs of insulin resistance (body mass index, acanthosis nigricans), and the American College of Obstetrics and Gynecology does not recommend routine measurements of insulin.[5] Although a few investigators have recommended measuring insulin along with glucose during an OGTT as an aid to the early diagnosis of diabetes mellitus, this approach is not recommended.[204]

Proinsulin

High proinsulin concentrations are usually noted in patients with benign or malignant β-cell tumors of the pancreas. Most patients with β-cell tumors have increased insulin, C-peptide, and proinsulin concentrations, but occasionally only proinsulin is increased[82] because the tumors have defective conversion of proinsulin to insulin. Despite its low biological activity, proinsulin production may be adequate to produce hypoglycemia. In addition, a rare form of familial hyperproinsulinemia, produced by impaired conversion to insulin, has been described. Measurement of proinsulin can be useful to determine the amount of proinsulin-like material that cross-reacts in an insulin assay. Patients with type 2 diabetes have increased proportions of proinsulin and proinsulin conversion intermediates,[143] high concentrations of which are associated with cardiovascular risk factors.[167] Even relatively mild hyperglycemia produces hyperproinsulinemia, with values greater than 40% of insulin concentration in type 2 diabetes.[143] Similarly, women with GDM have higher concentrations of proinsulin and split-32,33-proinsulin than pregnant normoglycemic control subjects. An increased ratio of proinsulin-like molecules to insulin-like molecules at screening may be a better predictor of GDM than age, obesity, or hyperglycemia.[226] Increased proinsulin concentrations may

tahir99-VRG & vip.persianss.ir

also be detected in patients with chronic renal failure, cirrhosis, or hyperthyroidism.

Accurate measurement of proinsulin has been difficult for several reasons: the blood concentrations are low; antibody production is difficult; most antisera cross-react with insulin and C-peptide, which are present in much higher concentrations; the assays measure intermediate cleavage forms of proinsulin; and reference preparations of pure proinsulin are not readily available. However, a more sensitive nonequilibrium RIA method for measuring proinsulin was developed by adsorbing the initial antiserum with biosynthetic human C-peptide coupled with agarose to eliminate cross-reactivity with C-peptide.[42,101] An enzyme-linked immunosorbent assay (ELISA) has been described that employs an antibody to C-peptide as the coating antibody and anti-insulin antibody for detection.[85] The detection limit is 0.25 pmol/L.[134]

C-Peptide

Measurement of C-peptide has a number of advantages over insulin measurement. Because hepatic metabolism is negligible, C-peptide concentrations are better indicators of β-cell function than is peripheral insulin concentration.[186] Furthermore, C-peptide assays do not measure exogenous insulin and do not cross-react with insulin antibodies, which interfere with the insulin immunoassay.

Fasting Hypoglycemia

The primary indication for measuring C-peptide is for the evaluation of fasting hypoglycemia. Some patients with insulin-producing β-cell tumors, particularly if hyperinsulinism is intermittent, may exhibit increased C-peptide concentrations with normal insulin concentrations. When hypoglycemia is due to surreptitious insulin injection, *insulin* concentrations will be high but C-peptide values will be low[108]; this occurs because C-peptide is not found in commercial insulin preparations and exogenous insulin suppresses β-cell function.

Insulin Secretion

Basal or stimulated (by glucagon or glucose) C-peptide concentrations provides estimates of a patient's insulin secretory capacity and rate. For example, diabetic patients with C-peptide concentrations greater than 1.8 μg/L (1.8 ng/mL) after stimulation with glucagon behave clinically like patients with type 2 diabetes, and those with low peak C-peptide values (<0.5 μg/L) behave like patients with type 1 diabetes.[105] In rare cases, this strategy may be helpful before discontinuation of insulin treatment (e.g., in an obese adolescent). Urinary and fasting serum C-peptide concentrations appear to be of some value in differentiating patients with type 1 diabetes from those with type 2 diabetes.[124] In addition, patients who have type 1 diabetes but who have no C-peptide response are usually more labile than those with some residual β-cell function. Despite these observations, C-peptide measurement has a negligible role in the routine management of patients with diabetes. A relatively new indication for C-peptide analysis is the recent requirement that Medicare patients in the United States must have low C-peptide concentrations to be eligible for coverage of insulin pumps.[204]

Monitoring Therapy

Measurement of C-peptide is used to monitor patients' response to pancreatic surgery. C-peptide should be undetectable after a radical pancreatectomy and should increase after a successful pancreas or islet cell transplant. In addition, a stable C-peptide concentration is used as an endpoint in immunomodulatory trials for the prevention of type 1 diabetes.[1]

Measurements of urine C-peptide are useful when continuous assessment of β-cell function is desired, or when frequent blood sampling is not practical. The 24-hour urine C-peptide content (in the absence of renal failure, which produces increased concentrations) correlates well with fasting serum C-peptide concentration or with the sum of C-peptide concentrations in sequential specimens after a glucose load. However, the fraction of secreted C-peptide that is excreted in the urine exhibits high intersubject and intrasubject variability, limiting the value of urine C-peptide as a measure of insulin secretion.[237]

Glucagon

Very high concentrations of glucagon are seen in patients with α-cell tumors of the pancreas called *glucagonomas*. Patients with this tumor frequently have weight loss, necrolytic migratory erythema, diabetes mellitus, stomatitis, and diarrhea.[252] Skin lesions often occur first and are frequently overlooked. Most tumors have metastasized when finally diagnosed. Low glucagon concentrations are associated with chronic pancreatitis and long-term sulfonylurea therapy.

METHODS FOR THE MEASUREMENT OF SPECIFIC HORMONES

Insulin

Although insulin has been assayed for over 50 years, no highly accurate, precise, and reliable procedure is available to measure the amount of insulin in a patient sample. Many insulin assays are commercially available.[52,150,160] The techniques most widely used are immunometric.[150,160] Bioassays, although of greater physiologic relevance because they measure biological activity, are labor intensive and are not widely used. A stable isotope dilution mass spectrometry assay yields lower values than an immunoassay.[132]

Patients treated with exogenous insulin may develop circulating anti-insulin antibodies, which compete with antibodies in the RIA. Endogenous antibodies and their bound insulin can be precipitated from serum with polyethylene glycol (PEG), and free insulin measured by RIA. Total insulin can be determined by eluting antibody-bound insulin with

tahir99-VRG & vip.persianss.ir

hydrochloric acid (HCl), precipitating the antibody with PEG, and performing RIA. The bound insulin is the difference between total and free insulin. Unless a patient's insulin requirements change dramatically, total insulin concentrations are usually constant in patients with type 1 diabetes, and repeated assays are not necessary.

Principle

In a typical RIA procedure for measuring insulin, ^{125}I-labeled insulin competes with insulin in a patient sample for binding to an insulin-specific antibody immobilized on the walls of a polypropylene tube. The supernatant is decanted, and the bound ^{125}I determined in a gamma counter. The amount of insulin in the sample is established by comparison with a calibration curve obtained by plotting on logit-log graph paper the percent of total radioactivity bound (B/T%) against the concentration of the calibrators. Various commercial kits for insulin measurement are now available.

Comments

General comments on the measurement of insulin include the following:

1. The term *immunoreactive insulin* is used in reference to assays that may recognize, in addition to insulin, substrates that share antigenic epitopes with insulin. Examples include proinsulin, proinsulin conversion intermediates, and insulin derivatives, produced by glycation or dimerization.
2. Various insulin preparations, including human insulin, are used as insulin calibrators. For ease of comparison of results among laboratories, the insulin calibrator is expressed in terms of international units (IU). One international unit of insulin is equal to approximately 43 μg of the World Health Organization (WHO) first International Reference Preparation (1st IRP) Code 66/304 (National Institute of Biological Standards and Control, South Mimms, Potters Bar, Hertfordshire, United Kingdom), which is 100% human insulin.
3. *Antisera raised against insulin show some cross-reactivity with proinsulin but not with C-peptide.* Specificity is not a problem in healthy individuals because the low proinsulin concentrations do not appreciably affect the absolute values of insulin. In certain situations (e.g., islet cell tumors and diabetic individuals), proinsulin is present at higher concentrations, and direct assay of plasma may falsely overestimate the true insulin concentration. Because proinsulin has very low activity, incorrect conclusions regarding the availability of biologically active insulin may be reached in patients with diabetes. The magnitude of the error depends on the concentration of proinsulin and the extent of cross-reactivity of the antiserum with proinsulin. Monoclonal antibody-based assays that are specific for insulin and do not measure proinsulin,[234] although theoretically advantageous, are not superior to nonspecific assays.[197]
4. A stable isotope dilution mass spectrometry (IDMS) assay has been developed to measure insulin, proinsulin, and C-peptide.[132] The difference in mass among the three analytes allows specific measurement of each protein. Comparison of patient samples revealed that most, but not all, results were higher by immunoassay than by mass spectrometry.[132] Thus immunoassays may overestimate insulin, particularly at low concentrations. The high protein concentration in the serum requires extraction of proteins (e.g., by immunoaffinity) and purification by high-performance liquid chromatography (HPLC) before quantification by mass spectrometry. This method is not suitable for routine laboratory analysis, but is the best higher-order measurement procedure available and can be used as a candidate reference measurement procedure.
5. The American Diabetes Association (ADA) appointed a task force to standardize the insulin assay.[197] Evaluation of unknown samples by 17 different laboratories revealed a wide range in insulin values, with interlaboratory variation up to threefold.[197] Large differences were observed even among laboratories using the same assays. Use of a common calibrator did not improve agreement among laboratories. Assay coefficients of variation (CVs) ranged from less than 2% to greater than 30%, with ELISAs exhibiting the lowest imprecision. Certain characteristics of some assays, including commercial kits, were unacceptable. The task force judged available proficiency and certification programs for insulin to be inadequate, and recommended the establishment of a central laboratory to provide certification for insulin assays. Complete interlaboratory standardization was deemed to be neither practical nor universally acceptable. ADA recommendations for analysis of insulin[197] are as follows:
   a. Each laboratory should carefully evaluate its insulin assay to ensure acceptable assay performance.
   b. Each laboratory should compare the performance of its assay with others using common calibrators and unknown samples.
   c. Because assay performance may change with time or with new reagents or equipment, performance characteristics must be remeasured periodically.
6. In 2004 the ADA convened an international workgroup to establish guidelines for acceptability of insulin assays and to develop a standardization program that can be used to achieve uniform accuracy-based values.[152] Evaluation of 10 commercial insulin methods from 9 manufacturers revealed within-assay CVs ranging from 3.7 to 39%, and 7 assays had a CV ≤10.6%.[152] Among-assay CVs ranged from 12 to 66%. Results from six assays agreed within a total error of 32%.[152] Cross-reactivity with proinsulin and split-32,33-proinsulin was <2% for nine methods and <3% for eight methods, respectively. A common insulin reference preparation failed to improve harmonization of results. The workgroup concluded that not all commercial insulin assays have acceptable performance characteristics. A study in the United Kingdom published at the same time[150] compared 11 commercially available insulin assays and made analogous observations. Insulin values among the different assays varied up to twofold.

tahir99-VRG & vip.persianss.ir

The ADA workgroup subsequently compared results of 10 commercial insulin assays against IDMS. Four methods were within 32% of the IDMS concentration.[160] Most methods had bias greater than 15.5%. Bias was reduced by calibration with serum pools, but remained high for many methods at low insulin concentrations (<60 pmol/L) (10 μIU/mL).

7. Based on biological variability, desirable measurement bias of ±15%, imprecision of 10.6% CV, and total analytical error of 32.0% have been proposed for a single insulin measurement.[152]
8. Patient samples with high values should be diluted with the zero calibrator.
9. The presence of antibodies to insulin produces spuriously increased or decreased (depending on the method used) insulin values.

Reference Intervals

Reference intervals vary among assays, and each laboratory should establish its own reference intervals. After an overnight fast, insulin concentrations in healthy, normal, nonobese people vary from 12 to 150 pmol/L (2 to 25 μIU/mL).* More specific assays that have minimal cross-reactivity with proinsulin reveal a fasting plasma insulin concentration of less than 60 pmol/L (10 μIU/mL). Concentrations up to 1200 pmol/L (200 μIU/mL) can be reached during a glucose tolerance test. Representative values for insulin concentrations after glucose are shown in Figure 46-4. Fasting insulin values are higher in obese, nondiabetic people and lower in trained athletes.

Insulin Antibodies

Assays for insulin antibodies fall into three categories: (1) quantitative radioimmunoelectrophoresis, which measures the binding of immunoglobulin (Ig)G antibody to radiolabeled insulin by rocket immunoelectrophoresis into anti–IgG-containing agarose; (2) RIAs with separation of bound and free insulin by precipitation with PEG or a second antibody; and (3) solid-phase immobilization of insulin to test tubes or Sepharose. These are discussed in greater detail in Reeves.[194]

Proinsulin

Principle

Accurate measurement of proinsulin has been difficult for several reasons: the blood concentrations are low; antibody production is difficult; most antisera cross-react with insulin and C-peptide, which are present in much higher concentrations; the assays measure intermediate cleavage forms of proinsulin; and reference preparations of pure proinsulin were not readily available.[247] Therefore few accurate data are available in the literature on plasma proinsulin. These problems have, to a large extent, been overcome by the availability of biosynthetic proinsulin, which has allowed the production of monoclonal antibodies to proinsulin[67,223] and has provided reliable proinsulin calibrators and reference preparations. An International Reference Preparation for human proinsulin (code 84/611) is available from the National Institute of Biological Standards and Controls (Potters Bar, United Kingdom). Earlier assays may have overestimated proinsulin concentrations.[180]

Reference Intervals

Reference intervals for proinsulin are highly dependent on the method of analysis, the degree of cross-reactivity of the antisera, and the purity of proinsulin calibrators. Each laboratory should establish its own reference intervals.

Reference intervals in healthy, fasting individuals reported in the literature vary from 1.1 to 6.9 pmol/L to 2.1 to 12.6 pmol/L (see Reference 109 and references therein).

C-Peptide

Principle

C-peptide undergoes minimal liver metabolism, and, in contrast to proinsulin assays, assays are not affected by anti-insulin antibodies. However, several methodologic problems produce large between-method variation. These difficulties include variable specificity among different antisera, variable cross-reactivity with proinsulin, and various types of C-peptide preparation used as a calibrator. A 2008 comparison of 40 serum samples using nine commercial C-peptide assay methods showed within- and between-run CVs varying from less than 2% to greater than 10%, and from less than 2% to greater than 18%, respectively.[146] Some methods had high imprecision, with between-run CVs exceeding 15%. Two isotope-dilution liquid chromatography–mass spectrometry methods for measuring C-peptide have been developed.[48,199] Calibrating C-peptide measurements to a reference method using mass spectrometry increased comparability among laboratories.[146]

Reference Intervals

Each laboratory should establish its own reference interval for C-peptide. Fasting serum concentrations of C-peptide in healthy people range from 0.78 to 1.89 ng/mL (0.25 to 0.6 nmol/L). After stimulation with glucose or glucagon, values range from 2.73 to 5.64 ng/mL (0.9 to 1.87 nmol/L), or three to five times the prestimulation value. Urinary C-peptide is usually in the range of 74 ± 26 μg/L (25 ± 8.8 μmol/L). C-peptide is excreted primarily by the kidney, and concentrations in the serum are increased in renal disease.

Glucagon

Principle

A competitive RIA is available for measuring glucagon (Siemens Medical Solutions Diagnostics, Malvern, Pa). ^{125}I-labeled glucagon competes with glucagon in the patient specimen for binding to the polyclonal glucagon antibody.

*The conversion factor of 6.0 used to convert μIU/mL (or mIU/L) of insulin to pmol/L is based on an MW of insulin of 5807.58 and specific activity of 30 IU/mg.

tahir99-VRG & vip.persianss.ir

Bound glucagon is separated from free glucagon by the use of PEG and a second antibody. Bound radioactivity for the patient specimen is compared with that of glucagon calibrators. Calibrator values are assigned at the manufacturer using the WHO glucagon international standard (69/194).

Reference Intervals

Fasting plasma concentrations of glucagon vary from 70 to 180 ng/L (20 to 52 pmol/L). Values up to 500 times the upper reference limit may be found in patients with autonomously secreting α-cell neoplasms.

PATHOGENESIS OF TYPE 1 DIABETES MELLITUS

Type 1 diabetes mellitus results from cellular-mediated autoimmune destruction of the insulin-secreting cells of pancreatic β-cells.[22,100] In the vast majority of patients, destruction is mediated by T cells. This is termed type 1A or immune-mediated diabetes (see Box 46-1). The α-, δ-, and other islet cells are preserved. The islet cells have a chronic mononuclear cell infiltrate, called *insulitis.* The autoimmune process leading to type 1 diabetes begins months or years before the clinical presentation, and an 80 to 90% reduction in the volume of β-cells is required to induce symptomatic type 1 diabetes. The rate of islet cell destruction is variable and is usually more rapid in children than in adults.

Antibodies

The most practical markers of β-cell autoimmunity are circulating antibodies, which have been detected in the serum years before the onset of hyperglycemia. The best characterized antibodies are as follows[22,100,204,251]:

1. *Islet cell cytoplasmic antibodies* (ICAs) react with a sialoglycoconjugate antigen present in the cytoplasm of all endocrine cells of the pancreatic islets. These antibodies are detected in the serum of 0.5% of normal subjects and 75 to 85% of patients with newly diagnosed type 1 diabetes. The antibodies are detected by immunofluorescence microscopy on frozen sections of human pancreatic tails. Results are compared with standard serum of the Immunology of Diabetes Workgroup[162] and are expressed in Juvenile Diabetes Foundation (JDF) units. Although not universal, many laboratories use 10 JDF units on two separate occasions or a single result of greater than or equal to 20 JDF units as a significant titer. The ICA assay is labor intensive and difficult to standardize. Few clinical laboratories are likely to implement this assay, which has marked interlaboratory variability in sensitivity and specificity.[204]
2. *Insulin autoantibodies* (IAAs) are present in more than 90% of children who develop type 1 diabetes before age 5, but in less than 40% of individuals who develop diabetes after age 12. Their frequency in healthy people is similar to that of ICA. A radioisotopic method that calculates the displaceable insulin radio ligand binding after the addition of excess nonradiolabeled insulin is recommended for IAA. Results are positive when concentrations exceed the 99th percentile or the mean + 2 (or 3) standard deviations (SDs) in healthy controls. Proficiency evaluation revealed poor concordance for IAA among laboratories.[35] An important caveat is that insulin antibodies develop after insulin therapy, even in those persons who use human insulin.
3. *Antibodies to the 65 kDa isoform of glutamic acid decarboxylase* (GAD_{65})[24] have been found up to 10 years before the onset of clinical type 1 diabetes and are present in ≈60% of patients with newly diagnosed diabetes. GAD_{65} antibodies may be used to identify patients with apparent type 2 diabetes who will subsequently progress to type 1 diabetes. Several different assay formats have been used for the measurement of anti-GAD_{65} antibodies, including enzymatic immunoprecipitation assay, radiobinding assay, ELISA, immunofluorescence, and Western blotting.[214] Considerable variability among laboratories has been significantly reduced by the Second International GADAb Workshop.[214] A monoclonal antibody, MICA 3, was suggested as a reference standard. A dual micromethod and RIA performed with ^{3}H-labeled human recombinant GAD_{65} in a rabbit reticulocyte expression system is used by many laboratories. Methods for measurement of GAD_{65} are now commercially available.
4. *Insulinoma-associated antigens* (IA-2A and IA-2βA), directed against two tyrosine phosphatases, have been detected in more than 50% of newly diagnosed type 1 diabetes patients. A widely used method to measure IA-2A uses ^{35}S-labeled recombinant IA-2 in a dual micromethod and RIA. Concurrent analysis of IA-2 and GAD_{65} in a single assay has been reported.[205]
5. *Zinc transporter ZnT8* was identified recently as a major autoantigen in type 1 diabetes.[251] Initial analysis identified ZnT8 in 60 to 80% of patients with new-onset type 1 diabetes compared with less than 2% of controls and less than 3% of individuals with type 2 diabetes.

Although antibodies to bovine serum albumin have been reported in patients with newly diagnosed type 1 diabetes,[123] this model is contentious, and conflicting data exist.[21,23,149]

The Centers for Disease Control and Prevention (CDC) and the Immunology of Diabetes Society have developed the Diabetes Autoantibody Standardization Program (DASP). The major goals of DASP are (1) to assist laboratories in improving methods, (2) to organize workshops for harmonization of antibody testing for type 1 diabetes, and (3) to provide reference materials.[35,239] DASP provides serum from 50 patients with newly diagnosed type 1 diabetes and from 50 to 100 control patients. A WHO standard for GAD_{65} and IA-2A (97-550) has been established and allows laboratories to express results in common units.[239] Several workshops have been held. The first assay proficiency evaluation revealed poor performance for IAA among 23 laboratories.[35] Good concordance among laboratories was observed for GAD_{65} and IA-2A, with the latter improving with successive

tahir99-VRG & vip.persianss.ir

comparisons.[239] Ongoing harmonization is likely to enhance assay performance.

Autoantibody markers of immune destruction are present in 85 to 90% of individuals with immune-mediated diabetes when fasting hyperglycemia is initially detected.[9] Approximately 5 to 10% of white adult patients who have the type 2 diabetes phenotype also have islet cell autoantibodies, particularly to GAD_{65}. This condition has been termed *latent autoimmune diabetes of adulthood (LADA).*[188] Up to 1 to 2% of healthy individuals have a single autoantibody and are at low risk of developing immune-mediated diabetes. Because the prevalence of immune-mediated diabetes is low (approximately 0.3% in the general population), the positive predictive value of a single autoantibody will be low. The presence of multiple islet autoantibodies (IAA, GAD_{65}, and IA-2A and/or IA-2βA) is associated with a greater than 90% risk of immune-mediated diabetes. However, no acceptable therapy has been documented to prevent the clinical onset of diabetes in islet cell autoantibody–positive individuals.[22] New strategies under development for treatment of type 1 diabetes focus on immunosuppressive therapy to attenuate the autoimmune response, replacement of insulin-producing β-cells by transplantation, or restoration of insulin with gene therapy.[86,176] Hyperglycemia in diabetic mice was completely reversed by gene therapy that induced the development of β-cells of the pancreas in the liver.[138] Although type 1 diabetes can be prevented in animal models,[41] the possible role of immune intervention in humans remains unresolved.

Genetics

Susceptibility to type 1 diabetes is inherited,[238] but the mode of inheritance is complex and has not been defined. It is a multigenic trait, and the major locus is the major histocompatibility complex on chromosome 6. At least 11 other loci on 9 chromosomes also contribute, with the regulatory region of the insulin gene *INS* on chromosome 11p15 being an important locus. The human leukocyte antigen (HLA)-DQ and -DR genetic factors are by far the most important determinants for risk of type 1 diabetes.[56] The concordance rate between identical twins is approximately 30%, and approximately 95% of whites with type 1 diabetes express HLA-DR3 or HLA-DR4 histocompatibility antigens. However, up to 40% of the nondiabetic population also express these alleles. In contrast, the *HLA-DQB1*0602* allele significantly decreases the risk of type 1 diabetes. HLA typing can indicate absolute risk of diabetes.[204] The risk of a sibling developing diabetes is 1%, 5%, and 10 to 20% if the number of haplotypes shared is none, one, and two, respectively. However, only 10% of patients with type 1 diabetes have an affected first-degree relative. Genome-wide association studies have also identified non-HLA genetic factors that increase risk, including the insulin gene variable number tandem repeat (*INS* VNTR, *CTLA4,* and *PTPN22*).[56] The multiplicity of independent chromosomal regions associated with a predisposition to type 1 diabetes suggests that other susceptibility genes will be identified. Routine measurement of genetic markers is not of value at this time for the diagnosis or management of patients with type 1 diabetes.[204]

Environment

Reports describe that environmental factors are involved in initiating diabetes. Viruses, such as rubella, mumps, and coxsackievirus B, have been implicated.[114] It seems likely that autoimmunity to β-cells is initiated by a viral protein (that shares amino acid sequence with a β-cell protein) or some other environmental insult. Genetic susceptibility and other host factors (e.g., HLA type) determine the progression of the β-cell destruction.

PATHOGENESIS OF TYPE 2 DIABETES MELLITUS

At least two major identifiable pathological defects have been reported in patients with type 2 diabetes.[66,121,206] One is a decreased ability of insulin to act on peripheral tissue. This is called *insulin resistance* and is thought by many to be the primary underlying pathologic process. The other is β-*cell dysfunction,* which is an inability of the pancreas to produce sufficient insulin to compensate for the insulin resistance. Thus a relative deficiency of insulin occurs early in the disease and absolute insulin deficiency late in the disease. The debate over whether type 2 diabetes is due primarily to a defect in β-cell secretion or to peripheral resistance to insulin, or to both, has been raging for decades. However, data are available to support the concept that insulin resistance is the primary defect, preceding the derangement in insulin secretion and clinical diabetes by as much as 20 years.[121,206] Despite the lack of consensus, it is clear that type 2 diabetes mellitus is an extremely heterogeneous disease, and no single cause is adequate to explain the progression from normal glucose tolerance to diabetes. The fundamental molecular defects in insulin resistance and insulin secretion result from a combination of environmental and genetic factors.

Loss of β-Cell Function

Increased β-cell demand induced by insulin resistance is ultimately associated with progressive loss of β-cell function that is necessary for the development of fasting hyperglycemia. The major defect is a *loss of glucose-induced insulin release* (see Figure 46-4), which is termed *selective glucose unresponsiveness.* Hyperglycemia appears to render the β-cells increasingly unresponsive to glucose (called *glucotoxicity*), and the degree of dysfunction correlates with both glucose concentration and duration of hyperglycemia. Restoration of euglycemia rapidly resolves the defect. Increased free fatty acids in serum have also been implicated in β-cell failure.[29] Other insulin secretory abnormalities in type 2 diabetes include disruption of the normal pulsatile release of insulin and an increased ratio of plasma proinsulin to insulin.[143] More recently, evidence obtained from knockout mice reveals that insulin resistance in the β-cells may contribute to alterations in insulin secretion, as occur in type 2 diabetes.[140]

tahir99-VRG & vip.persianss.ir

Insulin Resistance

Insulin resistance is defined as "a decreased biological response to normal concentrations of circulating insulin"[78]; it is found in obese, nondiabetic individuals and in patients with type 2 diabetes. The underlying pathophysiologic defect(s) has (have) not been identified, but insulin resistance is usually attributed to a defect in insulin action. Measurement of insulin resistance in a routine clinical setting is difficult, and surrogate measures, namely, fasting insulin concentration or the euglycemic insulin clamp,[10] are used to provide an indirect assessment of insulin function. The euglycemic clamp is performed in hospital under close supervision. The subject receives a constant intravenous infusion of insulin in one arm with concurrent intravenous infusion of variable amounts of glucose in the other arm to maintain blood glucose at a normal fasting concentration. A broad clinical spectrum of insulin resistance varies from euglycemia (with marked increase in endogenous insulin) to hyperglycemia (despite large doses of exogenous insulin). Several rare clinical syndromes are also associated with insulin resistance. The prototype is the type A insulin resistance syndrome, which is characterized by hyperinsulinemia, acanthosis nigricans, and ovarian hyperandrogenism.

The insulin resistance syndrome (also known as *syndrome X,* or *the metabolic syndrome*) is a constellation of associated clinical and laboratory findings, consisting of insulin resistance, hyperinsulinemia, obesity, dyslipidemia [high triglyceride and low high-density lipoprotein (HDL) cholesterol], and hypertension.[191] Individuals with this syndrome are at increased risk for cardiovascular disease. The metabolic syndrome is diagnosed if an individual meets three or more of the following criteria[76]:

- Abdominal obesity: waist circumference greater than 35 inches (women) or 40 inches (men)
- Triglycerides greater than 150 mg/dL
- HDL cholesterol less than 50 mg/dL (women) or less than 40 mg/dL (men)
- Blood pressure greater than or equal to 130/85 mm Hg
- Fasting plasma glucose greater than or equal to 110 mg/dL

The diagnostic criteria proposed by the WHO differ from those listed here.[264] The concept of the "metabolic syndrome" has been questioned by several experts, including the person who first described it,[192] and major clinical diabetes organizations.[122]

Environment

Environmental factors, such as diet and exercise, are important determinants in the pathogenesis of type 2 diabetes. Convincing evidence links obesity to the development of type 2 diabetes, but the association is complex. Although 60 to 80% of patients with type 2 diabetes are obese, diabetes develops in less than 15% of obese individuals. In contrast, virtually all obese subjects, even those with normal carbohydrate tolerance, have hyperinsulinemia and are insulin resistant. Other factors, such as family history of type 2 diabetes (genetic predisposition), the duration of obesity, and the distribution of fat are important. Nevertheless, the rising prevalence of diabetes is believed to be a consequence of the increase in obesity (defined as a body mass index ≥30 kg/m^2), which was reported to be 25.6% in U.S. adults in 2007.[2] Evaluation of 84,941 healthy women after 16 years in the Nurses' Health Study revealed that obesity was the most important predictor of type 2 diabetes.[110] Compared with women with a body mass indices less than 23, the relative risks of developing diabetes were 38.8 and 20.1 with body mass indexes greater than or equal to 35 and 30 to 34.9, respectively. It is important to note that intervention can delay or prevent the onset of type 2 diabetes. Two randomized studies documented that life-style changes (weight reduction and exercise) in individuals with IGT reduced the incidence of type 2 diabetes.[136,241] Although the weight loss was modest (5 to 7%), the rate of progression to type 2 diabetes was reduced by 58% in both studies.

An inverse relationship has been noted between the degree of physical activity and the prevalence of type 2 diabetes. For every 500 kcal increase in daily energy expenditure, a 6% decrease in age-adjusted risk of type 2 diabetes occurs. This effect is independent of both body weight and a parental history of diabetes. The mechanism of the protective effect of exercise is thought to be increased sensitivity to insulin in skeletal muscle and adipose tissue.

Diabetogenes

It is widely acknowledged that genetic factors contribute to the development of type 2 diabetes.[121] For example, the concordance rate for type 2 diabetes in identical twins approaches 100%. Type 2 diabetes is 10 times more likely to occur in an obese person with a diabetic parent than in an equally obese person without a diabetic family history. However, the mode of inheritance is unknown, and type 2 diabetes has been described as a "geneticist's nightmare."[175] Many less common diseases (e.g., cystic fibrosis, Duchenne muscular dystrophy) are caused by mutations at a single locus. More common diseases, such as diabetes mellitus, schizophrenia, atherosclerosis, hypertension, and osteoporosis, are not inherited according to simple mendelian rules. These conditions are genetically more complex, and multiple genetic factors interact with exogenous influences (such as environmental factors) to produce the phenotype.

Numerous mutations of the insulin receptor gene, *INSR,* have been identified.[78] Many patients with these defects have extreme insulin resistance, but the mutations are exceptionally rare and usually are found in only one patient or a single family. Mutations of substrates for the insulin receptor that causes diabetes are not known. Few mutations have been described in other potential candidate genes, including those coding for GLUT4 and glycogen synthase.

Initial success in the search for diabetogenes was seen in maturity-onset diabetes of the young (MODY), a rare group of disorders characterized by nonketotic diabetes.[29,204] The clinical spectrum of MODY is broad, ranging from asymptomatic hyperglycemia to an acute presentation. Several types of MODY may result from mutations in the genes that encode glucokinase (an enzyme that phosphorylates glucose in the

tahir99-VRG & vip.persianss.ir

β-cell) or several transcription factors. These can be diagnosed by molecular diagnostic testing. Although MODY is not a form of type 2 diabetes, interest in the genetics of MODY offers hope of insight into type 2 diabetes.

Multiple factors complicate the search for diabetogenes in type 2 diabetes.[206] A variety of approaches have produced several genes that are associated with type 2 diabetes. Recent genome-wide association studies (GWAS) have substantially contributed to our understanding of the genetic architecture of type 2 diabetes, with 17 genetic loci identified.[94,224] Most of these genetic loci are associated with the insulin secretion pathway, rather than with insulin resistance. Despite considerable effort to identify the genetic basis of type 2 diabetes mellitus, *genetic defects identified to date account for only ≈5% of patients with type 2 diabetes.* Therefore, the gene or genes causing common forms of type 2 diabetes remain unknown. Moreover, the risk alleles in these loci all have relatively small effects (odds ratios, 1.1 to 13). Incorporation of 18 different risk loci to construct a genotype score did not significantly improve clinical prediction based on current phenotype risk factors.[156]

DIAGNOSIS

For many years the diagnosis of diabetes mellitus was dependent solely on the *demonstration of hyperglycemia* (Box 46-3). In 2009, an International Expert Committee recommended that diabetes be diagnosed by measurement of hemoglobin A1c (HbA_{1c}), which reflects long-term blood glucose concentrations[235] (for additional information, see "Glycated Hemoglobin" section, later in this chapter). For type 1 diabetes, the diagnosis is usually easy because hyperglycemia appears abruptly, is severe, and is accompanied by serious metabolic derangements. Diagnosis of type 2 diabetes may be difficult because hyperglycemia often is not severe enough for the patient to notice symptoms of diabetes. Nevertheless, the risk of complications makes it important to identify people with the disease.

The diagnostic criteria recommended in 1979 were (1) classic symptoms of diabetes with unequivocal increase in plasma glucose, (2) FPG greater than or equal to 140 mg/dL on more than one occasion, or (3) a 2 hour and one other postload glucose concentration greater than or equal to 200 mg/dL during an OGTT.[174] These criteria were widely adopted but are imperfect. The OGTT is more sensitive than fasting glucose early in the course of type 2 diabetes, resulting in lack of equivalence between fasting and 2 hour glucose values. Virtually all persons with an FPG concentration greater than or equal to 140 mg/dL have 2 hour glucose greater than or equal to 200 mg/dL in an OGTT. In contrast, in persons without previously identified diabetes, fasting glucose greater than or equal to 140 mg/dL is present in only 25% of those who have 2 hour glucose greater than or equal to 200 mg/dL. To address these and other discrepancies, the diagnostic criteria were revised in 1997 (see Box 46-3).[9,201] The major modification was lowering the diagnostic threshold for fasting glucose from 140 to 126 mg/dL (7 mmol/L) to better identify individuals at risk of retinopathy and nephropathy. The lower cutoff was suggested to provide earlier diagnosis of diabetes, with consequent earlier therapeutic intervention.[201]

BOX 46-3 Criteria for the Diagnosis of Diabetes Mellitus

Any one of the following is diagnostic:

A. Glucose
   1. Fasting plasma glucose (FPG) ≥7.0 mmol/L (126 mg/dL)*
   OR
   2. Symptoms of hyperglycemia and casual plasma glucose ≥11.1 mmol/L (200 mg/dL)†
   OR
   3. 2 hour plasma glucose ≥11.1 mmol/L (200 mg/dL) during an oral glucose tolerance test (OGTT)‡

B. Hemoglobin A1c (HbA_{1c})§
   $HbA_{1c} \geq 6.5\%$

In the absence of unequivocal hyperglycemia, these criteria should be confirmed by repeating the same test on a different day. Mixing different methods to diagnose diabetes should be avoided.

*Fasting is defined as no calorie intake for at least 8 hours.
†Casual is defined as any time of day without regard to time since last meal. The classic symptoms of hyperglycemia include polyuria, polydipsia, and unexplained weight loss.
‡The OGTT should be performed as described by the World Health Organization (WHO), using a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water.
§The test should be performed in a laboratory that is NGSP-certified and standardized to the DCCT assay. Point-of-care assays should not be used for diagnosis.
From the American Diabetes Association. Standards of medical care in diabetes—2010. Diabetes Care 2010;33(Suppl 1):S11-61.

Fasting Plasma Glucose Concentrations

FPG concentrations of 126 mg/dL (7.0 mmol/L) or greater on more than one occasion are diagnostic of diabetes mellitus (see Box 46-3). The diagnosis of most cases of diabetes mellitus can be established with this criterion. However, some investigators believe that fasting hyperglycemia may be a relatively late development in the course of type 2 diabetes, delaying the diagnosis and leading to underestimation of the prevalence of diabetes mellitus in the population.[233] Complications of diabetes, such as retinopathy, proteinuria, and neuromuscular disease, are present in approximately 30% of patients at clinical diagnosis of type 2 diabetes, and onset of type 2 diabetes probably occurs at least 4 to 7 years before clinical diagnosis. Screening of high-risk individuals for diabetes is now recommended.[9,19,95] Fasting glucose should be measured in all asymptomatic persons at age 45 (or younger in subjects at increased risk), with follow-up testing every 3 years (see discussion later in this chapter). However, no published evidence indicates that treatment based on screening is efficacious.

Oral Glucose Tolerance Test

Serial measurement of plasma glucose before and after a specific amount of glucose given orally should provide a standard

tahir99-VRG & vip.persianss.ir

BOX 46-4 Factors Other Than Diabetes That Influence the Oral Glucose Tolerance Test

Patient Preparation
- Duration of fast
- Prior carbohydrate intake
- Medications (e.g., thiazides, oral contraceptives, corticosteroids)
- Trauma
- Intercurrent illness
- Age
- Activity
- Weight

Administration of Glucose
- Form of glucose (anhydrous or monohydrate)
- Quantity of glucose ingested
- Volume in which administered
- Rate of ingestion

During the Test
- Posture
- Anxiety
- Caffeine
- Smoking
- Activity
- Time of day
- Sample preservation

method by which to evaluate individuals and establish values for healthy and diseased subjects. Although more sensitive than FPG determinations, glucose tolerance testing is affected by multiple factors that result in *poor reproducibility* (Box 46-4).[6] Moreover, approximately 20% of OGTTs fall into the nondiagnostic category (e.g., only one blood sample exhibits increased glucose concentration). Unless results are grossly abnormal initially, *the OGTT should be performed on two separate occasions* to establish the diagnosis of diabetes.

The following conditions should be met before an OGTT is performed: discontinue, when possible, medications known to affect glucose tolerance; perform in the morning after 3 days of unrestricted diet (containing at least 150 g of carbohydrate per day) and activity; and perform the test after a 10 to 16 hour fast only in ambulatory outpatients (bed rest impairs glucose tolerance), who should remain seated during the test without smoking cigarettes. Glucose tolerance testing should not be performed on hospitalized, acutely ill, or inactive patients. The test should begin between 7 AM and 9 AM. Venous plasma glucose should be measured fasting, then 2 hours after an oral glucose load. For nonpregnant adults, the recommended load is 75 g, which may not be a maximum stimulus[174]; for children, 1.75 g/kg, up to 75 g maximum is given. The glucose should be dissolved in 300 mL of water and ingested over 5 minutes. A commercial, more palatable form of glucose may be ingested, but whether the anhydrous or monohydrate form of glucose should be used is still in question.[255]

An OGTT is rarely necessary for the diagnosis of diabetes mellitus. It continues to be recommended in a limited fashion by the WHO.[204,265] The sensitivity of FPG concentrations is lower than the OGTT for diagnosing diabetes, and some authors claim that the OGTT better identifies patients at risk for developing complications of diabetes. An FPG value less than 100 mg/dL or a random glucose concentration less than 140 mg/dL is sufficient to rule out the diagnosis of diabetes mellitus. An OGTT is indicated in the following situations:

1. Diagnosis of GDM (discussed later).
2. Diagnosis of IGT. This remains controversial. Individuals with IGT have increased risk of cardiovascular disease, but many of them do not have IFG by ADA criteria.[204]
3. Evaluation of a patient with unexplained nephropathy, neuropathy, or retinopathy, with random glucose concentration less than 140 mg/dL. Abnormal results in this setting do not necessarily denote a cause-and-effect relationship, and other diseases must be ruled out.
4. Population studies for epidemiologic data.

As mentioned earlier, 2009 guidelines advocate the use of HbA_{1c} for diagnosis of diabetes in nonpregnant individuals.[235]

Intravenous Glucose Tolerance Test

Poor absorption of orally administered glucose may result in a "flat" tolerance curve. Some patients are unable to tolerate a large oral carbohydrate load or may have altered gastric physiology (e.g., after gastric resection). In these patients, an intravenous glucose tolerance test may be performed to eliminate factors related to the rate of glucose absorption. In addition, measurement of the first-phase insulin response can identify the subgroup of individuals with increased concentrations of multiple autoantibodies who are at greatest risk of progression to type 1 diabetes.[36]

Preparation of patients is the same as for the OGTT. The dose of glucose is 0.5 g/kg of body weight (maximum 35 g), given as a 25 g/dL solution. The dose is administered intravenously over 3 minutes ± 15 seconds, and blood is collected every 10 minutes after the midinjection time for 1 hour. A single forearm vein cannula may be used for infusion and sampling, but it should be flushed with saline after the glucose is infused, and dead space should be cleared with several volumes of blood before each sample is drawn. If insulin assays are performed, a specimen is also obtained 5 minutes after the start of the injection. Blood glucose concentrations decrease in an exponential manner, and the rate of glucose disappearance can be calculated from the formula $K = 70/t_{½}$, where $t_{½}$ is the number of minutes required for the blood glucose value to decrease to one half of the 10 minute value, and K is the rate of disappearance of blood glucose, expressed as percent per minute. The glucose values are plotted on the log scale of semilog paper versus time on the abscissa. The best-fitting straight line is drawn through the points, and the time (in minutes) for the glucose concentration to decrease by 50% ($t_{½}$) is read. In healthy individuals, K usually exceeds 1.5%; values less than 1.0% are considered diagnostic of diabetes. A poor correlation is found between the results of

tahir99-VRG & vip.persianss.ir

intravenous and oral glucose tolerance tests.[81] Similar to oral glucose tolerance, intravenous glucose tolerance deteriorates with age.

In the formula $K = 70/t_{½}$, the value of 70 is derived from the logarithmic nature of the decrease in glucose concentration over time. The concentration of glucose at 10 minutes will be twice that of the value obtained from the plot $t_{½}$. Using natural logarithms, the rate of decrease in glucose concentration, expressed as percent per minute *(K),* is given by

$$K = 100\,(\ln 2 - \ln 1)/t_{½} = 69.3/t_{½} \cong 70/t_{½}$$

The main indication for the intravenous glucose tolerance test is in clinical research to evaluate the first-phase insulin response to glucose (see Figure 46-4).[37] The test is performed as described earlier, but samples are drawn as follows: two baseline samples 5 minutes apart (the latter immediately before infusion) and samples 1, 3, 5, and 10 minutes after the end of the glucose infusion. The first-phase insulin release is usually measured by the sum of the insulin concentrations 1 and 3 minutes after the glucose bolus. Alternatively, the 0 to 10 minute incremental insulin area may be used. Analogous to the OGTT, the intravenous glucose tolerance test has poor reproducibility.

GESTATIONAL DIABETES MELLITUS

Normal pregnancy is associated with increased insulin resistance, especially in the late second and third trimesters. Euglycemia is maintained by increased insulin secretion, with GDM developing in those women who fail to augment insulin sufficiently. Risk factors for GDM include a family history of diabetes in a first-degree relative, obesity, advanced maternal age, glycosuria, and selected adverse outcomes in a previous pregnancy (e.g., stillbirth, macrosomia). Recommendations for screening and diagnosis were formulated in 1984 at the Second International Workshop-Conference on Gestational Diabetes Mellitus,[225] and were refined at the Third, Fourth, and Fifth International Workshop-Conferences in 1990, 1998, and 2007,[157] respectively. Based on the Fourth Workshop-Conference, the ADA modified its recommendations for laboratory diagnosis of GDM by adopting 5 to 10% lower glucose values.[11] These modified guidelines are as follows[14,19]:

1. Low-risk patients require no testing. Low-risk status is limited to women who meet all of the following:
   - Age younger than 25 years
   - Weight normal before pregnancy
   - Member of an ethnic group with a low prevalence of diabetes
   - No known diabetes in first-degree relatives
   - No history of abnormal glucose tolerance
   - No history of poor obstetric outcome
2. Average-risk patients (all patients who fall between low and high risk) should be tested at 24 to 28 weeks' gestation (see below for testing strategy).
3. Very high-risk patients should undergo immediate testing. They are defined as having any of the following:
   - Severe obesity
   - Prior history of GDM or delivery of large-for-gestational age infant
   - Glycosuria
   - Strong family history of type 2 diabetes
   - Diagnosis of polycystic ovarian syndrome

Average- and high-risk patients receive a glucose challenge test given by one of two methods (Table 46-2):

1. One step: Perform a diagnostic 100 g OGTT without prior plasma or serum glucose screening. This one-step approach may be cost-effective in high-risk patients or populations (e.g., some Native American groups).
   - A 75 g OGTT is deemed acceptable by some, but it is not as well validated as the 100 g test.
2. Two step (see Table 46-2): The first step is a 50 g oral glucose load (the patient does not need to be fasting), followed by a plasma or serum glucose determination at 1 hour. A plasma glucose value greater than or equal to 140 mg/dL (7.7 mmol/L) indicates the necessity for definitive testing. Approximately 15% of patients have a 1 hour venous plasma glucose concentration of 140 mg/dL (7.7 mmol/L) or greater, and require a full diagnostic glucose tolerance test. That subgroup includes ≈80% of all women with GDM. Some experts have recommended a

TABLE 46-2 Screening and Diagnosis of Gestational Diabetes Mellitus

Screening

1. Perform at between 24 and 28 weeks' gestation on all average and very high-risk pregnant women not identified as having glucose intolerance.
2. Give 50 g oral glucose load without regard to time of day or time of last meal.
3. Measure venous plasma glucose at 1 hour.
4. If glucose is ≥140 mg/dL,* perform glucose tolerance test.

Diagnosis

1. Perform in the morning after an overnight fast of at least 8 hours.
2. Measure fasting venous plasma glucose.
3. Give 75 or 100 g of glucose orally.
4. Measure plasma glucose hourly for 3 hours (or for 2 hours if 75 g of glucose is given)
5. At least two values must meet or exceed the following:

	100 g Load	75 g Load
Fasting	95 mg/dL	95 mg/dL
1 hour	180 mg/dL	180 mg/dL
2 hour	155 mg/dL	155 mg/dL
3 hour	140 mg/dL	—

6. If results are normal in a clinically suspect situation, repeat during the third trimester.

*Some experts recommend a cutoff of 130 mg/dL.

tahir99-VRG & vip.persianss.ir

value of greater than or equal to 130 mg/dL. This cutoff will increase the sensitivity for GDM to greater than 90%, but will include ≈25% of all pregnant women. Women who exceed the chosen threshold on 50 g screening should have a diagnostic 100 g OGTT performed on a different day.

The criteria for diagnosis are different from those for nonpregnant patients (see Table 46-2).[181] The WHO recommends a one-step 75 g OGTT in the developing world.[3] In the 75 g test, diagnostic criteria for plasma glucose values are the same as for the 100 g test, except that there is no 3 hour measurement (see Table 46-2). Although the 75 g OGTT appears practical and acceptable, more data are obtained with the 100 g OGTT.

Screening and diagnostic criteria for GDM will almost certainly be modified extensively in the near future. Changes will be motivated by results of the HAPO (Hyperglycemia and Adverse Pregnancy Outcome) study, which was a prospective, randomized, multinational study of ≈25,000 women. Initial published results[159] show that risk of adverse maternal, fetal, and neonatal outcomes increased continuously as a function of maternal glycemia at 24 to 28 weeks, even within ranges previously considered normal for pregnancy. Based on outcomes in the HAPO study, an international group of experts representing both obstetric and diabetic organizations developed new diagnostic criteria that were published in 2010.[114A] The panel recommended that all pregnant women not previously known to have diabetes should be evaluated for GDM at 24-28 weeks of gestation by a 75 g OGTT. Diagnostic cut points were established for FPG (92 mg/dL), 1-hour (180 mg/dL) and 2-hour (153 mg/dL) plasma glucose concentrations. If one or more of these values is equaled or exceeded, a diagnosis of GDM is made. Using these criteria will result in a considerable increase in the prevalence of GDM because only one increased glucose value (as opposed to two increased glucose concentrations with prior recommendations) is required to diagnose GDM.

Although GDM is usually asymptomatic and not life-threatening to the mother, it is associated with an increased incidence of neonatal mortality and morbidity, including hypocalcemia, hypoglycemia, and macrosomia.[135,158] Maternal hyperglycemia causes the fetus to secrete more insulin, resulting in stimulation of fetal growth and macrosomia. Recognition is important because therapy can reduce perinatal morbidity and mortality.[172] Maternal complications include a high rate of cesarean delivery and hypertension. In addition, mothers with GDM are at significantly increased risk of subsequent diabetes, predominantly type 2. A 2009 meta-analysis and systematic review indicated that women with GDM have a sevenfold increased risk of developing type 2 diabetes compared with those who had a normoglycemic pregnancy.[30] The largest single study observed a 12.6-fold increased risk. The cumulative incidence of type 2 diabetes varies among populations, ranging from about 40 to 70%.[130] It rises markedly in the first 5 years and reaches a plateau after 10 years.

Distinct from GDM is pregnancy in a patient with preexisting diabetes (≈19,000 per annum in the United States). This is associated with an increased incidence of congenital malformation, but meticulous glycemic control during the first 8 weeks of pregnancy can significantly decrease the risk of congenital malformation.[133] Tight control results in an increased incidence of maternal hypoglycemia, which is teratogenic in animals but does not cause malformation in humans.[161]

Women with GDM should be screened for diabetes 6 to 12 weeks postpartum using nonpregnant OGTT criteria (see Box 46-3). If glucose values are normal, glycemia should be reassessed at least every 3 years.

CHRONIC COMPLICATIONS OF DIABETES MELLITUS

Pathogenesis

Patients with both type 1 and type 2 diabetes are at high risk for the development of chronic complications.[44,169] Diabetes-specific microvascular pathology in the retina, renal glomerulus, and peripheral nerve produces retinopathy, nephropathy, and neuropathy. As a result of these microvascular complications, diabetes is the most frequent cause of new cases of blindness in the industrialized world in persons between 25 and 74 years and the leading cause of end-stage renal disease. Diabetes is also associated with a marked increase in atherosclerotic macrovascular disease involving cardiac, cerebral, and peripheral large vessels. The consequence is that patients with diabetes have a high rate of myocardial infarction (the major cause of mortality in diabetes), stroke, and limb amputation. Prospective clinical studies document a strong relationship between hyperglycemia and the development of microvascular complications.[62,242] Both hyperglycemia and insulin resistance appear to be important in the pathogenesis of macrovascular complications.[44,88,242]

Progress has been made in our understanding of the molecular mechanisms underlying derangements produced by hyperglycemia.[44,218] Four main hypotheses have been proposed to explain how hyperglycemia causes the neural and vascular pathology. These include increased aldose reductase (or polyol pathway) flux; enhanced formation of advanced glycation end products (AGE); activation of protein kinase C; and increased hexosamine pathway flux. Inhibitors of each of these have been shown to ameliorate diabetes-induced abnormalities in cell culture and animal models.[44] Overproduction of superoxide by the mitochondrial electron transport chain integrates these four apparently disparate mechanisms. Clinical trials are under way using novel therapies specifically directed at the signaling molecules (such as protein kinase C) or employing antioxidants to neutralize the effects of the oxidants.

Effects of Intensive Therapy

Type 1 Diabetes

Although it had been theorized for many years that better glycemic control would decrease rates of long-term complications of diabetes mellitus, it was not until the publication of the Diabetes Control and Complications Trial (DCCT) in 1993[62] that this hypothesis was verified. The DCCT was a

tahir99-VRG & vip.persianss.ir

multicenter, randomized trial that compared the effects of intensive and conventional insulin therapy on the development and progression of complications in 1441 patients with type 1 diabetes. During the study period, which averaged 6.5 years, intensively managed patients maintained significantly lower mean blood glucose concentrations. Compared with conventional therapy, intensive therapy reduced the risk of retinopathy, nephropathy, and neuropathy by 40 to 75%.[62] Intensive therapy delayed the onset and slowed the progression of these three complications, regardless of age, gender, or duration of diabetes. The absolute risks of retinopathy and nephropathy were proportional to the mean glycated hemoglobin (GHb) (discussed later in the chapter). Although intensive therapy also reduced the development of hypercholesterolemia, major cardiovascular and peripheral vascular diseases were not significantly decreased in the initial assessment. However, analysis after 17 years of follow-up showed that the incidence of cardiovascular disease was 42% lower in the intensively treated group.[170] This landmark study has had a considerable impact on therapeutic goals and comprehension of the pathogenesis of complications of diabetes.

At the conclusion of the DCCT, 95% of participants enrolled in the long-term follow-up study, termed the Epidemiology of Diabetes Interventions and Complications (EDIC). Five years after the end of the DCCT, no difference in metabolic control (assessed by HbA_{1c} measurements) was noted between the former conventional and intensively treated groups. Nevertheless, further progression of retinopathy and neuropathy was significantly lower in the former intensive group, demonstrating that the beneficial effects of intensive treatment persisted for at least several years beyond the period of strictest intervention.[64,154]

Type 2 Diabetes

The role of hyperglycemia in the development of complications in individuals with type 2 diabetes was established in the United Kingdom Prospective Diabetes Study (UKPDS).[242] The UKPDS was a major randomized, multicenter clinical study that included 5102 patients with newly diagnosed type 2 diabetes who were followed for an average of 10 years. Analogous to the findings of the DCCT, the UKPDS demonstrated in patients with type 2 diabetes that intensive treatment diminishes by approximately 10 to 40% the development of microvascular complications.[242] Intensive treatment decreased the rate of occurrence of macrovascular complications. Although the reduction was not statistically significant initially, follow-up 10 years after the study ended showed a significant reduction in myocardial infarction among patients who had received intensive therapy.[107] Analogous to the EDIC findings, long-term benefits for microvascular complications were observed with follow-up of patients in the UKPDS despite loss of glycemic separation between intensive and standard cohorts after the study ended.[107] An important caveat of both the DCCT and the UKPDS was that intensive therapy produced a threefold increase in the incidence of severe hypoglycemia.[62,242]

ROLE OF THE CLINICAL LABORATORY IN DIABETES MELLITUS

The clinical laboratory has a vital role in both the diagnosis and management of diabetes mellitus.[203A] Some of the important variables assayed are outlined in Table 46-3. In 2002 the National Academy of Clinical Biochemistry (referred to as the NACB) published evidence-based guidelines for laboratory analysis in diabetes mellitus.[204] These guidelines were reviewed by the Professional Practice Committee of the ADA and were consistent in those areas where the ADA also published recommendations. Specific recommendations for laboratory testing based on published data or derived from expert consensus are presented.[204] An updated version of these guidelines was published in 2011.[203A] The revised guidelines were also published as a Position Statement by the ADA.[203B,203C] A brief overview is presented here.

Diagnosis

Preclinical (Screening)

Type 1 Diabetes

Evidence from animal studies suggests that immune intervention therapy before the appearance of clinical symptoms can delay or prevent type 1 diabetes. Results from human studies have been disappointing. Nevertheless, several large clinical trials are under way to assess a variety of therapeutic strategies designed to delay or prevent the onset of type 1 diabetes.[39,219] The Diabetes Prevention Trial-Type 1 (DPT-1) screened 84,228 relatives of patients with diabetes for islet cell antibodies.[68] Half of the 339 individuals deemed to be at high (greater than 50%) risk for disease were randomly assigned to low-dose insulin therapy. Unfortunately, neither insulin injections nor oral insulin delayed the development of type 1 diabetes.[68,221] Despite the negative results, the ADA encourages screening of first-degree relatives of patients with type 1 diabetes by measuring immune-related markers (autoantibodies), provided that individuals who have positive screening results are referred to defined research studies.[15] Until effective intervention therapy becomes available and cost-effective screening strategies are developed for young children, screening for antibodies is not recommended outside of clinical studies.[204]

Some experts have proposed that testing for islet cell autoantibodies may be useful in the following situations: (1) to identify a subset of adults initially thought to have type 2 diabetes but who have islet cell autoantibody markers of type 1 diabetes and progress to insulin dependency; (2) to screen nondiabetic family members who wish to donate a kidney or part of their pancreas for transplantation; (3) to screen women with GDM to identify those at high risk of progression to type 1 diabetes; and (4) to distinguish type 1 from type 2 diabetes in children to institute insulin therapy at the time of diagnosis.[204] Wide variability in clinical practice has been noted regarding the use of islet cell autoantibodies. Proponents argue that the results of autoantibody assays are clinically useful, whereas others point to lack of evidence. Although some clinicians, particularly those who treat

TABLE 46-3 Role of the Laboratory in Diabetes Mellitus

Diagnosis

	Eligibility for insulin pump (C-peptide)

pediatric patients, use autoantibody assays, clinical studies are necessary to provide outcome data to validate the clinical use of autoantibody assays.

Screening by determining HLA type is not currently warranted, except in research studies.[204] A decrease in glucose-stimulated insulin secretion is the first functional abnormality in both type 1 and type 2 diabetes. Nevertheless, tests of insulin secretion are not currently recommended for routine clinical use.

Type 2 Diabetes

Screening of asymptomatic individuals for type 2 diabetes has been the subject of much controversy.[95] The ADA, which previously did not support screening, now advocates screening in all asymptomatic individuals over the age of 45 years.[13,75] Prior screening recommendations were that FPG or the 2 hour OGTT could be used.[19] The new guidelines include the use of HbA_{1c} for screening.[235] If the HbA_{1c} is less than 5.7% or the FPG is less than 100 mg/dL, testing should be repeated at 3 year intervals. Testing may be considered at a younger age or may be carried out more frequently in individuals at increased risk of diabetes (e.g., family history, members of certain ethnic groups).[13] The rising incidence of type 2 diabetes in adolescents has led to the recommendation for screening overweight youths with any two of the following risk factors: (1) they have a family history of type 2 diabetes in first- and second-degree relatives; (2) they belong to a certain race and/or ethnic group; (3) they have signs of insulin resistance or conditions associated with insulin resistance; or (4) there is a maternal history of diabetes or GDM during the child's gestation.[13,19,204] Testing should be done every 3 years starting at 10 years of age. Rationales for screening are that at least 33% of individuals with type 2 diabetes are undiagnosed, complications are often present by the time of diagnosis, and treatment delays the onset of complications.[95] Notwithstanding these recommendations, no published evidence indicates that treatment based on screening has value.

Clinical

The laboratory diagnosis of diabetes is made exclusively by the demonstration of hyperglycemia, by measuring venous plasma glucose or HbA_{1c}. Although other tests (e.g., C-peptide, insulin analysis) have been proposed to assist in the diagnosis and classification of the disease, these do not at present have a role outside of research studies.[204]

Management

Acute

In diabetic ketoacidosis, hyperosmolar nonketotic coma, and hypoglycemia, the clinical laboratory has an essential role in both diagnosis and monitoring of therapy. Several analytes are frequently measured to guide clinicians in treatment regimens to restore euglycemia and correct other metabolic disturbances. The metabolic abnormalities of these conditions are beyond the scope of this book, and interested readers are referred to a standard textbook of medicine. The NACB guidelines also provide information on the tests that are used.

Chronic

The DCCT[62] and UKPDS[242] studies documented a correlation between blood glucose concentrations and the development of long-term complications of diabetes. Measurement of glucose and glycated proteins provides an index of short- and long-term glycemic control, respectively (see section on glycated proteins later in the chapter). Detection and monitoring of complications are achieved by assaying creatinine, urinary albumin excretion, and serum lipids. The success of newer therapies, such as islet cell or pancreas transplantation, can be monitored by measuring serum C-peptide or insulin concentrations.

SELF-MONITORING OF BLOOD GLUCOSE

Diabetic patients, especially those who need insulin therapy, require careful monitoring to maintain control of blood glucose. This has become particularly important with the results of the DCCT[62] and the recommendation that patients use intensive insulin therapy to achieve nearly normal glycemia. These regimens include multiple daily insulin injections, insulin pumps, and continuous subcutaneous insulin injections. Estimating blood glucose concentrations by monitoring urine glucose concentrations—a simple and convenient method—is undesirable for the following reasons:

1. The renal threshold (the blood glucose concentration above which glucose appears in the urine) averages 160 to 180 mg/dL but varies widely among individuals. It may increase in long-standing diabetes or with age and may be lower in pregnancy or childhood. A decreased threshold (±100 mg/dL) is known as *renal glycosuria.*
2. Monitoring of urine glucose concentrations lacks sensitivity and specificity. For example, one study demonstrated that patients with plasma glucose concentrations between 150 and 199 mg/dL exhibited normal urine test results 75% of the time. Furthermore, 9% of patients with plasma glucose concentrations below 149 mg/dL had glycosuria.[165]
3. A negative test result does not distinguish between hypoglycemia, euglycemia, and mild or moderate hyperglycemia.
4. Urine testing, which uses a color chart, is not accurate.
5. Other factors (e.g., fluid intake, urine concentration, ingestion of salicylates or ascorbic acid, urinary tract infections) may influence testing.

Testing urine for glucose is therefore not adequate for monitoring patients on insulin therapy.[8] Although some evidence suggests that it may be effective for monitoring type 2 diabetes,[4] the ADA states that limitations of urine testing make blood glucose measurements the preferred method of assessing glycemic control.[91]

Glucose Meters

Portable meters for measurement of blood glucose concentrations are used in three major settings: (1) in acute and chronic care facilities (at the patient's bedside and in clinics or hospitals); (2) in physicians' offices; and (3) by patients at home, work, and school. The last, self-monitoring of blood glucose (SMBG), used by approximately 1 million diabetic patients, is performed in the United States at least once a day by 40% and 26% of individuals with type 1 and 2 diabetes, respectively.[204] The worldwide market for SMBG is $2.7 billion per year, with annual growth estimated at 10 to 12%.[204]

Patients measure their own blood glucose concentration and modify their insulin dose based on this glucose value. It is impractical for patients themselves to perform glucose determinations by the methods described earlier, but a large number of simple test strips that are available permit rapid measurements on a drop of whole blood.[8] These use the same methodology as described earlier for glucose analysis—predominantly glucose oxidase or glucose dehydrogenase. In many strips, a dye is colored by the glucose oxidase-peroxidase chromogenic reaction. The reagents are combined in dry form on a small surface area of a test strip, and the colors that develop may be evaluated visually by comparison with a color chart (rarely used any more) or quantified in a specially designed meter. *Visual reading with a color chart is not accurate enough* for most clinical circumstances. More than 30 different blood glucose meters are commercially available; these vary in size, weight, calibration method, and other features. They are reviewed annually in the ADA's *Resource Guide.*[16]

To perform the measurement, a sample of blood [usually from a fingerstick, but anticoagulated whole blood collected in ethylenediaminetetraacetic acid (EDTA) or heparin may be used] is placed on the test pad, which is attached to a plastic support. The test strip is then inserted into the meter. (In some devices, the strip is inserted into the meter before the sample is applied.) After a fixed period of time, the result appears on a digital display screen. These meters use reflectance photometry or electrochemistry to measure the rate of the reaction or the final concentration of the products. Reflectance photometry measures the amount of light reflected from a test pad containing reagent. In electrochemical systems, the enzymatic reaction in an electrode incorporated on the test strip produces a flow of electrons. The current, which is directly proportional to the amount of glucose in the sample, is converted to a digital readout. Large variability has been noted among meters as to the test time (5 to 45 seconds) and the claimed reading range (30 to 500 mg/dL to 0 to 600 mg/dL). Calibration is automatic on some devices, whereas others use lot-specific code chips or strips. All manufacturers supply control solutions. Strict adherence to the instructions is necessary to obtain accurate results. Some meters have a porous membrane that separates erythrocytes, and analysis is performed on the resultant plasma. *Whole blood glucose concentrations are approximately 10 to 15% lower than plasma or serum concentrations, but meters can be calibrated to report plasma glucose values, even when the sample is whole blood.* An International Federation of Clinical Chemistry (IFCC) working group recommended that glucose meters be harmonized using a factor of 1.11× to report the concentration of glucose in plasma, irrespective of the sample type or technology.[70]

Analytical Goals

Multiple analytical goals have been proposed for the performance of glucose meters. The rationale for these is not always clear. In 1987 the ADA recommended a goal of total error (in the hands of users) of less than 10% at glucose concentrations of 30 to 400 mg/dL 100% of the time.[7] This recommendation was modified in response to the significant reduction in complications by tight glucose control in the DCCT. The revised performance goal, published in 1996,[8] is for analytical error to be less than 5%. No published studies of glucose meters have achieved this goal. The recommendations promulgated by the Clinical and Laboratory Standards Institute (CLSI) [previously called the National Committee for Clinical Laboratory Standards (NCCLS)] and the International Organization for Standardization (ISO)[173] are that 95% of results should fall within 20% of laboratory-measured glucose concentrations when greater than 75 mg/dL, and within 15 mg/dL of laboratory glucose if the glucose concentration is less than or equal to 75 mg/dL. Several experts believe these acceptance criteria to be too wide. The CLSI and ISO documents are undergoing revision at the time of this writing, with publication anticipated in 2012.

A different method was proposed by Clarke,[53] who developed an error grid that attempts to define clinically important errors by identifying fairly broad target ranges. In addition, a novel approach using simulation modeling reached the conclusion that meters that achieve both a CV and a bias less than 5% rarely lead to major errors in insulin dose.[43] Lack of consensus on quality goals for glucose meters reflects the absence of agreed-upon objective criteria. When biological variation criteria are used, a goal for total error (including both bias and imprecision) of less than or equal to 6.9% has been proposed.[203A]

Glucose meters are also used to calculate insulin dose in patients without diabetes on tight glucose control protocols in intensive care units (ICUs). Evidence in 2001[245] showed that intensive insulin therapy significantly reduced mortality and morbidity of critically ill patients in the surgical ICU. Although some subsequent studies were unable to replicate these findings,[77,257] tight glucose is used extensively in hospital ICUs. Many factors, such as hypoxia, shock, and low hematocrit, are common in these patients and can compromise glucose analysis in capillary blood samples.[72] The use of glucose meters in these settings has been questioned by some experts.[216]

Performance of Glucose Meters

The most common errors in SMBG, such as proper application, timing, and removal of excess blood, have been reduced by advances in technology but can still occur. Additional innovations that reduce operator error include (1) systems that abort testing if the sample volume is inadequate, (2) built-in programs that simplify quality control, and (3) increased memory that allows the instrument to store up to several hundred glucose readings that can be downloaded into a computer.

Several factors affect the accuracy and reproducibility of SMBG. These include (1) user variability—up to 50% of values may vary by more than 20% from reference values[8]; (2) hematocrit—the presence of anemia (false increase) or polycythemia (false depression) may result in up to 30% variability; and (3) defective reagent strips or instrument malfunction (rare). Other variables include changes in altitude, environmental temperature, or humidity; hypotension; hypoxia; and high triglyceride concentrations. In addition, *these assays are unreliable at very high and very low glucose concentrations* (<60 and >500 mg/dL). Because dehydration, a common feature of diabetic ketoacidosis, greatly increases blood viscosity, inaccurately low blood glucose results may be obtained. Several drugs interfere, but not with all meters.[230] Another important factor is the lack of correlation among meters, even from a single manufacturer, caused by different assay methods and architecture. Moreover, results from two meters of the same brand have been observed to differ substantially.[232] The analytical performance characteristics of several meters have been published.[118,244] Patient factors are also important, particularly adequacy of training. Recurrent education at clinic visits and comparison of SMBG with concurrent laboratory glucose analysis improved the accuracy of patients' blood glucose readings.[120] In addition, it is important to evaluate the patient's technique at regular intervals.

The performance of different meters varies widely. Although current meters, as predicted, exhibit performance superior to prior generations of meters,[249] imprecision remains high. Under carefully controlled conditions in which all assays were performed by a single medical technologist, ≈50% of analyses met the ADA criterion of less than 5% deviation from reference values.[249] Performance of older meters was substantially worse. Note that the performance of glucose meters achieved by medical technologists is better than that achieved by patients. Another study that evaluated meter performance in 226 hospitals by split samples analyzed simultaneously on meters and laboratory glucose analyzers revealed that 45.6%, 25%, and 14% differed from each other by greater than 10%, greater than 15%, and greater than 20%, respectively.[177] Comparison with laboratory values of almost 22,000 measurements of capillary glucose by patients using meters revealed no significant improvement in meter performance between 1989 and 1999.[38] The imprecision of meters precludes their use in the diagnosis of diabetes.[204]

Indications and Frequency of SMBG

The indications and frequency of self-monitoring vary among patients. *SMBG should be performed by all patients treated with insulin.* The role of SMBG in patients with type 2 diabetes not treated with insulin has not been defined.[204] A consensus statement by the ADA[8] recommended the following specific indications for SMBG: (1) patients undergoing intensive insulin treatment programs (in this group, glucose should be measured at least four times a day to achieve glycemic control); (2) prevention and detection of hypoglycemia, especially in people who are asymptomatic or unable to recognize the early warning signs; (3) avoidance of severe

hyperglycemia, particularly in situations of increased risk (e.g., medications that alter insulin secretion or action, intercurrent illness, elderly people); (4) adjusted pharmacologic therapy in response to changes in life-style, such as exercise or altering food intake; and (5) determination of the necessity for initiating insulin therapy in GDM. *Glucose meters should not be used to diagnose diabetes mellitus,* and their role in screening remains uncertain.[204]

Current ADA recommendations[19] are that SMBG should be performed three or more times per day in patients using multiple insulin injections or insulin pump therapy. Monitoring less frequently results in deterioration of glycemic control.[8,168,210] Published studies reveal that self-monitoring is performed by patients much less frequently than recommended: at least once a day by 39% of patients using insulin and by 5 to 6% of those treated with oral agents or diet alone.[98] Moreover, 29% and 65% of patients treated with insulin and oral agents, respectively, monitored their blood glucose less than once per month. More recent evidence shows a gradual increase, with 63.4% of patients with diabetes now reported to monitor blood glucose at least once daily.[103] Guidelines on the recommended frequency and timing of SMBG vary among international diabetes associations.[34] Recent recommendations suggest that the frequency and timing of SMBG should be dictated by the particular needs and goals of the individual patient.[19,34]

The value of SMBG for patients with type 2 diabetes not on insulin therapy is controversial owing, in part, to the lack of well-designed studies. A meta-analysis of SMBG in non–insulin-treated patients with type 2 diabetes showed that SMBG improved glycemic control.[250] However, many studies in this analysis included patient education, and the contribution of SMBG to glucose control in non–insulin-treated patients remains contentious.[103] Despite controversy in the literature, a survey conducted in 14 countries in 2007 revealed unexpectedly high SMBG use in non–insulin-treated patients, with up to 75% of patients performing SMBG.[222]

MINIMALLY INVASIVE MONITORING OF BLOOD GLUCOSE

A major limitation to performing SMBG is that it is painful and inconvenient. Since the 1960s, attempts have been made to develop a painless method for monitoring blood glucose concentrations. Three general approaches have been used, namely, implanted sensors, minimally invasive monitoring, and noninvasive monitoring.

Implanted Sensors

Several implanted biosensors have been developed and evaluated in both animals and humans. Detection systems are based on enzymes, electrodes, or fluorescence.[89,126] The most widely studied method is an electrochemical sensor that is usually implanted subcutaneously. The first device approved for patient use was the CGMS (Medtronic, Minneapolis, Minn); several others are now available.[89] All monitoring devices use glucose oxidase to measure glucose every 1 to 5 minutes. The values are sent to a monitor. Results are recorded and, depending on the system, may be downloaded later in the physician's office or are available to the patient in real-time. These devices are subject to some limitations. Implantation of a needle type of sensor into the subcutaneous tissue induces inflammatory responses in the host that alter the sensitivity of the device. Therefore, the devices can be worn for only 3 to 7 days. These sensors require calibration by the user several times per day with a glucose meter and are subject to the imprecision of the meter. In addition, changes in glucose concentration in the interstitial fluid occur 4 to 20 minutes later than in the blood. A 2008 randomized study of 322 patients with type 1 diabetes showed that adults age 25 and older using intensive insulin treatment and real-time continuous glucose monitoring had better long-term glycemic control than patients using intensive insulin therapy and SMBG.[229]

Another available strategy is the Glucoday (A. Menarini Diagnostics, Florence, Italy), which uses microdialysis and measures glucose outside the body. Fluid is pumped from a storage bag through a microfiber under the skin. The solution carries the glucose sample back to a biosensor, which displays the glucose result every second. This device, which is available in parts of Europe but not in the United States, can be worn for 48 hours.

Minimally Invasive Glucose Monitoring

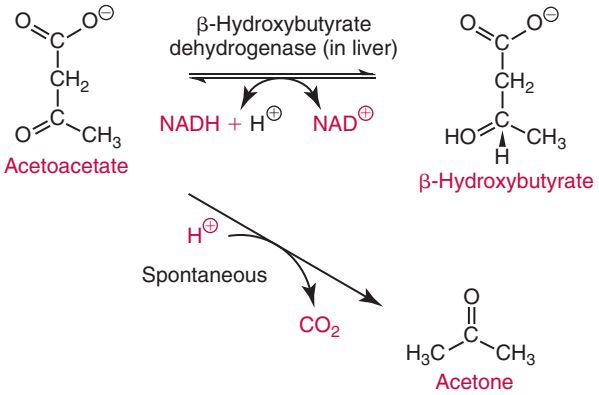
The concept underlying these methods is that the concentration of glucose in the interstitial fluid correlates with the blood glucose concentration. The principle of the FDA-approved Gluco Watch Biographer (Animas Corporation, West Chester, Pa) involves the application of a low-level electric current to the skin. This induces movement by electroosmosis of glucose across the skin, where it is measured by a glucose oxidase detector.[228] Glucose concentrations in transdermal fluid and plasma are highly correlated. The clearest application of the Gluco Watch, which is designed to measure glucose three times per hour for up to 12 hours, appears to be in the detection of unsuspected hypoglycemia. Calibration with reference plasma glucose is required. Initial clinical studies reveal reasonable correlation of the Gluco Watch with SMBG.[228] This device has been withdrawn from the market, but it is likely to stimulate enhanced efforts to bring other technologies into clinical use.

Noninvasive Glucose Monitoring

Noninvasive in vivo monitoring of glucose has been an area of active investigation for many years. Near-infrared spectroscopic devices measure the absorption or the reflection of light from subcutaneous tissue. Although glucose has a specific absorption at 1035 nm, many substances interfere. A computer, individually calibrated, screens out interfering information to obtain the glucose result. Alternative approaches include Raman scattering spectroscopy and photoacoustic spectroscopy. Notwithstanding the investment of considerable resources, no noninvasive sensing technology is approved for glucose measurement in patients.

KETONE BODIES

The development of ketosis requires changes in both adipose tissue and the liver. *The primary substrates for ketone body formation are free fatty acids* from adipose stores. Normally, long-chain fatty acids are taken up by the liver, re-esterified to triglycerides, and stored in the liver or incorporated in very low-density lipoproteins and returned to the plasma. In contrast to other tissue, the brain cannot use free fatty acids for energy. When glucose is unavailable, ketone bodies supply the vast majority of the brain's energy. After a 3 day fast, ketone bodies provide 30 to 40% of the body's energy requirements.[142] In uncontrolled diabetes, the low insulin concentrations result in increased lipolysis and decreased re-esterification, thereby increasing plasma free fatty acids. In addition, the increased glucagon/insulin ratio enhances fatty acid oxidation in the liver. Increased counter-regulatory hormones also augment lipolysis and ketogenesis in fat and liver, respectively. Thus increased hepatic ketone production and decreased peripheral tissue metabolism lead to acetoacetate accumulation in the blood. A small fraction undergoes spontaneous decarboxylation to form acetone, but most of it is converted to β-hydroxybutyrate.



The relative proportions in which the three ketone bodies are present in blood vary, depending on the redox state of the cell. In healthy people, β-hydroxybutyrate and acetoacetate—which are present at approximately equimolar concentrations[142,187,258]—constitute virtually all the serum ketones. Acetone is a minor component. In severe diabetes, the ratio of β-hydroxybutyrate to acetoacetate may increase to 6:1 owing to the presence of a large concentration of nicotinamide adenine dinucleotide (NADH), which favors β-hydroxybutyrate production.

None of the commonly used methods for the detection and determination of ketone bodies in serum or urine reacts with all three ketone bodies. Gerhardt's ferric chloride test reacts with acetoacetate only. Tests using nitroprusside are at least 10 times more sensitive to acetoacetate than to acetone, and give no reaction at all with β-hydroxybutyrate.

Most of the tests for ketosis essentially detect or measure acetoacetate only. This may produce a paradoxical situation. When a patient initially presents in ketoacidosis, the test results for ketones may be only weakly positive. With therapy, β-*hydroxybutyrate is converted to acetoacetate, and the ketosis appears to worsen.*

Traditional tests for β-hydroxybutyrate are indirect; they require brief boiling of the urine to remove acetone and acetoacetate by evaporation (acetoacetate first breaks down spontaneously to acetone), followed by gentle oxidation of β-hydroxybutyrate to acetoacetate and acetone with peroxide, ferric ions, or dichromate. The acetoacetate thus formed may be detected with Gerhardt's test or by one of the procedures in which nitroprusside is used.

Specific determination of β-hydroxybutyrate in urine is not considered to be a routine procedure. A paper strip for semiquantitative measurement of β-hydroxybutyrate in serum and urine has been described[97] but has not gained general acceptance. Quantitative enzymatic assays for β-hydroxybutyrate that can be performed directly on blood or serum have become commercially available. Originally available commercially as a bench-top analyzer (KetoSite, GDS Diagnostics, Elkhart, Ind), hand-held devices are also available now (Precision Xtra, Abbot and KetoSite, Stanbio Laboratory, Boeme, Tex).[47]

Clinical Significance

Excessive formation of ketone bodies results in increased blood concentrations *(ketonemia)* and increased excretion in the urine *(ketonuria).* This process is observed in conditions associated with decreased availability of carbohydrates (such as starvation or frequent vomiting) or decreased use of carbohydrates [such as diabetes mellitus, glycogen storage disease (von Gierke's disease), and alkalosis]. The popular high-fat, low-carbohydrate diets are ketogenic and increase ketone bodies in the circulation. Diabetes mellitus and alcohol consumption are the most common causes of ketoacidosis in adults. (Hyperglycemia is not usually present in the latter condition.) Ingestion of isopropyl alcohol and salicylate poisoning can also produce ketoacidosis. Urine ketone test results are positive in ≈30% of first morning void specimens from pregnant women. Semiquantitative determination of ketone bodies in blood is more accurate than determination of these compounds in urine in the treatment of diabetic ketoacidosis. Although not always excreted in proportion to blood ketone concentrations, because of convenience, urine ketones are widely used for monitoring control in patients with type 1 diabetes. The ADA states that *urine ketone testing is an important part of monitoring by patients with diabetes,* particularly those with type 1 diabetes, pregnancy with preexisting diabetes, and GDM.[91] Patients with type 1 diabetes should test for ketones during acute illness or stress, with consistent increases in blood glucose (greater than 300 mg/dL), during pregnancy, or when symptoms of ketoacidosis are present.[91] Measurement of ketones in urine and blood is widely performed in patients with diabetes for both diagnosis and monitoring of diabetic ketoacidosis.[204]

Determination of Ketone Bodies in Body Fluids

Although quantitative determination of individual ketone bodies is possible, these methods are not used as routine tests. The semiquantitative Acetest, Ketostix (Bayer Health Care, Pine Brook, NJ), and DiaScreen 1K (Arkray, Edina, MN) are frequently used but are insensitive to β-hydroxybutyrate.[236] It is important to bear in mind, therefore, that a *negative nitroprusside test result does not rule out ketoacidosis.*

Detection of Ketone Bodies by Acetest

The Acetest tablets contain a mixture of glycine, sodium nitroprusside, disodium phosphate, and lactose. Acetoacetate or acetone (to a lesser extent) in the presence of glycine forms a lavender-purple complex with nitroprusside. β-Hydroxybutyrate does not react with nitroprusside. The disodium phosphate provides an optimum pH for the reaction, and lactose enhances the color.[116]

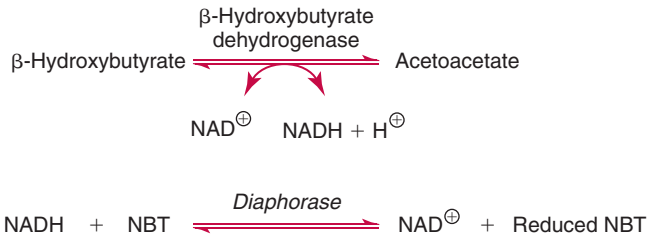
Detection of Ketone Bodies by Ketostix

Ketostix is a modification of the nitroprusside test in which a reagent strip is used instead of a tablet. The Ketostix test gives a positive reaction within 15 seconds with a specimen containing at least 50 mg of acetoacetate per liter. The accompanying color chart gives readings for ketone concentrations of 50, 150, 400, 800, and 1600 mg/L. Acetone also reacts, but the test is less sensitive to it.

Determination of β-Hydroxybutyrate

A 1995 short report on patients with diabetic ketoacidosis indicated that β-hydroxybutyrate correlated better than acetoacetate with changes in acid-base status.[243]

In this test, β-hydroxybutyrate in the presence of nicotinamide adenine dinucleotide (NAD^+) is converted by β-hydroxybutyrate dehydrogenase to acetoacetate, producing nicotinamide adenine dinucleotide phosphate (NADH). Diaphorase catalyzes the reduction of nitroblue tetrazolium (NBT) by NADH to produce a purple compound, and its absorbance is read in a special meter that provides a digital readout.



Determination of Ketone Bodies in Urine

Acetest and Ketostix are also suitable for detecting ketone bodies in urine. The sensitivity and specificity of these tests are the same as outlined for serum.

Reference Interval

Serum β-hydroxybutyrate values vary from 0.02 to 0.27 mmol/L (0.21 to 2.81 mg/dL) in healthy people after an overnight fast. Ketone bodies in the blood can reach 2 mmol/L (20 mg/dL) with prolonged exercise.[142] Patients with diabetic ketoacidosis usually have β-hydroxybutyrate concentrations greater than 2 mmol/L (20 mg/dL).

GLYCATED PROTEINS

Measurement of glycated proteins, primarily GHb, is effective in monitoring long-term glucose control in people with diabetes mellitus. It provides a retrospective index of integrated plasma glucose values over an extended period of time and is not subject to the wide fluctuations observed when blood glucose concentrations are assayed. GHb concentrations therefore are a valuable and widely used adjunct to blood glucose determinations for monitoring long-term glycemic control. In addition, GHb has recently been recommended for the diagnosis of diabetes and is a measure of risk for the development of microvascular complications of diabetes.

Glycated Hemoglobin*

Glycation is the nonenzymatic addition of a sugar residue to amino groups of proteins. Human adult hemoglobin (Hb) usually consists of HbA (97% of the total), HbA_2 (2.5%), and HbF (0.5%). HbA is made up of four polypeptide chains, two α- and two β-chains. Chromatographic analysis of HbA identifies several minor hemoglobins, namely, HbA_{1a}, HbA_{1b}, and HbA_{1c},which are collectively referred to as HbA_1, *fast hemoglobins* (because they migrate more rapidly than HbA in an electrical field), *glycohemoglobins,* or *glycated hemoglobins* (Table 46-4). The Joint Commission on Biochemical Nomenclature of the International Union of Pure and Applied Chemistry recommends the term *neoglycoprotein* for such derivatives and the term *glycation* to describe this process. Therefore although *glycosylated* and *glucosylated* have been widely used in the literature, the term *glycated* is preferred. HbA_{1c} is formed by the condensation of glucose with the *N*-terminal valine residue of each β-chain of HbA to form an unstable Schiff base (aldimine, pre-HbA_{1c}; see Figure 46-6). The Schiff base may dissociate or may undergo an Amadori rearrangement to form a stable ketoamine, HbA_{1c}. HbA_{1a1} and HbA_{1a2}, which make up HbA_{1a}, have fructose-1,6-diphosphate and glucose-6-phosphate, respectively, attached to the amino terminal of the β-chain (see Table 46-4). The structure of HbA_{1b}, identified by mass spectrometry, contains pyruvic acid linked to the amino terminal valine of the β-chain, probably by a ketamine or enamine bond. *HbA_{1c} is the major fraction,* constituting approximately 80% of HbA_1.

Glycation may also occur at sites other than the end of the β-chain, such as lysine residues, or the α-chain. These GHbs,

*A note on terminology: In this chapter, the term glycated hemoglobin is used to refer to the set of all glycated hemoglobins, and hemoglobin A1c is used to refer to a specific molecular form as described in text.

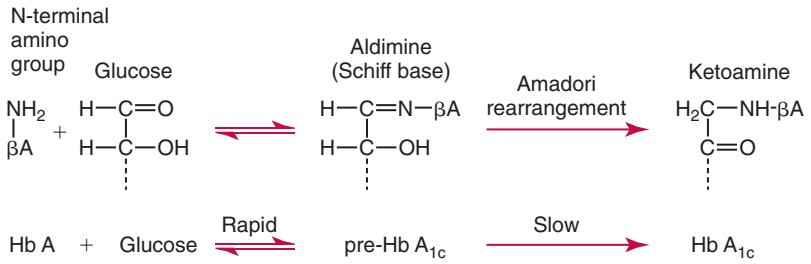


Figure 46-6 Formation of hemoglobin A_{1c}.

TABLE 46-4 Nomenclature of Selected Hemoglobins

Name	Component(s)
HbA	Constitutes ≈97% adult hemoglobin
HbA_0	Synonymous with HbA
HbA_{1a1}	HbA with fructose-1,6-diphosphate attached to the *N*-terminal of the β-chain
HbA_{1a2}	HbA with glucose-6-phosphate attached to the *N*-terminal of the β-chain
HbA_{1a}	Comprises HbA_{1a1} and HbA_{1a2}
HbA_{1b}	HbA with pyruvic acid attached to the *N*-terminal of the β-chain
HbA_{1c}	HbA with glucose attached to the *N*-terminal valine of the β-chain
Pre-HbA_{1c}	Unstable Schiff base (aldimine); a labile intermediary component in the formation of HbA_{1c}
HbA_1	Consists of HbA_{1a}, HbA_{1b}, and HbA_{1c}
Total glycated hemoglobin*	Consists of HbA_{1c} and other hemoglobin-carbohydrate adducts

*Also termed *glycated hemoglobin* or *glycohemoglobin*.
Hb, Hemoglobin.

referred to as glycated HbA_0 or total glycated hemoglobin (see Table 46-4), cannot be separated from nonglycated hemoglobin by methods based on charge, but are measured by boronate affinity chromatography.

Formation of GHb is essentially irreversible, and the concentration in the blood depends on both the lifespan of the red blood cell (RBC; average lifespan is 120 days) and the blood glucose concentration. Because the rate of formation of GHb is directly proportional to the concentration of glucose in the blood, *the GHb concentration represents integrated values for glucose over the preceding 8 to 12 weeks.* This provides an additional criterion for assessing glucose control because GHb values are free of day-to-day glucose fluctuations and are unaffected by recent exercise or food ingestion. It is important to realize that the contribution of the plasma glucose concentration to GHb depends on the time interval, with more recent values providing a larger contribution than earlier values. The plasma glucose in the preceding 1 month determines 50% of the HbA_{1c}, whereas days 60 to 120 determine only 25%.[227] After a sudden alteration in blood glucose concentrations, the rate of change of HbA_{1c} is rapid during the initial 2 months, followed by a more gradual change approaching steady state 3 months later.

Interpretation of GHb depends on red blood cells having a normal lifespan. Patients with hemolytic disease or other conditions with shortened red blood cell survival exhibit a substantial reduction in GHb.[46] Similarly, individuals with recent significant blood loss have falsely low values owing to a higher fraction of young erythrocytes. GHb concentrations can still be used to monitor these patients, but values must be compared with previous values from the same patient—not with published reference intervals. High GHb concentrations have been reported in iron deficiency anemia, probably because of the high proportion of old erythrocytes. The effects of hemoglobin variants (such as HbF, HbS, and HbC) depend on the specific method of analysis used (discussed later).[46] Depending on the particular hemoglobinopathy and assay, results may be spuriously increased or decreased. Most manufacturers of HbA_{1c} assays have modified their assays to eliminate interference from many of the common hemoglobin variants. Therefore, accurate measurement of HbA_{1c} is possible by selecting an appropriate instrument, provided the erythrocyte lifespan is not altered (see www.NGSP.org for additional information). Another source of error in selected methods is *carbamylated hemoglobin.* This is formed by attachment of urea and is present in large amounts in renal failure, which is common in diabetic patients. Most of the interferents produce relatively small effects, and for the vast majority of patients with diabetes, HbA_{1c} can be measured accurately.

Labile intermediates (pre-HbA_{1c}, Schiff base) may be included in measurements of HbA_{1c}, especially in the common ion-exchange methods,[166] and produce misleadingly high results. The *labile fraction changes rapidly with acute changes in blood glucose concentration and thus is not an indicator of long-term glycemic control.* Pre-HbA_{1c} amounts to 5 to 8% of total HbA_1 in healthy individuals and ranges from 8 to 30% in patients with diabetes, depending on the degree of control of blood glucose concentration at or near the time of blood sampling.[112] If the analytical method measures both fractions, the labile pre-HbA_{1c} should be removed first, to prevent falsely increased results. In the absence of glucose, pre-HbA_{1c} reverts to glucose and HbA (see Figure 46-6). This provides the basis for some procedures to eliminate the labile fraction by incubating washed red blood cells in saline. In some boronate affinity methods, the assay conditions favor rapid dissociation of the Schiff base.

Clinical Utility

Diagnosis of Diabetes

A major change in the diagnosis of diabetes was recommended in 2009.[203,235] An International Expert Committee advised that HbA_{1c} could be used for the diagnosis of diabetes (see Box 46-3). An HbA_{1c} value ≥6.5% was selected as the decision point, based on the prevalence of retinopathy.[235] This recommendation has been endorsed by both the ADA[19A] and the WHO. HbA_{1c} concentrations 5.7 to 6.4% indicate subjects at high risk of developing diabetes. HbA_{1c} was also recommended as an alternative to glucose for screening for diabetes. This last recommendation has also been accepted by the ADA.[19A]

Monitoring Diabetes

GHb has been firmly established as an index of long-term blood glucose concentrations and as a measure of the risk for development of microvascular complications in patients with diabetes mellitus.[91] GHb was a cornerstone of the DCCT.[62] [To prevent assay variability (see section on assay standardization later in this chapter), all GHb assays in the DCCT were done in a single laboratory that measured HbA_{1c} by HPLC.] The DCCT documented a direct relationship between blood glucose concentrations (assessed by HbA_{1c}) and the risk of microvascular complications.[62] The absolute risks of retinopathy and nephropathy were directly proportional to the mean HbA_{1c} concentration. The risk of retinopathy increased continuously with increasing HbA_{1c}, and a single measure of HbA_{1c} predicted the progression of retinopathy 4 years later. Subsequent analysis revealed that the mean HbA_{1c} was the dominant predictor of retinopathy progression, and a 10% lower HbA_{1c} concentration was associated with a 45% lower risk.[63] The risk of microvascular complications varies continuously with HbA_{1c}, and there is no HbA_{1c} concentration below which the risk is eliminated.

Analogous correlations between HbA_{1c} and complications were observed in patients with type 2 diabetes in the UKPDS trial.[242] To ensure that HbA_{1c} results in the UKPDS were comparable with DCCT findings, an ion-exchange HPLC method calibrated to the DCCT was used. Mean HbA_{1c} values for the intensively treated and conventionally treated groups were 7.0% and 7.9%, respectively.[242] Despite the small difference in HbA_{1c}, microvascular complications were reduced by ≈25%. Each 1% reduction in HbA_{1c} (e.g., from 8 to 7%) was associated with risk reductions of 37% for microvascular disease, 21% for death related to diabetes, and 14% for myocardial infarction.[242] In patients without diabetes, HbA_{1c} is directly related to cardiovascular disease. In the European Prospective Investigation into Cancer and Nutrition (EPIC-Norfolk), an increase of 1% in HbA_{1c} was associated with a 28% increase in the risk of death.[127] Based on the DCCT and the UKPDS, major clinical diabetes organizations recommend that the goal for most patients with diabetes should be HbA_{1c} less than 6.5 to 7%.[33] The more frequent use of this test in the management of patients is reflected in the increased number of laboratories participating in College of American Pathologists (CAP) GHb surveys. In 1985, 1990, 2003, and 2009, approximately 300, 700, 2000, and 3250 laboratories, respectively, were enrolled in the GHb surveys.

Methods for the Determination of Glycated Hemoglobins

More than 100 different methods may be used for the determination of GHbs. These methods separate GHb from nonglycated hemoglobin using techniques based on *charge differences* (ion-exchange chromatography, HPLC, electrophoresis, and isoelectric focusing), *structural differences* (affinity chromatography and immunoassay), or *chemical analysis* (photometry and spectrophotometry).[92] Regardless of the method used, the result is expressed as a percentage of total hemoglobin. Analysis by electrophoresis, isoelectric focusing, or chemical techniques is rarely used and is not addressed further here. (Interested readers are referred to earlier editions of this book.) The selection of method by a laboratory is influenced by several factors, including sample volume, patient population, and cost. It is advisable to consult clinicians in this process. The ADA recommends that laboratories use only HbA_{1c} assays that are certified by the National Glycohemoglobin Standardization Program (now known as the NGSP) as traceable to the DCCT reference.[91] These assays are listed on the NGSP Website (www.NGSP.org/accessed July 28, 2011) and are updated at least annually.

The GHb assays most widely used in the United States are depicted in Table 46-5. These data are based on results from 1947 laboratories participating in a 1995 quality control survey and 2398 laboratories participating in a 2009 quality control survey conducted by the CAP. The results demonstrate that in 2009, virtually all laboratories used immunoassay or ion-exchange chromatography. HbA_{1c} was measured by more than 99% of laboratories (see Table 46-5). Total GHb and HbA_1 measurements had essentially disappeared. These results reflect significant changes from the methods used in 1995, when affinity chromatography was the most common analytical method (see Table 46-5). Also, only 60% of laboratories reported HbA_{1c} in 1995. In addition, variation among mean values—both between and within methods—and imprecision were substantially lower in 2009. It should be borne in mind that these data refer only to these CAP surveys and are weighted to laboratories that participate. All of the methods described are commercially available from several different manufacturers.

Ion-Exchange Minicolumns

Ion-exchange chromatography separates hemoglobin variants on the basis of charge. The cation-exchange resin (negatively charged), packed in a disposable minicolumn, has an affinity for hemoglobin, which is positively charged. The patient's sample is hemolyzed, and an aliquot of the hemolysate is applied to the column. A buffer is applied and the eluent collected. The ionic strength and pH of the eluent buffer are selected so that GHbs are less positively charged than HbA, do not bind as well to the negatively charged resin, and therefore are eluted first. The GHbs—A_{1a} + A_{1b} + A_{1c},

[f]Number of participants was too low to permit statistical analysis.
CV, Coefficient of variation; *GHb,* glycated hemoglobin; *Hb,* hemoglobin.

expressed collectively as HbA_1—are measured in a spectrophotometer. A second buffer of different ionic strength can be added to the column to elute the more positively charged main hemoglobin fraction. This is read in the spectrophotometer, and GHb is expressed as a percentage of total hemoglobin. Alternatively, only the HbA_1 is eluted and a separate dilution of the original hemolysate is made, against which the HbA_1 is compared. Numerous commercial modifications have been developed. Simple agitation of resins with hemolysates (batch technique) to adsorb HbA has also been described. In this approach, the supernatant solution containing the HbA_1 fraction is removed by filtration or centrifugation. Methods that separate HbA_{1a+b} from HbA_{1c} by using two different buffers have also been described.[151] Most of the current commercial ion-exchange methods use HPLC.

In all ion-exchange column methods, it is important to *control the temperature of the reagents and columns* to obtain accurate and reproducible results. This is best done by thermostatting the columns. Alternatively, a temperature correction factor can be applied if the room temperature differs from the specified optimum. In addition, rigid control of pH and ionic strength must be maintained. Sample storage conditions are also important.

The labile pre-HbA_1 fractions elute with the stable ketoamine and produce spuriously high values unless destroyed by pretreatment of the red blood cells. Spuriously increased values are also obtained when the charge on hemoglobin is altered by the attachment of noncarbohydrate moieties, which may co-chromatograph with GHbs, as in uremia (carbamylated hemoglobin), alcoholism, lead poisoning, or chronic treatment with large doses of aspirin (acetylated hemoglobin). Hemoglobin variants or chemically modified hemoglobins that elute separately from HbA and HbA_{1c} have little effect on HbA_{1c} measurements. If the modified hemoglobin (or its glycated derivative) cannot be separated from HbA or HbA_{1c}, spuriously increased or reduced results will be obtained.[46] A variant that elutes with HbA_{1c} will yield a gross overestimation of HbA_{1c}, and a variant that coelutes with HbA will underestimate HbA_{1c}. Note that a single variant may falsely increase or decrease HbA_{1c}, depending on the method used.[46]

High-Performance Liquid Chromatography

HbA_{1c} and other hemoglobin fractions can be separated by HPLC, which employs cation-exchange chromatography.[61] Several fully automated systems are commercially available. Assays require only 5 µL of whole blood, and fingerstick samples can be collected in a capillary tube for analysis. Anticoagulated blood is diluted with a hemolysis reagent containing borate. Samples are incubated at 37 °C for 30 minutes to remove the Schiff base and are inserted into the autosampler. [Some instruments have a shorter preincubation step, and others (e.g., Tosoh A_{1c}2.2) separate labile A_{1c} chromatographically, eliminating the step to remove the Schiff base.[87]] A step gradient using three phosphate buffers of increasing ionic strength is passed through the column. Detection is performed at both 415 and 690 nm, and results are quantified by integrating the area under the peaks. Analysis time is as short

as 3 to 5 minutes. All HPLC methods had CVs less than or equal to 3.0% in a 2009 CAP survey (see Table 46-5). HbA_{1c} by HPLC was used for analysis of all patient samples in the DCCT.[61]

Immunoassay

Assays for HbA_{1c} have been developed using antibodies raised against the Amadori product of glucose (ketoamine linkage) plus the first few (four to eight) amino acids at the *N*-terminal end of the β-chain of hemoglobin.[74,117] A widely used assay measures HbA_{1c} in whole blood by inhibition of latex agglutination. The agglutinator, a synthetic polymer containing multiple copies of the immunoreactive portion of HbA_{1c}, binds the anti-HbA_{1c} monoclonal antibody that is attached to latex beads. This agglutination produces light scattering, measured as an increase in absorbance. HbA_{1c} in the patient's sample competes for the antibody on the latex, inhibiting agglutination, thereby decreasing light scattering. Enzyme immunoassays using monoclonal antibodies are commercially available, and most exhibit reasonable imprecision (see Table 46-5). These assays are generally calibrated to give values that match and correlate with HPLC values. The antibodies do not recognize labile intermediates or other GHbs (such as HbA_{1a} or HbA_{1b}) because both ketoamine with glucose and specific amino acid sequences are required for binding. Similarly, several hemoglobin variants, such as HbF, HbA_2, HbS, and carbamylated hemoglobin, are not detected.[46] The procedure has been adapted for capillary blood samples using a bench-top analyzer with reagent cartridges designed for use in physicians' office laboratories.

Affinity Chromatography

Affinity gel columns are used to separate GHb, which binds to the column, from the nonglycated fraction. *m*-Aminophenylboronic acid is immobilized by cross-linking to beaded agarose or another matrix (e.g., glass fiber). The boronic acid reacts with the *cis*-diol groups of glucose bound to hemoglobin to form a reversible five-member ring complex, thus selectively holding the GHb on the column (Figure 46-7). The nonglycated hemoglobin does not bind. Sorbitol is then added to elute the GHb. Absorbance of bound and nonbound fractions, measured at 415 nm, is used to calculate the percentage of GHb.

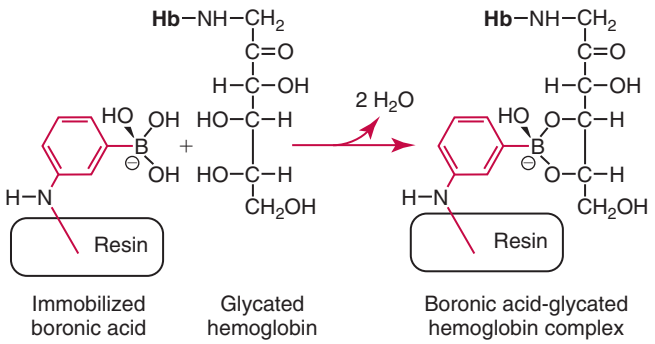

Figure 46-7 Reaction of glycated hemoglobin (GHb) with immobilized boronic acid.

A commercial assay is performed on an automated analyzer that uses a soluble reagent consisting of dihydroxyboronate coupled with high molecular weight polyacrylic acid.[259] GHb binds to the boronate. The polyanionic-glycated hemoglobin affinity complex attaches by electrostatic interactions to the cationic surface of the solid-phase matrix (ion capture). Nonglycated hemoglobin does not bind and is removed in a wash step. GHb is quantified by measuring quenching by hemoglobin of the fluorescence of an added fluorophore, 4-methyl-umbelliferone. Total hemoglobin is determined by fluorescence quenching of a second sample containing sorbitol. The sorbitol competes for boronate binding sites, and both nonglycated hemoglobin and GHb contribute to inhibition of the quenching. The fluorescence measurements are converted to glycated and total hemoglobin concentrations from separate stored calibration curves.

The major advantages of affinity chromatography are as follows: there is no interference from nonglycated hemoglobins and negligible interference from the labile intermediate form of HbA_{1c}. It is unaffected by variations in temperature and has reasonably good precision. Hemoglobin variants such as HbS, HbC, HbD, or HbE produce little effect. Affinity methods measure total GHb. This includes components other than HbA_{1c} because the assay detects ketoamine structures on lysine and valine residues on both α- and β-chains of hemoglobin.

Although the method detects all GHbs, most commercially available systems are calibrated to report a standardized HbA_{1c} value. The value is derived from an equation obtained from linear regression between total GHb and HbA_{1c} analysis by HPLC.[259] A linear relationship has been demonstrated, and standardized HbA_{1c} values are thus comparable to values obtained by methods specific for HbA_{1c}. Columns and reagents are commercially available.

Removal of Labile Glycated Hemoglobin from Red Blood Cells

The concentration of the labile form of HbA_{1c} (Schiff base) fluctuates rapidly in response to acute changes in plasma glucose concentrations and should be removed before analysis by charge-based assays. This may be accomplished by incubating red blood cells in saline[93] or in buffer solutions at pH 5 to 6,[28] or by dialysis or ultrafiltration of hemolysates. Most kits for column assays contain reagents to remove this labile component.

Assay Standardization

Clinical laboratories measure GHb with diverse assays that use multiple methods and quantify different components. The DCCT results accentuated the need for accurate GHb measurement and provided a strong impetus for standardization of GHb assays. At the end of the DCCT, it was noted that absence of both a reference method and a single GHb standard had generated confusion.[208] Interlaboratory comparisons were not possible, and even a single quality control sample analyzed by a single method exhibited interlaboratory CVs as high as 16.5%. Similar large variability

among laboratories was observed in Europe.[254] Committees were established under the auspices of the American Association for Clinical Chemistry (AACC) in 1993 and the IFCC in 1995 to standardize GHb assays.[146A]

The NGSP was established in 1996 to implement the protocol developed by the AACC to calibrate GHb results to DCCT-equivalent values. Employing a network of reference laboratories, the NGSP interacts with manufacturers of GHb methods to help them calibrate their methods and trace values to the DCCT.[147] Manufacturers apply for certification by performing precision testing according to CLSI EP5-A guidelines and report results in DCCT-equivalent HbA_{1c} values. This calibration effort has markedly improved harmonization of results and has reduced imprecision.[146A,147] Results obtained using NGSP-certified assays can be compared with results of the DCCT and UKPDS, allowing alignment with clinical outcomes data. The ADA recommends that clinical laboratories use only assays certified by the NGSP and participate in proficiency testing offered by the CAP. The CAP-GH2 survey uses pooled whole blood specimens at three HbA_{1c} concentrations. Target values are assigned by the NGSP network. Thus individual laboratories can directly compare their HbA_{1c} results with those of the DCCT (and UKPDS).

A different approach was adopted by the IFCC. A working group was established to devise a reference system for standardization based on HbA_{1c}. The IFCC group developed a mixture of purified HbA_{1c} and HbA_0 as primary reference material.[137] Two candidate reference methods, namely, electrospray ionization mass spectrometry (ESI-MS) and capillary electrophoresis, were proposed.[137] These specifically measure the glycated *N*-terminal valine of the β-chain of hemoglobin. Analysis is performed by digesting the hemoglobin molecule with endoproteinase Glu-C, which cleaves the β-chain between Glu-6 and Glu-7, releasing the *N*-terminal hexapeptide. Glycated and nonglycated hexapeptides are separated and quantified by HPLC-ESI-MS or by HPLC-capillary electrophoresis.[137] HbA_{1c} is measured as the ratio between glycated and nonglycated *N*-terminal hexapeptides. The IFCC Working Group has established a network of laboratories to implement and maintain the reference system.[253] Comparisons between IFCC and NGSP reference methods (and reference systems from Japan and Sweden) indicate a close and stable relationship and allow manufacturers to calibrate their instruments to a higher-level reference method.[253] However, HbA_{1c} results obtained using IFCC reference methods are 1.5 to 2% absolute HbA_{1c} units lower than those of the NGSP (and lower than other reference systems). The difference is possibly due to measurement of glycated components other than HbA_{1c} by HPLC. The IFCC method is time-consuming and technically complex, thus it is not designed to be used for routine analysis of patient samples.

Reporting HbA_{1c}

HbA_{1c} typically is reported as a percentage of total hemoglobin in the NGSP system. These values, which are equivalent to those reported in the DCCT and the UKPDS, represent the most widely used reporting system in patient care and the published literature. The IFCC method reports HbA_{1c} as mmol/mol (HbA_{1c}/total Hb).[168] Comparison between the IFCC and NGSP networks produced a master equation that permits conversion between the two reference systems.[106] For example, an HbA_{1c} result of 7% (in NGSP/DCCT/UKPDS units) is equivalent to 53 mmol/mol (in IFCC units). A 2008 multinational, prospective study [termed A_{1c} Derived Average Glucose (ADAG)] evaluated the relationship between HbA_{1c} concentrations and long-term glucose values.[171] A linear correlation was observed, permitting estimated average glucose (eAG) to be calculated from the HbA_{1c} measurement. The regression equations are as follows: eAG mg/dL = $28.7 \times HbA_{1c} - 46.7$, and eAG mmol/L = $1.59 \times HbA_{1c} - 2.59$. For example, an HbA_{1c} value of 7% translates into an eAG of 140 mg/dL. Some clinicians and many diabetes educators believe that the eAG will facilitate communication with patients.[202] The ADA and the AACC recommend that laboratories report both HbA_{1c} and eAG. Nevertheless, the concept of expressing HbA_{1c} in terms of average glucose is not accepted by all.[128,148]

Specimen Collection and Storage

Patients need not be fasting. Venous blood should be collected in tubes containing EDTA, oxalate, or fluoride. Sample stability depends on the assay method used.[204] Whole blood may be stored at 4 °C for up to 1 week. Above 4 °C, HbA_{1a+b} increases in a time- and temperature-dependent manner, but HbA_{1c} is only slightly affected.[220] Storage of samples at −20 °C is not recommended. For most methods, whole blood samples stored at −70 °C or colder are stable for at least 18 months.[71] Heparinized samples should be assayed within 2 days and may not be suitable for some methods of analysis (e.g., electrophoresis).

Reference Intervals

Values for GHbs are expressed as a percentage of total blood hemoglobin. One of three major GHb species, namely, HbA_1, HbA_{1c}, or total GHb, is usually measured. The United States and several other countries, including Canada, Australia, New Zealand, and the United Kingdom, now report virtually all results as HbA_{1c}. Reference intervals vary, depending on the GHb component measured. The reference interval for HbA_{1c} (using an NGSP-certified method) is 4 to 6% (20 to 42 mmol/mol).

The effects of age on reference intervals are controversial.[204] Some studies show age-related increases (≈0.1% per decade after age 30), and other reports show no increase.[129,182,256] It is not known whether these small, but statistically significant, increases in HbA_{1c} concentrations with age have any clinical significance. Results are not affected by acute illness. Intraindividual variability is minimal.[200] In patients with poorly controlled diabetes mellitus, values may extend to twice the upper limit of the reference interval or more, but rarely exceed 15%. Values greater than 15% should prompt additional studies to determine the possible presence

of variant hemoglobin.[46] Note that ADA target values derived from DCCT and UKPDS, not the reference values, are used to evaluate metabolic control in diabetic patients.

There is no specific value of HbA_{1c} below which the risk of diabetic complications is eliminated completely. The ADA states that the goal of treatment should be to maintain HbA_{1c} at less than 7%.[19] (Some organizations recommend an HbA_{1c} target of less than 6.5%.) These goal values are applicable only if the assay method is certified as traceable to the DCCT reference. Each laboratory should establish its own nondiabetic reference interval. Assay precision is important because each 1% change in HbA_{1c} represents an approximate 30 mg/dL change in average blood glucose.

No consensus has been reached on optimum frequency of testing. The ADA recommends that *HbA_{1c} should be routinely monitored at least every 6 months in patients meeting treatment goals (and who have stable glycemic control).*[19] These recommendations are for patients with type 1 or type 2 diabetes.

Fructosamine

Clinical Significance

In selected patients with diabetes mellitus (e.g., GDM, change in therapy), assays may be needed that are more sensitive than GHb to shorter-term alterations in average blood glucose concentrations. Nonenzymatic attachment of glucose to amino groups of proteins other than hemoglobin (e.g., serum proteins, membrane proteins, lens crystallins) to form ketoamines also occurs. Because serum proteins turn over more rapidly than erythrocytes (the circulating half-life for albumin is about 20 days), *the concentration of glycated serum albumin reflects glucose control over a period of 2 to 3 weeks.* Therefore, both deterioration of control and improvement with therapy are evident earlier than with GHb.

Fructosamine is the generic name for plasma protein ketoamines (for reviews, see Armbruster[20] and Hill and associates[102]). The name refers to the structure of the ketoamine rearrangement product formed by the interaction of glucose with the ε-amino group on lysine residues of albumin. Analogous to GHb, measurement of fructosamine may be used as an index of the average concentration of blood glucose over an extended period of time, but one that is about ¼ as long as the time examined with GHb.

Because all glycated serum proteins are fructosamines and albumin is the most abundant serum protein, measurement of fructosamine is thought to be largely a measure of glycated albumin, but this has been questioned by some investigators.[212] Although the fructosamine assay can be automated and is cheaper and faster than GHb, *there is a lack of consensus on its clinical utility.* For example, evaluation of 65 studies led the authors to conclude that fructosamine determination is not a reliable test, and it has not been evaluated sufficiently for routine clinical use.[260] In contrast, a review of essentially the same data concluded that fructosamine could provide information useful in the management of diabetes.[20] Early work using the original assay, introduced in 1983,[25,119] indicated that fructosamine concentrations were significantly higher in diabetic individuals than in healthy subjects. Over the succeeding decade, the assay underwent numerous modifications because several artifacts were identified that rendered data from the first-generation fructosamine assay difficult to interpret. These include apparent lack of specificity for glycated proteins (up to 60% of the value was due to nonfructosamine reducing substances), lack of standardization among laboratories, difficulty in calibrating the assay, and interference by urates and hyperlipidemia.[31] Substantial modifications produced second-generation assays that contain uricase and higher detergent concentrations and are calibrated with glycated lysine.[213] In addition, an industry standard was adopted. These improvements resulted in average fructosamine values in nondiabetic individuals that are approximately 10% of those obtained with the first-generation assay. Some clinical evidence suggests that fructosamine may be useful in the elderly[49] and in those with gestational diabetes.[125] The potential role of the second-generation fructosamine assay in providing rapid, reliable, inexpensive, and technically easy monitoring of glycemic control requires evaluation. The clinical value of fructosamine has not been firmly established, and no convincing evidence relates its concentration to the chronic complications of diabetes.[204]

Because fructosamine determination monitors short-term glycemic changes different from GHb, it may have a role in conjunction with GHb rather than instead of it. In addition, fructosamine may be useful in patients with hemoglobin variants, such as HbS or HbC, that are associated with decreased erythrocyte lifespan, where GHb is of little value. Gross changes in protein concentration and half-life may have large effects on the proportion of protein that is glycated. Thus fructosamine results may be invalid in patients with nephrotic syndrome, cirrhosis of the liver, or dysproteinemias, or after rapid changes in acute-phase reactants. Initial reports indicated that, in the absence of significant alterations in serum protein concentrations, fructosamine results were independent of protein concentrations.[26] However, this observation has been questioned by other investigators, who recommend that fructosamine values be corrected for protein concentrations. This issue remains to be resolved. It is generally accepted that the test should not be performed when serum albumin is less than 30 g/L. Although it was initially postulated that the fructosamine assay would replace the OGTT, *there is no role for the fructosamine assay in the diagnosis of diabetes mellitus.* The second-generation fructosamine assay has been reported to have sensitivity and specificity close to 80% in screening patients for GDM,[111] but this study requires verification.

Determination of Fructosamine

Methods for measuring glycated proteins include (1) affinity chromatography using immobilized phenylboronic acid (similar to the GHb assay)[266]; (2) HPLC of glycated lysine residues after hydrolysis of the glycated proteins[211]; (3) a

photometric procedure in which mild acid hydrolysis releases 5-hydroxymethylfurfural—proteins are precipitated with trichloroacetic acid and the supernatant is reacted with 2-thiobarbituric acid[69]; and (4) other procedures using phenylhydrazine and ε-*N*-(2-furoylmethyl)-L-lysine (furosine). None of these assays is popular because they are not suitable for routine clinical laboratories. The development of monoclonal antibodies to glycated albumin,[54] although theoretically advantageous, has not yet resulted in the widespread availability of commercial glycated albumin assays. It should be noted that prolonged storage at ultra-low temperatures (−96 °C) prevents in vitro glycation of serum proteins.[27]

An alternative method for the measurement of fructosamine is a modification[145,213] of the original method of Johnson and colleagues.[119] This method is conducted under alkaline conditions and results in fructosamine undergoing an Amadori rearrangement with the resultant compounds having reducing activity that can be differentiated from other reducing substances. In the presence of carbonate buffer, fructosamine rearranges to the eneaminol form, which reduces NBT to a formazan (Figure 46-8). Absorbance at 530 nm is measured at two time points, and the absorbance change is proportional to the fructosamine concentration. A 10 minute preincubation is necessary to allow fast-reacting interfering reducing substances to react. It is unnecessary to remove endogenous glucose from patients' samples because a pH greater than 11 is required for glucose to reduce NBT. The assay is easily automated and has excellent between-batch analytical precision. Hemoglobin (>100 mg/dL) and bilirubin (>4 mg/dL) may interfere; therefore moderate to grossly hemolyzed and icteric samples should not be used. Ascorbic acid concentrations greater than 5 mg/dL may cause negative interference. Kits are commercially available (Roche Diagnostics, Indianapolis, Ind). An assay that measures fructosamine by oxidizing the ketoamine bond using ketoamine oxidase, with release of H_2O_2 that is quantified by a photometric reaction, is available (Randox, Oceanside, Calif). An alternative approach has been described.[246] Samples are incubated with proteases, followed by the enzyme fructosaminase, resulting in the release of H_2O_2, which is quantified. The assay, which can be run on an automated analyzer, is commercially available (Diazyme, San Diego, Calif).

A different way to measure glycated albumin is used in Japan. Glycated albumin is hydrolyzed by proteinases to glycated amino acids, which are oxidized by ketoamine oxidase, producing H_2O_2.[139] The H_2O_2 is quantified and glycated albumin is expressed as a percentage of total albumin. This assay is not available in the United States at the time of this writing, but the manufacturer has applied to the FDA for approval.

Reference Intervals

Values in a nondiabetic population vary from 205 to 285 µmol/L. The reference interval corrected for albumin is 191 to 265 µmol/L.

Advanced Glycation End Products

The molecular mechanism by which hyperglycemia produces toxic effects is unknown, but glycation of tissue proteins may be important. Nonenzymatic attachment of glucose to long-lived proteins, lipids, or nucleic acids produces stable Amadori early-glycated products. These undergo a series of additional rearrangements, dehydration, and fragmentation reactions, resulting in stable *advanced glycation end products* (AGEs). The amounts of these products do not return to normal when hyperglycemia is corrected, and they accumulate continuously over the lifespan of the protein. Hyperglycemia accelerates the formation of protein-bound AGE, and patients with diabetes mellitus thus have more AGE than healthy subjects. Through effects on the functional properties of protein and extracellular matrix, AGE may contribute to the microvascular and macrovascular complications of diabetes mellitus.[45,90] AGEs can also activate the receptor for AGE (RAGE) to induce intracellular signaling that leads to enhanced oxidative stress and the production of proinflammatory cytokines.[90] Moreover, inhibitors of AGE formation, such as aminoguanidine, have been shown to prevent several of the complications of diabetes in experimental animal models and are undergoing clinical trials in patients.

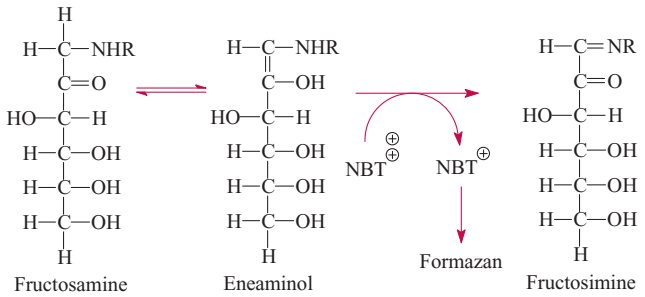

Figure 46-8 Reaction of fructosamine with nitroblue tetrazolium (NBT).

URINARY ALBUMIN EXCRETION

Clinical Significance

Patients with diabetes mellitus are at high risk of suffering renal damage. End-stage renal disease requiring dialysis or transplantation develops in approximately one third of patients with type 1 diabetes,[193] and diabetes is the most common cause of end-stage renal disease in the United States and Europe.[164] Although nephropathy is less common in patients with type 2 diabetes, approximately 60% of all cases of diabetic nephropathy occur in these patients because of the higher incidence of this form of diabetes. Early detection of diabetic nephropathy relies on tests of urinary excretion of albumin. Persistent proteinuria detectable by routine screening tests [equivalent to a urinary albumin excretion (UAE) rate ≥200 µg/min] indicates overt diabetic nephropathy. This

is usually associated with long-standing disease and is unusual less than 5 years after the onset of type 1 diabetes. Once diabetic nephropathy occurs, renal function deteriorates rapidly and renal insufficiency evolves. Treatment at this stage can retard the rate of progression without stopping or reversing the renal damage. Preceding this stage is a period of increased UAE not detected by routine dipstick methods. This range of 20 to 200 μg/min (or 30 to 300 mg/24 h) of increased UAE has been called *microalbuminuria.* Note that it is not defined in terms of urinary albumin concentration, although the ratio of the urinary albumin concentration to the urinary creatatinine concententration (albumin-to-creatinine ratio) in an untimed urine specimen can be used as a substitute for albumin measurements in a timed collection of urine, as described later. The term *microalbuminuria,* although widely used, is misleading. It implies a small version of the albumin molecule rather than an excretion rate of albumin greater than normal but less than that detectable by routine methods. Use of the term is discouraged.

The presence of increased UAE denotes an increase in the transcapillary escape rate of albumin and therefore is a marker of microvascular disease. Persistent UAE greater than 20 μg/min represents a 20-fold greater risk for the development of clinically overt renal disease in patients with type 1 and type 2 diabetes. Prospective studies have demonstrated that increased UAE precedes and is highly predictive of diabetic nephropathy, end-stage renal disease, cardiovascular mortality, and total mortality in patients with diabetes mellitus.[163,164] The DCCT and the UKPDS showed that intensive diabetes therapy can significantly reduce the risk of development of increased UAE and overt nephropathy in individuals with diabetes.[62,242] In addition, increased UAE identifies a group of nondiabetic subjects at increased risk for coronary artery disease.[85,141] Interventions, such as control of blood glucose concentrations and blood pressure, particularly with angiotensin-converting enzyme (ACE) inhibitors, slow the rate of decline in renal function.[164]

Methods for Measuring Urinary Albumin Excretion

No consensus has been reached about how a urine sample should be collected for measuring UAE. Variations in urine flow rate in a person may be corrected by expressing albumin as a ratio to creatinine (i.e., albumin:creatinine). *UAE is increased by physiologic factors* (e.g., exercise, posture, diuresis), and the method of urine collection must be standardized. Samples should not be collected after exertion, in the presence of urinary tract infection, during acute illness, immediately after surgery, or after an acute fluid load. All the following urine samples are currently acceptable: (1) 24 hour collection; (2) overnight (8 to 12 hours, timed) collection; (3) 1 to 2 hour timed collection (in laboratory or clinic); and (4) first morning sample for simultaneous albumin and creatinine measurement. Only results for timed specimens can be reported as mg albumin excreted per hour, but the albumin-to-creatinine ratio is more practical and convenient for the patient and is the recommended method. A first morning void sample is recommended because it has lower within-person variation for the albumin-to-creatinine ratio than a random urine sample.[204,261] *At least three separate specimens, collected on different days, should be assayed* because of high intraindividual variation (CV of 30 to 50%) and diurnal variation (50 to 100% higher during the day). Urine should be stored at 4 °C after collection. Alternatively, 2 mL of 50 g/L sodium azide can be added per 500 mL of urine, but preservatives are not recommended for some assays. Bacterial contamination and glucose have no effect. Specimens are stable for 2 weeks at 4 °C and for at least 5 months at −80 °C. Freezing samples has been reported to decrease albumin,[73] but mixing immediately before assay eliminates this effect.

Semiquantitative Assays

Several semiquantitative assays are available for screening for increased UAE. These test strips, most of which are optimized to read "positive" at a predetermined albumin concentration, have been recommended for screening programs. In view of the wide variability in UAE, it must be borne in mind that a "normal" value does not rule out renal disease. *Because these assays measure albumin concentration, dilute urine may yield a false-negative test result.* Refrigerated urine samples should be allowed to reach at least 10 °C before analysis. Albu Screen and Albu Sure (Cambridge Life Sciences, Cambridge, United Kingdom) detect urinary albumin concentrations exceeding 20 and 30 mg/L, respectively. The assay is a latex agglutination inhibition test. Briefly, one drop of urine is mixed with one drop of goat antihuman albumin, the titer of which is adjusted so that all antibody-binding sites are occupied at urinary albumin concentrations of 30 mg/L or greater. Excess albumin-binding sites are detected by adding one drop of albumin-coated latex microspheres and rocking for 2 minutes. Albumin concentrations less than 20 mg/L produce agglutination. Microbumintest (Bayer Diagnostics Tarrytown, NY) uses bromophenol blue in an alkaline matrix to detect albumin concentrations exceeding 40 mg/L. The assay sensitivity for increased urinary albumin as measured by quantitative assays is approximately 95%, but because other proteins are also detected, the specificity is approximately 80%.

Micral (Roche Diagnostics Indianapolis, IN) uses a monoclonal antialbumin IgG complexed to β-galactosidase. The albumin in the urine binds to the antibody-enzyme conjugate in the test strip. Excess conjugate is retained in a separation zone containing immobilized albumin, and only albumin bound to the antibody-enzyme immunocomplex diffuses to the reaction zone. Here it reacts with a buffered substrate (chlorophenol red galactoside) to produce a red color when the β-galactosidase hydrolyzes galactose. The test strip is dipped into the urine for 5 seconds, and the intensity of the color after 5 minutes is proportional to the urinary albumin concentration. Direct visual comparison is made with printed color blocks, with yellow, light brown, medium brown, brick red, and burgundy representing 0, 10, 20, 50, and 100 mg/L, respectively. No interference is observed with drugs, glucose, urea, or other proteins. Comparison with a

reference method demonstrates a sensitivity and specificity for albumin concentrations greater than 20 mg/L (not for microalbuminuria defined by UAE rate) of approximately 100% and 91%, respectively.[153] The *time that the stick is in contact with the urine and the time of reading are critical.* A modification (Micral II) uses a gold-labeled, instead of an enzyme-labeled, antibody. This enhances the stability, allowing the strip to be read at any time from 1 to at least 60 minutes. Urine samples with albumin concentrations greater than 100 to 300 mg/L may be diluted and reassayed. The assigned concentration of the color block is multiplied by the dilution factor to obtain the concentration in the sample. These semiquantitative assays have been *recommended for screening only.* However, published studies reveal sensitivities for detection of increased UAE from 67 to 91%.[204] These low sensitivities limit the value of semiquantitative tests even for screening, and additional studies are necessary before dipstick tests can be recommended as replacements for quantitative tests.[204]

Quantitative Assays

All sensitive, specific assays for urine albumin use immunochemistry with antibodies to human albumin. Four methods are available: RIA, ELISA, radial immunodiffusion, and immunoturbidimetry.[155] Each method has advantages and disadvantages, and the choice depends on local experience and technical support. In general, these *methods have similar imprecisions, detection limits, and reference intervals.* A comparison of these methods has been performed.[248] Although dye-binding[215] and protein-precipitation[185] assays have been described, these are insensitive and nonspecific and should not be used.

Radial Immunodiffusion

Radial immunodiffusion has not gained wide acceptance because it requires long incubation and a high level of technical skill and cannot be automated. The antibody is incorporated into an agar gel. Aliquots of samples and calibrators are added to wells and are allowed to diffuse into the agar. The antigen-antibody complexes precipitate at equilibrium, and after staining, the distance of migration is measured.

Radioimmunoassay

Standard RIA methods have been described[262] with ^{125}I-labeled albumin and antialbumin antiserum, but reagents are radioactive and have a short shelf life. Commercial kits are available.

Enzyme-Linked Immunosorbent Assay

Both competitive and "sandwich" ELISAs are available.[51,240] Although the competitive ELISA is faster because it uses only one incubation with an antibody, it is reported to be less sensitive and exhibits large imprecision. ELISA can be performed on a microplate reader, allowing semiautomation. In the sandwich assay, the primary antibody (antialbumin antiserum) is fixed on the plastic plate, which is then washed. Samples, controls, and calibrators are added, and the complexes are detected and quantified by a second antibody conjugated to an enzyme label.

Immunoturbidimetry

Albumin in the urine sample forms an insoluble complex with antibodies to human albumin. PEG accelerates complex formation. The turbidity caused by these complexes is measured by a spectrophotometer at 340 nm and is a measure of albumin concentration. The background absorbance of the initial urine sample is subtracted automatically. This method is simple and less expensive than RIA, and rapid analysis of large numbers of samples is possible. Assays may be performed as kinetic or equilibrium reactions. Kits are commercially available for use with automated analyzers (Roche Diagnostics).

Reference Intervals

URINARY ALBUMIN EXCRETION

	µg/min	mg/24 h	Corrected (mg/g Urine Creatinine)
Normal	<20	<30	<30
Increased UAE	20-200	30-300	30-300
Clinical albuminuria*	>200	>300	>300

*Also termed *overt nephropathy.*

The ADA position statement[19] recommends initial UAE measurement in patients with type 1 diabetes who have had diabetes for 5 years or longer, and in all type 2 diabetic patients. Because of the difficulty involved in dating the onset of type 2 diabetes, screening should commence at diagnosis. Analysis should be performed annually in all patients who have a negative screening result. Screening may be performed with a semiquantitative assay. If the screening result is positive, UAE should be evaluated by a quantitative assay. Diagnosis requires the demonstration of increased UAE in at least two of three tests measured within a 3 to 6 month period.

If the confirmatory test result is positive, treatment with an ACE inhibitor or an angiotensin-receptor blocker should be initiated. ACE inhibitors delay progression to overt nephropathy, and the National Kidney Foundation recommends their use in both normotensive and hypertensive type 1 and 2 diabetic patients.[32] The role of monitoring UAE in patients on ACE inhibitor therapy is less clear, although many experts recommend continued surveillance. Untreated, the UAE would increase by 10 to 30% per year, whereas the albumin-to-creatinine ratio in patients on ACE inhibitors should stabilize or decrease by up to 50%.

CHAPTER 47

Cardiac Function

Fred S. Apple, Ph.D., Jens Peter Goetze, M.D., D.M.Sc., and Allan S. Jaffe, M.D.

Although the heart is an efficient and durable pump, a variety of pathologies are known to diminish cardiac function, possibly leading to a multiplicity of dysfunctional clinical states. Heart failure, which is increasing as we improve the treatment of acute ischemic heart disease, and acute ischemic heart disease itself are the most common cardiac diseases that rely on a biochemical diagnosis and thus will be the focus of this chapter.[41]

The term *acute myocardial infarction (AMI)* refers to a situation in which death of myocytes is due to an imbalance between myocardial oxygen supply and demand. When the blood supply to the heart is interrupted, "gross necrosis" of the myocardium results. In addition, a substantial number of cells die as the result of apoptosis. Such extensive damage is most often associated with a thrombotic occlusion superimposed on coronary atherosclerosis. Initially, it was thought that the population of myocytes was fixed; however, it is now believed that the migration of a variety of precursor stem cells has the potential at least to replace some of the damaged myocytes. It is now thought that the process of plaque rupture or erosion and thrombosis is one of the ways in which coronary atherosclerosis progresses, and that we recognize only more severe events.[283,284] Total loss of coronary blood flow results in a clinical syndrome associated with what is known as ST segment elevation AMI (STE AMI). Partial loss of coronary perfusion if severe can lead to necrosis as well, which is generally less severe and is known as NSTEMI (non–ST elevation myocardial infarction). Other events of still lesser severity may be missed entirely or may be called *angina,* which can range from stable to unstable.

In the United States, approximately 700,000 patients suffer from an initial AMI annually and another 500,000 from recurrent AMI. Coronary heart disease causes 20% of all deaths in the United States, and cardiovascular disease causes up to 38.5% of all mortality in the United States. About 1.7 million patients are hospitalized each year in the United States with acute coronary syndrome (ACS). Historically, most deaths caused by ischemic heart disease were acute, but as our therapeutic abilities have increased, the disease is becoming more chronic. Deaths that occur acutely result from ventricular arrhythmias or pump dysfunction and congestive heart failure with or without cardiogenic shock. Death rates are sharply age dependent, both during hospitalization and in the year following infarction. In the United States, the yearly economic burden of coronary artery disease (CAD) is in excess of $133.2 billion—more than a third of the total of $503.2 billion attributed to cardiovascular disease overall.

Before the advent of coronary care units, treatment of AMI was directed toward allowing healing of the infarcted area. The concept that infarctions evolve over time and that their size can be moderated led to rethinking of this passive philosophy.[319] We now know that re-establishment of perfusion reduces the extent of myocardial injury and is an important determinant of prognosis.[330] Today the management of AMI suggested by most guidelines is aggressive and invasively oriented in the hope of reducing the extent of myocardial damage and thus improving prognosis.[63A,67] In addition, prevention is finally being recognized as a key element in the long-term treatment of patients with atherosclerosis.

BASIC ANATOMY

The average human adult heart weighs approximately 325 g in men and 275 g in women and is 12 cm in length. The heart is a hollow muscular organ, shaped like a blunt cone, and is about the size of a human fist. It is located in the mediastinum, between the lower lobes of each lung, and rests upon the diaphragm. It is enclosed in a sac called the *pericardium.* The cardiac wall is composed of three layers: the *epicardium,* which is the outermost layer; a middle layer; and an inner layer, called the *endocardium*. The heart has four chambers. The two upper chambers are termed the *right* and *left atria,* and the two lower chambers are termed the *right* and *left ventricles* (Figure 47-1). Under normal circumstances, the atria are compliant structures, so that intracavitary pressure is low. When anatomy is normal, each atrium is connected to its ventricle through an atrioventricular (AV) valve, which opens and closes (see discussion later in this chapter). The valve on the left side is called the *mitral valve* and the one on the right side, the *tricuspid valve.* The right ventricle is banana shaped and pumps blood into the *pulmonary artery* through a tri-leaflet *pulmonic valve.* The left ventricle pumps blood into the *aorta* through a tri-leaflet *aortic valve.* The ventricles, especially the left ventricle, are thicker and less compliant in keeping with the need to generate higher pressures than the right ventricle, and intercavitary pressures are much higher

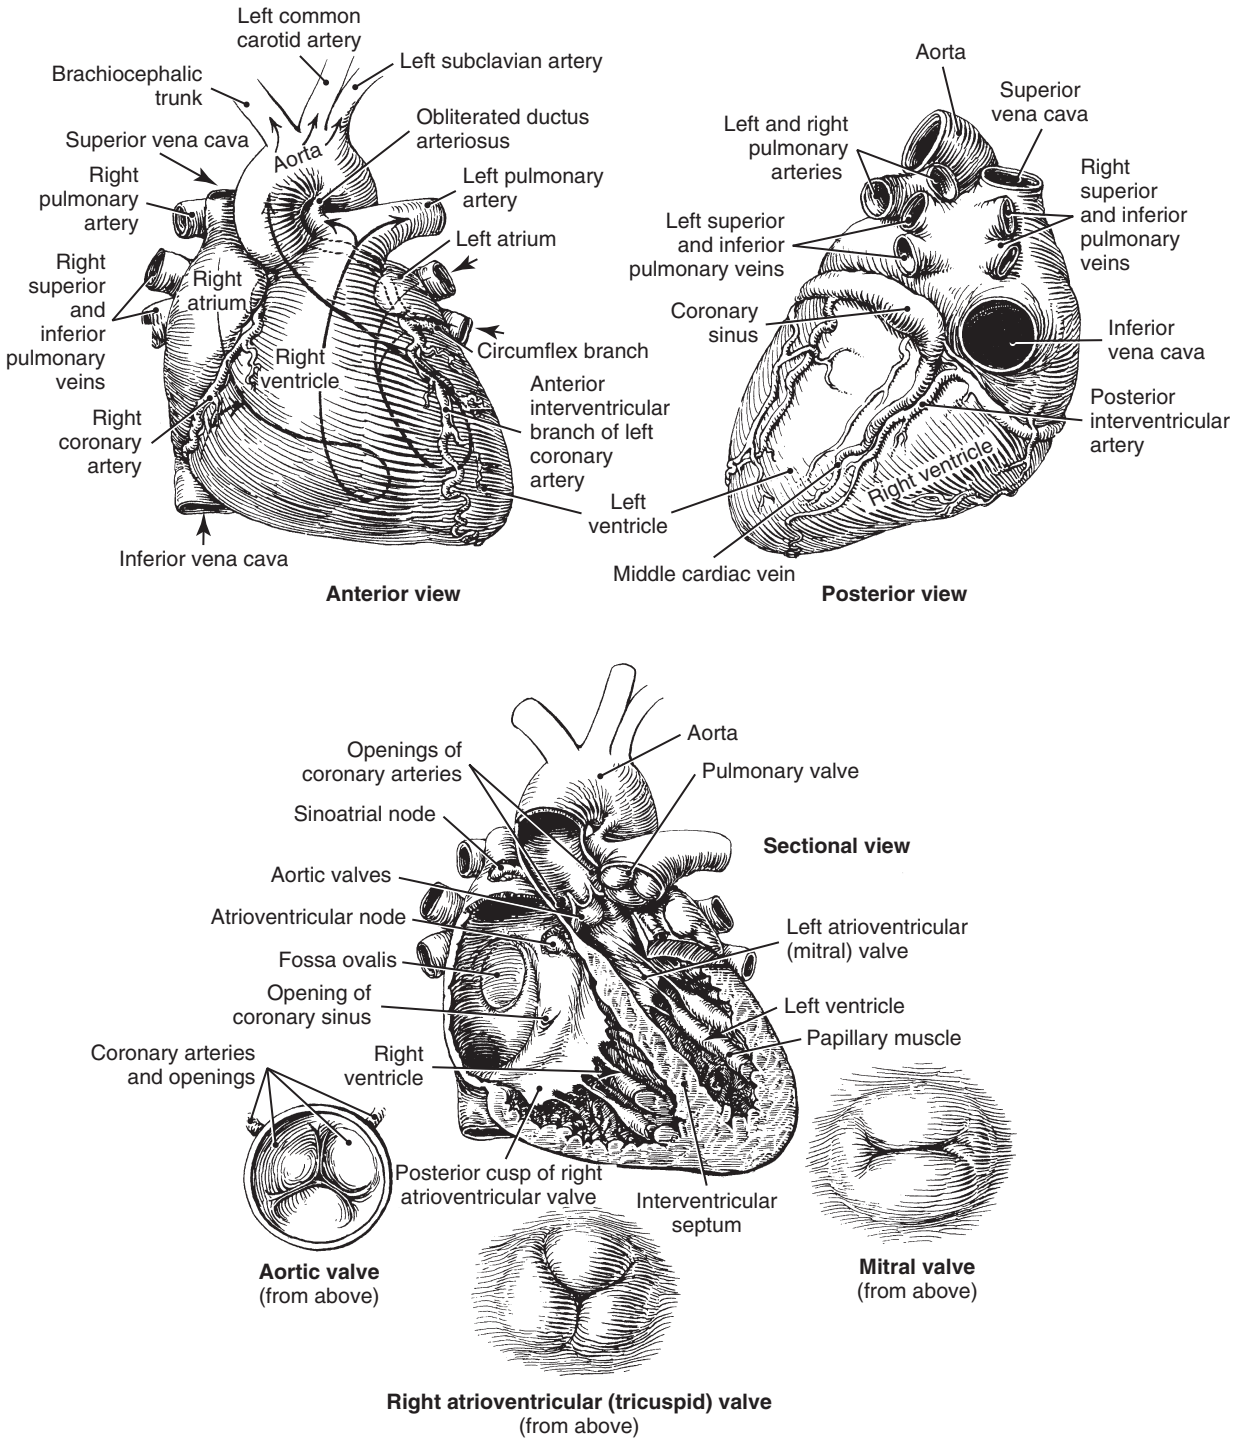

Figure 47-1 Anatomy of the heart. *(From Dorland's illustrated medical dictionary, 30th edition. Philadelphia, Pa: WB Saunders, 2003:Panel 20.)*

than in the atria. Under normal conditions, the conduction or electrical system of the heart coordinates the sequential contraction of first the atria and then the ventricles. Given that they are connected, each side can affect the other. Under normal circumstances, the sequence of activation optimizes this interaction and thus the efficiency of cardiac function. The right and left coronary arteries originate from two of three cusps of the aortic valve. They provide blood flow and thus nutritive perfusion to the heart. The largest vessels are on the epicardium, and these can be accessed therapeutically fairly easily. Subsequent smaller branches divide to supply the remaining myocardium. The endocardium is the layer most susceptible to ischemia because its perfusion relies on the smallest vessels.

The myocardium contains bundles of striated muscle fibers, each of which is typically 10 to 15 mm in diameter and

30 to 60 mm in length. Work of the heart is generated by the alternating of contraction and relaxation of these fibers. The fibers are composed of the cardiac-specific contractile proteins actin and myosin, and regulatory proteins called *troponins*. They also contain a variety of enzymes and proteins that are vital for energy use, such as myoglobin, creatine kinase (CK), and lactate dehydrogenase (LD), some of which can be used as markers of cardiac injury.

PHYSIOLOGY

Cardiac Cycle

A typical cardiac cycle consists of two intervals known as *systole* and *diastole* (Figure 47-2). During diastole, oxygenated blood returns from the lungs to the left atrium via the pulmonary veins, and deoxygenated blood returns from other parts of the body to fill the right atrium. During this period, the AV valves are open, allowing passive filling of the ventricle. At the end of diastole, the atria contract, forcing additional blood through the AV valves and into the respective ventricles. During systole, the ventricles contract. This closes the AV valves when ventricular pressure exceeds atrial pressure, and the pulmonary and aortic valves are opened when ventricular pressure exceeds pressure in the pulmonary arteries and/or the aorta, and blood flows into those conduits. During systole, a normal blood pressure in the aorta is typically 120 mm Hg; during diastole, it falls to about 70 mm Hg. At rest, the heart pumps between 60 and 80 times per minute. Stroke volume (i.e., the amount of blood expelled with each contraction) is roughly 50 mL, so cardiac output per minute is roughly 3 L. Typically, values are corrected for body surface area and are usually in the range of 2.5 to 3.6 L/min/m^2. Measurements of cardiac output and ventricular filling pressures are the standards for assessing cardiac performance and function. Furthermore, therapeutic intervention in patients with heart disease often includes assessment of cardiac output and ventricular pressures.

Cardiac Conducting System

The cardiac cycle is tightly controlled by the cardiac conducting system, which initiates electrical impulses and carries them, via a specialized conducting system, to the myocardium. The surface electrocardiogram (ECG) records changes in potential and is a graphic tracing of the variations in electrical potential caused by excitation of the heart muscle and detected at the body surface.[264] Clinically, the ECG is used to identify (1) anatomic, (2) metabolic, (3) ionic, and (4) hemodynamic changes in the heart. The clinical sensitivity and specificity of ECG abnormalities are influenced by a wide spectrum of physiologic and anatomic changes and by the clinical situation.

Under normal circumstances, cardiac cycles are similar and each includes three major components (Figure 47-3): atrial depolarization (the P wave), ventricular depolarization (the QRS complex), and repolarization (the ST segment and T wave). Atrial depolarization, which is depicted by the P wave, produces atrial contraction. Ventricular depolarization, marked by the QRS complex, produces contraction of the ventricles. It is composed of as many as three deflections: (1) the Q wave, which when present is the first negative deflection; (2) the R wave, which is the first positive deflection; and (3) the S wave, which is a negative deflection following the R wave. On occasion, there is an R prime, which is a second positive deflection. Whether each of these occurs depends on the path of depolarization of the ventricles, as does the significance. Thus not every QRS complex will have discrete Q, R, and S waves. The ST segment and the T wave are produced by electrical recovery of the ventricles, and their mean electrical vector is under normal circumstances concordant (i.e., in roughly the same direction) with the mean QRS vector.

A routine ECG is composed of 12 leads. Six are called limb leads (I, II, III, aVR, aVL, and aVF), because they are recorded between arm and leg electrodes; six are called precordial or chest leads (V_1, V_2, V_3, V_4, V_5, and V_6) and are recorded across the sternum and left precordium. Each lead records the same electrical impulse but in a different position relative to the heart. Areas of pathology shown on the ECG can be localized by analyzing differences between the tracing in question and what is known to be normal in the 12 different leads.

CARDIAC DISEASE

Cardiac disease occurs in many forms. This chapter briefly covers congestive heart failure (CHF) and acute coronary syndromes, such as AMI. The vast number of other cardiac diseases is not discussed in depth here because of the smaller role of clinical laboratory tests in these disorders.

Congestive Heart Failure

CHF is a syndrome characterized by ineffective pumping of the heart leading to an accumulation of fluid in the lungs. Typically, it results from loss of cardiac tissue and subsequent function.[88] Medically, it is defined as the pathophysiologic condition in which an abnormality of cardiac function is responsible for failure of the heart to pump sufficient blood to satisfy the requirements of metabolizing tissues. Encompassed in this definition are a wide spectrum of clinical conditions, ranging from (1) a primary impairment in pump function, such as might occur after a large AMI; (2) increased cardiac stiffness, which causes increased pressure in the heart, restricts filling, and increases hydrostatic pressures behind the area of reduced compliance; and (3) situations in which peripheral demand is excessive, resulting in what is known as high-output heart failure, which is defined as the inability of the heart to increase pumping sufficiently to meet the peripheral demands for blood.

Epidemiology

In the United States, CHF is the only cardiovascular disease with an increasing incidence. The National Heart, Lung, and Blood Institute estimates current prevalence at 4.9 million Americans with CHF, with an incidence of approximately 400,000 new cases each year.[171] CHF is the leading cause of

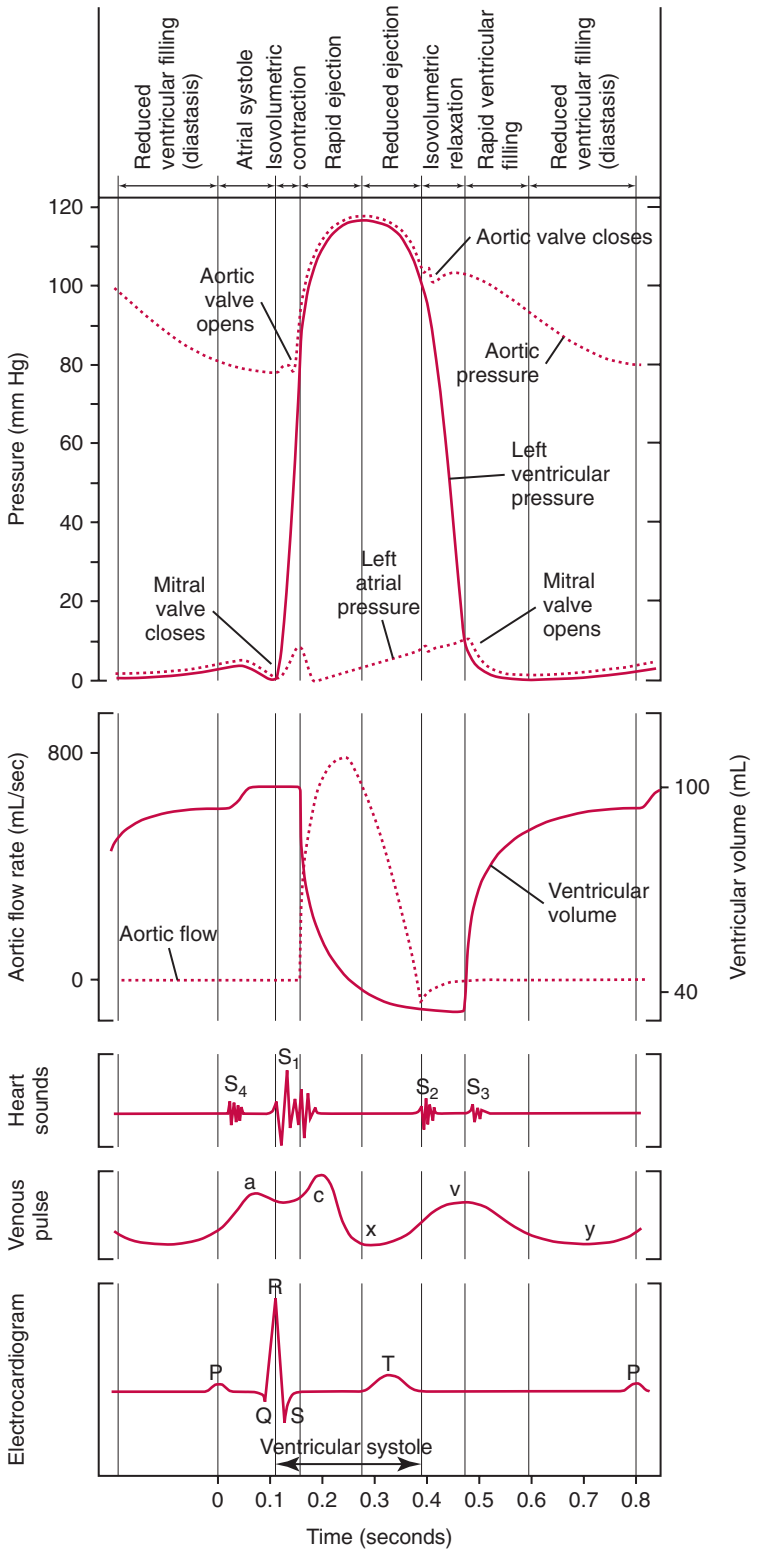

Figure 47-2 The cardiac cycle. *(From Dorland's illustrated medical dictionary, 30th edition. Philadelphia, Pa: WB Saunders, 2003, with permission from the National Kidney Foundation.)*

hospitalization in individuals 65 years of age and older. It has become clear that a larger component of heart failure is attributable to what has been called diastolic dysfunction, or heart failure (HF) with preserved ejection fraction (HFPEF). Therapeutic options for such patients are more limited than for those who have systolic abnormalities.[313] Current prognosis is dependent on disease severity, but overall it is poor. Five-year mortality is approximately 10% in mild CHF, 20 to 30% in moderate CHF, and up to 80% in end-stage disease.[205] These poor outcomes are not without substantial cost, estimated at $18.8 billion per year in the United States.

Currently, CHF patients are staged with the New York Heart Association (NYHA) functional classifications I to IV. Class I patients are generally considered asymptomatic, with no restrictions on physical activity; class IV patients are often symptomatic at rest, with severe limitations on physical activity. The problem with this classification system is that much of it is based on subjective criteria. Thus patients with comorbidities that reduce their activities are hard to classify. In addition, dyspnea, which is the primary symptom in many of these individuals, has many causes. Finally, many patients with ventricular dysfunction modify their activities to accomplish activities of daily living and thus lack overt symptoms until late in their disease. Thus patients with CHF often go undiagnosed and untreated early in their disease or are misdiagnosed because of conditions such as pulmonary disease. Initiating treatment in the more advanced disease state (higher degree of irreversible cardiac function and patient deconditioning) is challenging and more expensive (often requiring extended inpatient stay) and leaves patients with considerable morbidity on a daily basis. Obviously, misdiagnoses often lead to patient morbidity.

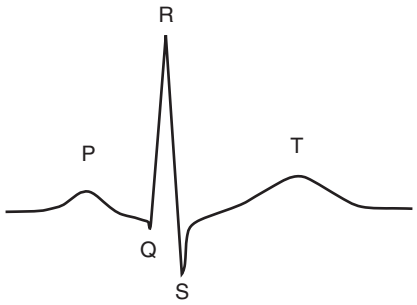

Figure 47-3 Electrocardiogram, serial tracing of a normal single heartbeat. Each beat manifests as five major waves: P, Q, R, S, and T. The QRS complex represents the ventricular contraction.

Acute Coronary Syndrome

The term *acute coronary syndrome (ACS)* encompasses patients who present with unstable ischemic heart disease.[67] If they have ST segment elevation, they are called STEMI (Figure 47-4). Usually, but not always, these individuals will develop Q waves on their ECGs, hence the term *Q-wave MI*. If patients do not have STE but have biochemical criteria for cardiac injury, they are called NSTEMI, and most do not develop ECG Q waves. Those who have unstable ischemia and do not manifest necrosis are designated patients with unstable angina (UA). Most of these syndromes occur in response to an acute event in the coronary artery, when circulation to a region of the heart is obstructed for some reason. If the obstruction is high grade and persists, then necrosis usually ensues. Because necrosis is known to take some time to develop, it is apparent that opening the blocked coronary artery in a timely fashion can often prevent some of the death of myocardial tissue. This is clearly the case with STEMI. With non-STEMI [American Heart Association (AHA)/American College of Cardiology (ACC) guidelines], early but not immediate intervention is advocated, because most often the infarct-related coronary artery is not totally occluded, and thus immediate intervention is less necessary. These syndromes are usually but not always associated with chest discomfort (see discussion later in this chapter).[286]

The major cause of ACS is atherosclerosis, which contributes to significant narrowing of the artery lumen and a tendency for plaque disruption and thrombus formation.[67,283,284] Myocardial ischemia and infarction are usually segmental diseases. In up to 90% of patients with these diseases, focal

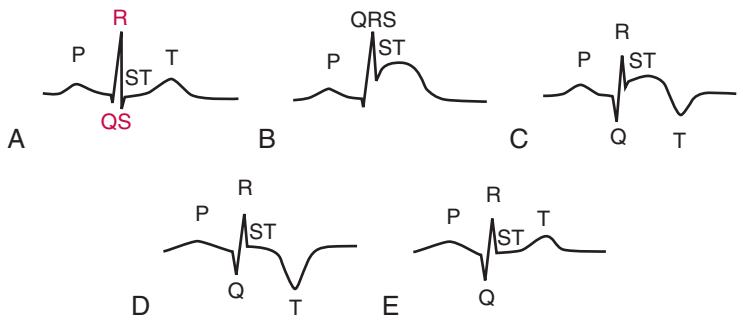

Figure 47-4 Electrocardiogram, serial tracing of a patient with an acute myocardial infarction. The sequence is (A) normal; (B) hours after infarction, the ST segment becomes elevated; (C) hours to days later, the T wave inverts and the Q wave becomes larger; (D) days to weeks later, the ST segment returns to near normal; and (E) weeks to months later, the T wave becomes upright again, but the large Q wave may remain.

occlusion of only one of the three large coronary vessels or branches occurs. The resulting impaired contractile performance of that segment occurs within seconds and is initially restricted to the affected segment(s). Myocardial ischemia and subsequent infarction usually begin in the endocardium and spread toward the epicardium.[319] The extent of myocardial injury reflects (1) the extent of occlusion, (2) the needs of the area deprived of perfusion, and (3) the duration of the imbalance in coronary supply. Irreversible cardiac injury consistently occurs in animals when the occlusion is complete for at least 15 to 20 minutes. Most damage occurs within the first 2 to 3 hours. Restoration of flow within the first 60 to 90 minutes evokes maximal salvage of tissue, but benefits of increased survival are possible up to 4 to 6 hours. In some situations, the restoration of coronary perfusion even later is of benefit.[330] The percentage of tissue at risk of necrosis (infarct size) depends on the amount of antegrade flow, the existing collateral flow, which is highly variable and difficult to predict, and the metabolic needs of the tissue.[246,328,366]

In almost all instances, the left ventricle is affected by AMI. However, with right coronary and/or circumflex occlusion, the right ventricle can also be involved, and there is a clinical syndrome in which damage to the right ventricle predominates and is the major determinant of hemodynamics. Coronary thrombi will undergo spontaneous lysis, even if untreated, in about 50% of cases within 10 days. However, for patients with STE AMI, opening the vessel earlier with clot-dissolving agents (thrombolysis) and/or percutaneous intervention can often save myocardium and lives (Figure 47-5). At present, immediate percutaneous intervention (PCI) with

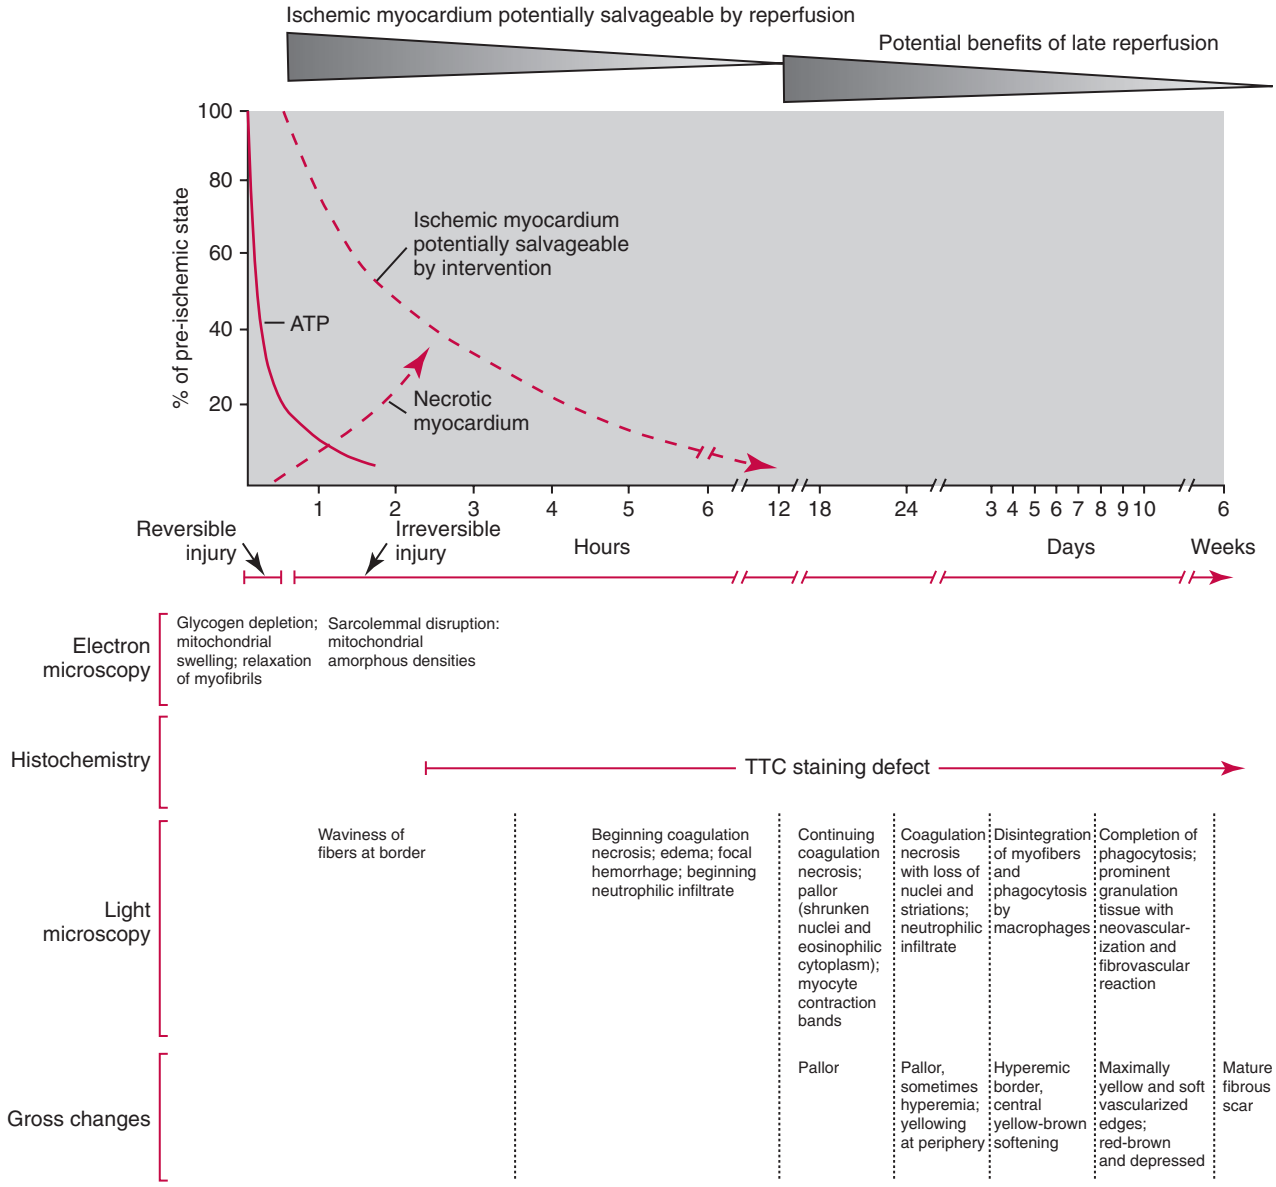

Figure 47-5 Temporal sequence of myocardial infarction. *(From Antman EM, Braunwald E. Acute myocardial infarction. In: Braunwald E, ed. Heart disease: a textbook of cardiovascular medicine, 5th edition. Philadelphia, Pa: WB Saunders, 1997:1189.)*

stenting is the preferred therapy for STE AMI. However, many hospitals cannot or do not offer urgent PCI 24 hours a day, 365 days per year. Thus clot-dissolving medications still play a major role in the treatment of these patients. In addition, it is now apparent that urgent but not necessarily immediate invasive revascularization benefits those with NSTEMI.[67] These individuals usually have only partial coronary occlusion and smaller amounts of cardiac damage acutely. However, untreated, repetitive episodes often eventually damage larger amounts of myocardium, leading to increased morbidity and mortality over time. Treatments such as newer anticoagulants and antiplatelet and anti-inflammatory agents, in conjunction with coronary revascularization, save lives in this group.

The prognosis for patients with ischemia but without necrosis is far better. Some studies based on biomarkers would suggest that in patients with no troponin elevation, interventional therapies may be harmful.[395] A major determinant of mortality and morbidity is the amount of myocardial damage that occurs. With STE AMI, most damage is acute, whereas with NSTEMI, damage may evolve as the result of repetitive events over many months; thus, interrupting the process improves survival.

Precipitating Factors

In many patients with AMI, no precipitating factor can be identified. Studies have noted the following patient activities at the onset of AMI: (1) heavy physical exertion, 13%; (2) modest or usual exertion, 18%; (3) surgical procedure, 6%; (4) rest, 51%; and (5) sleep, 8%. Exertion before infarction is somewhat more common among patients without preexisting angina than in those who have a history of angina.[342]

Causes of infarction other than acute atherothrombotic coronary occlusion have been identified. For example, prolonged vasospasm can induce infarction, and spontaneous dissection is becoming more commonly appreciated, especially in pregnant females.[67] In addition, it is now clear that some patients, particularly women, can have acute infarction with normal-appearing angiographic coronary arteries.[247] Other conditions (Box 47-1) can also cause the death of cardiomyocytes, leading to a biochemical signal (such as increased circulating concentrations of cardiac troponins) of myocyte damage, but these conditions should not be confused with myocardial infarction.[176] Pulmonary embolism (PE) is another common cause of biochemical elevations that is caused by right ventricular damage related to acute increases in wall stress and reduced subendocardial perfusion.[132,170,216]

Chronobiology

There is a pronounced periodicity for the time of onset of STE AMI.[68,115,342] Often an AMI occurs in the morning hours soon after arising; this is a period of (1) increasing adrenergic activity, (2) increased plasma fibrinogen levels, (3) increased inhibition of fibrinolysis, and (4) increased platelet adhesiveness. Studies have demonstrated that the early morning peak in MI parallels the peak incidence of death from ischemic heart disease, which occurs at about 8 AM to 9 AM. A second peak has been noted at approximately 5 PM. Diurnal differences affect many physiologic and biochemical parameters; the early morning hours are associated with rises in plasma catecholamines and cortisol and increases in platelet aggregability. Tissue plasminogen activator activity is low and plasminogen activator inhibitor activity is high during the early morning hours. Thus it is possible that some cyclic aspects of combined vasospastic, prothrombotic, and fibrinolytic factors, in the setting of preexisting atherosclerosis, lead to AMI. NSTEMI does not exhibit this diurnal pattern.

Prognosis

STE and non-STE infarctions have distinctly different short-term prognoses. STE AMI is associated with higher early and in-hospital mortality. It is said that mortality associated with STE AMI can occur up to 6 months post event, but the vast majority (at least two thirds) occur during the first 30 or 40 days. It is this risk that coronary recanalization seems to benefit. NSTE AMI is associated with lower acute mortality and complication rates but a longer period of vulnerability to reinfarction and death. As a result, 1- to 2-year survival rates

BOX 47-1 Elevation of Troponins Without Overt Ischemic Heart Disease

- Trauma (including contusion, ablation, pacing, and cardioversion)
- Congestive heart failure—acute and chronic*
- Aortic valve disease and HOCM with significant LVH*
- Hypertension
- Hypotension, often with arrhythmias
- Postoperative noncardiac surgery patients who seem to do well*
- Renal failure*
- Critically ill patients, especially those with diabetes, respiratory failure*
- Drug toxicity (e.g., Adriamycin, 5-FU, herceptin, snake venoms)*
- Hypothyroidism
- Coronary vasospasm, including apical ballooning syndrome
- Inflammatory disease (e.g., myocarditis, parvovirus B19, Kawasaki disease, sarcoid, smallpox vaccination)
- Post-PCI patients whose condition appears to be uncomplicated*
- Pulmonary embolism, severe pulmonary hypertension*
- Sepsis*
- Burns, especially if TBSA > 30%*
- Infiltrative disease, including amyloidosis, hemochromatosis, sarcoidosis, and scleroderma*
- Acute neurologic disease, including CVA, subarachnoid bleeds*
- Rhabdomyolysis with cardiac injury
- Transplant vasculopathy
- Vital exhaustion

*Designation implies that prognostic information has been reported.
CVA, cerebrovascular accident; *5-FU,* 5-fluorouracil; *HOCM,* hypertrophic cardiomyopathy; *LVH,* left ventricular hypertrophy; *PCI,* percutaneous intervention; *TBSA,* total body surface area.

are similar to those for STEMI.[67] This is why intervention has been so effective in this group.

Clinical History

The clinical history remains of substantial value in establishing a diagnosis.[330] A prodromal history of angina can be elicited in 40 to 50% of patients with AMI. Among patients with AMI who present with prodromal symptoms, approximately one third have had symptoms from 1 to 4 weeks before hospitalization; in the remaining two thirds, symptoms predate admission by a week or less, with one third of patients having had symptoms for 24 hours or less.

In most patients the pain of AMI is severe, but it is rarely intolerable. The pain may be prolonged, lasting up to 30 minutes. The discomfort is described as constricting, crushing, oppressing, or compressing; often the patient complains of something sitting on or squeezing the chest. Although usually described as a squeezing, choking, viselike, or heavy pain, it may be characterized as a stabbing, knifelike, boring, or burning discomfort. The pain is usually retrosternal in location, spreading frequently to both sides of the chest, favoring the left side. Often the pain radiates down the left arm. Some patients note only a dull ache or numbness in the wrists in association with severe substernal discomfort. In some instances, the pain of AMI may begin in the epigastrium, simulating a variety of abdominal disorders; this often causes MI to be misdiagnosed as indigestion. In other patients, the discomfort of AMI radiates to the shoulders, upper extremities, neck, and jaw, again usually favoring the left side. In patients with preexisting angina, the pain of infarction usually resembles that of the angina pain with respect to features and location. However, it is generally much more severe, lasts longer, and/or is not relieved by rest and nitroglycerin.

Older individuals, patients with diabetes, and women often present atypically. For example, among individuals older than 80 years, less than 50% of those with AMI will have chest discomfort at the time of AMI. Sometimes these patients will present with shortness of breath, fatigue, or even confusion. The pain of AMI may have disappeared by the time physicians first encounter the patient (or the patient reaches the hospital), or it may persist for a few hours.

Myocardial Changes Following Acute Myocardial Infarction

Figure 47-5 shows the temporal sequence of early biochemical, histochemical, and histologic findings after the onset of AMI. On gross pathologic examination, AMI can be divided into subendocardial (nontransmural) infarctions and transmural infarctions.[11] In the former, necrosis involves the endocardium, the intramural myocardium, or both without extending all the way through the ventricular wall to the epicardium. In the latter, myocardial necrosis involves the full thickness of the ventricular wall. The histologic pattern of necrosis may differ: contraction band injury occurs almost twice as often in nontransmural infarctions as in transmural infarctions. Unfortunately, the pathologic changes correlate poorly with clinical, ECG, and biochemical markers of necrosis, which is why those terms are no longer used clinically. Statistically, patients are more apt to have STE MI Q waves on the ECG and larger biochemical signals when the infarction is transmural pathologically.

Ultrastructural (Electron Microscopic) Changes in Myocardium

In experimental infarction, the earliest ultrastructural changes in cardiac muscle following occlusion of a coronary artery, noted within 20 minutes by electron microscopy, consist of reduction in the size and number of glycogen granules, intracellular edema, and swelling and distortion of the transverse tubular system, the sarcoplasmic reticulum, and the mitochondria. These early changes are partially reversible. Changes after 60 minutes of occlusion include myocardial cell swelling; mitochondrial abnormalities, such as swelling and internal disruption; development of amorphous, flocculent aggregation and margination of nuclear chromatin; and relaxation of myofibrils. After 20 minutes to 2 hours of ischemia, changes in some cells become irreversible, and progression of these alterations occurs; additional changes include swollen sacs of the sarcoplasmic reticulum at the level of the A band, greatly enlarged mitochondria with few cristae, thinning and fractionation of myofilaments, disorientation of myofibrils, and clumping of mitochondria. Cells irreversibly damaged by ischemia are usually swollen, with an enlarged sarcoplasmic reticulum. Defects in the plasma membrane may appear, and the mitochondria are fragmented. Many of these changes become more intense when blood flow is restored.

Histologic (Light Microscopic) Changes in Myocardium

Although it was previously believed that no light microscopic changes could be seen in infarcted myocardium until 8 hours after interruption of blood flow, in some infarcts a pattern of wavy myocardial fibers may be seen 1 to 3 hours after onset, especially at the periphery of the infarct.[11] After 8 hours, edema of the interstitium becomes evident, as do increased fatty deposits in the muscle fibers, along with infiltration of neutrophilic polymorphonuclear leukocytes and red blood cells.

By 24 hours, clumping of the cytoplasm and loss of cross-striations are seen, with the appearance of irregular cross-bands in the involved myocardial fibers. The nuclei sometimes even disappear. Myocardial capillaries in the involved region dilate, and polymorphonuclear leukocytes accumulate, first at the periphery and then in the center of the infarct. During the first 3 days, the interstitial tissue becomes edematous. Generally, on about day 4 after infarction, removal of necrotic fibers by macrophages begins, again commencing at the periphery. By day 8, the necrotic muscle fibers have become dissolved; by about 10 days, the number of polymorphonuclear leukocytes is reduced, and granulation tissue first appears at the periphery. Removal of necrotic muscle cells continues until the fourth to sixth week following infarction, by which time much of the necrotic myocardium has been

removed. This process continues, along with increasing collagenization of the infarcted area. By the sixth week, the infarcted area usually has been converted to a firm connective tissue scar with interspersed intact muscle fibers.

Gross Changes in Myocardium

Gross alterations of the myocardium are difficult to identify until at least 6 to 12 hours following the onset of necrosis.[11] However, several histochemical approaches have been used to identify zones of necrosis that can be observed after only 2 to 3 hours. Initially, the myocardium in the affected region may appear pale and slightly swollen. By 18 to 36 hours after onset of the infarct, the myocardium is tan or reddish purple (because of trapped erythrocytes). These changes persist for approximately 48 hours; the infarct then turns gray, and fine yellow lines, secondary to neutrophilic infiltration, appear at its periphery. This zone gradually widens and during the next few days extends throughout the infarct.

Eight to 10 days following infarction, the thickness of the cardiac wall in the area of the infarct is reduced as necrotic muscle is removed by mononuclear cells. The cut surface of an infarct of this age is yellow and is surrounded by a reddish purple band of granulation tissue that extends through the necrotic tissue by 3 to 4 weeks. Over the next 2 to 3 months, the infarcted area gradually acquires a gelatinous, gray appearance, eventually converting into a shrunken, thin, firm scar that whitens and firms progressively with time. This process begins at the periphery of the infarct and gradually moves centrally. In addition, more hemorrhage is seen in the area of damage because of the use of potent thrombolytic and anticoagulant agents.

Development and Progression of Atherosclerosis[229]

Intrinsic to modern day understanding of ischemic heart disease and to the intense interest in the development of markers of inflammation is the concept that atherosclerosis is a chronic inflammatory disease. The concept is that some event damages the endothelium of blood vessels, which facilitates the egress of lipid into the subendothelial space. Putative injurious stimuli include turbulent flow in a blood vessel, which could occur for example because of hypertension or a noxious metabolite from a lipid fraction. This damage tends to occur at branch points of blood vessels. Regardless of the initial stimulus, once damaged, low-density lipoprotein (LDL) can cross into the vessel wall more easily in a nicotinamide adenine dinucleotide phosphate (NADPH) oxidase–mediated fashion. Whether minimal oxidation facilitates that egress or whether it occurs once the LDL is within the vessel wall is unclear, but a minimal degree of oxidation once in the vessel wall facilitates the egress of smooth muscle cells from the media of the vessel and macrophages that ingest cholesterol, hence the rationale for the measurement of oxidized lipids in blood. The process of atherosclerosis progresses slowly with involvement of lymphocytes, monocytes, macrophages, and smooth muscle cells. The dynamic within a given plaque may vary, but there clearly is an inflammatory milieu, in part mediated by substances such as CD40 ligand, which can be measured directly or indirectly as C-reactive protein (CRP). Interleukins-1, -6, -8, and -18 also participate to various extents as part of this chronic inflammatory process. This process involves adherence of white blood cells to the damaged endothelial surface with subsequent degranulation and elaboration of myeloperoxidase. A procoagulant component is due predominantly to the presence of tissue factor, which is localized immediately under the cap of the plaque. Intermittent instability is noted because of inflammatory products within the plaque that release chemicals, such as metalloproteinases. Initially the plaque expands by stretching the adventitia through a process of small ruptures with release of procoagulant and proinflammatory materials and then remodeling over time as anti-inflammatory and anticoagulant and thrombolytic substances are elaborated. This process of stretching the adventitia preserves the lumen such that by the time luminal encroachment occurs, there is a very large plaque burden.[136]

A categorization of plaques has been proposed to facilitate identification of those at risk of rupture that could lead to an acute event. It is acknowledged that the propensity for a plaque to rupture probably reflects a systemic predilection rather than a local one. Thus for a given patient at risk, there likely are many plaques that are metabolically at risk of rupture at any given time.[283,284] High-risk plaques have

1. An active inflammatory environment that not only may be intrinsic but may be stimulated additionally by systemic infection.
2. A thin fibrous cap on the endothelial surface with a large lipid core that is filled with procoagulant substances, predominantly tissue factor.
3. Endothelial denudation and fissuring caused by the elaboration of metalloproteinases.
4. Local high shear stress, usually because they are severe, at branch points in the vessel.

Events likely occur because of superimposed thrombosis. This can be the result of erosions on the surface of the plaque or more often rupture of the plaque at its edges, where the cap is thinnest and most of the metalloproteinases reside. If rupture induces total thrombotic occlusion, the event is usually an STE AMI. If lesser degrees of occlusion occur, an NSTE AMI or UA may ensue. One of the causes that may participate in subtotal occlusive plaque rupture involves platelets and abnormal coronary vasomotion. It is known that diseased coronary arteries respond atypically to many stimuli, often constricting rather than dilating. Because the cross-sectional area of a vessel is related to the square of the radius, even modest amounts of constriction can markedly increase the extent of occlusion. Whether constriction occurs first, leading to changes of coronary flow and platelet aggregation on the plaque, or whether platelets stick and cause the aggregation, is not certain, but these processes reinforce one another. Platelets secrete vasoconstricting substances in response to a denuded area, which expresses cell adhesion molecule (CAM) receptors. This, in addition to stagnant blood flow, will cause platelets and white blood cells to adhere to the surfaces of vessels. It appears likely that platelets adhere

and enhance vasoconstriction and then break off, causing small vessel emboli, sometimes in association with plaque debris and sometimes without. These processes, in addition to a reduction in flow, can lead to necrosis or at least recurrent ischemia. It is apparent that the process that eventually leads to acute events involves a systemic propensity to platelet aggregation and inflammation, because effluent flowing from the nonculprit vessel (distant from the putative coronary lesion causing the acute event) elaborates inflammatory mediators (e.g., myeloperoxidase) similar to those observed from the affected vessel. Finally, necrosis when present stimulates an acute-phase reaction and inflammation. Given this pathophysiology, many therapies are now oriented toward inhibition of thrombosis, fibrinolysis, platelet aggregation, and inflammation. Many inflammatory markers are used diagnostically and for assessment of therapeutic efficiency.

Diagnosis of Acute Myocardial Infarction

The diagnosis of AMI established by the World Health Organization in 1986 included biomarkers as an integral part of the disorder and required that at least two of the following criteria be met: (1) a history of chest pain, (2) evolutionary changes on the ECG, and/or (3) elevations of serial cardiac markers to a level two times the normal value. However, over time, it became rare for a diagnosis of AMI to be made in the absence of biochemical evidence of myocardial injury. A 2000 European Society of Cardiology/American College of Cardiology (ESC/ACC) consensus conference[66] updated in 2007 (Global Task Force)[372] codified the role of markers by advocating that the diagnosis should be regarded as evidence of myocardial injury based on markers of cardiac damage in the appropriate clinical situation (Box 47-2).[372] The criteria for diagnosis of an established MI are listed in Box 47-3. The guidelines thus recognized the reality that neither the clinical presentation nor the ECG had adequate sensitivity and specificity. This guideline does not suggest that all elevations of these biomarkers should elicit a diagnosis of AMI—only those associated with appropriate clinical and ECG findings (see discussion later in this chapter). When elevations that are not caused by acute ischemia occur, the clinician is obligated to search for another cause for the elevation.[176,181,401,406] The criteria suggested for use with these markers by the Biochemistry Panel of the ESC/ACC Committee are listed in Box 47-4.[181] In the 2007 revision of the guidelines, several types of AMI were recognized, including the spontaneous type, which is associated with plaque rupture or erosion, and the type associated with fixed or transient coronary abnormalities but not thrombotic occlusion. These are discussed in greater detail in the following paragraphs. It is also recognized that one can have a classic AMI and succumb before markers are obtained or become elevated, and cardiac injury can occur in association with cardiac procedures.[372] In addition, criteria for use with coronary interventions and bypass surgery were suggested.

ECG Findings

At one time, the initial ECG was thought to be diagnostic of AMI in about 50% of patients.[179] As the frequency of STE AMI has diminished and the diagnosis has been made with greater and greater sensitivity, this percentage has been greatly reduced. Serial tracings are helpful for STE AMI but not for what is now almost 70% of AMIs that are known as non-STE (NSTE) AMIs. The classic ECG changes of an STE AMI are ST segment elevation, which often evolves to the

BOX 47-2 Criteria for the Definition of Acute Myocardial Infarction

1. Detection of rise and/or fall of cardiac biomarkers (preferably troponin) above the 99th percentile of the upper reference limit, together with evidence of ischemia with at least one of the following:
   a. Ischemic symptoms
   b. Electrocardiogram (ECG) changes of new ischemia [new ST-T changes or new left bundle branch block (LBBB)]
   c. Development of pathologic Q waves on the ECG
   d. Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality

From reference 372.

BOX 47-3 Diagnosis of Established Myocardial Infarction

Any one of the following criteria satisfies the diagnosis for established MI:

1. Development of new pathologic Q waves on serial electrocardiograms (ECGs). The patient may or may not remember previous symptoms. Biochemical markers of myocardial necrosis may have normalized, depending on the length of time that has passed since the infarct developed.
2. Pathologic findings of a healed or healing myocardial infarction (MI).

BOX 47-4 Clinical Classification of Different Types of Myocardial Infarction

Type 1: spontaneous myocardial infarction related to ischemia due to a primary coronary event, such as plaque fissuring or rupture

Type 2: myocardial infarction secondary to ischemia due to imbalance between oxygen demand and supplies (e.g., coronary spasm)

Type 3: sudden cardiac death with symptoms of myocardial ischemia, accompanied by new ST elevation or left bundle branch block (LBBB), or verified coronary thrombus by angiography, but with death occurring before blood samples could be obtained

Type 4: myocardial infarction associated with percutaneous innervation (PCI)

Type 5: myocardial infarction associated with coronary artery bypass grafting (CABG)

From reference 372.

development of Q waves if intervention is not provided (see Figure 47-4). Pericarditis, some normal variants, and transient causes that may result in myocardial injury such as myocarditis are well described and on occasion can mimic the changes of AMI. Most NSTE AMIs present as ST segment depression, with or without T-wave changes; as T-wave changes alone; or on occasion in the absence of any ECG findings. Those with ST segment change have a substantially worse prognosis.[372]

In some patients, the clinical history and ECG may be definitive. In others, they may not be as clear. Many other clinical aspects might suggest acute ischemia as the origin of a given biomarker elevation. For example, the finding of significant coronary obstructive lesions, especially in a pattern suggestive of recent plaque rupture, is highly suggestive. At times, a positive stress test with or without imaging may be what helps in making the diagnosis. However, if the clinical situation is not suggestive, other sources for cardiac injury should be sought.

BIOMARKERS IN ACUTE CORONARY SYNDROME

Analytical Considerations

Myocardial damage detected by elevations of cardiac troponin (cTn) are almost invariably associated with impaired clinical outcomes for patients. This statement summarizes more than 20 years of analytical and clinical investigations pertaining to the clinical utility of cTnI and cTnT. This section of the chapter will focus on cTn biochemistry; the analytical aspects of assays used to measure cTn in whole blood, serum, and plasma; preanalytical and analytical specifications that manufacturers of assays need to strive to optimize; reference (normal) limit determinations; and point-of-care (POC) testing strategies.

Biochemistry

The contractile proteins of the myofibril include the three troponin regulatory proteins (Figure 47-6).[85,196,244] The troponins are a complex of three protein subunits: troponin C (the calcium-binding component), troponin I (the inhibitory component), and troponin T (the tropomyosin-binding component). The subunits exist in a number of isoforms. The distribution of these isoforms varies between cardiac muscle and slow and fast twitch skeletal muscle. Only two major isoforms of troponin C are found in human heart and skeletal muscle. These are characteristic of slow and fast twitch skeletal muscle. The heart isoform is identical to the slow twitch skeletal muscle isoform, thus the reason why cTnC was never developed as a cardiac specific biomarker. Isoforms of cardiac-specific troponin T (cTnT) and cardiac-specific troponin I (cTnI) also have been identified and are the products of unique genes.[62,63,94,194] Troponin is localized primarily in the myofibrils (94 to 97%), with a smaller cytoplasmic fraction

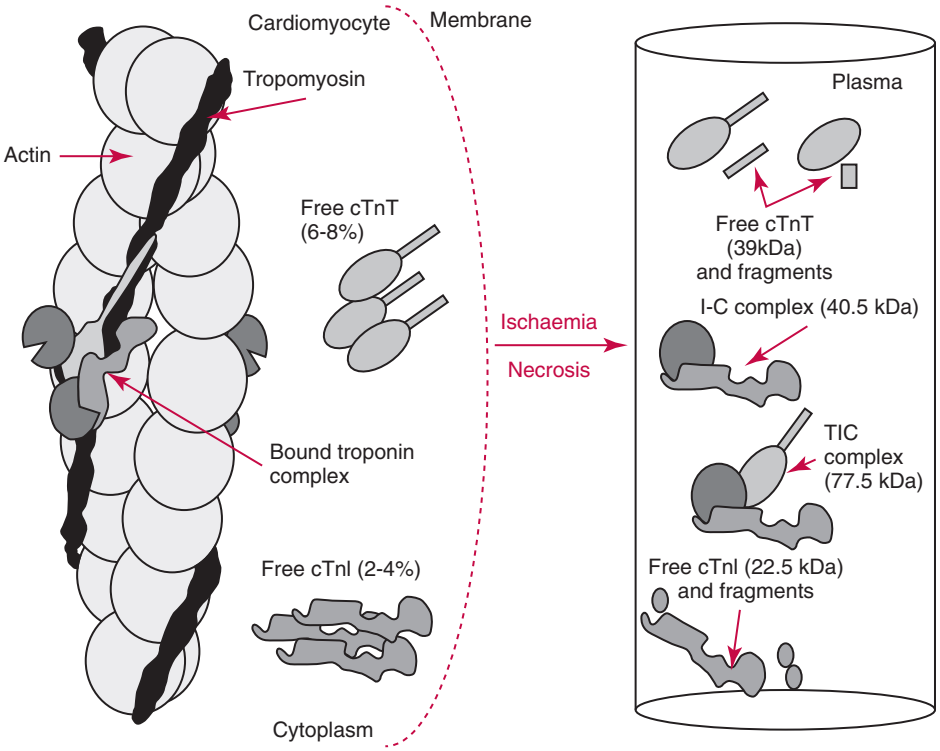

Figure 47-6 Structure of cardiac troponin complex and troponin forms released following myofibril necrosis. *(From Gaze DC, Collinson PO. Multiple molecular forms of circulating cardiac troponin: analytical and clinical significance. Ann Clin Biochem 2008;45:349-59. Figure courtesy Paul Collinson.)*

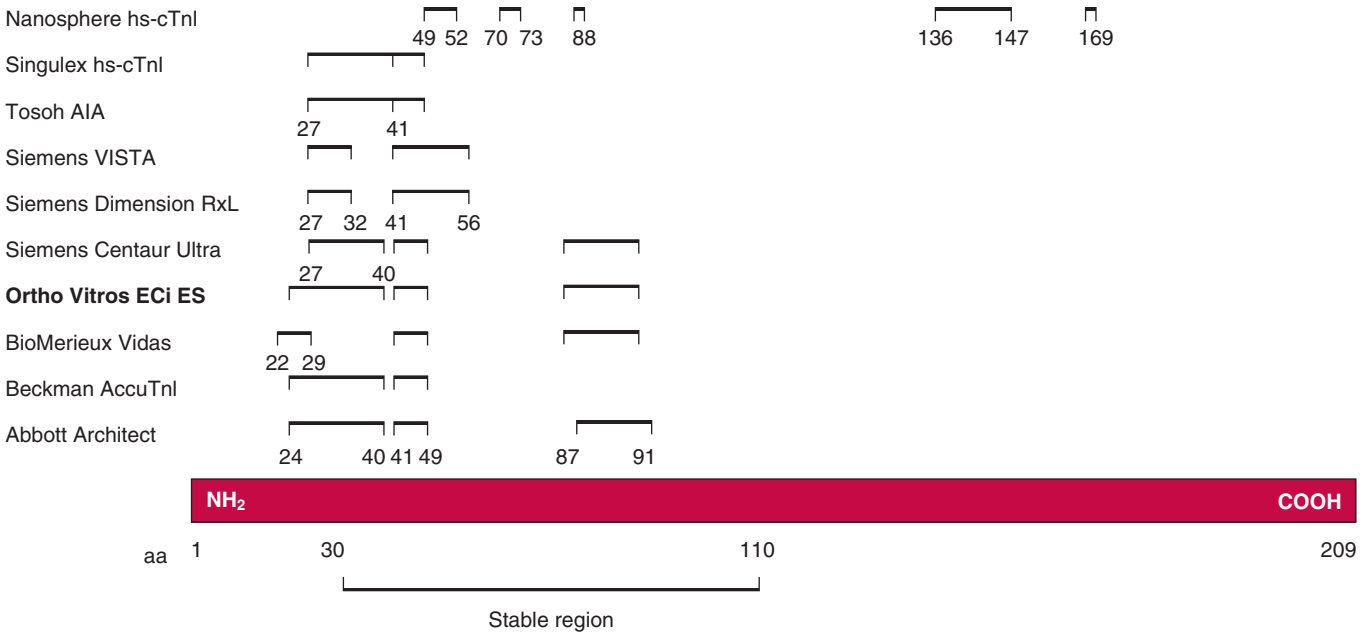

Figure 47-7 Amino acid sequence of cardiac troponin I (cTnI), with identification of epitopes used by antibodies in cTnI assays. Antibodies are named in the boxes that have attached arrows. *(Figure courtesy David Gaze and Paul Collinson.)*

(3 to 6%).[122] Some experts in the field think that 100% of cTn is myofibril bound and that the "cytoplasmic fraction" represents a more easily mobilizable fraction, rather than representing a different cellular localization.

cTnI and cTnT have different amino acid sequences from the skeletal isoforms and are encoded by unique genes. Human cTnI has an additional 31-amino-acid residue on the amino terminal end compared with skeletal muscle TnI, giving it complete cardiac specificity (Figure 47-7). Only one isoform of cTnI has been identified. cTnI has never been shown to be expressed in normal, regenerating, or diseased human or animal skeletal muscle.[62] cTnT is encoded for by a different gene than the one that encodes for skeletal muscle isoforms. An 11 amino acid amino-terminal residue gives this marker unique cardiac specificity. However, during human fetal development, in regenerating rat skeletal muscle, and in diseased human skeletal muscle, small amounts of cTnT are expressed as one of four identified isoforms in skeletal muscle.[10,63,335] In humans, cTnT isoform expression has been demonstrated in skeletal muscle specimens obtained from patients with muscular dystrophy, polymyositis, dermatomyositis, and end-stage renal disease.[63,255,298,320,371] Thus, care is necessary to choose antibody pairs for the cTnT assay that do not detect these re-expressed isoforms.[130,217]

A substantial body of evidence shows that following myocardial injury or because of genetic disposition, multiple forms of cTn are elaborated both in tissue and in blood (Figure 47-8).[193,194,406] These include the following: T-I-C ternary complex, IC binary complex, and free I; multiple modification of these three forms can occur, involving oxidation, reduction, phosphorylation, and dephosphorylation, as

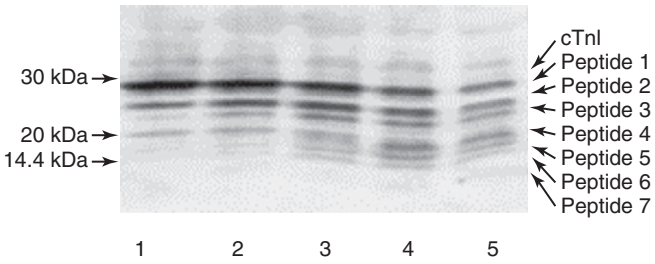

Figure 47-8 Western blot analysis of endogenous cardiac troponin I (cTnI) proteolysis in human heart tissue visualized with monoclonal anti-cTnI antibody. Protein extracts from tissue samples were incubated at 37 °C for 0 h (lane 1), 2 h (lane 2), 5 h (lane 3), 8 h (lane 4), and 20 h (lane 5), separated by 10%–20% gradient SDS-gel electrophoresis, transferred to a nitrocellulose membrane, and visualized by MAb 19C7. The apparent molecular masses and peptides are marked by arrows. *(From Katrukha AG, Bereznikova AV, Filtaov VL, Esakova TV, Kolosova OV, Pettersson K, et al. Degradation of cardiac troponin I: implication for reliable immunodetection. Clin Chem 1998;44: 2433-40.)*

well as both C- and N-terminal degradation. Depending on the selection of antibodies used to detect cTnI, different antibody configurations can lead to a substantially different recognition pattern (Figure 47-9).[85] The conclusions derived from these observations are that assays need to be developed in which the antibodies recognize epitopes in the stable region of cTnI and, ideally, demonstrate an equimolar response to the different cTnI forms that circulate in the blood.

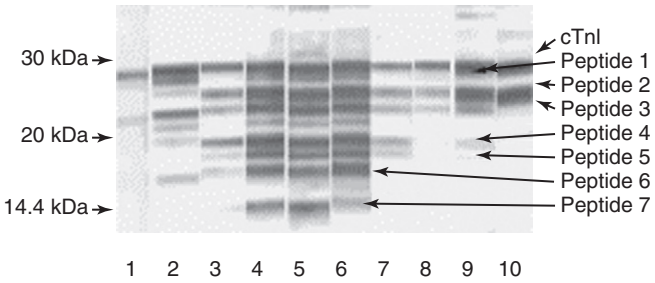

Figure 47-9 Western blot analysis of endogenous proteolytic fragments of cardiac troponin I (cTnI) antibodies. Human cardiac tissue was incubated for 8 h at 37 °C. Proteins were extracted and separated using 10–20% gradient SDS-gel electrophoresis, and then transferred to a nitrocellulose membrane. Bands corresponding to cTnI proteolytic peptides were visualized by different MAbs: lane 1, 10B11; lane 2, 4G6; lane 3, 10F4; lane 4, 19C7; lane 5, 414; lane 6, 16A11; lane 7, 18H7; lane 8, 10B7; lane 9, 6F9; lane 10, 7F4. The apparent molecular masses and peptides are marked by arrows. *(From Katrukha AG, Bereznikova AV, Filtaov VL, Esakova TV, Kolosova OV, Pettersson K, et al. Degradation of cardiac troponin I: implication for reliable immunodetection. Clin Chem 1998;44: 2433-40.)*

Immunoassays

Cummins and coworkers were the first to develop an RIA to measure cTnI, using polyclonal anti-cTnI antibodies.[94] The first monoclonal enzyme-linked immunosorbent assay (ELISA), an anti-cTnI antibody–based immunoassay, was described by Bodor and Ladenson.[61] Numerous manufacturers have now described the development of monoclonal antibody–based diagnostic immunoassays for the measurement of cTnI in serum.[14,17,18,22,28,29,34,37,85,87,90,161,195] As shown in Table 47-1, numerous assays have been approved by the U.S. Food and Drug Administration (FDA) for patient testing within the United States on central laboratory and POC testing platforms. In addition to these quantitative assays, several assays have been cleared by the FDA for the qualitative determination of cTnI. Further development has led to the design of research (prototype) high-sensitivity cTn (hs-cTn) I and T assays. In practice, two obstacles limit the ease of switching from one assay to another in clinical practice or research. First, no primary reference cTnI material is currently available for manufacturers to use in standardizing cTnI assays. Second, assay concentrations fail to be consistent because cTnI circulate in its various forms and the different antibodies use in the available assays recognize different epitopes of cTnI.

The cTnI standardization subcommittee of the American Association for Clinical Chemistry (AACC) in collaboration with the National Institute of Standards and Technology (NIST) developed a cTnI reference material (SRM #2921) that is a TnC-cTnI-cTnT complex purified from human heart under nondenaturing conditions.[74] A cTnI value was assigned by a combination of reversed-phase liquid chromatography with ultraviolet detection and amino acid analysis. However, because this material demonstrated commutability with only 50% of current cTnI assays, it is of limited value for assay harmonization of current assays and cannot be used as a common calibrator. Although standardization of assays remains elusive, differences of cTnI concentrations reported by studied assays has been narrowed from a 20-fold difference to a twofold to threefold difference using the SRM 2921. Further, this material allows for traceability to a common reference material. It appears that the only way to achieve complete standardization for cTnI would be for manufacturers to agree to use the same antibodies showing similar specificity for the cTnI molecule; this would also overcome matrix effects with a serum-based common reference material for calibration.

Several adaptations of the Roche cTnT immunoassay have been described over the years.[383,405] The current FDA-cleared assay available worldwide involves two monoclonal, anti–cardiac troponin T antibodies. Skeletal muscle TnT is no longer a potential interferant, as was found in the first-generation ELISA cTnT assay. In contrast to cTnI, no standardization bias exists for cTnT, because the same antibodies (M11, M7) are used in the central laboratory and in POC assay systems.

Assay Specifications

In 2001 and 2004, the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) Committee on Standardization of Markers of Cardiac Damage (C-SMCD) recommended quality specifications for cTn assays.[300,301] These specifications were intended for use by the manufacturers of commercial assays and by clinical laboratories utilizing cTn assays. The overall goal was to attempt to establish uniform criteria so that all assays could be evaluated objectively for their analytical qualities and clinical performance. Both analytical and preanalytical factors were addressed and are in the process of being updated with an expected publication date of 2012. An adequate description of the analytical principles, method design, and assay components should include the following: (1) antibody specificity and epitope locations identified need to be delineated; (2) epitopes located on the stable part of the cTnI molecule should be a priority; (3) assays need to clarify whether different cTnI forms (e.g., binary vs. ternary complex) are recognized in an equimolar fashion by the antibodies used; (4) specific relative responses need to be described for each of the cTnI forms (free cTnI, the 1-C binary complex, the T-I-C ternary complex, and oxidized, reduced, and phosphorylated isoforms of the three cTnI forms); (5) the effects of different anticoagulants on binding of cTnI need to be addressed; and (6) the source of material used to calibrate cTn assays, specifically for cTnI, should be reported (Box 47-5).

Defining Normal Reference Limits for Cardiac Troponin

Advancements in cTn assay technology have created a conundrum for clinicians and laboratory scientists, who must determine which assays are best for optimal patient care.

BOX 47-5 Quality Specifications—Cardiac Troponin Assays

Analytical Factors
1. Antibody specificity—recognize epitopes as part of molecule and equimolar for all forms
2. Influence of anticoagulants
3. Calibration against natural form of molecule
4. Defined type of material useful for dilutions
5. Demonstrated recovery and linearity of method
6. Described detection limit and imprecision (10% CV)
7. Addressing interferants (i.e., RF, heterophile antibodies)

Preanalytical Factors
1. Storage time and temperature conditions
2. Centrifugation effects—gel separators
3. Serum-plasma—WB correlations

CV, Coefficient of variation; *RF,* rheumatoid factor; *WB,* whole blood.
Adapted from Panteghini M, Gerhardt W, Apple FS, Dati F, Ravkilde J, Wu AH. Quality specifications for cardiac troponin assays. Clin Chem Lab Med 2001;39:174-8.

Unfortunately, few resources are available to guide the medical and scientific communities in this regard. International guidelines have defined an increased cTn above the 99th percentile limit as an abnormal result, as described in the clinical section.[17,273,372] What is lacking, unfortunately, is an approach to define the 99th percentile limit across the heterogeneity of assays. In spite of evidence-based literature demonstrating that cTn concentrations tend to increase in individuals older than 60 years, likely because of unrecognized comorbidities, 99th percentile reference limits are often determined across wide age ranges using subjects as old as 80 years (convenience samples).[14,21,116] Further frustrating the problem of selecting relevant reference subjects is the fact that in clinically defined normal individuals without known cardiovascular disease, increased cTn concentrations are indicative of a significantly higher risk of death. Given such problems, most laboratories (1) accept the manufacturer's reference limit from the FDA-cleared package insert; (2) perform an underpowered normal range study to establish a reference limit; or (3) accept a cutoff value published in the literature.

Consensus guidelines from the Global Task Force for the Universal Definition of Myocardial Infarction and the National Academy of Clinical Biochemistry (NACB) plus the updated American College of Cardiology/American Heart Association and Epidemiology[133,240] guidelines have recommended that, in patients who present with ischemic symptoms, at least 1 cTn concentration higher than the 99th percentile value during the first 24 hours after onset of symptoms indicates myocardial necrosis. If this elevation occurs in a clinical situation consistent with myocardial infarction (MI), that diagnosis should be made (see Box 47-2). It is recommended that cTn assays with appropriate quality control and optimal total imprecision [coefficient of variation (CV) ≤10%] at the 99th percentile limit are preferred.[86,301] Better imprecision at low cTn concentrations appears to improve the value of cTn as a diagnostic and risk indicator. Use of cTn assays with intermediate imprecision (10 to 20% CV) at the 99th percentile, however, does not lead to significant patient misclassification when serial cTn results are interpreted.

A challenge that arises as the FDA clears improved cTn assays with higher analytical sensitivity for use in laboratory practice is determining how these new assays compare with the older assays. Diagnostic sensitivities using specimens collected at presentation for detection of myocardial infarction (MI) have improved from 15 to 35% for early cTn assays to 50 to 75% for contemporary assays (Table 47-2). Unfortunately, definitive data about how long it takes to totally exclude AMI are still lacking. Over the past 10 years, the science of reagent and technology formulation of cTn assays has allowed measurement of this biomarker with greatly improved precision at concentrations approaching the 99th percentile limit of an assay. The goal is to better define the clinical playing field for assays used to assist the diagnosis of MI and to better stratify patients by risk of adverse events. To summarize these discussions, the optimal goals that the FDA would like to achieve include the following: (1) to transition from the current practice of approving assays based on

TABLE 47-2 Diagnostic Accuracy of Current cTn Assays 99th Percentile at Presentation of Patient to Hospital

	Sensitivity	Specificity
2003 Collinson, Roche Elecsys cTnT	82%	60%
2004 Eggers, Siemens Dimension cTnI	78%	NA
2006 Apple, Siemens Stratus CS cTnI	68%	82%

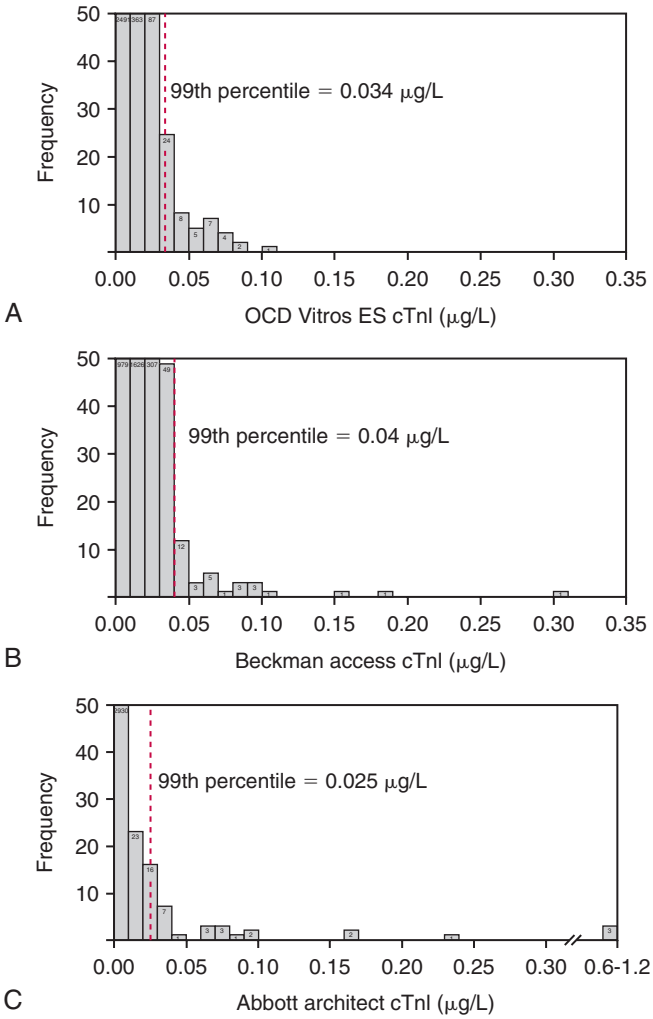

Figure 47-10 Histograms of serum specimens from apparently healthy individuals measured for cardiac troponin I (cTnI) by the (A) OCD, (B) Beckman, and (C) Abbott assays. *(From Apple FS, Murakami MM. Serum and plasma cardiac troponin I 99th percentile reference values for 3 2nd-generation assays. Clin Chem 2007;53:1558-60.)*

receiver operating characteristic (ROC)-optimized cutoffs to using the 99th percentile value; (2) to ensure that cTn assays are accurate enough at the 99th percentile values for clinical use; and (3) to define the effects of implementing the 99th percentile value in clinical practice on minimizing false-negative and false-positive findings. Understanding what is truly normal for cTn, once high-sensitivity assays are incorporated into clinical practice, will be a major step forward in the cardiac biomarker field. The authors advocate for worldwide acceptance of the 99th percentile cTn value as the MI diagnostic cutoff—not ROC curve–derived cTn cutoff values.

To solve the conundrum of assay-to-assay differences, head-to-head comparison of leading market share assays used in clinical practice, as well as hs-cTn assays that will enter the marketplace within 2 years, is needed. One rational approach would be to use a common normal reference population within a focused, young, healthy age group to establish 99th percentile limits. Multiple studies using first-generation, contemporary, and prototype hs-cTn assays have demonstrated that the cTn 99th percentile limit strongly depends on selection of individuals to be included in the reference population. In one study examining four contemporary assays, measurable concentrations below the 99th percentile concentration ranged from 1 to 67% across assays (Figure 47-10). Studies using high-sensitivity assays detect cTn in almost 100% of normal samples, with results appearing to have a near-Gaussian distribution* (Figure 47-11). Some manufacturers report gender differences at these very low levels, but others do not.

To overcome the barrier for accurate interpretation of cTn values in clinical practice, a two-tiered system of analysis using both 99th percentiles and imprecision values at the 99th percentile, based on a young, healthy reference population that is diversified by sex, race, and ethnicity, has been proposed. This approach has been challenged because it does not provide an age-matched normal cohort matching the ACS patient population that typically presents to rule out an AMI. This approach establishes a scorecard (1) to capture the essence of which assays are acceptable for use in clinical practice; (2) to assist the FDA in assay clearance criteria; and (3) to facilitate the transition to future generations of hs-cTn assays. The proposed assay-dependent scorecard shown in

[a]Per manufacturer's package insert; NA, insufficient information to designate.
Adapted from Apple FS. A new season for cardiac troponin assays: it's time to keep a scorecard. Clin Chem 2009;55:1303-6.
Acceptance criteria based on CV at 99th percentile: "Guideline acceptable", CV ≤ 10%; "Clinically useable", CV >10 to ≤ 20%; "Not acceptable", CV > 20%.
Assay designations based on % of normal subjects in whom cardiac troponin is measureable: Level 4, ≥95% of subjects have measurable concentrations; Level 3, 75 to <95% measurable; Level 2, 50 to <75% measurable; Level 1, <50% measurable.

Table 47-3 is based on designations of the total imprecision (CV%) of each assay at the 99th percentile and how many specimens from normal individuals have cTn concentrations that are actually measurable below the 99th percentile.[14] The ultimate goal is to have all assays be level 4 (third-generation) guideline acceptable.

The likely clinical effects of using assays rated by the scorecard as guideline acceptable or clinically usable include the following: (1) emergency medicine physicians will achieve improvements in triage through earlier ruling out (improved specificity) and ruling in (improved sensitivity) of patients with MI; (2) cardiology and internal medicine physicians will see improved outcomes for both inpatients (hospitalized, short-term risk) and outpatients (post hospitalization, long-term risk); (3) other medical specialty physicians will be better able to identify patients, often without clinical symptoms, who may be at risk of cardiac-related adverse outcomes; and (4) clinical trial investigators will be able to identify appropriate and optimal patient re-enrollment and outcome measures.

Optimal discrimination between a small amount of myocardial injury and analytical noise requires assays that have low limits of quantitation (LoQ) and detection (LoD), both of which require high precision at low cTn concentrations. Efforts to improve the precision of cTn assays are warranted. Irrespective of how the testing is performed, whether in the central laboratory or at the bedside using POC assays, manufacturers need to define the imprecision profile [i.e., the scattergraph showing the %CV vs. increasing cTn concentrations obtained using the Clinical and Laboratory Standards Institute (CLSI) EP5-A2 protocol] by assessing pools of human samples containing different cTn concentrations (Figure 47-12).[301] In particular, at least two cTn concentrations that cover the range between the LoD and the 99th percentile decision limit of the assay are recommended to be included. Imprecision characteristics, including the 10% CV concentration, the LoD, and 99th percentile data from currently commercially available assays, are shown in Table 47-1. It is a matter of concern that in clinical practice, different cTn concentrations are obtained with the same manufacturer's assay by independent users of the assay. Such discrepancies highlight the need for local analytical validation whenever feasible. Laboratories at a minimum should determine total imprecision and should continue to monitor

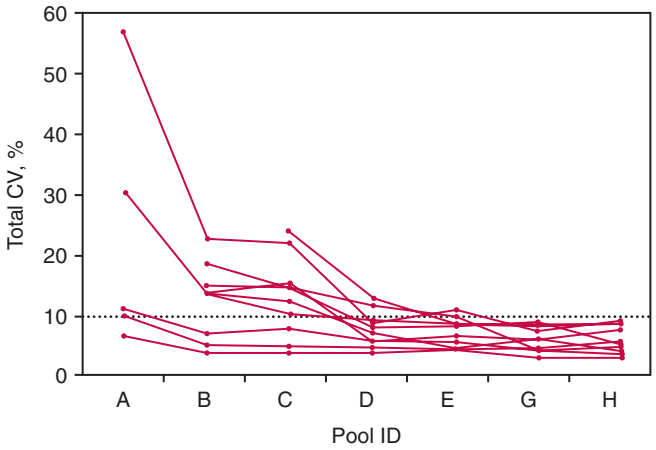

Figure 47-12 Cardiac troponin I imprecision profiles for human serum pools using different cardiac troponin I (cTnI) assays, with 10% coefficient of variation (CV) concentration indicated by the *dashed line*. *(From Panteghini M, Pagani F, Yeo KT, Apple FS, Christenson RH, Dati F, et al. Evaluation of the imprecision at low range concentrations of the assays for cardiac troponin determination. Clin Chem 2004;50:327-32.)*

assay performance over time using internal quality control materials that include the lowest concentration corresponding to the 10% CV, as well as at the 99th percentile value if different from the 10% CV concentration. Patient specimen comparisons such as regression analysis and bias assessment should be performed according to CLSI guidelines.

The 2007 NACB and IFCC C-SMCD laboratory medicine practice guidelines outlined the following analytical recommendations for cTn and other biomarkers of ACS. Objectives were to recommend the appropriate implementation and utilization of cardiac biomarkers, specifically, cTn, to aid in the diagnosis of MI, complementing the quality specifications for the cTn assay previously published. It should be noted that these recommendations build on and, in many cases, are identical to the previously established 1999 IFCC C-SMCD guidelines and the 2007 Global Task Force for the Universal Definition of MI guidelines.[372,398]

1. Reference decision limits should be established for each cardiac biomarker based on a population of normal, healthy individuals without a known history of heart disease (reference population). For cardiac troponin I (cTnI) and T (cTnT), as well as for CK-MB mass, the 99th percentile of the reference population should be the decision limit for myocardial injury. The CLSI (formerly, the NCCLS) recommends a minimum of 120 individuals per group of healthy individuals for appropriate statistical determination of a normal reference limit cutoff. [This number was suggested as a minimum number of subjects for estimating endpoints of a central 95% reference interval (with limits at the 2.5 and 97.5 percentile) by use of the nonparametric estimation method. This number of subjects is not adequate for determination of a 99th percentile for which *N* s of 300 to 500 individuals have been recommended.[161A]] Sex-specific reference limits should be used in clinical practice for CK-MB mass.
2. One decision limit, the 99th percentile, is recommended as the optimum cutoff for cTnI, cTnT, and CK-MB mass. Patients with ACS with cTnI and cTnT results above the decision limit should be labeled as having myocardial injury and at high risk.
3. Assays for cardiac biomarkers should strive for total imprecision (%CV) of less than 10% at the 99th percentile reference limit. Before introduction into clinical practice, cardiac biomarker assays must be characterized with respect to potential interferences, including rheumatoid factors, human antimouse antibodies, and heterophile antibodies. Preanalytical and analytical assay characteristics should include biomarker stability (over time and across temperature ranges) for each acceptable specimen type used in clinical practice and identification of antibody/epitope recognition sites for each biomarker. Analytical and preanalytical specifications developed by professional groups such as the IFCC should be followed.
4. Serum, plasma, and anticoagulated whole blood are acceptable specimens for the analysis of cardiac biomarkers. Choice of specimen must be based on sufficient evidence and the known characteristics of individual biomarker assays.

Point-of-Care Testing

The NACB has developed Laboratory Medicine Practice Guidelines for point-of-care testing for the use of cardiac biomarkers in ACS.[10A] These guidelines address administrative issues, cost-effective utilization, and clinical and technical performance of cardiac biomarkers in the emergency medicine department (ED). Eleven proposed elements of the guidelines are:

1. Members of EDs, primary care physicians, cardiologists, hospital administrators, and clinical laboratory staff should work collectively to develop an accelerated protocol for the use of biomarkers in the evaluation of patients with possible ACS.
2. This protocol should be applied to facilitate the diagnosis of MI in the ED, or to continue the diagnosis at other locations in the hospital.
3. Quality assurance measures should be used with monitoring to reduce medical errors and improve patient treatment.
4. Blood collection should be referenced to the time of presentation in the ED and, if available, to the reported time of symptom onset.
5. The interdisciplinary team should include personnel who are knowledgeable about local reimbursement.
6. The laboratory should perform biomarker testing with a maximum turnaround time (TAT) of 1 hour, optimally 30 minutes. The TAT is defined as the time from blood collection to reporting of results to the provider.
7. Institutions that cannot consistently provide a 1 hour TAT should implement POC testing assays.
8. Performance specifications and characteristics for central laboratory and POC testing assays should not differ.

9. Laboratory personnel must be involved in selection of POC assays, training of individuals to perform the analysis (whether laboratory or nonlaboratory personnel), maintenance of POC equipment, oversight of proficiency and competency of operators, and compliance with requirements of regulatory agencies.
10. POC assays should provide quantitative results.
11. Manufacturers are encouraged to work closely with professional organizations to develop structured committees and to establish quality performance specifications for new biomarkers.

For both point-of-care and central laboratory testing, and for practical considerations, anticoagulated whole blood or plasma appears to be the optimal specimen for rapid emergent processing. This eliminates the extra time needed for clotting and additional sample handling. However, differences have been described between plasma, whole blood, and serum specimens for cTnI concentration measurement by an individual assay. Both ethylenediaminetetraacetic acid (EDTA) and heparin are known to interfere with cTnI and cTnT antibody-binding affinity, as well as produce some matrix effect differences.[131] It is not recommended that different sample types are mixed during an individual's workup when serial, timed samples are being drawn to rule in or out an MI. Although clinicians and laboratorians continue to publish guidelines supporting TATs of less than 60 minutes for cardiac biomarkers, the largest TAT study (published in 2005) demonstrated that TAT expectations are not being met in a large proportion of hospitals. A College of Pathologists (CAP) Q-probe survey study[293] of 7020 cardiac troponin and 4368 CK-MB determinations in 159 hospitals demonstrated that median and 90th percentile TATs for troponin and CK-MB were as follows: 74.5 minutes, 129 minutes; and 82 minutes, 131 minutes, respectively. Less than 25% of hospitals were able to meet the less than 60 minute TAT, representing the biomarker order-to-report time. However, data have shown that implementation of POC cardiac troponin testing can decrease TATs to less than 30 minutes in cardiology critical care and short stay units.[10A,15,16,224,249,287,352]

The following example demonstrates how an institution that addressed a poor TAT problem for cTn improved laboratory services through cross-department cooperation.[16,281] Based at a 400 bed county hospital with 120,000 patient presentations a year through the emergency department, approximately 30,000 cTn orders per year were tested for both outpatients and the 1800 to 2000 patients admitted for short- or long-term care. A 2 month survey of the TAT for cTn showed a 90% TAT of 118 minutes. To better meet the published guideline of 60 minutes 100% of the time, the laboratory medical director, the emergency medicine staff whose primary responsibility involved ACS MI presentations, and the cardiology medical director who was responsible for the 11 bed cardiac 24 to 48 hour observation unit [cardiac short stay unit (CSSU)], 28 bed telemetry unit, and 8 bed cardiac care unit (CCU) met and designed an ACS triage protocol, outlined in Figure 47-13. Two point-of-care cTnI assay systems were placed in the small ED laboratory, staffed by

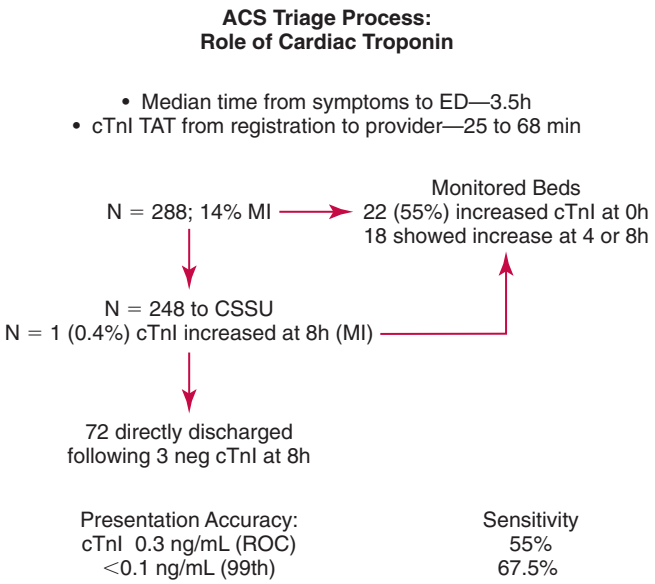

Figure 47-13 Role of cardiac troponin testing correlated with patient flow in the triage process from the emergency room, cardiac short stay unit, and coronary care unit. *(From Betti I, Castelli G, Barchielli A, Beligni C, Boscherini V, De Luca L, et al. The role of N-terminal PRO-brain natriuretic peptide and echocardiography for screening asymptomatic left ventricular dysfunction in a population at high risk for heart failure. The PROBE-HF study. J Card Fail 2009;15:377-84.)*

the clinical laboratory around the clock, in support of the hospital's level 1 trauma center. Two additional POC assays were placed in the CSSU, in which 42 nurses were trained by the laboratories' POC coordinators. The flow of specimens was such that initial presentation cTnI requests ordered through the ER were analyzed in the ED laboratory—about 6000 to 8000 per year. TAT from the time of blood draw to the provider result report was less than 18 minutes, 100% of the time. Patients admitted to the hospital to rule in/out MI who were at low risk were admitted to the CSSU, where staff nurses provided less than 20-minute TAT 100% of the time from blood draw to results to provider. In the CSSU, in compliance with the hospital protocol that at least a 6-hour postpresentation sample had to remain normal for cTnI, two blood specimens, in addition to the ED presentation sample, were measured at 4 and 8 hours. The uniform timed ordering protocol for ruling out MI included four timed draws at 0, 4, 8, and 12 hours. In patients admitted to the telemetry unit or the coronary care unit, a dedicated blood draw was tubed to the central laboratory, where specimens were given priority testing status, and thus met a TAT of less than 60 minutes 98% of the time.

During this process, it was recognized that POC testing was not cost-effective for patients in telemetry or CCU units; these were mostly patients at moderate to high risk in whom a clinical diagnosis had already been made; thus urgent cTn values were less necessary. The CSSU was successful in decreasing the length of stay in the unit by 0.8 day through implementation of POC testing, allowing triage to lower levels of care and/or discharge on a 24/7 basis. Although the

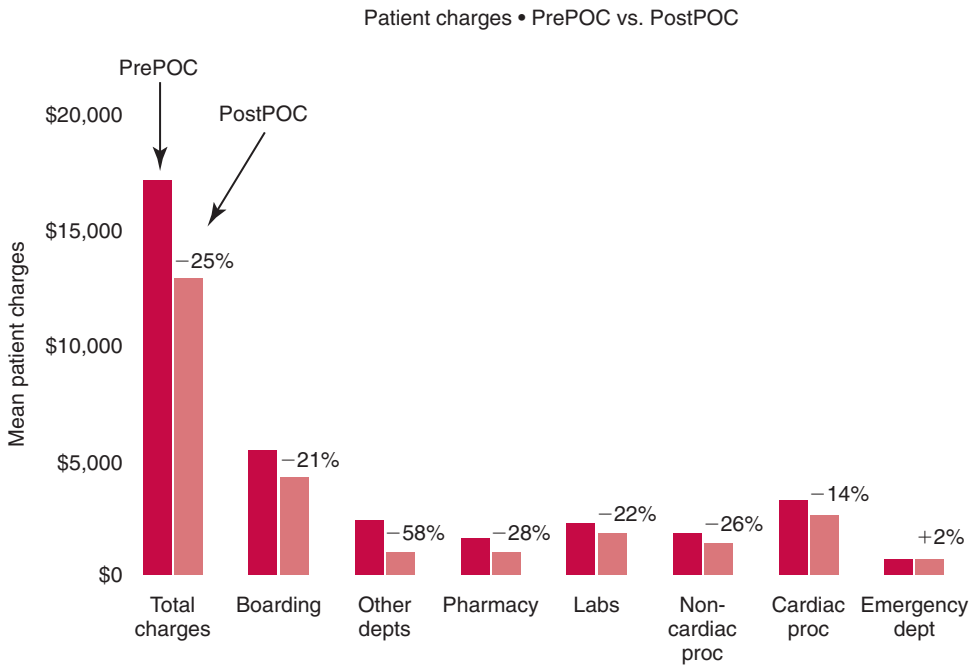

Figure 47-14 Financial impact of incorporating point-of-care (POC) cardiac troponin I (cTnI) testing into a cardiology service compared with central laboratory cTnI testing. In each pair of bars, the left and right bars indicate the costs before and after introduction of POC testing, respectively. *(From Betti I, Castelli G, Barchielli A, Beligni C, Boscherini V, De Luca L, et al. The role of N-terminal PRO-brain natriuretic peptide and echocardiography for screening asymptomatic left ventricular dysfunction in a population at high risk for heart failure. The PROBE-HF study. J Card Fail 2009;15:377-84.)*

direct cost per assay reagent increased from $3.83 (central laboratory) to $10.51 (POC testing), the overall cost to the patient decreased by more than $4000 per admission (Figure 47-14), primarily based on decreased bed charges from a more costly cardiac bed to a less expensive general medicine bed or to discharge. These data highlight the continued need for laboratory services and healthcare providers to work together to develop better processes to meet a less than 60 minute TAT, as requested by physicians. It is important to indicate that the POC testing assay used in the previous study example (Siemens Stratus CS; Siemens Healthcare Diagnostics, Inc., Deerfield, Ill) appears to be the only POC cTn assay with adequate analytical sensitivity, similar to central laboratory contemporary assays, and that other POC assays that are not as analytically sensitive will need to be independently validated. Further, it has been shown that a less sensitive POC assay may miss a positive cTn value that would be detected as increased by a more sensitive contemporary assay, as noted in Figure 47-15.

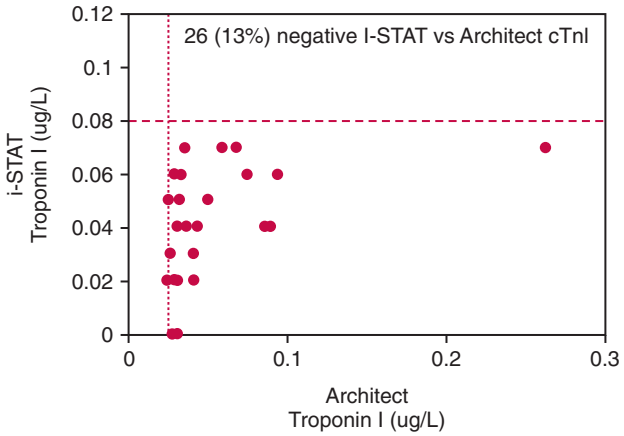

Figure 47-15 Scatterplot of i-STAT-negative and Architect-positive samples. The *dotted line* represents the 99th percentile cutoff for each instrument. *(From Singh J, Akbar MS, Adabag S. Discordance of cardiac troponin I assays on the point-of-care i-STAT and Architect assays from Abbott Diagnostics. Clin Chim Acta 2009;403:59-260. Figure courtesy Jasbir Singh.)*

Clinical Use of Cardiac Troponin

cTns have been available for clinical use since 1995, when the first cTn T (cTnT) assay was approved. Since that time, it has become clear that enhanced cardiac specificity and particularly improved sensitivity lead to more frequent and more accurate diagnosis of cardiovascular abnormalities (see Table 47-2, Figure 47-16).[178] Initial use of these assays was influenced in large part by the previous use of markers such as CK-MB. CK-MB is substantially less sensitive and less cardiac specific than cTn, but because of its long use, it had become entrenched in the thinking of clinicians and laboratorians. For this reason perhaps, the first set of guidelines by the NACB attempted to compromise between the use of these two markers in setting guidelines for clinical use.[398] These guidelines suggested that there should be two cutoffs.

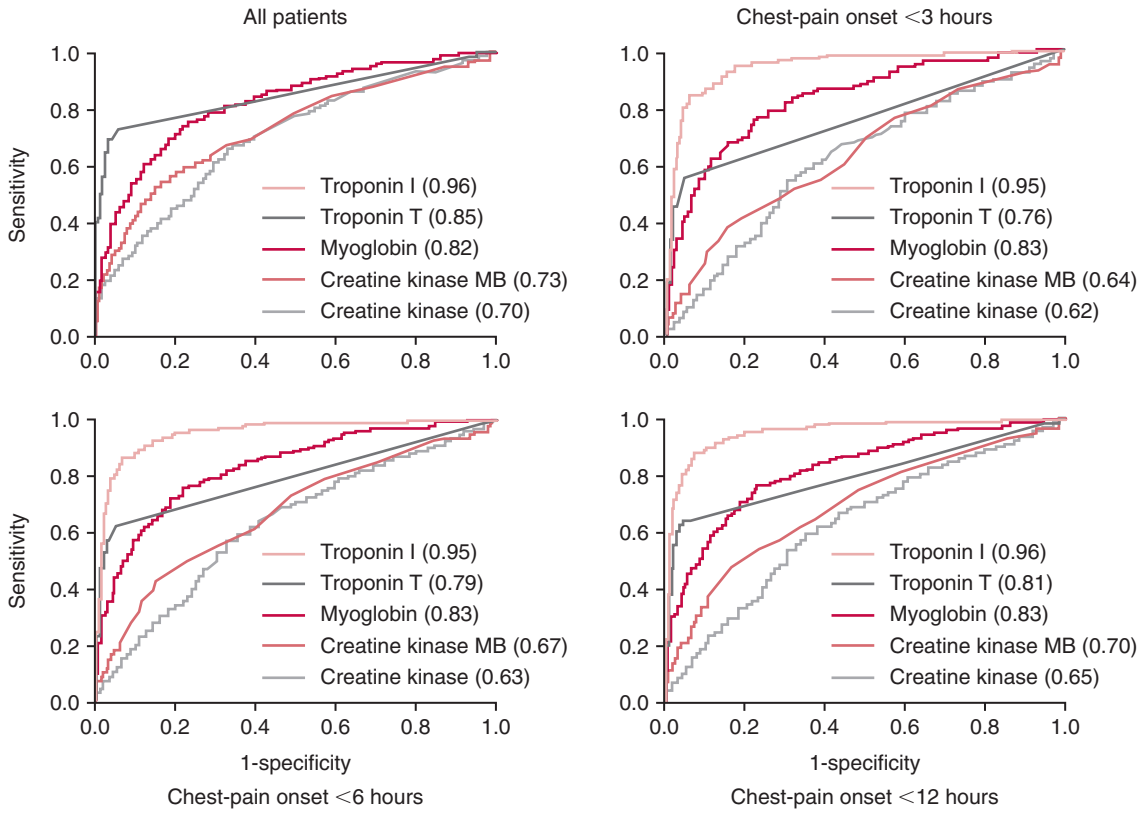

Figure 47-16 Receiver operating characteristic (ROC) curve analysis of troponin, myoglobin, and CK-MB by time from onset of symptoms to presentation.

One cutoff was selected to be equivalent to values of CK-MB in the clinical identification of patients. This cutoff, known as the ROC curve–derived cutoff value, considered CK-MB as the gold standard, as it had been for years. However, this cutoff did not take advantage of the increased sensitivity of cTn values.[299] A second cutoff was recommended for use at a lower level (the 97.5th percentile of a normal patient population), which was poorly clinically defined, above which patients were considered to have cardiac injury. But even patients with a classic history of AMI were designated as having "unstable angina with minimal myocardial necrosis." The guidelines followed extensive research demonstrating large numbers of patients with chest pain (roughly an additional 33%) whose prognoses in terms of subsequent frequency and timing of events were identical, and who had increased cTn values but normal CK-MB values.[299] These findings were documented despite the fact that the initial version of cTn assays was relatively insensitive compared with contemporary assays.

This concept of using prognosis to confirm diagnosis rapidly became the paradigm not only for cTn but for the validation of most other markers as well. It was not until 1999, when a task force empaneled by the American College of Cardiology (ACC) and the European Society of Cardiology (ESC) took issue with these guidelines, that the concept of using only one cutoff value was initiated.[6] ESC/ACC guidelines suggested the use, not of the 97.5th percentile of a reference population but, in recognition of increased sensitivity of the marker that led to many elevations that were difficult to explain, of the 99th percentile. This had the potential benefit of reducing the overlap to 1% between those with disease and normal individuals.[181] It was conceptually important because even by this time, it was clear that enhanced sensitivity of cTn was leading to the identification of a substantial number of patients in whom the cause of cardiac injury (see later sections) could not be determined. This is often the case when one moves from a relatively insensitive measure to one that has substantially greater sensitivity (i.e., when one uncovers new diagnostically and prognostically important increases).[148,233,234] Nonetheless, clinicians had difficulty understanding this because such elevations had not been described previously, and the pathophysiology was obscure. This problem continues today as newer assays become more and more sensitive. The ESC/ACC biochemical group at that time also recommended that the 99th percentile should be measurable with excellent precision and suggested, not mandated, a criterion of 10% CV or less at the 99th percentile. The group did not, however, recommend that if assays did not reach that level of precision, the values should be raised. Unfortunately, this was the extrapolation of some, and it led to even greater heterogeneity in how cTn values were interpreted.

Some individuals persisted in using the NACB recommendations, some utilized the ESC/ACC recommendations, and some because of fear of false positives caused by imprecision employed a value higher than the 99th percentile, usually

at the level of the 10% CV value. Add to this the fact that local laboratories often felt the need (appropriately) to validate the assays in their own hands and came up with different values, and one can see how the use of cTn values became fragmented and idiosyncratic. This problem also led to tremendous heterogeneity in the published literature and attendant confusion on the part of clinicians.[128,172,392]

It is now very clear that normal cTn values are substantially lower than concentrations that are being reported for healthy individuals by contemporary assays (see Table 47-1). (The reported concentrations in healthy individuals often represent "noise" in the contemporary assays.) Research assays are beginning to have the ability to measure healthy individuals' low concentrations accurately, but only one (the high-sensitivity cTnT assay) has been released for clinical use and, as of this time, it is unavailable in the United States.[197,394,399] Nonetheless, this documentation and a wealth of clinical information has made it clear that for contemporary assays, the 99th percentile value is the key value to use when measuring cardiac cTn.[33,184,274] Any value above the 99th percentile should be considered abnormal. Concerns about false positives induced by such criteria should be minimal because assuming adequate quality assurance of the assays, even reduced precision should not lead to false-positive results.[26] Usually, reduced precision simply impairs the sensitivity of the assay. Statistical modeling of this issue suggests that as long as one does not look at a huge number of consecutive samples, the clinical impact of utilizing even an imprecise assay is negligible with regard to false-positive results. For this reason, along with the clinical data, the criteria in all guidelines now include use of the 99th percentile.[273,372] Once one recognizes that the 99th percentile is the criterion for abnormality, and therefore is the criterion that one should at least keep in mind, one can progress to understanding how to use cTn in a variety of clinical situations. The recent publication of several papers has clearly demonstrated this point, which will be discussed in the following section.

Use of cTn for the Diagnosis of Acute Myocardial Infarction

Acute myocardial infarction is a state characterized by abnormalities between nutrient perfusion and myocardial oxygen consumption. It is usually diagnosed when abnormalities in coronary flow at least in part contribute to the pathogenesis of cardiac injury. Because of the high sensitivity and specificity of cTn, it has become the cornerstone of the diagnosis of myocardial infarction (see Box 47-2, Figure 47-17). Accordingly, one needs an increased value of cardiac cTn in the appropriate clinical setting with values that manifest a rising pattern for the diagnosis of acute myocardial infarction. Some clarification concerning the specifics of that definition are necessary:

1. The clinical substrate (usually risk factors for AMI in the patient) is key. An increased cTn value is not synonymous with the diagnosis of myocardial infarction.[178] First, both the substrate (such as risk factors) and the presentation (most often chest discomfort) must be compatible with the diagnosis. At times, imaging, whether performed at the time of intervention by angiography or thereafter, may provide proof of the substrate.[273,372]
2. Many clinical situations can mimic acute myocardial infarction, the most common of which is myocarditis. Apical ballooning is another.[119,354,363]
3. Because of the increased sensitivity of cardiac cTn, clinicians need to be astute to the possibility that a given elevation in cTn even with a rising pattern suggesting that it is acute may not be due to ischemic heart disease (see Box 47-1).[178] This is conceptually difficult for many clinicians because with CK-MB, which was reasonably insensitive, most substantive elevations were associated with coronary heart disease, albeit not all.
4. Acute events leading to cardiac injury usually will manifest a changing pattern of values.[175] The rationale for this is that as assays have become more sensitive, it has become clear that elevations of cTn can exist chronically.[24,95,189,386,417] The

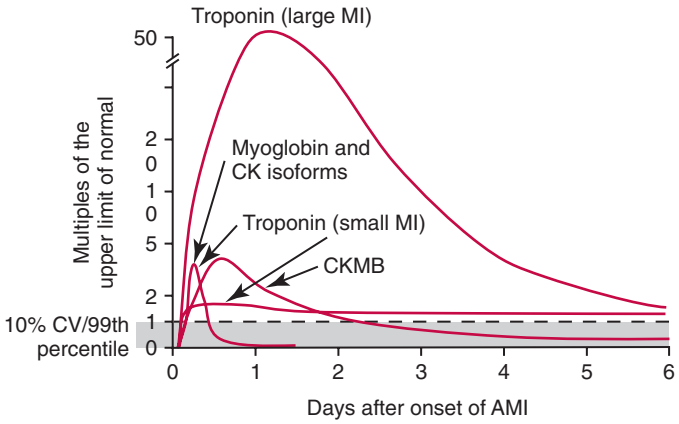

Figure 47-17 Kinetics of myoglobin, troponin, and CK-MB. With contemporary assays, cardiac troponin (cTn) rises more rapidly than do other markers. With small myocardial infarctions (MT), two types of time courses are possible, as indicated by the two arrows.

most overt case of this is seen in patients with renal failure,[29] but as indicated later, in a large number of clinical circumstances, elevations of cTn exist and are maintained over time. This is also the pattern manifest when artifactual increases occur as the result of analytical problems caused by interferences from substances in the blood of some patients.[123,210] Although patients with chronic elevations (not those with artifactual causes) are at high risk over time, they are not necessarily at high risk short term. For this reason, the guidelines groups have advocated the need for a rising pattern of cTn values in patients who present early after the onset of symptoms, because such increases usually are indicative of an acute process. However, the acute process may not be acute myocardial infarction. Whether acute myocardial infarction is present is a clinical decision, but if the values are not rising, one might seriously question whether acute disease of any kind is present, or whether the elevations are of a more chronic nature. Care is necessary to ensure that one does not miss individuals who come in late, after the onset of symptoms, whose cTn values may be near peak values, or whose values are on the long persistent tail of the time-concentration curve (see Figure 47-17). They may appear not to have a changing pattern of values because they are near the peak of the time-concentration curve or on the gradual down slope.

5. With contemporary assays, values should exceed the 99% value of the reference population. Use of such a value maximizes the sum of sensitivity and specificity.[33,184,273,274,372]

The guidelines distinguish five different types of acute myocardial infarction (see Box 47-4); two will be considered here because they both present with chest discomfort and increased biomarkers. One is the so-called spontaneous, or what some would call "wild type", in which acute plaque rupture leads to some degree of thrombosis, or an episode wherein platelet accretion occurs on a plaque, leading to thrombosis.[273] The second type includes coronary abnormalities with possible supply-demand imbalance, vasospasm, or endothelial dysfunction, which provides evidence of myocardial injury. For example, supply-demand imbalance with fixed coronary artery disease is thought to be the cause of most perioperative myocardial infarctions,[218] and these patients do not require the same care as those with a spontaneous AMI.[273]

Individuals with spontaneous AMI can have STEMI or non-STEMI as indicated by the ECG pattern that they manifest.[9,273] Data indicate that immediate treatment aimed at opening the occluded artery is mandatory for patients with STEMI; this should be done based on the ECG pattern alone, even before biomarker values become available to assist with diagnosis. Opening of the artery is done nowadays with primary PCI and/or thrombolytic agents. The former is preferred whenever the two are available in similar timeframes. With prompt coronary recanalization, the amount of myocardium that is lost is minimized, and mortality is reduced. It should be noted that coronary recanalization increases the rapidity of cTn release, and thus the rate of rise of the time-concentration curve is increased, and the time to peak values is shortened.[178]

A non-STEMI is less often associated with total coronary occlusion and usually is identified by ECG changes, which show not ST segment elevation, but rather ST segment depression or T-wave changes. Given the sensitivity of cTn for this diagnosis, the ECG is even at times totally normal. Patients who present with chest pain due to coronary artery disease should have risk factors, an appropriate presentation, or imaging evidence of this syndrome; patients with an increased cTn, using contemporary assays and recommended cutoff values, are known to have more severe coronary heart disease than individuals without increased cTns. Likely for this reason, they also have more procoagulant activity; multiple intervention studies have shown that these patients benefit from aggressive anticoagulation, including heparin (the data for low molecular weight heparin are much stronger than the data for unfractionated heparin), glycoprotein IIb/IIIa antiplatelet agents, and an early invasive strategy consisting of PCI or coronary artery bypass grafting (CABG). Use of these strategies in patients without increased cTn values has been shown to be of no benefit and, in some trials, has actually proved detrimental.[14]

However, not all patients have easily identifiable culprit lesions[42,81,247,297] upon which to intervene, and this explains some apparent spontaneous AMIs without severe coronary artery disease. These patients, often women, may have endothelial dysfunction, coronary vasospasm, or some other transient process that has resolved prior to investigation. These patients might be designated as having type 2 myocardial infarction according to the guidelines. This group might also include those individuals who have fixed but stable coronary artery disease but have some degree of damage due to excessive myocardial oxygen consumption, such as that caused by severe tachycardia or by hypotension or hypertension. Coronary arteries that are diseased tend to vasoconstrict rather than dilating in response to stimuli that would normally evoke vasodilation and increases in coronary flow.[218] This can be identified by special studies utilizing provocative stimuli and documenting these paradoxical responses; these paradoxical responses occur in response to cold, to changes in catecholamines, and to changes in potassium that probably induce a degree of vasoconstriction on top of coronary lesions.[362] Because the cross-sectional area of a tube is related to the square of the radius, small degrees of vasoconstriction can cause marked changes in blood flow through the artery. Thus, some patients, whether with vasoconstriction or simply because fixed coronary disease inhibits the ability to increase coronary perfusion, have increased cTns and myocardial necrosis caused by an inability to improve coronary blood flow in response to increased oxygen consumption. These patients are probably fundamentally different from individuals who have spontaneous MIs and likely are not a subgroup that has nearly as much procoagulant activity; it is unclear whether they benefit from interventional therapy. This may be one of the reasons why women who tend to have more severe endothelial dysfunction seem to have a different profile.[81,247] Nonetheless, depending on the specific study reviewed, substantial numbers—10 to 15% of patients at least,

and perhaps as high as 30% of patients—may not have an identifiable lesion that has caused the event, leading to consideration of this alternative pathophysiology.[297] From the perspective of diagnosis, however, the cTn criteria are identical. Distinctions between types has to be made on the basis of clinical characteristics and other diagnostic studies.

Three other types of MIs are recognized.[372] One does not use biomarkers at all. This case includes patients who may present classically with both chest pain and ECG changes but succumb either (1) before blood tests can be obtained, or (2) before enough time has elapsed for the circulating concentration of cTn to exceed the 99th percentile. Two other types of myocardial infarctions have been designated; these are related to PCI and CABG and will be covered later under "Special Situations."

Operationalization of a Changing Pattern of cTn Values

This is a challenging area. Minor changes in values may be due to analytical causes. In general, two values are different if they differ by more than 2.77 standard deviations (SDs) (assuming the variances are comparable at the two concentrations).[400] Ideally, one would like to include both analytical and biological variation in calculation of the SDs.[402] Unfortunately, analysis of biological variation requires studies of stable subjects, and only the developing high-sensitivity assays can provide data on healthy people. Thus, at present, the analysis has focused on the use of data on analytical imprecision alone. At high concentrations of troponins, the analytical coefficient of variation (CV) is 5 to 7%, so a difference of 20% is unlikely to be attributable to measurement imprecision.[273] But as values begin to approach the low concentrations corresponding to the 99th percentile value, analytical CV increases, making the relative difference between two consecutive values prone to increases by chance alone.[400] To calculate percent changes, one might need the values to be reported with more than the number of decimal points usually reported for clinical use of troponin assays. Local analysis of imprecision should be used to guide interpretation of differences in results for consecutive samples, with larger percentage changes necessary to suggest real change at very low levels of troponin. Obviously, defining a consistent period of time for analysis is also key to an accurate approach to this analysis. High-sensitivity assays will help with this problem because they make it possible to calculate a reference change value, i.e., the value that must be exceeded before a change in consecutive test results is statistically significant.[126,274]

Special Situations With Acute Myocardial Infarction

Post Percutaneous Coronary Intervention

It has long been appreciated that interventions done on the coronary arteries can result in the release, from heart muscle, of biomarkers indicative of cardiac injury.[58] For this reason, a variety of criteria have been promulgated, starting years ago with CK-MB. It was shown initially that elevations of CK-MB that occurred post procedure were highly predictive of adverse events over the long term. These findings were difficult to explain because the amount of injury involved often was very minor but was nonetheless easy to document with sophisticated techniques such as cardiac magnetic resonance (cMR) imaging. However, controversy about the mechanisms continued, and a large number are being hypothesized. The advent of cTn markers has rendered this issue far less complex. Patients who have elevations of circulating cTn and who present with acute coronary problems have much more severe abnormalities in coronary anatomy than those who do not have elevations of cTn.[9] In recent studies, the baseline cTn value has been added to the analysis of these post-PCI elevations.[260,309] This was done for many years by others, but not with assays that measured cTn concentrations even close to the 99th percentile. Accordingly, it is only recently that the data have confirmed several important conceptual issues.

The first concept is that a vast majority of patients with significant elevations (threefold to fivefold increase in CK-MB or cTn) that in the past were associated with an adverse prognosis are those with increased cTn values at baseline. This usually (although not always) is indicative of an acute presentation and therefore a rising pattern of values. In the setting with a rising pattern of values, it is hard know whether one should attribute the increases to the PCI or to the initial insult. Nonetheless, when one incorporates the baseline value into the analysis, most of the prognostic significance of the cTn values post procedure is ablated.[260,309] Indeed, those data suggest that it is only when one has an elevation of cTn at baseline that one is apt to frequently find marked elevations in cTn post procedure, suggesting that in most instances, at least a blend of the two processes occurs. These issues have been confounded not only by failure to use appropriate cutoffs for cTn, but by the use of insensitive assays. More recent guidelines clarify this circumstance substantially by indicating that if one has an increased cTn at baseline prior to PCI, the diagnosis of post-PCI injury is confounded and cannot be made.[273] Thus, one requires a normal baseline cTn in almost all instances to identify procedure-related myocardial injury. If the baseline cTn is increased, then subsequent increases may not be attributable to the procedure itself, and a diagnosis of post-PCI injury cannot be made.

Marked elevations as indicated previously are uncommon but can occur. When they do occur, they are rarely of cardiovascular importance in the sense that the more marked elevations are easily presaged by clinical information at the time of the procedure. Thus, cTn adds very little that is new. In addition, it is unclear whether patients have an adverse cardiovascular prognosis over time. In the most recent analysis done by using the most appropriate cutoff values and contemporary cTn assays, borderline statistical significance was attributed to elevations post PCI.[309] However, most events that did occur were noted during procedures in patients who had severe underlying noncardiac comorbidities and therefore underwent palliative procedures. The event rate if one excluded patients with non–cardiac-related subsequent complications would not have been of statistical importance and even with their inclusion was of only borderline significance. Thus, it

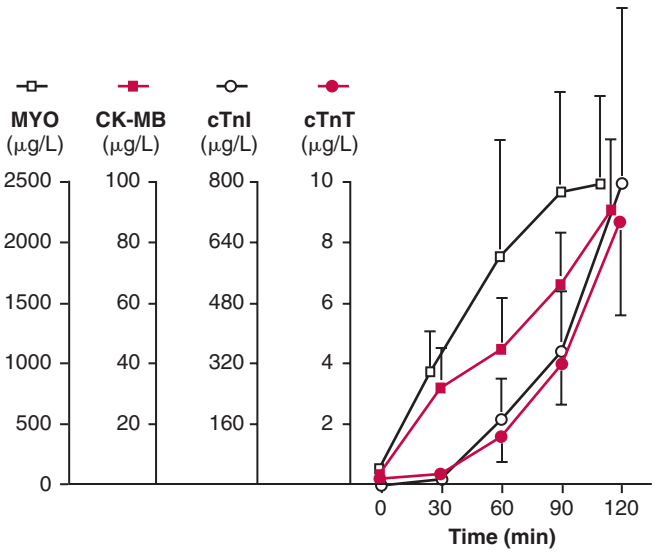

Figure 47-18 Time course (mean and standard error) of serum cardiac troponin I (cTnI), cardiac troponin T (cTnT), creatine kinase-2 (CK-MB), and myoglobin (MYO) concentrations after initiation of thrombolytic therapy in patients with thrombolysis in myocardial infarction (TIMI) grade 3 reperfusion flow. *(From Apple FS, Sharkey SW, Henry TD. Early serum cardiac troponin I and T concentrations following successful thrombolysis for acute myocardial infarction. Clin Chem 1995;41:1197-8.)*

now appears that collection of this information post PCI is not necessary. Nonetheless, criteria still exist for these occasional patients who may have post-PCI injury. The appropriate cutoff value is unclear, but it is clear that very few patients will reach the marked threefold to fivefold elevations previously advocated if the baseline cTn is not increased.[260] Thus, if cTn is increased post-PCI more than threefold, with a normal baseline cTn value assumed, they can be diagnosed as having had a periprocedural myocardial infarction. No specific therapy is mandated. Regarding biomarker changes that occur following reperfusion of an occluded vessel after PCI or thrombolytic therapy[1] in AMI patients, greater than twofold increases in biomarkers occur within 90 minutes of reperfusion, the rate of increase of biomarkers within the first 4 hours separates reperfused from nonreperfused patients, and after myocardial reperfusion in AMI patients, washouts of all biomarkers parallel each other (Figure 47-18).[12,36,390,414] However, increased washout does not define the level of reperfusion; this is what clinicians need to know diagnostically, so this approach has not become clinically widespread.

One unique subset needs to be taken into account, and that is the small group of patients who may have chronic preprocedure elevations in cTn. These individuals will manifest a rising pattern, albeit from an increased baseline, when they have events including post-PCI events. Accordingly, what has been suggested is that the criteria used for reinfarction of an increased value of 20% or more should be used to define post-PCI infarction in this group.[273] This, as with other values that utilize changing patterns, must be done over a constrained period of time.

Post-CABG Myocardial Infarction

Abundant data indicate that patients post cardiac surgery have elevations in cardiac cTn. Indeed in the vast majority of studies, such elevations are of prognostic importance: the higher the elevation, the worse the prognosis.[267,336,369] However, the underlying propensity for elevation is moderated in part by the details of the procedure. Thus, for example, procedures that are done off cardiopulmonary bypass evoke less cTn release,[267] as one might expect, because they cause less direct cardiac injury. In addition, a relationship has been noted between the duration of cross-clamp time and the amount of marker that is elaborated, the temperature of the cardioplegia, and the duration of the procedure. Most of the injury as assessed from cMR studies is subendocardial and often apical. Higher biomarker values post CABG are associated with transmural injury.[340,359] Thus procedures that are longer, such as those that include valve replacement, are very likely to evoke more cardiac damage than those that are shorter. Accordingly, finding a single value that separates all of these different subsets is impossible. Accordingly, most recent guidelines have elected not to try to define separate criteria for subsets of these procedures, but instead have preferred to define a single cutoff that can be used for all the situations already described for which ancillary criteria need to be employed. The decision of most of the most recent guidelines has been that one should employ a fivefold increase in cTn post procedure and add to that additional criteria such as ECG changes, changes with imaging, and the development of new regional wall-motion abnormalities.

The value of such an approach is that it allows one to use a single cutoff. The downside of the approach is that this cutoff lacks some precision when it comes to the types of procedures performed. Thus, one might well do better if one could devise specific criteria for each subset of the procedures. This is an extensive task because of multiple variations in the way in which cardiac surgery is done, but it is a task that at some point in time might be worthwhile. Nonetheless, the key concept is that the prognostic impact of increased cTn concentrations is related to the magnitude of the increase. Unfortunately, because of the complexity of these considerations, no one has been able to define a value at which one can attribute increases in cTn to a specific coronary-related event such as graft or native vessel occlusion.[370] Thus, although the aggregate amount of marker that is released is prognostic (for both CK-MB and cTn), it does not distinguish the mechanism of injury.

Patients Who Have Increased cTns at Baseline

As indicated previously, some patients may have cardiovascular comorbidities such as heart failure, left ventricular hypertrophy, renal failure, and diabetes, along with elevations in cTn that are stable and chronic. In these circumstances, it is known that dialysis patients, to take but one example, increase their values from the increased baseline after AMI and the values come back down over time to the original baseline, suggesting that a changing pattern can be used despite increased baseline. This is likely the case for these

other entities and is what has been incorporated into most of the guideline documents.

Evaluating Possible Acute Myocardial Infarction

Between 5 and 6 million individuals present to emergency departments yearly with complaints that could be compatible with acute myocardial infarction. The screening done in emergency room settings takes a very broad approach because many patients have atypical symptoms. For example, patients with diabetes and hypertension often have what has been termed *silent,* or perhaps a better term would be *unrecognized*, acute myocardial infarction.[9,227] In addition, patients who are older (e.g., over the age of 80) often present with myocardial infarction in the absence of chest discomfort. Thus, a very broad screen in the emergency department is appropriate. Accordingly, the diagnosis of AMI often relies heavily on abnormalities in cardiac biomarkers such as cTn. The criteria for ruling in myocardial infarction are listed in Box 47-2 and often can be accomplished in a fairly short time.[29,201,242,317] Recent data suggest that use of a changing pattern can identify 80% of patients with acute myocardial infarction within 2 to 3 hours of presentation.[242] Although at times not adequately emphasized, this of course implies the use of more sensitive rather than less sensitive assays and use of appropriate cutoff values.[177] Of course, these data take advantage of the fact that often patients with chest discomfort do not immediately come to the hospital; thus, often it is many hours since their initial chest discomfort.

Exclusion of myocardial infarction is far more problematic. In the United States,[9] at most 20% of patients who are evaluated with ischemic symptoms suggestive of ACS (it is somewhat higher in Europe,[201,317] where selection seems to be done in a different manner) rule in for AMI or have increased cTn values. Thus, in the United States, one must identify the relatively small proportion of the patients who have ACS. Data suggest that patients sent home with a missed diagnosis do poorly; it is perhaps not surprising that they are a common source of litigation. A variety of protocols have been advocated for the early evaluation of patients with possible acute myocardial infarction. These have often presumed that cTn rises late because the initial assays were relatively insensitive, causing that to occur. Thus, there has been advocacy for myoglobin, heart fatty acid–binding protein, or even CK-MB as early markers. Recent data utilizing contemporary assays and contemporary cutoffs suggest that use of other markers is rarely necessary because cTn, as measured with current assays, increases rapidly (see Figure 47-17).[118,197,201] With criteria of the 99th percentile and a rising pattern, 80% of rule-ins are detected within 2 to 3 hours.[201,242,317]

It appears from the most recent literature that the cumulative value of additional markers is small, if not totally negated, by the use of the 99th percentile and criteria for interpreting changes of concentration of cTns. In fact, it appears that with contemporary (i.e., those in use today) assays, cTn rises more rapidly than the other so-called early rising markers. How long it takes to rule out AMI, however, is less clear. This is a difficult issue to study because one needs longer periods of observation to see who eventually will be determined to have AMI at a time when protocols are attempting to move people more rapidly through systems. Thus, present standards suggest that 6 hours is the length of time that should be designated for cTn monitoring to occur. Some data suggest that one should make sure that the patient is at least 6 hours from the onset of chest pain to completely ensure that infarction has not occurred.[147] Others, because of relative insecurity of the timing of onset of chest symptoms, believe that the clock for this timing should be started at the time the patient presents to the emergency room. This at present is an unadjudicated issue, but 6 hours appears to be the preferred time. It would be ideal if this time could be cut substantially in the interest of more rapid discharge. Additional research is needed.

Other Causes of Acute cTn Elevation in the Absence of Acute Ischemic Heart Disease

Many acute diseases are associated with elevated cTns (see Box 47-1). This can occur for many reasons,[78,112,208,257,358] including direct trauma to the heart; we know that contemporary cTn assays are sufficiently sensitive to detect implantable cardioverter-defibrillator (ICD) firings, biopsies, cardioversions, and so forth. Also, some patients may have type 2 myocardial infarction, as indicated previously. Critically ill patients often have tachycardia, hypertension, or hypotension with or without drugs that may be given therapeutically such as catecholamines, which in and of themselves can directly damage myocardium. Thus in some instances, these individuals have what could be called type 2 AMI. On the other hand, in the absence of at least some coronary artery abnormality to negatively affect perfusion, these episodes would not be designated as type 2 AMIs. Patients in the absence of coronary artery disease who have very severe supply/demand imbalance may have elevated cTn; these individuals probably do not have AMI. Finally, direct toxic effects of circulating cytokines and catecholamines can end up causing severe myocardial toxicity. Such is the case in sepsis. Thus, consideration of each mechanism for a given elevation is important. A short, brief tabulation is provided here:

1. *Trauma:* Contusion, slow potential (S/P) cardiac ablation, pacing, ICD firings, cardioversion, myocardial biopsy, and closure following a variety of interventional procedures commonly cause elevations in cTn and should be expected. These elevations are usually modest. More marked elevations should engender suspicion of additional processes.
2. *Congestive heart failure:* Heart failure can cause acute elevations,[302] and elevations have been noted during long-term monitoring of patients as well.[261] In both circumstances, they are markedly adverse prognostic signals and indicate more severe heart failure and an increased proximate likelihood of mortality. Such patterns can be rising but need not be, especially with more chronic heart failure. The prognostic significance of cTn is additive to that of the natriuretic peptides. Elevations are usually modest.

3. *Severe valvular heart disease* with volume or pressure overload can be associated with elevations in cTn. Elevations may be more apt to occur with cTnI for volume overload via a calpain-mediated mechanism and may be more common with cTnT with left ventricular hypertrophy (LVH).
4. *Hypertension:* Hypertension in and of itself can cause LVH or cardiac enlargement, which increases wall stress and reduces nutritive perfusion, causing increases in cTn. LVH is associated with reduced subendocardial perfusion caused by increased wall stress; therefore, subendocardial injury may occur in response to severe hypertension.[149] Obviously, because hypertension is a risk factor for coronary artery disease, these processes may be exacerbated by each other, but this is not necessary for elevations to be observed. Elevations most often are modest.
5. *Hypotension and tachycardia:* These can be synergistic with underlying coronary abnormalities or may occur independently.[48] Nonetheless, at some point, their severity can be sufficient to cause some degree of cTn release, usually modest.
6. *Postoperative noncardiac surgery patients:* Data suggest that most of these events are similar if not identical to type 2 MI, that is to say, most often among vascular surgery patients who have been best studied, these cTn elevations seem to be related to underlying coronary heart disease in association with an abnormality in acute myocardial oxygen consumption, usually hypertension or hypotension and/or tachycardia, anemia, and the like.[204] This is an area of expanding interest as it has become clear that more and more noncardiac surgery patients suffer events in the hospital, and it is likely that a more diverse group of patients will soon be elucidated. Data have already been gathered from some orthopedic surgery patients.[100] Causes of observed elevations may differ among the groups involved and may include, for example, pulmonary embolism, which is common in postoperative patients.
7. *Patients with renal failure*[43]: Patients with renal failure often have elevations in cTn that are highly prognostic. Elevations occur more frequently with cTnT than with cTnI, perhaps because processing of the two proteins is different in the renal failure circumstance. Nonetheless, elevations are highly prognostic in this group, but not necessarily for coronary artery disease.[162] A large percentage of renal failure patients die of sudden cardiac death. One should not presume that all cTn elevations occur in such groups, although this group does have an increased prevalence of coronary artery disease.
8. *Critically ill patients:* These individuals may or may not have underlying coronary heart disease, which is negatively synergistic with their acute illness, but they often have reasons for very substantial increases in myocardial oxygen consumption.[46,144] Elevations in cTn are common and usually modest but nonetheless are highly negative prognostically in the short and long term. An understanding of various subsets of patients in the large group should in the long run provide better ideas about how to treat such patients. Unfortunately, these data are missing at present.
9. *Drug toxicity:* Carbon monoxide poisoning is an archetypical example.[159] Elevations in response to drug toxicity have prognostic significance. Recent data show that one can detect[77] and with early treatment obviate the effects of some toxic chemotherapies by monitoring cTn and, when elevations occur, by using angiotensin-converting enzyme (ACE) inhibitors.[76] Snake bite venom can be another cause. It is very likely that over time, a far larger number of drug toxicities will be documented.
10. *Inflammatory heart disease:* Myocarditis, when acute, commonly causes elevations of cTn.[125] Myocarditis can also cause coronary vasospasm and is a common mimicker of acute coronary syndromes.[413] Elevation in this circumstance can be very high, even higher than that associated with acute infarction, or very modest, depending on whether patients have acute or chronic conditions.
11. *Pulmonary embolism*[132,216]: In general, the degree of cTn elevation is related to the degree of right ventricular (RV) dysfunction, and therefore to the severity of pulmonary hypertension induced. Increased cTn defines a patient who is at high risk; some have advocated that it should be used as an indication for the use of thrombolytic therapy of PE. This recommendation is premature at the present time. Elevations that occur with PE usually resolve within 40 hours. If they do not, one should consider recurrent emboli or another cause, along with or independent of pulmonary embolism.
12. *Sepsis*[7,46,384]: Severe septicemia with hypotension probably has multifactorial causes for increases in cTn. Such increases are often related to elaboration of toxic cytokines such as tumor necrosis factor (TNF) alpha and heat shock proteins; a relationship has also been noted between the magnitude of cTn elevation and the extent of myocardial depression associated with cTn elevation. Nonetheless, the extent of myocardial suppression is over and above that associated with a modest increase in cTn. In addition, catecholamines often used to treat these patients may contribute to the supply-demand imbalance associated with type 2 AMI.
13. *Burns:* Only when they are severe are elevations observed; this probably reflects the marked hemodynamic changes associated with severe burns.[282]
14. *Acute neurologic disease*[183,285,377]: Increases probably represent reflex stimulation from the central nervous system. A very substantial literature suggests that such is the case, and that such increases seem to be related to insults in the midbrain[44]; they are particularly prominent with subarachnoid bleeds. Such elevations are highly prognostic but not necessarily for coronary heart disease.
15. *Rhabdomyolysis:* Rhabdomyolysis can occur systemically with associated cardiac injury.[37]
16. *Transplant vasculopathy:* Monitoring of cTn has not been useful as an early marker, but elevations do occur with both transplant vasculopathy and rejection.[259]

17. *Vital exhaustion*[80,99,263,327]: Severe exercise has been shown to cause release of cTn. Whether this implies an element of minor myocardial injury or whether this could be release of cTn from the "cytosolic" pool is a difficult issue. Nonetheless, studies suggest that patients, despite some having cMR evidence of cardiac injury, do well and do not require emergency hospitalization.[70]
18. *Chronic elevations of cTn:* Any chronic cardiac comorbidity, whether it is coronary artery disease, LVH, heart failure, or diabetes, can be associated with elevations in cTn. In general, these patients are the ones who have the most severe disease and poorest prognosis. Recent data suggest that one can identify patients with chronic heart disease at risk for subsequent events by looking simply at whether a cTn is detectable or not. This suggests that with more sensitive assays, we may be able to identify patients who are at greater versus lesser risk from chronic heart disease. In addition, left ventricular hypertrophy and heart failure, both of which can cause increased wall stress and reduced subendocardial myocardial perfusion, are known to be associated with elevations in cTn. The prognostic significance of such elevations in older individuals is clear.
19. *Hypothyroidism:* This is a rare cause of cTn elevation.[349] Usually, hypothyroidism in the modern era is detected fairly early and treated, and it seems to take fairly severe hypothyroidism for elevations in cTn to occur. This is in contrast to previous literature, which suggested a high frequency of elevated CK-MB. Given the cTn data, it is likely that CK-MB elevations were due to skeletal muscle abnormalities, rather than to cardiac problems, as some might have initially surmised.
20. *Infiltrative disease such as amyloid*[113,114] and cardiomyopathies such as hemochromatosis are capable of causing increased cTns. In general, elevations are modest but very negatively prognostic.

In addition, one should always consider the possibility that chronic elevations are artifactual. Heterophilic antibodies can interfere in cTn assays (though less commonly than in the past) by binding to antibodies in the reagent. Some patients have antibodies that bind cTn, creating immunoglobulin-cTn complexes that are poorly cleared from the circulation, leading to increased concentrations of cTn in blood that do not indicate cardiac injury. Unexpected cTn results should be evaluated by the laboratory. Usually, when an interferant is present, dilution studies fail to give a linear pattern. Heterophile-blocking reagents can be used to minimize the effects of heterophilic antibodies. On occasion, even more sophisticated methods may be necessary to document false positives. Nonetheless, false-positive elevations appear to be relatively uncommon with present day cTn assays.

The Future

High-sensitivity cTn assays are being developed (see Table 47-1).* They have the ability to define normal values in most, if not all, individuals (see Figure 47-11). Present data indicate that these assays have the ability to allow for much more rapid diagnosis of acute myocardial infarction, and that values have prognostic significance (Figure 47-19). Perhaps with this approach, patients previously thought to have unstable angina (no cTn elevations) will be detected as having elevations. In addition, recent information suggests that positive stress tests might be predicted by increases of cTn measured by hs-cTn assays, although this result is controversial.[215,332] If so, a very rapid rule-out strategy might be possible that involves eliminating an acute coronary syndrome by finding the absence of an increasing pattern of cTn, precluding the need for stress testing. This would allow for the very rapid triage of patients with chest discomfort. In addition, recent data suggest that cTn increases may be useful in monitoring patients with more chronic heart disease, as indicated by data showing an adverse prognosis related to cTn levels in the Prevention of Events with Angiotensin Converting Enzyme Inhibition (PEACE) trial. Essential to the ability to use these assays properly will be the need to eliminate the use of large numbers of zeros. Thus, values will need to be reported as pg/mL or ng/L.

Clinical Use of Creatine Kinase-MB (CK-MB)

Considering CK-MB an obsolete test has met with considerable resistance,[60,67,134,334] in part because of difficulty clinicians have had in understanding how to utilize cTn measurements. This has been fueled in part by heterogeneity in the cTn assays available, diversity in the cutoffs intermittently advocated, and difficulty in understanding how to respond to elevations in cTn that are seen with cTns but not with CK-MB because troponin is so much more diagnostically sensitive than CK-MB. Nonetheless, several groups have advocated that CK-MB assays should be eliminated. The major push for this comes from the thought that not only do they add expense while not adding value, but because clinicians who continue to rely on CK-MB often do patients a disservice. In addition, these assays retard clinicians' ability to learn how to use cTn measurements properly, which would be more efficacious in almost every situation. Accordingly, serious consideration should be given by laboratories to discontinuing the use of CKMB. Testing is not essential even for skeletal muscle disease in which total CK is appropriate, but it does eliminate a source of what some would argue is confusion for clinicians. This position has been well articulated in a recent editorial.[334]

Those who advocate continued use of CK-MB point to a small number of instances that are worthy of consideration. The first includes the most controversial, which is the area of recurrent infarction after an index AMI. When initial guidelines for the use of cTn were developed, how well one would do in diagnosing recurrent injury with cTn was called into question because cTn elevations persist for so long. Recent data suggest that cTn values detect acute recurrent injury very well (Figure 47-20), and that re-elevations occur with sufficient robustness that they can be detected promptly.[20] From first principles related to both sensitivity and specificity (see earlier), some would argue that cTn would be clearly superior

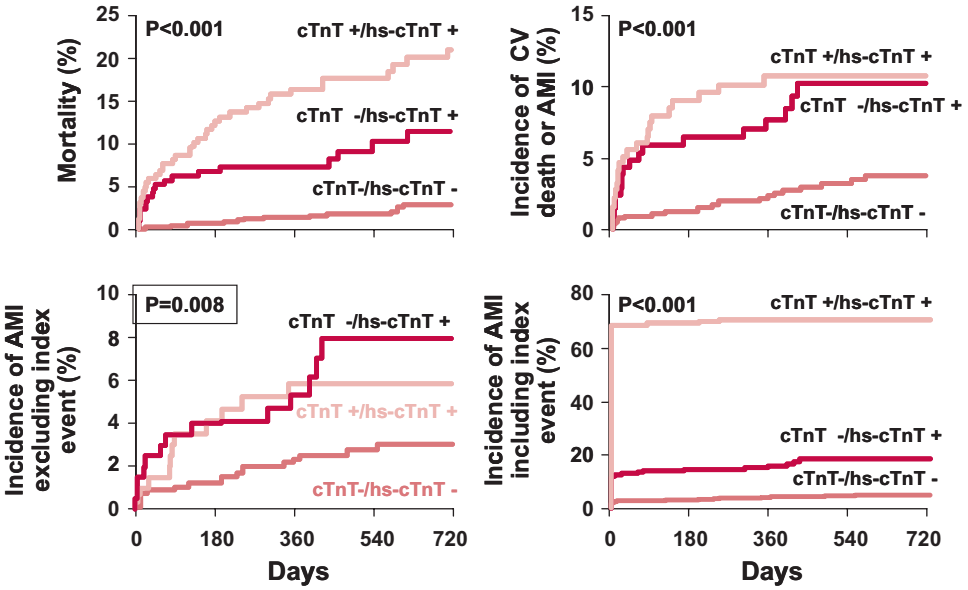

Figure 47-19 Kaplan-Meier analyses according to cutoffs of troponin T assays. Result above the cutoff is indicated by +; result equal to or below the cutoff is indicated by –. The cTnT assay used a cutoff of 0.010 μg/L (i.e., the lower limit of detection) because the 99th percentile was below this cutoff). The hs-cTnT used a cutoff of 0.014 μg/L (99th percentile). *P* value by log-rank test. *(From Hochholzer W, Reichlin T, Twerenbold R, Stelzig C, Hochholzer K, Meissner J, et al. Incremental value of high-sensitivity cardiac tropinin T for risk prediction in patients with suspected acute myocardial infarction. Clin Chem 2011;57:1318-26.)*

in this area. Nonetheless, the diagnosis of reinfarction is common after non–Q-wave myocardial infarction, and because CK-MB was initially used to unmask this, people have retained some enthusiasm for its use. This occurred in part because in the past, if individuals had had chest pain, this did not trigger a rapid evaluation. Thus, because CK-MB returns to normal earlier, its elevation was helpful. In modern practice, most patients with ACS are seen when chest pain is present and serial values are obtained. Thus, in the series by Apple,[20] every patient identified had normal values of CK-MB, which subsequently increased to reach an abnormal threshold (see Figure 47-20). Accordingly, serial samples are required for both analytes; if this is done, CK-MB possesses no characteristics that would make it superior to cTn. This early surveillance is needed in part because non-STEMI in the modern era is optimally treated by an invasive strategy, meaning that almost all patients go for cardiac catheterization and often undergo percutaneous intervention.

When such patients have recurrent chest discomfort, most immediately go back for coronary angiography to evaluate whether the chest pain is indicative of a problem with the area that has undergone intervention (e.g., stent thrombosis), or whether severe diminution in flow is present in that vessel. Thus, the only patients who are really held for evaluation are those in whom there is uncertainty about the diagnosis, and for this group, one needs to wait for serial samples. Indeed, this is the recommendation of the ACC/AHA committee on the management of patients with unstable angina and non–Q-wave myocardial infarction. Despite this recommendation, the committee does suggest in its guidelines that CK-MB may be useful. As indicated earlier, a substantial number of individuals would disagree.

Other uses for which CK-MB is often talked about have to do with patients with renal failure. Such an advocacy is misplaced because prior data suggest that as many as 20% of renal failure patients have increased CK-MB, probably as the result of concurrent skeletal muscle myopathy.[182] Similar claims have been made for the evaluation of patients after extreme or severe exercise, because it is well known that cTn elevations occur in these individuals. However, this advocacy does not take into account the very extensive literature documenting marked elevations in serum CK-MB in almost all individuals after extreme exercise; these elevations are due predominantly to the release of skeletal muscle CK and re-expression of the B chain of CK, which increases the percentage of CK-MB with respect to total CK in skeletal muscle.[5,350]

Very few other indications exist for the use of CK-MB, except when cTn measurements are unavailable. This is a rare circumstance in the United States and in most of western Europe but probably does occur elsewhere in the world, perhaps in countries with a much lower incidence of myocardial infarction, or countries that are resource poor and cannot afford the equipment needed to measure cTn. In this circumstance, most countries would rely on total CK moving back even another step. In addition, immunoassays for cTn and CK-MB are reasonably comparably priced and use similar types of equipment. Nonetheless, if CK-MB is to be used, mass assays are considered far preferable. This is due to the fact that they are more sensitive and less prone to artifactual

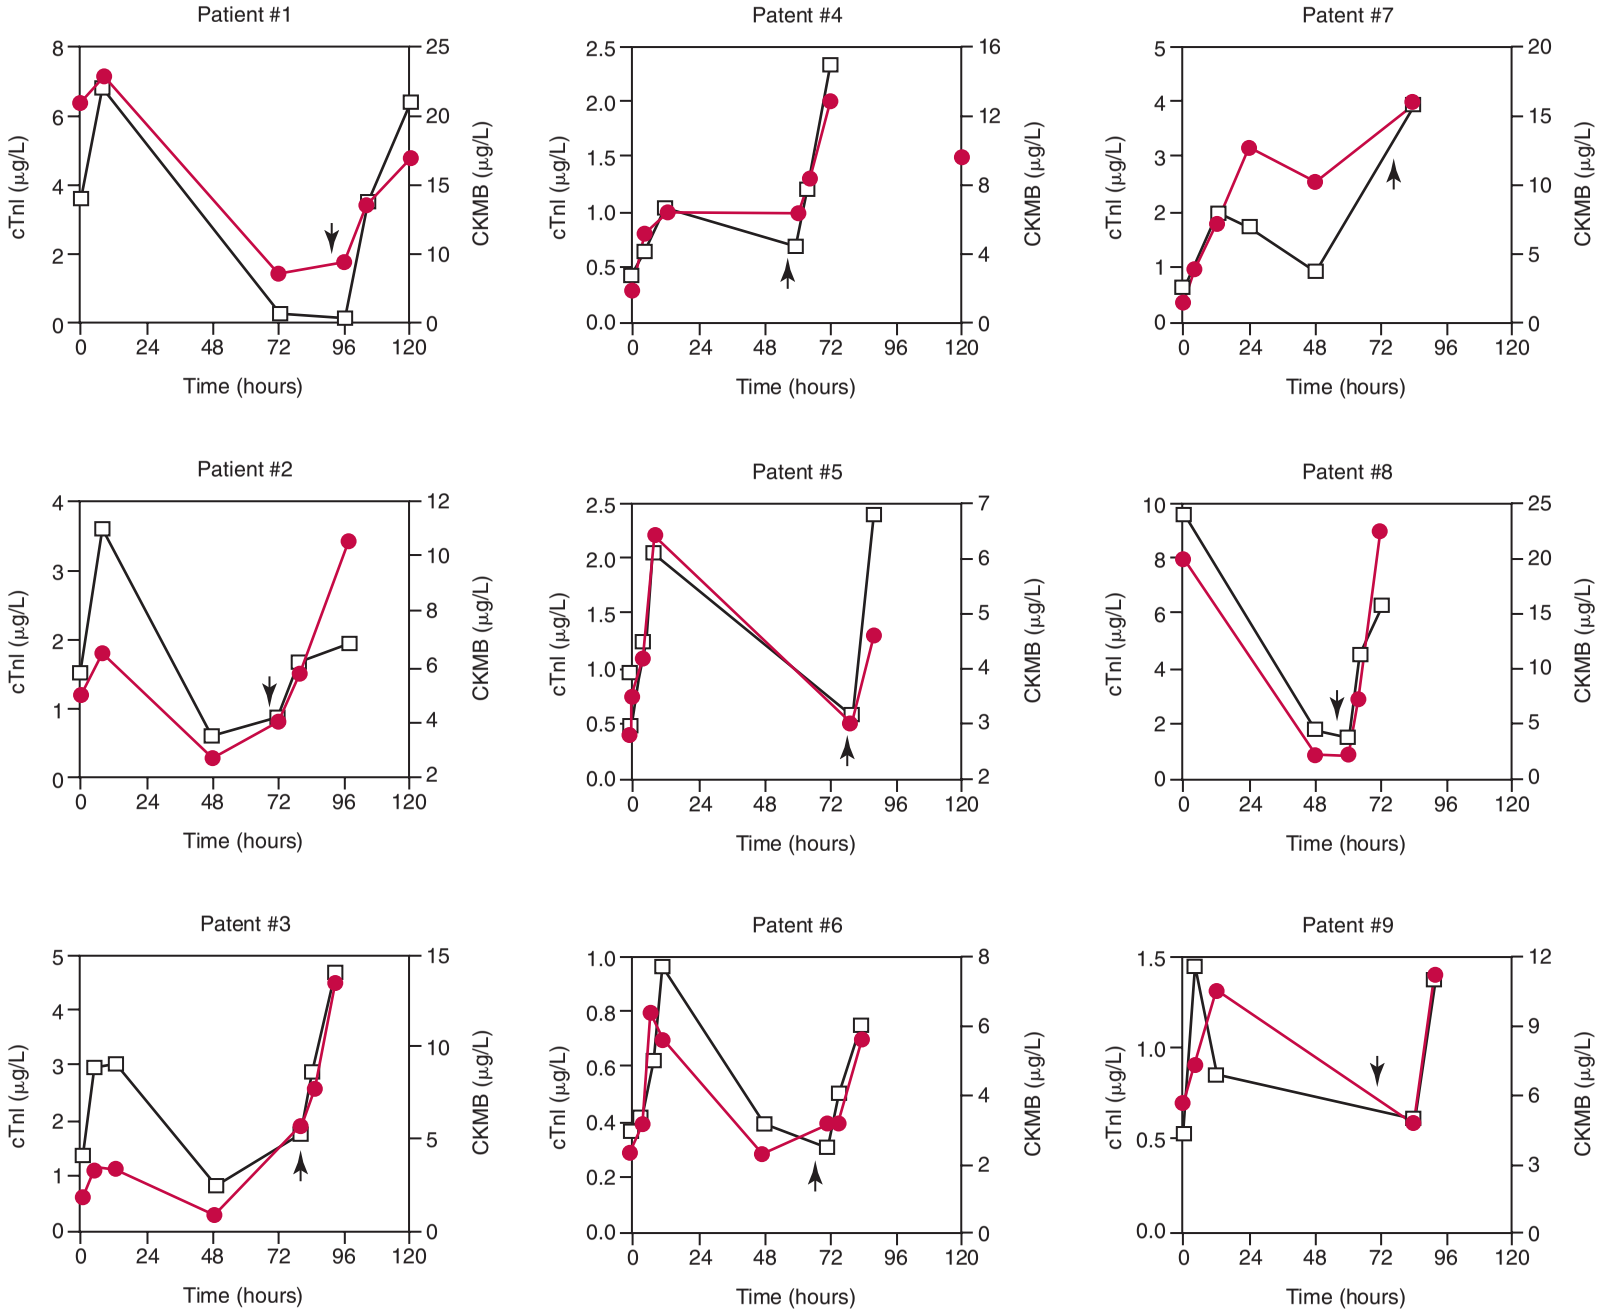

Figure 47-20 Time course of changes in biomarker concentrations in nine myocardial infarction patients who experienced reinfarction during hospitalization. *Red closed circles,* CTnI; *black open squares,* CKMB. *(From Apple FS, Murakami MM. Cardiac troponin and creatine kinase MB monitoring during in-hospital myocardial reinfarction. Clin Chem 2005;51:460-3.)*

elevations. However, increases in CK-MB from skeletal muscle injury clearly confound this measure and need to be taken into account. Use of the relative index (CK-MB divided by total CK), which used to be advocated by some because the percentage of CK-MB in cardiac muscle is so much higher than that in skeletal muscle, was discredited during the initial evaluation of cTn assays. The specificity of diagnosis is clearly improved when the index is used, but because so much CK is present in skeletal muscle, modest concurrent cardiac injury does not provide an adequate signal, so that sensitivity is lost.

Differences between males and females in reference values for CK-MB are likely related to differences in body mass.[30] Thus, if one is using CK-MB, one is obligated to use gender-specific reference intervals, which improve the sensitivity.[209,230,396] This will correct in part for the relative lack of sensitivity of CK-MB, particularly in women. When used, the same criteria as with cTn should be employed (i.e., a rising and/or falling pattern of results with at least one value above the 99th percentile of a normal reference population). However, very clear data indicate that elevations of CK-MB when cTn is normal identify patients who have skeletal muscle injury and not cardiac injury, as suggested strongly by the fact that these individuals do extremely well prognostically and do not appear to have an increased incidence of subsequent cardiovascular events.[141]

Early studies involving animal hearts or specimens obtained at autopsy from human hearts suggested a uniform distribution of CK-MB ranging from 5 to 50% of total CK activity.[220] However, it has been shown that the proportion of CK-MB was 6 to 15% lower in surrounding normal areas of tissue than in infarcted myocardium in humans. Further, in response to acute and chronic coronary artery occlusion in a dog model, myocardium showed twofold to threefold increases in CK-MB in both ischemic and nonischemic myocardium.[343,344] When studied more completely in humans, CK-MB concentrations in heart tissue were found to be variable, ranging from 15 to 24% of total CK in myocardial tissue obtained from patients with LVH caused by aortic stenosis, from patients with CAD without LVH, and from patients with CAD and LVH due to aortic stenosis. In contrast, patients with normal left ventricular tissue had a low percentage of CK-MB (<2%).[173] These data suggest that changes in CK isoenzyme distribution are dynamic and occur in hypertrophied and diseased human myocardium. Diseased cells also have less total CK per cell.

Normal skeletal muscle, depending on its location, contains very little CK-MB.[220] Percentages as high as 5% to 7% have been reported, but values less than 2% are much more common. Some differences are related to slow versus fast twitch muscle, and thus also to race. Severe skeletal muscle injury following trauma or surgery can lead to absolute elevations of CK-MB to above the upper reference limit of CK-MB in serum. However, the percent CK-MB in serum would be low (percentages advocated vary, but in comparisons of activity versus activity, a percentage less than 5% is often used, and when one compares CK activity with CK-MB mass, a percentage less than 2.5% is usually advocated).[220] Increases in serum total CK and CK-MB in several patient groups present a diagnostic challenge to the clinician. Persistent elevations of serum CK-MB resulting from chronic muscle disease occur in patients with muscular dystrophy, end-stage renal disease, or polymyositis, and in healthy subjects who undergo extreme exercise or physical activity. The increase in serum CK-MB in runners, for example, may be related to adaptation by skeletal muscle during regular training and after acute exercise, resulting in increased CK-MB tissue concentrations.[32]

Biomarkers No Longer of Clinical Use

Creatine Kinase (CK) Isoenzyme Electrophoresis and CK Isoforms

Three cytosolic isoenzymes (CK-3, CK-2, CK-1) and one mitochondrial isoenzyme (CK-Mt) of creatine kinase (CK) (MW 80,000 Da for all four isoenzymes) have been identified and are easily separated on agarose and cellulose acetate by electrophoresis.[13,311] Three different genes have been identified that encode for and are specific for CK-M, CK-B, and mitochondrial CK subunits.[306,329] Although CK-3 (CK-MM) is predominant in both heart and skeletal muscle, CK-2 (CK-MB) has been shown to be more specific for the myocardium, which contains 10 to 20% of its total CK activity as CK-MB, compared with amounts varying from 2% to 5% in skeletal muscle.

Numerous investigators have shown that electrophoresis of CK isoenzymes, with extended electrophoresis times or electrophoresis at higher voltages, further separates the bands of CK-MM and CK-MB.[391] At least three CK-MM isoforms and at least four CK-MB isoforms (subtypes of individual isoenzymes) exist. The tissue isoform (gene product) of CK-MM is designated $CK\text{-}MM_3$. When this protein/enzyme is released into the circulation, a time-mediated carboxypeptidase hydrolysis of C-terminal lysine residues occurs, giving rise to at least two post-translational products: $CK\text{-}MM_2$ and $CK\text{-}MM_1$.[305] Similarly, following release of the CK-MB tissue isoform into the circulation, carboxypeptidase cleavage of the CK-B carboxy-terminal lysine residue gives rise to a B-chain–negative product, and then a product devoid of lysines on both chains. Only tiny amounts of the M-chain–negative, B-chain–positive form are reproduced. Because only two forms are separated by electrophoresis (the B-chain–negative, M-chain–positive form comigrates with the tissue form and a small amount of the M-chain–negative, B-chain–positive form migrates with the ultimate conversion product), only two forms have been used diagnostically, and they have been labeled $CK\text{-}MB_2$ and $CK\text{-}MB_1$.[1,2,59] The clearance rate of total CK activity from blood is a composite of the clearance rates of the individual isoforms.[3] More prolonged half-lives are associated with the post-translational degradation isoforms. Thus the orders of half-lives are $CK\text{-}MM_1 > CK\text{-}MM_2 > CK\text{-}MM_3$, and $CK\text{-}MB_1 > CK\text{-}MB_2$. Studies in an experimental animal model and in humans have shown

that post-translational modifications of isoforms occur in blood, are unidirectional, and do not occur in the lymphatic system or in necrotic tissue.[4]

Myoglobin

Myoglobin is an oxygen-binding protein of cardiac and skeletal muscle with a molecular mass of 17,800 Da. The low molecular weight and cytoplasmic location of the protein probably account for its early appearance in the circulation following muscle (heart or skeletal) injury. No difference in myoglobin protein localization has been noted in the heart versus skeletal muscle. Increases in serum myoglobin occur after trauma to skeletal or cardiac muscle, as is seen in crush injury or MI.[378] Serum myoglobin methods are unable to distinguish the tissue of origin because the proteins are identical.[351] Even minor injury to skeletal muscle may result in elevated concentrations of serum myoglobin, which may lead to misinterpretation of myocardial injury.[376] Because myoglobin is cleared renally, changes in the glomerular filtration rate (GFR) will cause increases. It has a very short half-life of 10 minutes in blood.

Lactate Dehydrogenase Isoenzymes

Lactate dehydrogenase (LD) (MW 180,000 Da) is localized in the cytoplasm of tissue.[231] Even though LD isoenzymes are rarely used in clinical practice anymore, for historical purposes their biochemistry will be described here, and readers are referred to previous versions of this chapter. The highest activities of LD are found in skeletal muscle, liver, heart, kidney, and red blood cells. Electrophoresis on a variety of gels and buffer media, combined with kinetic and immunologic studies, has provided convincing evidence of the existence of at least five isoenzymes, composed of four subunit peptides of two distinct types, designated M (for muscle) and H (for heart). LD-1 (H_4) moves fastest toward the anode, while LD-5 (M_4) is closest to the cathode on an electrophoretic gel. LD-1 is found in highest concentrations in the heart, kidney (cortex), and red blood cells. LD-5 is found in highest concentrations in liver and skeletal muscle. The hybrid LD isoenzymes LD-2 (H_3M), LD-3 (H_2M_2), and LD-4 (HM_3) are also found in these and several other tissues.

Because LD is not a tissue-specific enzyme, it is not surprising that serum total LD is increased in a wide variety of diseases. Studies have demonstrated that activities of total LD and LD-1 increase from right to left ventricles, with H subunit activity varying twofold between different locations of the heart. As with CK-2 in skeletal muscle, the heart-specific LD-1 isoenzyme in skeletal muscle can increase twofold (from 10 to 20% of total LD activity) during a 9 week period of exercise training, with parallel decreases in LD-5.[19] Thus one must be aware that acute and chronic injury incurred during exercise training and racing increases total LD in serum, especially LD-1 and the ratio of LD-1 to LD-2. The tissue source of these increases is likely skeletal muscle as opposed to myocardium.[19,31,180]

CONGESTIVE HEART FAILURE

Natriuretic Peptides—Analytical Considerations

Biochemistry

An endocrine phenotype of the heart muscle was suggested by anatomic findings half a century after the discovery of endocrine substances by Drs. Starling and Bayliss.[51] In the 1960s, electron microscopy revealed granules in the cytoplasm of atrial myocytes, which structurally resemble secretory granules in known peptide hormone–producing cells.[186,206] In 1981, the Canadian physiologist Adolfo de Bold and his colleagues reported that infusion of atrial tissue extracts elicits renal excretion of sodium and water.[102] Moreover, a rapid decrease in blood pressure and increase in blood hematocrit were observed, and the substance was named *atrial natriuretic factor.* Soon after, this factor was purified and identified as a peptide comprising 28 amino acid residues; it was renamed *atrial natriuretic peptide (ANP).*[103,124] This discovery paved the way for identification of two structurally related peptides in the porcine brain: brain natriuretic peptide (BNP) and C-type natriuretic peptide (CNP).[288,360,361] However, BNP is mainly expressed in the heart, and the name *brain natriuretic peptide* is now often replaced with B-type natriuretic peptide (Figure 47-21).[360,361] CNP is expressed in the invertebrate heart and can be considered the ancestor gene for the natriuretic peptide family.[174] Nevertheless, the CNP gene is not expressed to the same extent in mammalian hearts and should not be considered as a cardiac-derived peptide in humans, where the gene is expressed dominantly in other tissues, including the vasculature and the male reproductive glands.[291,338]

The endocrine heart gained clinical interest when it was reported that patients with cardiac disease displayed increased concentrations of ANP in plasma.[72,75] In parallel, BNP circulates in highly increased concentrations in patients suffering from congestive heart failure.[277,278] The concept of a quantitative plasma marker of the heart failure syndrome was thereby introduced and has been intensely pursued with a dominant focus on clinical applications. In addition to the bioactive end products, N-terminal fragments from the precursors of ANP and BNP, proANP and proBNP, were shown to circulate in heart failure plasma and provided new molecular targets for biochemical detection.[65,72,169,228] As of today, proBNP-derived peptides have become the preferred routine markers in heart failure diagnosis and prognosis because of the available automated assays; the clinical relevance of peptide measurement is frequently and extensively reviewed.[84,91,92,96]

In contrast to the clinical focus on the diagnostic possibilities, much less is known concerning the biosynthesis of proBNP-derived peptides.[137] The post-translational phase of gene expression and the cellular secretion still remain incompletely characterized. The first data on molecular composition in tissue and plasma suggested an overall simple cellular maturation with only one endoproteolytic cleavage of proBNP prior to secretion of BNP. However, cardiac myocytes possess

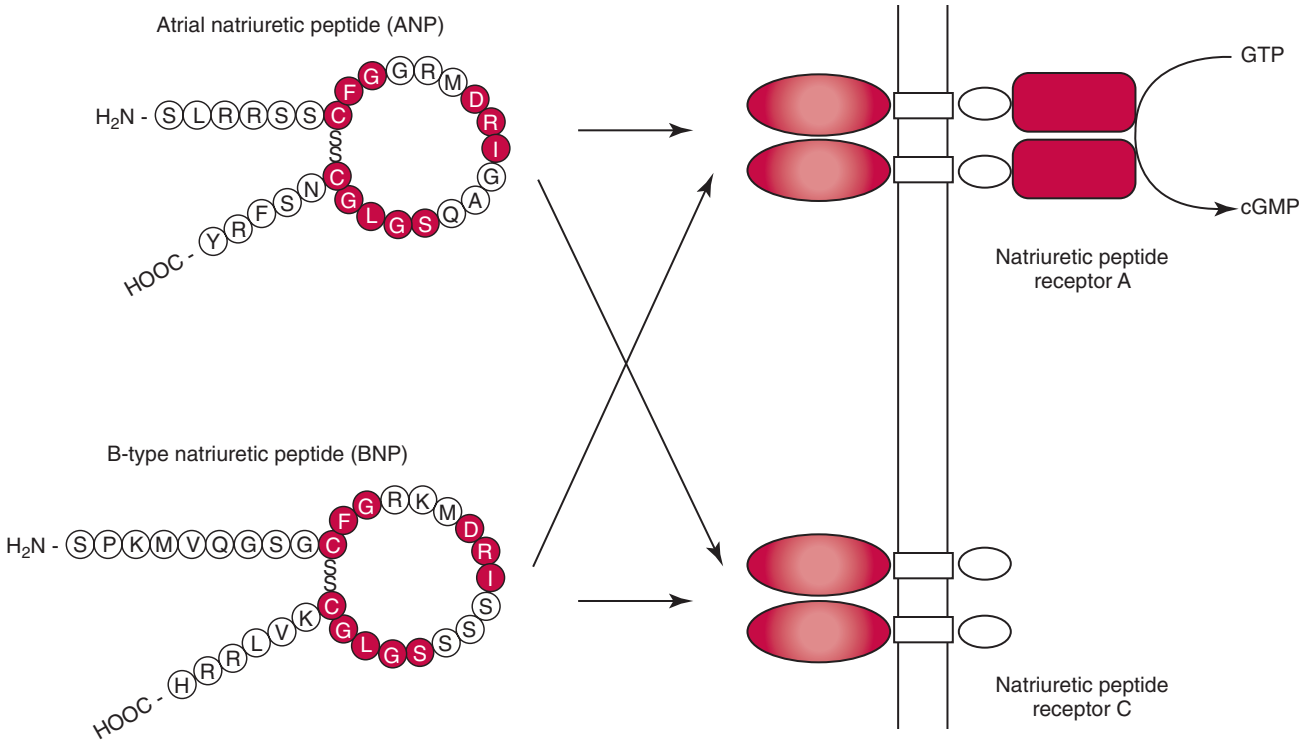

Figure 47-21 Schematic presentation of human atrial and B-type natriuretic peptides with their principal receptors. Homolog amino acid residues between the natriuretic peptides are marked in *bold circles*. The natriuretic peptide receptor (NPR)-A mediates atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) signal transduction through induction of cyclic guanosine monophosphate (cGMP); the NPR-C receptor lacks the intracellular domain and has been classed primarily as a clearance receptor.

a biosynthetic apparatus, including several enzymes for propeptide processing, and cardiac prohormone maturation has proved to be much more complex than was initially assumed. Clinical studies have also revealed that plasma concentrations of the different proBNP-derived peptides vary greatly, which suggests that cardiac myocytes may not always release different biosynthetic products on a simple equimolar basis.[137,167]

Peptide Nomenclature and Biosynthesis

Some confusion has arisen as the result of an incoherent nomenclature for cardiac natriuretic peptides. In some ways, this confusion reflects underlying lack of knowledge of biosynthetic products, which has led researchers to apply nonspecific terms for the measured substances. However, a stringent nomenclature is essential for an understanding of peptide structure and function.[315] If the measured peptide is not readily distinguishable by its name, simple comparisons of reported concentrations may confuse and at worst may lead to incorrect decisions. For instance, some of the abbreviations used do not identify the measured peptide(s), which should be the primary goal of a name. A common abbreviation "NT-proBNP" is used for one particular analytical method; this refers to the measurement of nonglycosylated proBNP 1-76, against which the immunoanalysis is calibrated. However, the abbreviation does not provide specific information on the primary structure that is actually measured, which includes the intact precursor (proBNP 1-108) with some cross-reactivity to the glycosylated forms (see later). Other investigators have used broader terms for plasma measurement, as for instance "N-BNP," which refers to measurement of intact proBNP 1-108, as well as its N-terminal fragment(s). However, this abbreviation leaves the less astute user with the impression that it is the N-terminus of BNP that is measured. The use of abbreviations such as "BNP 77-108" is simply incorrect (BNP includes only 32 amino acid residues). Thus, BNP-32 is synonymous with proBNP 77-108. A rational nomenclature needs to be structurally informative and should see the name in relation to its origin (i.e., with insight into and reference to biosynthesis of the precursor). If this information is not available, then that should be stated. In the following section, a nomenclature based on these premises will be attempted.

Pretranslational Phase of B-Type Natriuretic Peptide Gene Expression

Human atrial natriuretic peptide (ANP) is encoded by the gene natriuretic peptide A (symbol *NPPA*), and B-type natriuretic peptiede (BNP) is encoded by the gene natriuretic peptide B (gene symbol *NPPB*). Both are located on chromosome 1.[40,411] In rodents, these genes are located on

chromosome 4 (mouse) or chromosome 5 (rat). The overall gene structure is simple and resembles that of other peptide hormone genes in size and composition, with three exons separated by two introns. For both ANP and BNP, the major part of the coding sequence resides in exon 2. Genetic polymorphisms and mutations have been reported in both genes, as well as in the natriuretic peptide receptor genes.[219] Although the impact of genetic variation on the ANP and BNP systems remains to be fully established, it seems reasonable to suspect that it may affect the plasma concentrations in a heritable manner, which in fact has been reported in the general population.[387] A common polymorphism in the BNP promoter region has been associated with the prevalence of type 2 diabetes.[256] Genetic variation in cardiac natriuretic peptides may thus be involved in the pathophysiology of a common metabolic disorder. To complicate matters, diabetes mellitus induces increased risk for development of cardiovascular disease with concomitant changes in cardiac natriuretic peptide expression.[83] In addition to the promoter polymorphism, a frameshift mutation in the ANP gene has been reported in heritable atrial fibrillation. The frameshift introduces a C-terminally extended ANP peptide.[164] The "mutant" ANP exerts an exaggerated effect on potassium current in a cultured cell line.[4A]

Mature ANP and BNP transcripts consist of approximately 500 to 700 base pairs. Although intracellular regulation of natriuretic gene transcription is extensive as has been reviewed elsewhere,[129,221,253,254] both genes seem regulated by the same transcriptional factors, including p38 mitogen-activated protein kinase (MAPK). p38 MAPK activates the transcription factor nuclear factor-kappaB (NF-κB) and subsequently ANP and BNP gene transcription.[228A,371A] Vasoactive substances such as catecholamines and angiotensin II increase natriuretic gene transcription in a p38 MAPK–dependent manner. Myocyte stretching increases the intracellular calcium concentration and modulates calcium-binding proteins that regulate downstream modulators, including calcineurin, which stimulates myocyte natriuretic gene expression.[214A] Thus, cardiac natriuretic gene expression can be modulated by blocking p38 MAPK and calcineurin pathways. Finally, the hypoxia-inducible transcription factor (HIF) 1-alpha activates both ANP and BNP transcription, which is of importance in ischemic heart disease.[83A,389A] One scenario in which ANP and BNP genes seem not to be coregulated is inflammation driven by specific cytokines, where BNP gene expression is increased and ANP gene expression is unaffected.[241A] This differential gene expression has led to the suggestion that concurrent measurements of ANP and BNP and their related peptides might be clinically useful in conditions with both hemodynamic changes and a proinflammatory drive on the cardiac myocytes, as seen after cardiac transplantation.[101]

One feature of ANP and BNP messenger RNA (mRNA) regulation should be recapitulated. Although gene expression is regulated at the transcriptional level, another relevant mechanism involves changes in mRNA stability and the half-life of transcripts. This RNA regulatory mechanism has been demonstrated for BNP mRNA through stimulation of alpha-adrenergic receptors.[149A,149B] BNP mRNA stabilization is thought to be mediated through AU-rich elements in the 3′-untranslated region, which is not present in the ANP gene. Consequently, mRNA stabilization seems to involve only BNP, not ANP, mRNA.

Primary Structure of proBNP

Human proBNP comprises 108 amino acid residues (Figure 47-22). The primary structure is slightly shorter in mouse but with a similar C-terminal region, including the bioactive receptor–binding motif. Mammalian precursor sequences have been deduced from complementary DNA (cDNA) sequences that encode the entire preprostructure.[41A,236A,359A,360A] Amino acid homology between species is largely confined to the amino- and carboxy-terminal regions, whereas the remaining prostructure varies considerably between animals. Moreover, the principal motifs for amino acid modifications and enzymatic prohormone processing are not well conserved between species.

Human preproBNP contains an N-terminal hydrophobic signal peptide of 26 amino acid residues (see Figure 47-22). As with most regulatory peptides, this sequence is removed

Figure 47-22 The primary structure of proBNP (pro-brain natriuretic peptide) in four mammals. The human proBNP sequence comprises 108 amino acid residues. The precursor sequence is evolutionary and is conserved in the C-terminal region that makes up the bioactive natriuretic peptide. In contrast, the cleavage site corresponding to position 73-76 in the human sequence is not well conserved. Amino acids are indicated by their single-letter codes.

during translation before synthesis of the C-terminal portion of the precursor is completed. Therefore, preproBNP does not exist as a separate entity but is only a theoretical structure. On the other hand, proBNP is likely to be an existing polypeptide; this has been indicated by chromatographic profiling and sequence-specific immunoassays.[135,169,338A,339A] The precursor molecule remains to be purified together with the processing intermediates there of—apart from the C-terminal 32 amino acid cleavage product (i.e., BNP-32) and the N-terminal region of the precursor.[4B,124A,163A,192A,262A] Thus, whenever the primary proBNP structure is mentioned, it still refers to the cDNA-deduced preprosequence combined with antibody-based data derived from chromatographic elution, Western blotting, or immunoassays.

Post-Translational Phase of B-Type Natriuretic Peptide Gene Expression

Post-translational BNP processing has only recently become a subject of interest. One contributing factor to this may relate to the troublesome lack of useful in vitro cellular models. Although neonatal atrial myocytes can be cultured for short periods of time, they do not anatomically or functionally resemble differentiated atrial or, for that matter, ventricular myocytes. Moreover, only a few immunoassays have been available for characterizing the molecular heterogeneity of the processing intermediates. Recent advances through mass spectrometry combined with the development of sequence-specific antibodies nevertheless have revealed a complex cardiac biosynthesis of cardiac natriuretic peptides.

Disulfide Bond Formation

The proBNP structure appears simple (see Figures 47-21 and 47-22). In humans, it is divided into two principal regions by a cleavage site in position 73-76 (Arg-Ala-Pro-Arg). The first region is the N-terminal fragment proBNP 1-76, and the second region is the C-terminal BNP-32 (proBNP 77-108). In contrast to other prohormones, proBNP does not contain a C-terminal flanking region. The C-terminal region contains a ring structure formed by a disulfide bond between the cystyl residues in positions 86 and 102, respectively (see Figure 47-21). The ring formation is essential for receptor binding and biological activity.[265] This crucial modification in ANP and BNP synthesis takes place in the endoplasmic reticulum and may be considered the first step in post-translational processing. The protein disulfide isomerase family and thiol-disulfide oxidoreductases are likely candidate enzymes involved in cardiac myocyte disulfide bond formation. Cardiac expression of the protein disulfide isomerase transcript was recently reported to be upregulated in cardiac disease.[341A] Cellular in vitro experiments further suggest a direct cardioprotective effect of this regulation. It may even be that not all cardiac natriuretic peptides are activated through this enzymatic process, which introduces the earliest possible regulatory step in natriuretic peptide biosynthesis and hormone activation. Regulation of protein disulfide isomerase has been classified as *endoplasmic reticulum stress,* which is a hallmark of several pathologic disorders, including diabetes mellitus, neurodegenerative disorders, and ischemic heart disease.

Glycosylation

Larger forms of BNP than the purified BNP-32 were first suspected from gel filtration studies of cardiac tissue extracts and plasma from patients with severe cardiac disease.[136A,169,338A,347,348] Some data even suggested molecular forms larger than the predicted precursor. Independently, several groups observed immunoreactive forms with molecular masses of 25 to 45 kDa in cardiac tissue and plasma (Figure 44-23). Intact proBNP, however, has an expected mass of ≈11 kDa based on the primary structure. Whether the peculiar elution patterns were in vitro artifacts or represented peptide binding to other molecules was put aside when it was shown that human proBNP exists as an O-linked glycoprotein.[337A] In the precursor structure, the midregion (proBNP 36-71) contains seven seryl and threonyl residues, where O-linked glycosylation occurs fully or partially (see Figure 47-23). This major modification of a polypeptide apparently does not affect the overall structure of the precursor.[93] On the other hand, the presence of carbohydrate groups clearly affects immunodetection if the epitope recognition resides within this region.[339] No specific immunoassay has yet been developed against the glycosylated forms, and the ratio between glycosylated versus nonglycosylated proBNP products can be deduced only from assays that specifically measure the nonglycosylated forms or cross-react with both forms. Whether O-linked glycosylation is an "unlimited" post-translational modification or is affected by increased BNP gene expression, as in heart disease, will be an important question for future studies. It should also be noted that the ANP precursor may be subject to glycosylation. In addition, the proBNP sequence varies considerably between species in the midregion (see Figure 47-22), which probably makes glycosylation a species-specific modification. Finally, it is not known whether atrial and ventricular myocytes possess the same capacity to glycosylate natriuretic precursor peptides.

Glycosylation could perhaps be a biochemical target for diagnostic applications, if the modification is affected by cardiac disease and/or reflects changes in BNP gene expression. Most captivating, however, is the potential impact of early biosynthetic glycosylation on cellular sorting and subsequent precursor processing. Because O-linked glycosylation can occur close to the principal maturation site in position 74-76 (on the threonyl residue in position 71), it should be suspected that the presence of carbohydrate groups can affect processing and hormonal maturation. In turn, this modification could regulate prohormone cleavage by blocking or guiding endoproteolytic enzymes, which may leave the propeptide with reduced or no biological activity. Such post-translational regulation has been shown for other regulatory peptides, as for instance insulin-like growth factor (IGF)-2.[98] Conceptually, immunoreactive BNP with little or no biological activity has been nicknamed "junk-BNP." This "junk" may nevertheless prove to be the most useful peptide forms for diagnostic measurement.

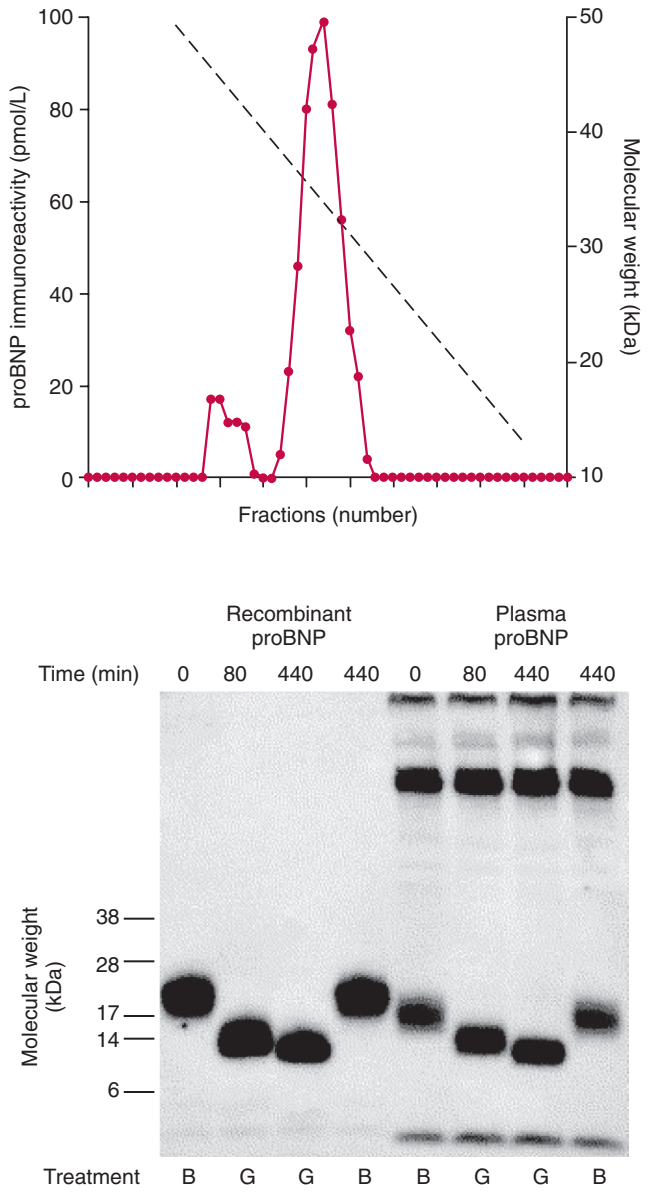

Figure 47-23 The *upper panel* shows a chromatographic profile of proBNP (pro-brain natriuretic peptide) immunoreactivity in human atrial tissue. Cardiac tissue extract was subjected to size exclusion high-performance liquid chromatography (HPLC). Molecular size calibrators, eluted in a separate run, were used in determining molecular sizes *(dashed line)*. The proBNP immunoreactivity eluted in positions approximately three times higher than the theoretical molecular weight of intact proBNP. The *lower panel* displays Western blotting of recombinant *(left)* and patient *(right)* proBNP in buffer *(B)* or after deglycosylation *(G)*. The incubation time is also listed. *(Modified with permission from Schellenberger U, O'Rear J, Guzzetta A, Jue RA, Protter AA, Pollitt NS. The precursor to B-type natriuretic peptide is an O-linked glycoprotein. Arch Biochem Biophys 2006;451:160-6.)*

Endoproteolysis

Human proBNP was first suggested to be cleaved by the ubiquitous endoprotease furin, because furin and the BNP gene are coexpressed in cardiac myocytes.[336A,336B] The Arg-Ala-Pro-Arg motif in position 73-76 in human proBNP has been shown to be a target for furin-mediated cleavage. In fact, endoproteolytic processing can be blocked in vitro by inhibition of furin, and furin has been shown to be essential for maturation of the structurally related CNP.[407] A novel protease named *corin* has been identified from human heart cDNA.[129,408,409] Corin is a serine protease that can cleave both proANP and proBNP in vitro, presumably at a similar cleavage site.[408,409] Corin contains a transmembrane domain anchored in the cell membrane and is thought to cleave the precursors upon secretion. The enzymatic activity, however, does not require the transmembrane domain because a mutant soluble form also is capable of processing proANP.[206A] A role of corin in the processing of cardiac natriuretic peptides in vivo has been further substantiated by genetic coupling of corin mutations to clinical phenotypes that can be explained by reduced ANP and BNP bioactivity in circulation such as hypertension.[114B,388A] Corin thus seems to be a relevant candidate for cardiac processing of natriuretic peptides generating the N-terminal processing fragments and C-terminal bioactive peptides.[408,410] Of note, no study has yet demonstrated exactly where corin cleaves the proBNP structure. Moreover, atrial post-translational processing of proANP and proBNP is likely to differ from ventricular processing, because isolated atrial granules have been reported to contain both unprocessed proANP and mature BNP-32.[413A] Corin activity alone therefore cannot fully explain the endoproteolytic maturation of cardiac natriuretic propeptides. It should be mentioned that the putative corin site in the BNP precursor is not conserved between mammals, and accordingly, it would be interesting to examine whether human corin can cleave precursor peptides from other mammalian species.

A well-established family of intracellular processing enzymes deeply involved in prohormone maturation is the proprotein/prohormone convertases, or the PCs. In addition to the already mentioned furin, the subtilisin-like endoproteases PC1/3 and PC2 are expressed in the mammalian heart,[51A,60A] and PC1/3 expression has been demonstrated in both normal and pathologic human cardiac tissue.[114C] Atrial myocytes transfected with an adenoviral vector expressing PC1/3 process proANP both to mature ANP and to a truncated form.[248] Although the precise cleavage site was not established and the processing capacity was somewhat inefficient, this singular report does underscore the possibility that other proteases than furin and corin may be involved in the post-translational endoproteolysis of proANP and proBNP. PC1/3 is active in secretory granules and therefore could be an important regulator of atrial proBNP processing. Cardiac PC1/3 expression has been reported to be upregulated at the transcriptional level in heart disease.[190A] Unfortunately, no data are available on other proBNP-derived fragments stemming from endoproteolytic processing. This may reflect the lack of specific tools for identifying such peptide fragments,

which requires antibodies directed at epitopes other than the ones used so far for biochemical identification. Sandwich-based immunoassays usually are not ideal for this type of experiment. The precursor sequence contains several basic amino acid residues that potentially could represent cleavage sites for the PCs, and molecular characterization may not be complete when it comes to identifying processing intermediates from the natriuretic peptide precursors.

Exoproteolysis

N-terminal trimming of proBNP-derived peptides seems to be a biological feature, as both the N-terminus of the biosynthetic precursor and the C-terminal bioactive BNP product contain an amino acid motif for aminopeptidase recognition and cleavage. The N-terminus of both proBNP and BNP-32 (proBNP 77-108) contains a prolyl residue in position 2 (His-Pro and Ser-Pro, respectively). Although prolyl residues are important for peptide structure and folding, they can also be involved in exoproteolytic trimming when located near the N-terminus.[379] N-terminal trimming has in fact been demonstrated for BNP in vitro.[65] When synthetic BNP-32 (proBNP 77-108) is incubated in its presence, dipeptidyl peptidase (DPP)-IV removes the N-terminal Ser-Pro residues. DPP-IV is an enzyme located mainly on endothelial cells and in the circulation, with a preference for cleaving N-termini with prolyl or alanyl residues in the second position.[5A] Thus, this DPP-IV cleavage in BNP-32 cannot per se be considered part of the biosynthetic maturation, but rather is related to the elimination phase. An N-terminally trimmed form of proBNP lacking the His-Pro residues in position 1-2 has been reported in heart failure patients.[217A] This report disclosed that a truncated proBNP 3-108 form circulates in increased concentrations in heart failure patients. In this context, it is noteworthy that the initial report on glycosylated proBNP in a recombinant expression system (CHO cells) also identified a truncated proBNP 3-108 form in cell extracts.[337A] Although this finding may be explained by experimental handling of extracts and medium, it could also imply that N-terminal exoproteolysis is a biosynthetic event. N-terminal trimming as a part of peptide biosynthesis has for instance been demonstrated for melittin, which is a secretory peptide produced in honey bee venom glands.[209A,209B] In mammalian cells, intracellular aminopeptidase has been reported in compartments different from the lysosomes, suggesting N-terminal trimming as a possible part of the biosynthetic peptide maturation.[80A,377A] Whether the trimming of BNP and its molecular precursor serves an actual regulatory function in cardiac natriuretic peptide physiology remains an open question for future experimental research. One could speculate that amino-terminal trimming affects the metabolic fate of the peptides and thus their turnover in circulation. However, no data are available on the actual biological relevance of these trimmings.

Cellular Storage and Secretion

BNP gene expression is a feature of both atrial and ventricular myocytes. In the normal heart, the main site of BNP expression is in the atrial regions.[82,238A] Ventricular BNP gene expression increases drastically in cardiac disease that affects the ventricles (i.e., congestive heart failure).[278] The observation of ventricular BNP gene expression in ventricular disease may have given rise to the common statement that BNP is predominantly a ventricular hormone. Atrial and ventricular myocytes, however, differ considerably with respect to their endocrine phenotypes, and it is reasonable to expect major differences in peptide storage and secretion patterns.[114A,140A] For instance, atrial myocytes contain intracellular granules for peptide storage and maturation; this actually contributed to the primary hypothesis of the endocrine heart.[186,206] Atrial granules contain both intact precursors and biosynthetic end products (i.e., bioactive ANP-28 and BNP-32). In contrast, normal ventricular myocytes do not seem to express such granules, and normal ventricular myocytes do not contain proBNP-derived peptides.[82] A few reports have observed granules and proBNP-derived peptides in ventricular myocytes sampled from pathologic hearts.[152,289,364] Thus, ventricular myocytes not only regulate the BNP gene at the transcriptional and post-translational levels but also seem to be able to differentiate with respect to the biosynthetic apparatus per se.

An acidic protein class involved in granule formation is the chromogranins.[368] Chromogranins, or just granins, comprise at least three proteins (A, B, and C) that possess aggregation characteristics suggesting a function in the formation of secretory granules. Cardiac expression of chromogranin A and B has been established.[156,356,374] With cardiac chromogranins, however, the focus has mainly been on the potential biological activity of chromogranin-derived fragments (the vasostatins) or on plasma measurement for diagnostic purposes. Whether cardiac chromogranins are involved in the biosynthesis of ANP and BNP through formation of granules remains an area for future study. It should be recapitulated that chromogranin A–deficient mice do not reveal obvious changes in granule formation in, for instance, adrenal chromaffin cells.[157] Cardiac chromogranin B has also been suggested to be directly involved in BNP gene expression through a Ca^{2+}-dependent induction of the BNP promoter.[156] Future in vitro experiments targeted at proANP and proBNP maturation in cardiac cell systems devoid of chromogranin A and B may thus reveal a specific role for the granins in storage and secretion of natriuretic peptides.

ProBNP-Derived Peptides in Plasma

ProBNP-derived peptides are secreted by cardiac myocytes and circulate in plasma. Their molecular heterogeneity has been characterized primarily by chromatography in combination with sequence-specific immunoassays. Much of our present conception of cellular synthesis in fact is derived from the plasma phase, which represents the sum of secretion and metabolism. The picomolar concentrations in plasma limit the possibilities for full biochemical identification and underscore careful understanding of epitope recognition by the immunoassays. With this in mind, it is established that bioactive BNP is secreted from the heart and circulates without binding to plasma proteins.[154] Synthetic BNP-32 (proBNP

77-108) is trimmed when incubated in whole blood, generating a BNP form lacking the two N-terminal amino acid residues.[153,347] As mentioned earlier, this molecular form can also be generated in vitro by enzymatic trimming by DPP-IV and possibly other aminopeptidases.[65] Further processing of plasma BNP seems to involve degradation with loss of bioactivity through disruption of the ring structure mediated by neutral endopeptidase (NEP 24.11) or by receptor-mediated cellular uptake. This has been known for some time; however, the therapeutic potential of inhibiting neutral endopeptidase with increased plasma concentrations of "beneficial" natriuretic peptides is still an appealing strategy.[89] The metabolic fate of BNP-32 has been reported to be 13 to 20 minutes.[321,353] Immunoreactive BNP is also excreted in urine, but the precise contribution of renal excretion to renal metabolism has not yet been clarified. A minor degree of hepatic clearance has been shown; this is not significantly altered in patients with liver failure.[158]

In addition to bioactive BNP, other proBNP-derived fragments circulate in plasma.[140,243] These fragments are commonly referred to as *N-terminal proBNP,* but molecular heterogeneity also includes the intact precursor, in particular in heart failure patients.[139,167,169] Cardiac secretion of proBNP and its N-terminal fragments has been demonstrated by blood sampling from the coronary sinus. The molar ratio of secreted proBNP 1-76 to intact proBNP is not yet fully clarified but is likely to depend on cardiac status (i.e., more unprocessed precursor compared with biosynthetic cleavage products in severe heart failure) (Figure 47-24). In the metabolic phase, major discrepancies remain in the suggested half-life of N-terminal precursor fragments, which at least partially reflect epitope recognition in the assays. Theoretically, the half-life of proBNP 1-76 in circulation should be around 25 minutes[211] and thus does not differ greatly from the established metabolism of BNP-32 (proBNP 77-108). One report, however, suggested a considerably longer half-life (≈90 minutes after cardiac pacing), which would fit well with the higher plasma concentrations of N-terminal proBNP fragments compared with bioactive BNP in healthy individuals and in cardiac patients.[304] Our perception of molecular heterogeneity in plasma has changed radically over recent years; therefore, new pharmacokinetic experiments are urgently needed to separate the biosynthetic phase from peripheral elimination. Ideally, experiments should be performed by classical peptide infusion strategies with measurement across organ beds.

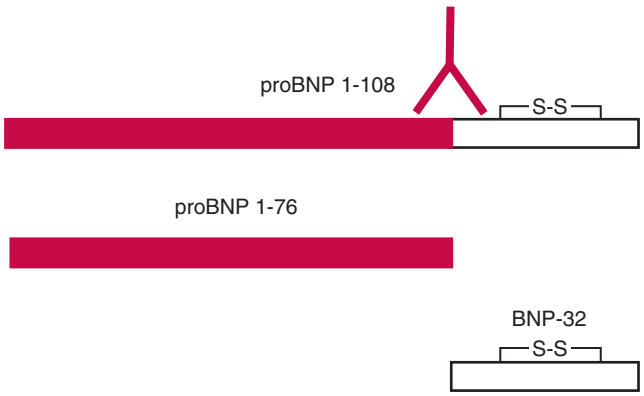

Figure 47-24 Immunoassay for detection of unprocessed human proBNP (pro-brain natriuretic peptide). The assay utilizes antibody recognition of an epitope spanning the Arg-Ala-Pro-Arg site (proBNP74-76) thought to be cleaved by Corin.

Biosynthesis and Assay Calibration

Elucidation of cardiac natriuretic peptide biosynthesis has disclosed a complex post-translational maturation that produces a variety of peptides targeted for cellular secretion (Figure 47-25). The different phases of gene expression not only are region specific but also depend on changes within the secretory apparatus in cardiac myocytes. The main clinical application of the peptides today strongly relates to plasma measurement in cardiovascular diagnosis and prognosis. Immunoassays thus need to be designed with insight into the biosynthesis of the peptides. Another defining aspect of immunoassay measurement is the choice of calibrator. This aspect so far has not been scrutinized by researchers, apart from observations of disturbingly large discrepancies between the different assays.[239] On the other hand, it has not been possible to raise meaningful assay calibration issues before now, because the existence of a complex molecular heterogeneity had not been established. One way of bypassing this lack of information has been introduced as a "processing-independent-assay," which in principle quantifies one in vitro cleavage product that represents all secreted precursor molecules. This assay can then be calibrated with the specific cleavage product and assay measurement performed on a stoichiometricly correct basis.

If one is to choose a proBNP-derived calibrator peptide for plasma measurement, the situation becomes more blurry. As the ratio of bioactive BNP to intact precursor shifts toward fewer processed biosynthetic products, one would perhaps choose the dominant "disease" form over the more prevalent forms in healthy individuals. However, large comparative studies have not revealed major differences between BNP and proBNP measurements in terms of overall clinical performance. One report on assay calibration has shown that assays directed at the C-terminal BNP region do not really cross-react with larger biosynthetic products.[239] However, plasma measurement based on assays directed against the N-terminal proBNP fragment is greatly influenced by the degree of O-linked glycosylation. Clearly, this issue is far from settled, and our present perception of "normal" concentrations of various biosynthetic products may have to be redefined.

Inefficient Prohormone Maturation in Heart Failure

Heart failure patients display highly increased plasma concentrations of bioactive ANP and BNP. With dramatic upregulation of gene expression and concomitant high concentrations of immunoreactive ANP and BNP in plasma, it seems reasonable to expect increased natriuresis. The

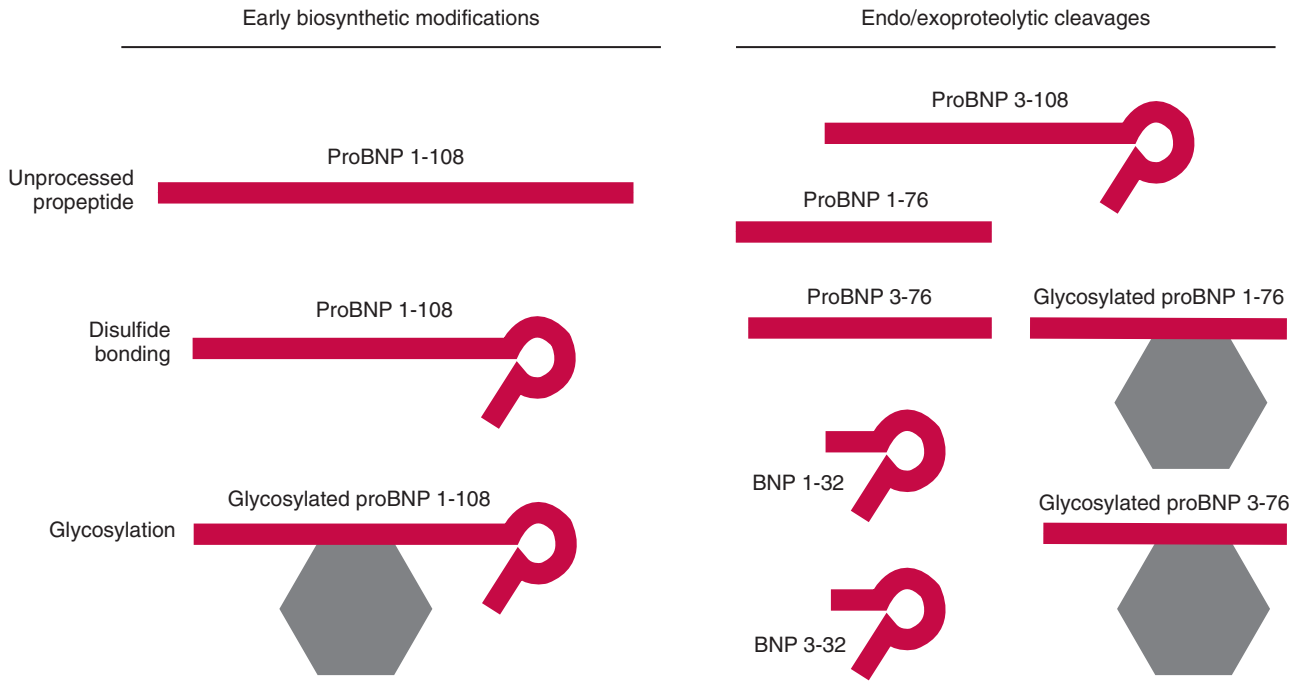

Figure 47-25 Schematic presentation of possible proBNP-derived peptide products. Note that most peptides are not chemically identified but rather are suggested by biochemical methods that rely on antibody recognition. Carbohydrate is indicated by the hexagons.

common presentation of heart failure, however, consists of congestion, sodium retention, and edema. Although heart failure is a complex syndrome with both activation and inhibition of multiple neurohumoral systems, the paradoxical lack of ANP and BNP bioactivity is still compelling. Heart failure patients respond to intravenous administration of chemically synthesized ANP and BNP, which has led to the introduction of a BNP-32 analog: nesiritide.[268] This peptide is a potent drug in heart failure; it has raised serious concerns regarding patient safety by causing unwanted hypotension.[373] Experts have further explored the possibilities of natriuretic peptide drugs by constructing structurally related peptides that possess natriuretic effects but without the undesirable hypotension.[235] Obviously, this research area could prove of major relevance to medical therapy, because all the different physiologic effects of natriuretic peptides could have specific roles in the modern treatment of heart failure and other cardiovascular pathologies.

The endocrine paradox of sodium and water retention in heart failure, where the gold standard biomarkers are the cardiac natriuretic peptides, relates to insufficient post-translational maturation of the biosynthetic precursors.[138] A well-established analogy to this phenomenon is enhanced secretion of proinsulin over mature insulin in patients with type 2 diabetes. In the early stages of the disease, selective proinsulin measurement is therefore a valuable tool in evaluating pancreatic β-cell dysfunction. A shift toward secretion of unprocessed precursors in cardiac disease may represent early involvement of ventricular expression and secretion, as efficient precursor maturation seems to be an endocrine feature of atrial biosynthesis. In support of this explanation, the intracellular processing enzymes involved in ANP and BNP maturation are dominantly expressed in atrial myocytes. Moreover, ventricular myocytes do not, at least in the early stages of disease, contain secretory granules for peptide storage and maturation. The post-translational processing of ventricular precursors may not be efficient in the production of needed natriuretic potency, while immunoassays cross-react to various degrees with the unprocessed biosynthetic products. Although speculative, there may be large individual differences in the ability of the heart to process the precursor peptides; this could help explain the highly variable heart failure phenotypes. The ratio of mature BNP to unprocessed proBNP might be of diagnostic relevance in parallel with the present application of proinsulin to insulin measurement. If specific assays for the various forms are applied in concert, it may be possible to define an early endocrine hallmark of the heart failure syndrome that could aid clinicians in tailoring diuretic therapy according to patient-specific ability to ameliorate congestion through secretion of bioactive natriuretic hormones.

ANALYTICAL CONSIDERATIONS OF BIOMARKER ASSAYS IN HEART FAILURE

In 2005, the IFCC C-SMCD established recommended analytical and preanalytical quality specifications for natriuretic peptide (NP) assays.[25] The objectives were intended for use by the manufacturers of commercial assays and by clinical laboratories utilizing NP assays. The overall goal was to attempt to establish uniform criteria so that all NP assays could be evaluated objectively for their analytical qualities

and clinical performance. As BNP and NT-proBNP become more integrated into clinical practice as diagnostic and prognostic biomarkers, understanding differences between individual assay characteristics becomes extremely important. The influence of clinical and analytical and preanalytical factors on increasing numbers of commercially available BNP and NT-proBNP assays (as shown in Table 47-4), shows the need for improved understanding by clinicians of how to interpret findings of different studies predicated on BNP or NT-proBNP concentrations monitored by different assays.[168,365,412] The laboratory community must work closely with in vitro diagnostics companies to assist in defining the numerous assay characteristics.[38] When BNP or NT-proBNP assays are used as biomarkers for diagnosis, therapy decisions, and prognosis, or when they are used in clinical trials or studies, they should be well characterized, as suggested in the list of recommendations that follow. It is further recommended that when designing studies using BNP or NT-proBNP, investigators should review the STARD (Standards for Reporting Diagnostic Accuracy)[64] initiative for assay characterization issues and for clinical and patient enrollment issues when BNP or NT-proBNP levels are monitored.

A growing diversity of BNP and NT-proBNP assays are used worldwide, emphasizing the need for both analytical and clinical validation of all commercial assays to support definitive clinical acceptance of these new biomarkers. At present, four companies have BNP assays that have been cleared by the U.S. Food and Drug Administration (FDA) [Inverness Biosite, Siemens (Bayer), Abbott including POC, and Beckman Coulter using Biosite reagents], and at least seven companies have FDA-cleared NT-proBNP assays [Roche, and six others that use Roche antibodies and calibrators: Siemens (Dade Behring and DPC), bioMérieux, Response Biomedical, Mitsubishi Chemical, Ortho-Clinical Diagnostics, and Nanogen]. POC platforms (Response Biomedical, Mitsubishi Chemical, Inverness Biosite) are suitable for whole blood use. Research and development is under way for commercialization of proBNP assays, with preliminary assays described by BioRad, HyTest, and Biosite Inverness. As the number of assays for all three NP biomarkers grows, it is even more essential that appropriate clinical and analytical assay criteria are uniformly adopted. The accurate clinical performance of each BNP or NT-proBNP assay, and likely proBNP in the future, which may serve as the basis for life and death medical decisions, sets the stage in establishing assay criteria as indispensable.

BNP and NT-proBNP are determined by a number of different immunoassays using antibodies directed to different epitopes located on the antigen molecules (see Table 47-4). For BNP, one antibody binds to the ring structure and the other antibody to the carboxy- or amino-terminal end. Degradation of BNP is known to occur by proteolytic cleavage of serine and proline residues in vivo and in vitro (see Figure 47-25).[25,346,348] This degradation may affect antibody affinities and thus may be responsible for differences in stability of BNP32 monitored by different commercial BNP assays, as discussed earlier. For NT-proBNP (a.a.1-76) monitoring, an improved understanding of potential cross-reactivity with split products of the N-terminal portion of NT-proBNP and proBNP itself is needed. For both assays—BNP and NT-proBNP—minimizing interference from heterophilic antibodies and rheumatoid factor, for example, needs to be optimized. The influence, stabilizing or destabilizing, of anticoagulant additives, as well as the type of collection tube, has been well described.[52,346] For BNP, EDTA-anticoagulated whole blood or plasma appears to be the only acceptable specimen choice. For NT-proBNP, serum, heparin plasma, and EDTA plasma (reads 10% lower) appear acceptable. Plastic blood collection tubes are necessary for BNP; for NT-proBNP, either glass or plastic is acceptable.

In the clinical setting,[35,226,236,238,381] BNP and NT-proBNP assay characteristics need to be better understood or better established for optimal consideration as diagnostic and prognostic biomarkers, as discussed later. Further, proBNP, the precursor peptide that splits into BNP and NT-proBNP, appears to be detected in both BNP and NT-proBNP assays; this may have substantial implications regarding clinical utilization of these assays.[135] The influence of age, gender, ethnicity, and non-HF pathologies has been shown to substantially influence what may otherwise be considered a normal reference concentration.[25,314] Renal impairment has been shown to substantially increase NT-proBNP concentrations and, to a lesser extent, BNP concentrations.*

For BNP, a single cutoff has been designated at 100 pg/mL, likely driven by FDA clearance of this value as the ROC curve value optimized for diagnostic accuracy. However, as shown in Figure 47-26, normal subjects older than 75 years have concentrations above the 100 pg/mL cutoff. For NT-proBNP, the FDA-cleared cutoffs are based on age: for patients younger

than 75 years, 125 pg/mL, and for those older than 75 years, 450 pg/mL. Again, these cutoffs appear to misclassify many normal individuals, as shown in Figure 47-27. Clinical studies [ProBNP Investigation of Dyspnea in the Emergency Department (PRIDE) Study] have more appropriately defined cutoffs by sex, age, and renal function, as shown in Figure 47-27, and estimated GRF, with an optimal negative predictive value at less than 300 pg/mL that is independent of age, gender, and eGFR. Obesity has also been shown to have an impact on BNP and NT-proBNP measurements[150,160,203,279]; an inverse relationship has been noted between increased BMI and decreased BNP in CHF patients. HF patients who receive the drug nesiritide (human recombinant BNP) for therapy and management may have confounding BNP results because nesiritide is molecularly identical to endogenous BNP. Thus, if BNP were to be monitored for regulation of nesiritide infusion within a time window before an appropriate decrease in exogenous BNP could occur (half-life ≈22 minutes), the potential for falsely increased concentrations could arise. Nesiritide does not directly confound NT-proBNP measurements. Finally, lack of understanding of the physiologic and biological variability of BNP and NT-proBNP in HF patients may cause clinicians to misinterpret changing (increasing or decreasing) BNP and NT-proBNP concentrations in the context of establishing the success or failure of therapy.

BNP and NT-proBNP exhibit intraindividual biological variability (CV) of 33 to about 50%.[404] The authors of this study [404] suggested that changes of 130% for B-type natiuretic peptide (BNP) and 90% for N-terminal (NT)-proBNP are necessary before results of serially collected data can be considered statistically different. A small study has shown that in HF patients monitored for BNP over at least 2 time periods during a 2 week period, less than 50% of concentrations were found to be outside the expected biological variability (Figure 47-28).[403] This implies that results of BNP or NT-proBNP monitoring may be overinterpreted and re-emphasizes the role of these tests as confirmatory biomarkers, not as a tests that clinicians should rely upon solely when managing HF patients.

Presently, no available data have established a correlation between BNP and NT-proBNP concentrations using commercially available technology. In addition, the literature is

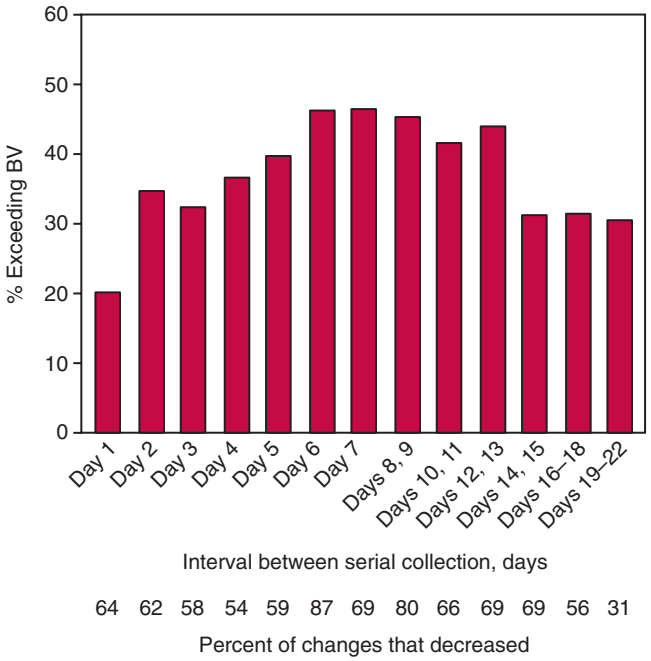

Figure 47-28 Variability of brain natriuretic peptide (BNP) concentrations by day from initial admission order, with demonstration that more than 50% exceed biological variability (100% change) over a 2 week time period. *(From Reference 403 with permission from Excerpta Medica.)*

scattered with BNP and NT-proBNP assays that were developed and standardized in individual laboratories. All of these factors add to the confusion of clinicians when interpreting and comparing data from different studies, whether for diagnosing or ruling out HF, managing HF, screening for asymptomatic left ventricular dysfunction, or determining risk stratification and prognostication for patients with HF, ACS, or other pathologies. One must consider the assay used, the available clinical evidence based on the individual assay, and the aim of the biomarker-based studies. No peer-reviewed studies have demonstrated that the two tests (BNP and NT-proBNP) are equivalent. Thus until large studies become available that include proBNP measurements as well, caution is suggested before conclusions based on one particular BNP or NT-proBNP assay are translated to another assay.

The following practice guidelines pertaining to analytical issues for biomarkers of heart failure have been recommended by the NACB and the IFCC Committee for Standardization of Markers of Cardiac Damage:

1. Normal reference limits (95th or 97.5th percentile) should be established independently for both BNP and NT-proBNP based on age (by decade) and by gender. Each commercial assay should be validated separately. The effects of ethnicity and renal function need to be evaluated as possible independent variables.
2. ROC curves should be established to evaluate clinical effectiveness and to establish optimal medical decision cutoffs for BNP and NT-proBNP assays for diagnostic usefulness.
3. Assays for BNP and NT-proBNP should have total imprecision (%CV) ≤15% at their age- and gender-defined upper reference limits, as well as at the New York State Heart Association (NYSHA)-defined medical decision concentrations.
4. Before introduction into clinical practice, BNP and NT-proBNP assays must be characterized with respect to the following preanalytical and analytical issues:
   Preanalytical:
   a) Effects of storage time and temperature
   b) Influence of different anticoagulants
   c) Influence of gel separator tubes
   d) Need for plastic blood collection tubes for BNP; for NT-proBNP, either glass or plastic is acceptable
   Analytical:
   a) Identification of both antibody recognition epitopes
   b) Cross-reactivity characteristics with related natriuretic peptides, including NT-proANP, ANP, CNP, BNP, and glycosylated and nonglycosylated NT-proBNP and proBNP
   c) Identification of interference from heterophile antibodies, rheumatoid factors, human antimouse antibodies
   d) Description of calibration material used, how the material was defined, and the concentration value assigned
   e) Clarification of dilution response
5. For both BNP and NT-proBNP, until a primary reference material is defined for either assay for appropriate calibration of assays, measurements should be reported in ng/L, not in pmol/mL; and patient specimen comparisons and regression analysis should be performed, in accordance with CLSI [formerly National Committee for Clinical Laboratory Standards (NCCLS)] guidelines, to establish the degree or lack of harmonization across the dynamic range of each assay. Specifically, harmonization around the current presumed optimal diagnostic medical decision cutoff of 100 ng/L for BNP should be validated. Because there is only one source of antibodies and calibrators for NT-proBNP (Roche), harmonization of NT-proBNP assays should not be a problem.
6. For both BNP and NT-proBNP, biological variability has been determined to be at least 50%, and in many studies higher. Therefore, caution should be exercised in interpreting concentration changes of less than 50 to 80% as reflective of medical therapy. However, consistent trends should be followed as clinically important.

In summary, laboratorians and clinicians must be cognizant of numerous considerations inherent in NPs as markers for management of cardiology patients, including (1) the form of the biomarker itself (BNP or NT-proBNP); (2) lack of standardization of immunoassays; (3) that reference and medical decision limits are dependent on age and gender; (4) that biological variation among NPs in individuals is inherently high; (5) the diagnostic time window (admission or monitoring of trends over time); (6) the clinical setting in which NPs are used (e.g., general practice, emergency room, coronary care unit); (7) the patient subset being tested (e.g., renal failure, sepsis); and (8) whether application is for

diagnostic use, for prognostic use, or for a future potential application of therapeutic guidance. All of these aspects must be taken into consideration with the implementation of biomarkers such as NPs, to avoid the possibility of misinterpretation of a result for patient care.

Clinical Use of Natriuretic Peptides

BNP, NT-proBNP, and novel assays that are being developed have been shown to be of assistance to clinicians in the evaluation of patients with impaired left ventricular function, with or without congestive heart failure, and with coronary heart disease.* On the other hand, the more we have learned about natriuretic peptides, the more complicated the biology of these biomarkers has become (see earlier).

Use in the Diagnosis of Congestive Heart Failure

Natriuretic peptides were initially validated on the basis of their ability to facilitate the diagnosis of congestive heart failure. The situations chosen to test this hypothesis did not occur in sophisticated cardiology offices, but in the emergency department and in primary care practices.[187,245] The emergency setting is an extremely busy environment where there is often a severe press for time, making cautious and careful evaluation difficult. In addition, emergency department physicians are generalists who must triage problems related to trauma, infectious disease, and a variety of other complaints related to almost any organ system. Some are very sophisticated with regard to cardiovascular issues and the presenting symptoms and cardiovascular examination associated with heart failure; others are not. Accordingly, some have objected to the use of this setting as the primary testing ground for the use of natriuretic peptides in the diagnosis of heart failure. General internists are in a similar position, especially in the outpatient setting where these evaluations were done, where physicians have limited resources and a heterogeneity of expertise related to this particular diagnosis. Thus, the relatively marginal improvement in diagnostic yield [74 to 81% in the Breathing Not Properly (BNP) trial and 92 to 96% in the PRIDE trial] is not terribly impressive in one sense. However, in parsing the data, it is clear that most of the benefit derived from the use of natriuretic peptides for diagnosis resides in the triage of patients about whom clinicians are ambivalent, as was recently elegantly documented.[357]

When patients have a very low risk of heart failure, it is not clear whether natriuretic peptides help at all; similarly, with a classic presentation, patients have such a high frequency of heart failure and such a high pretest probability that natriuretic peptides are unlikely to be helpful. However, in the group of patients with dyspnea about whom the clinician is ambivalent, natriuretic peptides are helpful. Of importance in the interpretation of natriuretic peptides in this situation is that marginal values often are not helpful. The Breathing Not Properly Trial suggested the use of one cutoff value at 100 ng/mL in making the diagnosis of heart failure. This value could have been altered to increase sensitivity or specificity (Figure 47-29).[251] However, 26% of the population had values between 100 and 500 ng/mL. One third of this group did not have congestive heart failure according to subsequent adjudication, and two thirds did, but unfortunately, no cutoff value distinguished these groups. For this reason, a group of investigators [ICON (International Collaborative on NT-proBNP) study] have analyzed their data with NT-proBNP, looking to generate values that will help to both include and exclude disease.[188] This is an extremely valuable approach. Investigators have reported that a value for NT-proBNP less than 300 ng/mL effectively excludes congestive heart failure. Values greater than 450 ng/mL in individuals younger than 50 rule in heart failure, and values greater than 900 ng/mL permit diagnosis of heart failure in patients over the age of 50.

As is clear, gaps between these values describe the fact that clinical judgment is still importantly necessary in the use of natriuretic peptides. It is for this reason that most guideline groups have not suggested the routine use of natriuretic peptides for diagnosis in every patient who presents with dyspnea.[111,170,367] Instead, group members recommend their judicious use in patients in whom the diagnosis is not clear. It is axiomatic to suggest that consideration of gender, age, and weight (see earlier) in interpreting such values is advised. In addition, it is clear that the worse the clinical class of heart failure is, the higher are the natriuretic peptide levels (Figure 47-30). The diagnosis may be problematic, especially in patients who have other comorbidities.[212,310,401] Chronic obstructive pulmonary disease and cardiovascular disease frequently overlap, and it is in these types of patients that the optimal use of natriuretic peptides for diagnosis likely can be applied. Other disease processes (Box 47-6) can cause elevations and must be taken into account by including the clinical situation in interpretation of natriuretic peptide values.

Special Situations

Several additional caveats are necessary clinically. The epidemic of heart failure with preserved ventricular function is increasing (Box 47-7). Controversy continues concerning the mechanisms involved in this clinical entity, and some even question its existence; however, a stiff, noncompliant left

ventricle is clearly an important contributor. Unfortunately, the therapeutic modalities used for treatment have been shown to be ineffective.[313] In addition, because natriuretic peptides are predominantly released in response to end-systolic wall stress, values are much lower in this disease state. Thus natriuretic peptides provide aid in the inclusion or exclusion of heart failure due to systolic dysfunction, but they do not provide similarly robust triage in patients with diastolic dysfunction, or so-called heart failure with preserved systolic function. The presence of primary or secondary valvular abnormalities, which increase pressure or volume overload, particularly the latter, will cause increases in natriuretic peptide values because they increase wall stress. Thus, the presence of these abnormalities must be taken into account when natriuretic peptide values are interpreted. Additionally, the presence of atrial fibrillation defines a group of patients with underlying cardiovascular disease. Natriuretic peptides in the presence and the absence of heart failure will be higher in this setting; this needs to be taken into account when values are interpreted for diagnostic purposes.[207] Abnormalities in right ventricular function, even when due to volume overload that will cause increased wall stress, are associated with a blunted natriuretic peptide response, likely due to the smaller mass of myocardium involved. Because the pericardium inhibits increases in wall stress, natriuretic peptide values often are not elevated in constrictive pericarditis despite overt heart failure, unless the constrictive process is superimposed on prior cardiac disease.[45]

Screening for Ventricular Dysfunction

The use of natriuretic peptides in screening to identify patients with impaired ventricular function that has not previously been appreciated has been proposed. The sensitivity and specificity of such an approach are far less than those of the acute circumstance; for this reason, most groups have not advocated use of this analyte in this particular area; however, as the criteria for diagnosis improve, as more specific assays are developed, this is an area where natriuretic peptides may prove to be of value, especially if confined to high-risk groups.[56,120,163,337]

Prognostic Use of Natriuretic Peptides

Some have argued for the ubiquitous use of natriuretic peptides in all patients with dyspnea. The logic for such an approach is related to the fact that individuals with higher natriuretic peptide values have a more adverse prognosis (Figure 47-31) in general than those with lower levels when they present acutely or chronically.* There may be an exception to the idea that higher levels are always more negatively prognostic.[258] (It has been reported that in the extremely ill end-stage patient, lower values are observed, and this could reflect exhaustion of the natriuretic peptide system; however, these observations remain to be confirmed.) One could argue that obtaining a natriuretic peptide value at the time of admission to hospital in a patient who has suspected congestive heart failure is valuable from the perspective of determining eventual risk. Indeed, it is well established that values obtained in this circumstance are highly prognostic, with very high risk ratios and higher values by and large associated with worse disease. Maximal prognostic significance usually is associated with the value at the time of discharge. Thus, a reasonable strategy would be to obtain one level at the time of admission and another at the time of discharge.

Recent data suggest that if natriuretic peptide values are reduced substantially during hospitalization, patients tend to do better. However, most of the reductions that have been reported are modest compared with the biological variability (see earlier). Thus, it is difficult to know how to interpret these changes, especially in individual patients. Recent data in the outpatient setting suggest that the changes needed to overcome biological variability of 80% or greater (Figure 47-32) lead to substantive alterations in prognosis.[71,262] Nonetheless, in the clinical perspective, there probably are differences between those individuals with more chronic disease and those with only acute disease. Those with more chronic disease have a chronically induced natriuretic peptide system that probably responds more slowly than the system in individuals who have simply an acute diathesis and in whom

Covariates for adjustment: age, gender, NYHA class, ischemic etiology, LVEF, LVIDd, serum creatinine and bilirubin, randomized treatment, prescription of beta-blockers, digitalis and diuretics, presence of AF or diabetes at study entry.

Figure 47-31 Relationships of brain natriuretic peptide (BNP) and N-terminal pro brain natriuretic peptide (NTproBNP) values and outcomes. *(With permission from Anand IS, Fisher LD, Chiang YT, Latini R, Masson S, Maggioni AP, et al. Changes in brain natriuretic peptide and norepinephrine over time and mortality and morbidity in the Valsartan Heart Failure Trial (Val-HeFT). Circulation 2003;107:1278-83.)*

natriuretic peptide levels may respond somewhat more rapidly. Accordingly, some effort in subclassifying these patients with regard to these parameters is essential.

Unfortunately, studies have not defined what should be done if natriuretic peptide levels do not respond rapidly. It would be important if one could show that keeping patients in the hospital, for example, would mitigate some of these problems, but this information simply is not available at present. Some studies have actually claimed benefit in reducing costs, but at times those studies have included very long hospital stays.[276] Thus, management decisions cannot be made solely on the basis of the natriuretic peptide concentrations. In addition, one needs to be extremely careful because of the subset of patients who may have low levels if they are chronically ill, and because of the heterogeneity of values associated with differences in body physiognomy likely related to clearance of the natriuretic peptides.

Use of Natriuretic Peptides to Guide Therapy

Perhaps the most interesting use of these markers is seen in the patient with heart failure, in whom they are used in the hope of titering therapy more efficaciously.[151,200,322,324] The logic of this approach suggests that many individuals are not as astute as they could be regarding their symptoms, and that having an objective measure may be helpful. This theory has been tested in several randomized controlled trials. The first, STARS-BNP, suggested benefit of such an approach, but subsequent trials have not confirmed those findings.[192] Two other studies have been presented, but not published, at this time. It has been argued that negative results may be due to the fact

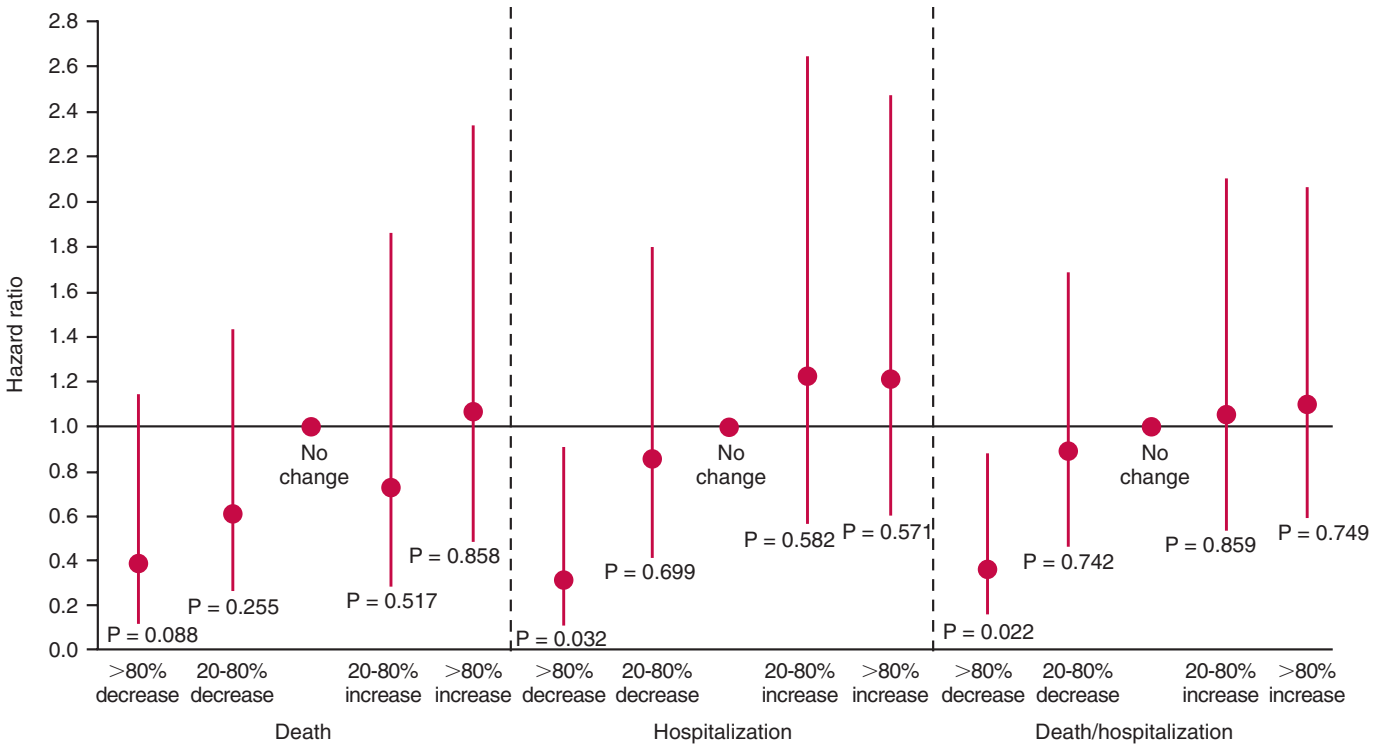

Figure 47-32 Relationship of the change in brain natriuretic peptide (BNP) values over time to outcomes. *(With permission from Jeremias A, Kleiman NS, Nassif D, Hsieh WH, Pencina M, Maresh K, et al; Evaluation of Drug Eluting Stents and Ischemic Events [EVENT] Registry Investigators. Circulation 2008;118:632-8.)*

that, in many of the trials, a large percentage of patients have been elderly (>75 years), and the thought is that elderly patients may not tolerate the increased doses of therapeutic agents used in the management protocols predicated on natriuretic peptides. Indeed, if one excludes those older than 75 years, substantial benefit is associated with this strategy.[307] If this were a finding in only one trial, one might be highly cynical; this is why reports of the other studies are awaited anxiously. If confirmed, the idea of utilizing natriuretic peptides to adjust therapy so as to reduce values toward normal or to attain a change from baseline greater than 80% has the possibility of markedly improving prognosis. Time will tell.

Other Situations

Several investigations have suggested that one can use natriuretic peptides to determine when to intervene in patients with aortic stenosis and mitral regurgitation.[54,110,308,389] Unfortunately, usually only one value has been used, and that value (corrected for differences in the assays) tends to be quite low. Thus, how to distinguish these values from those of normal or less severely affected individuals is unclear. However, it is possible that using changes in natriuretic peptides over time might provide a better paradigm. Several situations can be associated with severe congestive heart failure in the absence of increased concentrations of natriuretic peptides. These include very acute heart failure that manifests before the stimulus to produce increased levels of natriuretic peptides has had time to occur. In addition, patients in situations where the abnormality is above the ventricle, such as atrial myxoma or mitral stenosis, can present with heart failure and normal natriuretic peptide values. Finally, constrictive pericarditis is associated with low values because increases in wall stress are precluded by the constricting pericardium.

Other situations in which natriuretic peptide concentrations are increased in blood include any disease that increases blood volume and thus wall stress, such as sepsis, anemia, renal dysfunction, Cushing's syndrome and/or hyperaldosteronism, hypertension with LVH, and cirrhosis. Some have suggested that values can be used to assess prognosis in patients with renal failure, albeit using higher cutoff values, and it does appear that the mechanisms for release are the same.[289] However, mixing values between GFR groups is likely to lead to confusion. Using values within groups (e.g., those with severe disease on or off long-term dialysis) appears much more salutary.[109,292]

Ischemic Heart Disease

Several investigations have suggested that natriuretic peptides can be used to assess prognosis in patients who present with acute coronary syndromes and normal cardiac troponin values.* Most of these studies have used relatively insensitive cardiac troponin assays or higher cutoff values, but such

*References 104-106, 190, 275, 284, 295, 296, 323, 333, and 388.

assays and cutoff values are still in common use. If so, the finding of an elevated natriuretic peptide level may be helpful. In one study, such patients benefited from an invasive strategy.[395] The subgroup involved was mostly female, and it appears that women may have lower cardiac troponin levels than men. However, if this strategy is to be used, a relatively low cutoff value has been advocated (80 ng/L with the Biosite BNP assay). Whether these low values will allow adequate discrimination in large groups of patients is unclear. However, it is clear that use of natriuretic peptides may be helpful after the acute episode in predicting the subsequent risk of events. Indeed, over time in some studies, they appear to be even more prognostic than troponin.[117] Thus, eventually, it is likely that natriuretic peptides may become part of a long-term risk stratification panel. Natriuretic peptides are also elaborated, albeit to a modest extent, in those with positive treadmill stress tests.[332] Some of this release comes directly from the coronary arteries. Elevations also occur in those with diastolic abnormalities.[269] The changes appear too small to be used diagnostically.

The Future

The potential future use of natriuretic peptides, as indicated in the analytical sections, is growing as we understand more about the biochemistry and mechanisms of natriuretic peptide release. It appears that congestive heart failure is in part a clinical syndrome characterized by abnormalities in how the natriuretic peptide system works. The system synthesizes and releases large amounts of protein, but much of the protein is poorly functional. Whether this is because it is inadequately cleaved or whether it is due to glycosylation[93,339] or to other biochemical processes has yet to be determined. However, what is clear is that very little circulating active BNP is present in patients with heart failure.[341] Most of what appears to circulate is proBNP,[153] which is uncleaved, suggesting probable abnormalities in corin and furin that are indigenous to the pathophysiology of congestive heart failure. If one could manipulate these systems to facilitate the presence of active BNP or of other fragments that might have biological importance, one might substantially improve congestive heart failure. These are some of the approaches currently being pursued in the hope of improving therapy for this very large group of patients.

In addition, novel biomarkers (Tables 47-5 and 47-6) have the potential to contribute substantially to this work. Recent data suggest that one can measure intact proBNP directly, which may lead to better understanding of underlying pathophysiology. As with other natriuretic peptides, its circulating concentration tracks with the clinical class of heart failure (see Figure 47-29).[135] In addition, a new test for ANP has been developed (MR-proANP) that may have some advantages.[271] Preliminary data suggest that it is equivalent to other natriuretic peptides in its ability to diagnose acute heart failure.[266] Such testing might allow the more rapidly responding atrial peptide and the more slow to respond B-type natriuretic peptide to be used synergistically. Again, additional research is necessary.

Natriuretic peptides may be of additional value in several different intriguing areas that are being explored. One is sudden cardiac death. Several studies have associated elevated natriuretic peptide values with mortality and/or ICD discharges.[53,385] A second area involves the follow-up of patients who received cardiac resynchronization therapy (CRT) devices. It appears that higher values help define a group apt to benefit, and although it takes some time for natriuretic peptides to fall, their reduction is associated with clinical benefit over time.[127,225] Finally, several suggestions have indicated that BNP may be useful in helping to diagnose pulmonary emboli when they occur and to determine prognosis. Unfortunately, levels often are not markedly elevated,

but with time this indication may be developed more fully.[213,214]

Two other major areas need to be discussed: multimarker testing and ST2. First, it is clear that for ischemic heart disease, the addition of natriuretic peptides to other markers in a multimarker strategy improves risk stratification, especially over the long term.[331,416,419] It also appears that benefit may be derived from the prediction of events in older, less acutely ill individuals. Recently, the group from Upsalla reported a rather striking improvement in the prediction of events (changes in the kappa c statistic from 0.644 to 0.766) with the use of a multimarker panel that included natriuretic peptides. The panel included cTn, NT-proBNP, cystatin C, and CRP. If confirmed, this approach may become more widely used for risk prediction. Second, markers have been found that may be synergistic with the natriuretic peptides. One such marker, ST2, a "decoy receptor for IL33," has substantially better predictive ability for mortality than the natriuretic peptides.[316] Other "death markers" such as GDF-15 may also provide benefit in this area.[202]

BIOMARKERS OF INTEREST, ALTHOUGH THEY ARE NOT CURRENTLY USED ROUTINELY

Figure 47-33 portrays a biochemical profile in coronary vascular disease that correlates staging of biomarker release into the circulation with various pathophysiologic mechanisms of acute coronary syndrome and heart failure. As shown in Tables 47-5 and 47-6, numerous biomarkers have been studied and used for different clinical reasons, and other promising novel biomarkers are trying to establish themselves alongside cTn and NPs as routine clinical tools. We highlight some characteristics of several of these here. This list is not meant to be all inclusive.

C-Reactive Protein

CRP is an acute-phase reactant that was initially developed to evaluate patients with infection.[73,185,303,325] It now appears that concentrations below those seen in infection but above healthy values (as measured by so-called high-sensitivity CRP, or hsCRP, assays) can be a marker of the atherosclerotic process, because both chronic and acute atherosclerotic processes involve an inflammatory component (see Chapter 27). Among the ligands that can stimulate CRP are tissue necrosis factor (TNF) and interleukin 1 (IL-1), which are thought to stimulate IL-6, which then causes the elaboration of CRP from the liver (see Chapters 21 and 27). It is now clear that CRP itself can enhance the inflammatory and prothrombotic response. A large number of assays for hsCRP are available, as is a standard protocol for their reporting.

For primary prevention, values greater than 3 mg/L are considered high risk. Recent data suggest that using hsCRP data with the calculated low-density lipoprotein (LDL) is a potent way to predict risk. For risk stratification in primary prevention, the use of routine hsCRP is not recommended by the AHA/CDC panel. When used, less than 1 mg/L is

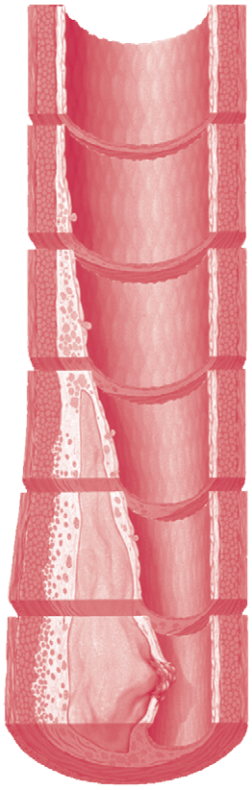

Figure 47-33 Complete spectrum of acute coronary pathophysiologic process from initiation of atherosclerosis to cell death to myocardial dysfunction. *(Modified from Apple F. Cardiac ischemia: where no biomarker has gone before. Clin Lab News 2009;35:8-10.)*

considered low risk, 1 to 3 mg/L intermediate risk, and more than 3 mg/L high risk.

In patients who present with ACS, the initial value for hsCRP has prognostic significance. Whether it is short or long term depends on the study. In most studies, the influence of cardiac troponin measurements is the predominant short-term prognostic factor, and hsCRP adds to long-term prognosis. However, this is not always the case. Of interest, hsCRP measurements, similar to BNP, seem to predict death, but not recurrent infarction. This could be true because of the effect of mortality, which can confound multivariable models, but it is different from the data related to cardiac troponin (see discussion in this chapter).[184] It should be appreciated that once necrosis has occurred, hsCRP values rise and the ability to use them prognostically is attenuated.

Serum Amyloid Protein A

Serum amyloid protein A, an acute-phase protein and an apolipoprotein, has been used with hsCRP in cross-sectional studies. It can be synergistic with hsCRP[326] but is much less commonly used. At present, no standardized assays, reference interval studies, nor consistent assay validations are available.

sCD40 Ligand

CD40 ligand is a transmembrane protein related to TNF. It has multiple prothrombotic and proatherogenic effects. What is usually measured is the soluble form of the receptor, sCD40 ligand, which has been shown to be a predictor of events after acute presentation.[380] At present, standardized assays, reference interval studies, nor consistent assay validations are not available.

Cytokines

A variety of stimulatory and inhibitory interleukins (TNF, IL-1, IL-6, IL-8, IL-12, IL-18) are thought to help mediate the elaboration of CRP and the development of atherosclerosis and acute events.[121] These cytokines may stimulate or inhibit leukocytes, often through T cell–mediated processes and effects on monocytes, which are indigenous to atherogenesis.[237] In some studies, IL-6 is more prognostic than hsCRP. These cytokines often have inhibitors and/or binding proteins that modulate their effects. At present, standardized assays, reference intervals studies, and consistent assay validations are not available.

Myeloperoxidase

Myeloperoxidase (MPO) is released when neutrophils aggregate; this may indicate an active inflammatory response in blood vessels. It has been shown to be elevated chronically when chronic CAD is present.[418] It is increased when patients present with ACS.[39A,69] Initial prognostic studies were encouraging but were done without adequate consideration of other analytes and specifically cardiac troponin. A multi-biomarker study has shown that myeloperoxidase as a prognostic tool

was dependent on the outcomes studied (cardiac death) and the demographics of the patient population enrolled.[27] Accordingly, additional studies are needed. At present, no standardized assays, reference interval studies, nor consistent assay validations are available. Further, it has been demonstrated that the type of specimen collected is critical for the stability and accurate measurement of myeloperoxidase.[345] For further information on this enzyme, see Chapter 22.

Lipoprotein-Associated Phospholipase A_2

Phospholipase A2 (Lp-PLA_2) is a phospholipase associated with LDL that is thought to be an inflammatory marker. It was previously known as platelet-activating factor (PAF) acetyl hydrolase. It is synthesized by monocytes and lymphocytes and is thought to cleave oxidized lipids to produce lipid fragments that are more atherogenic and that increase endothelial adhesion. An FDA-approved assay for this analyte includes obligatory reference intervals. It has been shown to be predictive of events in a primary prevention cohort, even when hsCRP is present in the model, suggesting that it measures something different from what is measured by the acute-phase reactants associated with hsCRP.[49] For more information on Lp-PLA_2, see Chapter 22.

Pregnancy-Associated Plasma Protein A

Pregnancy-associated plasma protein A (PAPP-A) is a metalloproteinase that is thought to be expressed in plaques that may be prone to rupture. The literature in this regard is mixed at present concerning its use.[50,241,312] At present, standardized assays, reference interval studies, and consistent assay validations are not available. Recent data suggest that heparin administration in MI patients is associated with increased PAPP-A concentrations; this may limit its prognostic role. For further information on this enzyme, see Chapter 22.

Oxidized LDL

Oxidized LDL has been attributed a key role in the development of atherosclerosis (see Chapter 27). Several methods have been used to measure it, but they yield potentially different data. Some have correlated malondialdehyde LDL with the development of atherosclerosis and short-term events.[165] Direct identification with antibodies suggests that oxidized LDL may be released from vessels and may colocalize with lipoprotein a [Lp(a)] after acute events.[375]

Placental Growth Factor

Placental growth factor is an angiogenic factor related to vascular endothelial growth factor (VEGF), which stimulates smooth muscle cells and macrophages.[135A,155] It also increases TNF and MCP-1. A novel assay for this analyte is thought to provide additional prognostic information on patients who present with ACS.[39] At present, standardized assays, reference interval studies, and consistent assay validations are not available.

Matrix Metalloproteinases

Matrix metalloproteinases (MMPs) can degrade the collagen matrix in coronary artery or myocardium. They are integral to remodeling of the coronary artery and/or the heart after acute events. Elaboration of MMP-9, a gelatinase, is thought to be important in plaque destabilization; thus some have tried to measure it as a prognostic index.[39] Other MMPs participate in the elaboration of extracellular matrix in the heart. Many MMPs also have inhibitors [tissue inhibitors of metalloproteinase (TIMPs)] that modulate their effects. At present, standardized assays, reference intervals studies, and consistent assay validations are not available.

Monocyte Chemotactic Protein

Monocyte chemotactic protein (MCP-1) is a chemokine that is thought to be responsible for the recruitment of monocytes into atherosclerotic plaque (see Chapter 22). It has been reported to be elevated in patients with ACS and to have long-term predictive value.[107] However, at present, standardized assays, reference interval studies, and consistent assay validations are not available.

Tissue Plasminogen Activator Antigen (t-PA) and Plasminogen Activator Inhibitor 1 (PAI-1)

t-PA is the body's physiologic fibrinolytic activator. PAI-1, its endogenous inhibitor, binds to t-PA (see Chapter 59). Inhibition of fibrinolysis has been suggested to be a reason for recurrent infarction; the fact that maximal inhibition usually occurs in the early morning hours provides a potential explanation for the circadian variability of AMI.[166] It may also be the reason why persons with diabetes have such unstable disease; the growth factor properties of insulin stimulate increases in PAI-1.[355] An accurate assessment of this system includes both t-PA and PAI-1, along with some assessment of bound versus free levels.

Secreted Platelet Granular Substances

Both platelet factor 4 (PF4) and beta thromboglobulin (BTG) are secreted when platelets aggregate. PF4 has a short half-life and is released by heparin (see Chapter 59). BTG is not released by heparin and has a longer half-life. Both markers have been used to assess platelet aggregation.[145] BTG is by far the more reliable. At present, standardized assays, reference interval studies, and consistent assay validations are not available.

Isoprostanes

Isoprostanes are the end breakdown products of lipid peroxidation, and urinary levels have been used to assess the level of oxidative stress.[142,143] It is thought that oxidation of LDL is essential for the development of atherosclerosis, and that HDL and other antioxidants work by antagonizing this oxidative stress. Urinary isoprostanes give some assessment of this critical process. The most commonly measured are F_2-isoprostanes, but a large number of others are available for measurement. It does appear that they will eventually be helpful in assessing oxidative stress.

Urinary Thromboxane

Urinary thromboxane is the end metabolite of thromboxane A2, which is a measure of platelet aggregation. Urinary levels are elevated in patients with unstable coronary disease, in keeping with the known participation of platelets in the pathogenesis of CAD. This level is difficult to ascertain, and collecting urine in the acute situation is at times problematic.

Adhesion Molecules

Adhesion molecules are a wide variety of molecules that can potentially be measured as a way of assessing the adherence of leukocytes and/or platelets or other adhesive proteins to the endothelial matrix.[232] Some are receptors. Examples include PECAM-1 (platelet-endothelial adhesion molecule 1), P-selectin, e-selectin, and VCAM-1 (vascular cell adhesion molecule 1). At times, the receptor itself is measured, but often it is a soluble portion that circulates that is measured. At present, standardized assays, reference interval studies, and consistent assay validations are not available.

Choline

Choline is released after stimulation by phospholipase D and has been touted as a test of prognosis in patients with chest discomfort.[97] At present, standardized assays, reference interval studies, and consistent assay validations are not available.

Unbound Free Fatty Acid

Unbound free fatty acid (uFFA)[39] has also been touted as a marker of ischemia. Most fatty acid is bound, and ischemia is thought to increase the small unbound fraction. Initial studies have reported mixed results. At present, standardized assays, reference interval studies, and consistent assay validations are not available.

Nourin

Nourin I is a small protein released rapidly by "stressed myocytes." It induces changes in a variety of inflammatory cytokines and attracts neutrophils. Preliminary studies have been done to attempt to validate its use. At present, standardized assays, reference interval studies, and consistent assay validations are not available.

Copeptin

Copeptin, a 30 amino acid glycoprotein constituting the C-terminal portion of arginine vasopressin, has been shown to be a prognostic biomarker in hemorrhagic and septic sepsis. More recently, data have shown that measurement of copeptin serves as a rapid and early rule-out biomarker for AMI at presentation in patients with symptoms suggestive of ACS with a normal cTn value.[256A,318] An assay measuring copeptin (CT-proAVP) has been described using the Brahms Kryptor Immunology Analyzer, Diamond Diagnostics Holliston, MA.[270] Additional clinical and analytical validation studies will be necessary, especially head-to-head comparisons of copeptin versus the new hs-cTn assays.
