The kidneys play a central role in the homeostatic mechanisms of the human body, and reduced renal function strongly correlates with increasing morbidity and mortality. Biochemical investigations, both routine and specialized, are an important part of the clinician's diagnostic armamentarium, and investigations of kidney function constitute a significant element of the workload of most laboratories. The aim of this chapter is to ensure that the clinical chemist/biochemist understands the perspective of the nephrologist when dealing with laboratory investigations for patients with kidney disease. The basic anatomy and physiology of the kidneys are described as a foundation for understanding the pathophysiology of disease and the rationale for diagnostic and management strategies in kidney disease. Key analytical methods employed during the investigation of kidney disease are discussed in Chapter 25.

ANATOMY

The kidneys form a paired organ system located in the retroperitoneal space. They extend from the the lower part of the eleventh thoracic vertebra to the upper portion of the third lumbar vertebra, with the right kidney situated slightly lower than the left. The adult kidney is about 12 cm long and weighs about 150 g (Figure 48-1). The kidneys have both sympathetic and parasympathetic nerve supplies, whose function appears to be predominantly associated with vasomotor activity. The renal lymphatic drainage includes fine lymphatics in the glomerulus, some in close proximity to the juxtaglomerular apparatus (JGA; see Box 48-1 for a list of abbreviations), which are associated with removal of material from the glomerular mesangial cells.

Blood Supply

In most cases, each kidney receives its blood supply from a single renal artery derived from the abdominal aorta. However, multiple renal arteries occur commonly. The renal artery divides into posterior and anterior elements, and ultimately into the afferent arterioles, which expand into the highly specialized capillary beds that form the glomerulus (Figure 48-2). These capillaries then rejoin to form the efferent arteriole that forms the capillary plexuses and the elongated vessels (the *vasa recta*) that pass around the remaining parts of the nephron, the proximal and distal tubules, the loop of Henle, and the collecting duct, providing oxygen and nutrients and removing ions, molecules, and water, which have been reabsorbed by the nephron. The efferent arteriole then merges with renal venules to form the renal veins, which merge into the inferior vena cava.

In adults, the kidneys receive approximately 25% of the cardiac output, about 90% of which supplies the renal cortex, maintaining the highly active tubular cells. Maintenance of renal blood flow is essential to kidney function, and a complex array of intrarenal regulatory mechanisms ensure that it is maintained across a wide range of systemic blood pressures (see discussion later in this chapter). The renal glomerular perfusion pressure is maintained at a constant 45 mm Hg across systemic pressures between 90 and 200 mm Hg.

Nephron

The functional unit of the kidney is the *nephron.* Each kidney has been reported to contain between 600,000 and 1.5 million nephrons.[323] The number of nephrons that an individual is born with (the "nephron dose") may determine that individual's susceptibility to renal injury. The nephron consists of a glomerulus, proximal tubule, loop of Henle, distal tubule, and collecting duct (see Figure 48-2). The collecting ducts ultimately combine to develop into the renal calyces, where the urine collects before passing along the ureter and into the bladder. The kidney is divided into several lobes. The outer, darker region of each lobe, the cortex, consists of most of the glomeruli and the proximal and distal tubules. The cortex surrounds a paler inner region, the medulla, which is further divided into a number of conical areas known as the renal

pyramids, the apex of which extends toward the renal pelvis, forming papillae. Medullary rays are visible striations in the renal pyramids that connect the kidney cortex with the medulla. They are composed of descending (straight proximal) and ascending (straight distal) thick limbs of Henle and collecting ducts and associated blood vessels (the vasa recta). The central hilus is where blood vessels, lymphatics, and the renal pelvis (containing the ureter) join the kidney.

Glomerulus

The glomerulus is formed from a specialized capillary network. Each capillary develops into approximately 40 glomerular loops around 200 μm in size and consisting of a variety of different cell types supported on a specialized basement membrane (Figure 48-3, *top*). Some endothelial and epithelial cells act in concert with the specialized glomerular basement membrane (GBM) to form the glomerular filtration barrier, in addition to mesangial cells.

The *capillary endothelial* cells are about 40 nm thick and are in contact with each other. However, in contrast to the continuous endothelial linings seen elsewhere in the body, circular fenestrations (pores) with diameters of approximately 60 nm collectively constitute 20 to 50% of the glomerular endothelial surface.[170] The endothelium permits virtually free access of plasma and small solutes to the basement membrane. However, although the fenestrations are far larger than the diameter of albumin (3.5 nm), it is thought that perm selectivity to such larger molecules begins at the

BOX 48-1 List of Abbreviations

$1,25(OH_2)D_3$	calcitriol
11β-HSD	11β-hydroxysteroid dehydrogenase
^{99m}Tc-DMSA	technetium-99 m-dimercaptosuccinic acid
^{99m}Tc-DTPA	^{99m}Tc-diethylenetriaminepentaacetic acid
^{99m}Tc-MAG3	^{99m}Tc-mercaptoacetyltriglycerine
AII	angiotensin II
ACE	angiotensin-converting enzyme
ADH	antidiuretic hormone
ADPKD	autosomal dominant polycystic kidney disease
ADQI	Acute Dialysis Quality Initiative
AE1	anion exchanger 1
AGE	advanced glycation end products
AIN	acute interstitial nephritis
AKI	acute kidney injury
AKIN	Acute Kidney Injury Network
ALG	antilymphocyte globulin
ANA	antinuclear antibody
ANCA	antineutrophil cytoplasmic antibody
ANP	atrial natriuretic peptide
anti-GBM	anti–glomerular basement membrane
APD	automated peritoneal dialysis
AQP	aquaporin
ARAS	atheromatous renal artery stenosis
ARB	angiotensin receptor blocker
ARF	acute renal failure
ATG	antithymocyte globulin
ATN	acute tubular necrosis
AVF	arteriovenous fistula
AZT	azathioprine
BJP	Bence Jones protein
BP	blood pressure
BPH	benign prostatic hyperplasia
BSA	body surface area
CA II	carbonic anhydrase II
CA IV	carbonic anhydrase IV
CAN	chronic allograft nephropathy
CAPD	continuous ambulatory peritoneal dialysis
CFU	colony-forming units
CHD	coronary heart disease
CKD	chronic kidney disease
CMV	cytomegalovirus
CNI	calcineurin inhibitor
CO_2	carbon dioxide
COL4A5	A5 chain of type IV collagen
COX	cyclooxygenase
CRF	chronic renal failure
CRP	C-reactive protein
CT	computed tomography
CVP	central venous pressure
DCCT	Diabetes Control and Complications Trial
dRTA	distal renal tubular acidosis

BOX 48-1 List of Abbreviations—cont'd

DTPA	^{99m}Tc-diethylenetriaminepentaacetic acid
DVT	deep vein thrombosis
EDTA	ethylenediaminetetraacetic acid
EM	electron microscopy
EMT	epithelial-mesenchymal transition
EMU	early morning urine
ENaC	apical sodium channel
EPO	erythropoietin
ERF	established renal failure
ESA	erythropoiesis-stimulating agent
ESRD	end-stage renal disease
ESWL	extracorporeal shock wave lithotripsy
FENa	fractional excretion of sodium
FGF-23	fibroblast growth factor-23
FSGS	focal segmental glomerulosclerosis
GBM	glomerular basement membrane
GFR	glomerular filtration rate
GN	glomerulonephritis
GSC	glomerular sieving coefficient
H_2CO_3	carbonic acid
HD	hemodialysis
HDF	hemodiafiltration
HDL	high-density lipoprotein
HF	hemofiltration
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
HOT	Hypertension Optimal Treatment
HPLC	high-performance liquid chromatography
IDL	intermediate-density lipoprotein
ID-MS	isotope dilution mass spectrometry
Ig	immunoglobulin
IL-6	interleukin-6
IM	immunoperoxidase
IVP	intravenous pyelography
IVU	intravenous urography
JGA	juxtaglomerular apparatus
JNC 7	Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure
KDIGO	Kidney Disease Improving Global Outcomes
LDL	low-density lipoprotein
LM	light microscopy
LVH	left ventricular hypertrophy
LVMI	left ventricular mass index
MCD	minimal change disease
MCGN	mesangiocapillary glomerulonephritis
MCP-1	monocyte chemoattractant protein-1
MDRD	Modification of Diet in Renal Disease
MHC	major histocompatibility complex
MMF	mycophenolate mofetil
6-MP	6-mercaptopurine
MPA	mycophenolic acid
MR	mineralocorticoid receptor
MRA	magnetic resonance angiography
MRI	magnetic resonance imaging
Na^+-K^+-ATPase	sodium-potassium adenosine triphosphatase
NAG	*N*-acetyl-β-D-glucosaminidase
NBC-1	Na^+-HCO_3^- cotransporter
NCCT	Na^+-Cl^- cotransporter
NCXl	sodium calcium exchanger
NHANES III	Third National Health and Nutrition Examination Survey
NHE-3	Na^+-H^+ exchanger
NHS	National Health Service
NICE	National Institute for Health and Clinical Excellence
NKCC2	Na^+-K^+-$2Cl^-$ cotransporter
NKF-K/DOQI	National Kidney Foundation–Kidney Disease Outcomes Quality Initiative
NO	nitric oxide
NOS	nitric oxide synthase
NSAID	nonsteroidal anti-inflammatory drug
PD	peritoneal dialysis
PET	peritoneal equilibration test
pIgA	polymeric IgA
PKC-β1	protein kinase C-β1
pmp	per million population
PR3	proteinase 3
PRA	panel-reactive antibody
pRTA	proximal renal tubular acidosis
PTH	parathyroid hormone
QOF	Quality and Outcomes Framework
RAAS	renin-angiotensin-aldosterone system
RBP	retinol-binding protein
rhEPO	recombinant human erythropoietin
RIFLE	Risk, Injury, Failure, Loss, End-stage kidney disease
RPGN	rapidly progressive glomerulonephritis
RRF	residual renal function
RRT	renal replacement therapy
RTA	renal tubular acidosis
RVT	renal vein thrombosis
SAP	serum amyloid protein
SIGN	Scottish Intercollegiate Guideline Network
SLE	systemic lupus erythematosus
SPK	simultaneous pancreas and kidney
TGF-β	transforming growth factor-β
THG	Tamm Horsfall glycoprotein
TIN	tubulointerstitial nephritis
Tm	tubular maximal uptake
TMB	tetramethyl benzidine
TNF-α	tissue necrosis factor-α
TPMT	thiopurine methyltransferase
UF	ultrafiltration
UK	United Kingdom
UKM	urea kinetic modeling
UKNEQAS	United Kingdom National External Quality Assessment Scheme
UKPDS	United Kingdom Prospective Diabetes Study
UKT	United Kingdom transplant
UNOS	United Network for Organ Sharing
URR	urea reduction ratio
US	United States
USRDS	United States Renal Data System
UTI	urinary tract infection
VDR	vitamin D receptor
VLDL	very low-density lipoprotein

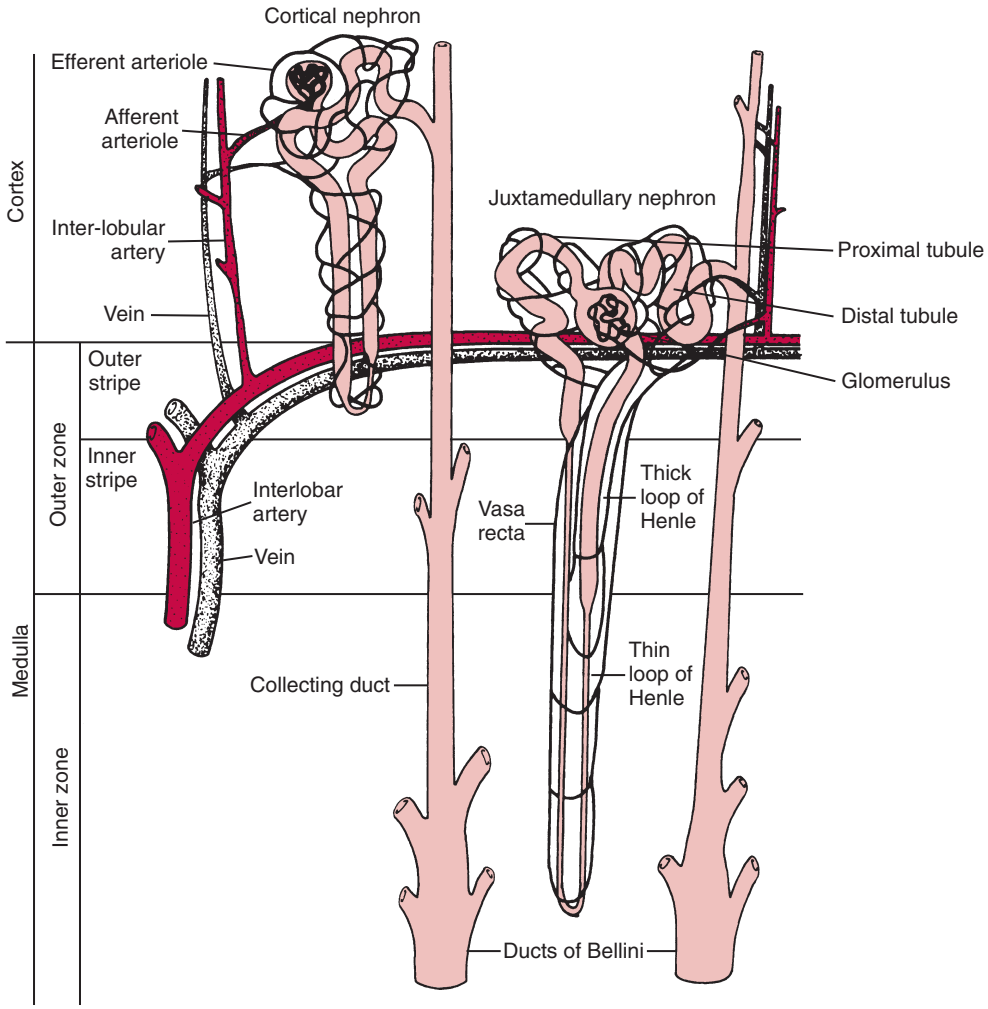

Figure 48-2 Diagrammatic representation of the nephron, the functional unit of the kidney, illustrating anatomic and vascular arrangements. *(From Pitts RF: Physiology of the kidney and body fluids, 3rd edition. Chicago, Ill: Year Book Medical Publishers, 1974.)*

endothelium because of the endothelial surface lining—a glycocalyx coating of negatively charged glycoproteins, glycosaminoglycans, proteoglycans, and absorbed plasma proteins, including orosomucoid and albumin. Estimates of the thickness of this layer vary depending on the visualization and preparation techniques used, but it may be between 200 and 400 nm thick.[170]

The *basement membrane* (Figure 48-3, *bottom*) of the glomerular capillaries is much thicker (approximately 300 nm) than that of other vascular beds and consists of three distinct electron-dense layers: the *lamina rara interna,* the *lamina densa,* and the *lamina rara externa.* The lamina densa consists of a close feltwork of fine, mainly type IV, collagen fibrils (each 3 to 5 nm thick) embedded in a gel-like matrix of laminin, nidogen/entactin, glycoproteins, and proteoglycans such as agrin and perlecan. The lamina densa forms the main size discriminant barrier to protein passage into the tubular lumen. The other two layers of the basement membrane are rich in negatively charged polyanionic glycoproteins, such as heparan sulfate; these may form a charge discriminant barrier to the passage of proteins, although the importance of the GBM in charge discrimination is still uncertain.[170]

The *epithelial cells* of the glomerulus line the outside of the glomerular capillaries, thus facing Bowman's capsule and the primary urine (see Figure 48-3, *top*). These cells are called *podocytes* and have an unusual octopus-like structure in that they have a large number of cytoplasmic extensions or foot processes that are embedded in the basement membrane. Foot processes are anchored to the GBM via integrin molecules and dystroglycans and are divided into primary and secondary. The secondary processes between adjacent cells interdigitate to form filtration slits, which are 25 to 60 nm wide.[170] The podocytes are covered by a complex diaphragm ("slit diaphragm"), some of the molecular components of which (e.g., nephrin) appear crucial for the maintenance of larger proteins within the circulation. The resulting structure is relatively impermeable to most proteins above 60 kDa, but passage of proteins is modulated by their charge and shape.

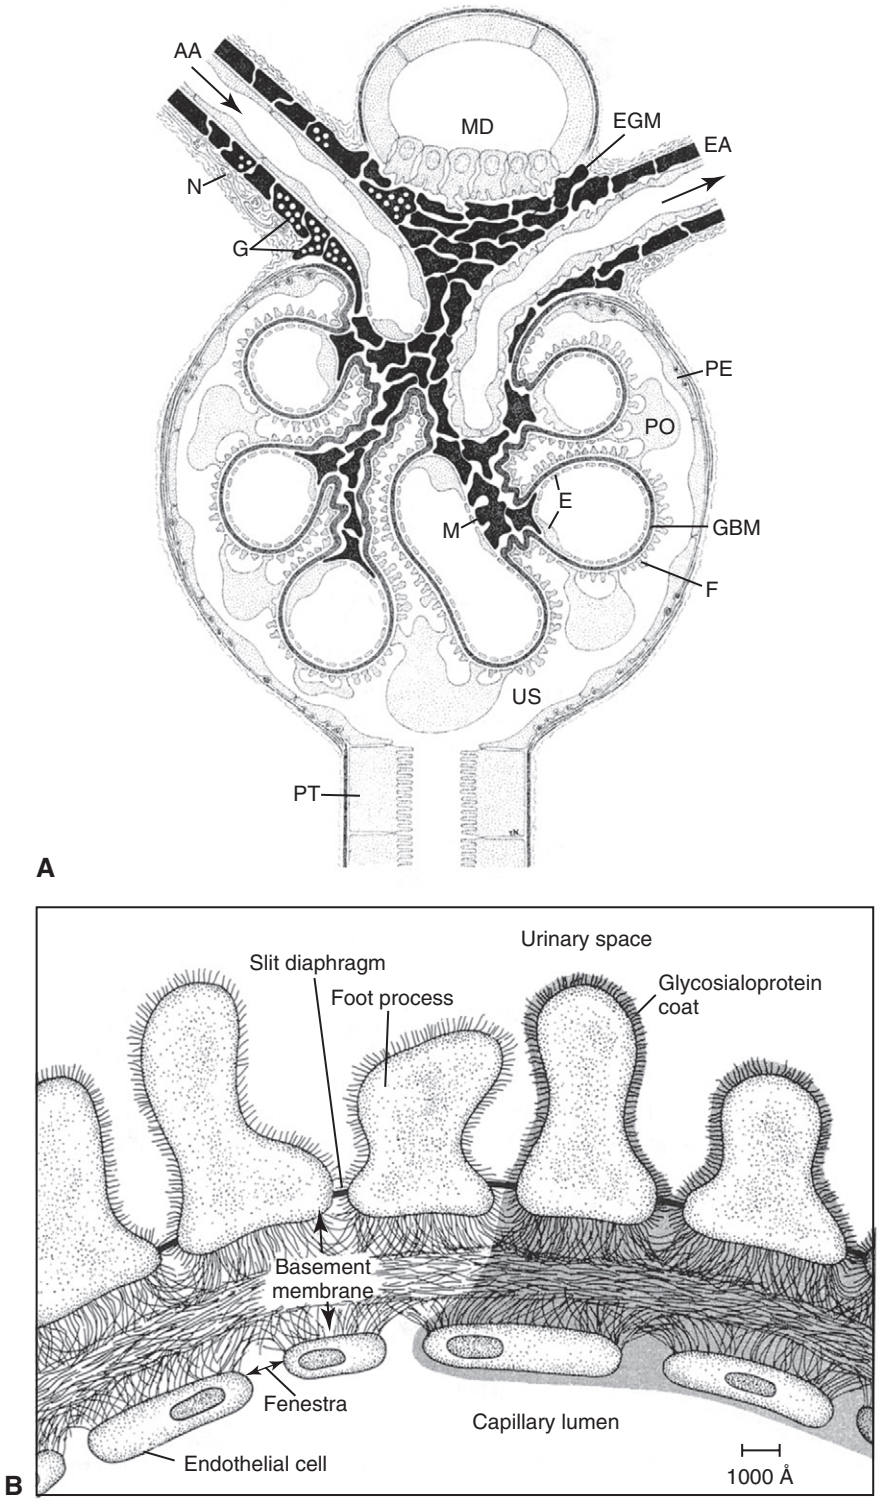

Figure 48-3 **The glomerular cells and the glomerular filtration barrier. A, Longitudinal section through a glomerulus and its juxtaglomerular apparatus. The capillary tuft consists of a network of specialized capillaries, which are outlined by a fenestrated endothelium *(E)*. At the vascular pole, the afferent arteriole *(AA)* enters, branching into capillaries immediately after its entrance; the efferent arteriole *(EA)* is established inside the tuft and passes through the glomerular stalk before leaving at the vascular pole. The capillary network and the mesangium are enclosed in a common compartment bounded by the glomerular basement membrane *(GBM)*. Note that there is no basement membrane at the interface between the capillary endothelium and the mesangium. The glomerular visceral epithelium consists of highly branched podocytes *(POs)*, which, in a typical interdigitating pattern, cover the outer aspect of the GBM. At the vascular pole, the visceral epithelium and the GBM are reflected into the parietal epithelium *(PE)* of Bowman's capsule, which passes over into the epithelium of the proximal tubule *(PT)* at the urinary pole. At the vascular pole, the glomerular mesangium is continuous with the extraglomerular mesangium *(EGM)*, which consists of extraglomerular mesangial cells and an extraglomerular mesangial matrix. The EGM and the granular cells *(G)* of the afferent arteriole, along with the macula densa *(MD)*, establish the juxtaglomerular apparatus. All cells that are suggested to be of smooth muscle origin are shown in black. *US*, Urinary space; *F*, foot processes; *N*, sympathetic nerve terminals; *M*, messenger cells. B, Glomerular capillary wall. In glomerular filtration, filtered fluid is believed to traverse the capillary wall via an extracellular route, that is, through endothelial fenestrae, basement membrane, and slit diaphragms. Circulating polyanions (e.g., albumin) are thought to be retarded by the rich distribution in inner barriers of negatively charged sialylated glycoproteins (*shaded area* in schematic diagram).** *(**A** From Elger M, Kriz W. The renal glomerulus—the structural basis of ultrafiltration. In: Cameron JS, Davison AM, Grunfeld JP, Kerr D, Ritz E, eds. Oxford textbook of clinical nephrology, volume 1, 2nd edition. Oxford: Oxford University Press, 1998:Chapter 3.1. Reproduced by permission of Oxford University Press; **B** From Brenner BM, Beeuwkes R III. The kidney in health and disease: III. The renal circulations. Hosp Pract 1978;13:35-46.)*

Podocytes are also covered by a glycocalyx of sulfated molecules, including glycosaminoglycans and glycoconjugates (e.g., podocalyxin). The surface anionic charge helps to maintain the foot process structure and the distance between the parietal and visceral epithelial cells constituting Bowman's space.[170]

The final cellular components of the glomerulus are the *mesangial cells,* which are found in the central part ("stalk") of the glomerulus between and within the capillary loops suspended in a matrix that they synthesize. They are in direct contact with glomerular endothelial cells and the inner layer of the GBM (lamina rara interna), and also with the extraglomerular mesangium and the JGA (see Figure 48-3, *top*). Mesangial cells have the characteristics of smooth muscle cells (pericytes), in that they are rich in microfilaments and respond to and produce a variety of stimuli [e.g., angiotensin II (AII) and antidiuretic hormone (ADH) or arginine vasopressin].[391] Mesangial matrix is rich in collagens and proteoglycans but is different in composition from the matrix of the GBM. Its composition and volume are tightly regulated in health but can be markedly altered during certain diseases [e.g., diabetic nephropathy, immunoglobulin (Ig)A nephropathy]. Mesangial cells have both structural and housekeeping functions. They have anchoring filaments to GBM opposite the podocytes, and their contractile properties enable them to alter intraglomerular capillary flow and glomerular ultrafiltration surface area, and thereby single nephron glomerular filtration rate (GFR). The cells appear to respond to capillary stretch by generating soluble factors such as vascular endothelial growth factor and transforming growth factor-β (TGF-β), and by activating intracellular signaling pathways. Mesangial cells also have specific and nonspecific mechanisms for removing macromolecules that reach the mesangial and subendothelial space, preventing their accumulation. These mechanisms include phagocytosis and degradation by the cells and trafficking along the mesangial stalk to the juxtaglomerular region, followed by elimination via the renal lymphatics, or by regurgitation into the glomerular capillary.

Proximal Tubule

Bowman's capsule forms the beginning of the tightly coiled, proximal convoluted tubule *(pars convoluta),* which on its progress toward the renal medulla becomes straightened and is then called the *pars recta.* The proximal tubule is about 15 mm long. Epithelial cells lining the convoluted section are cuboidal/columnar cells with a luminal brush border consisting of millions of microvilli, which expand the surface area for absorption of tubular fluid. The proximal tubule is the most metabolically active part of the nephron (Table 48-1).

Loop of Henle

The pars recta drains into the descending thin loop of Henle, which, after passing through a hairpin loop, becomes first the thin ascending limb, and then the thick ascending limb. The cells of the thin ascending limb are very similar to those in the descending (with little brush border, flattened and interdigitated), but important differences are evident in their permeability to water and in their capability for active transport. The thick ascending limb is lined with cuboidal/columnar cells similar in size to those in the proximal tubule, but they do not possess a brush border. At the end of the thick ascending limb, near where it re-enters the cortex and is closely associated with the glomerulus and the efferent arteriole, a cluster of cells known as the *macula densa* is present (Figure 48-4; see later). The main role of the loop of Henle is to assist in generating concentrated urine, hypertonic with respect to plasma; it also has several other functions (see Table 48-1).

Distal Convoluted Tubule

The distal convoluted tubule begins at a variable distance beyond the macula densa and extends to the first fusion with other tubules to form the collecting ducts. The cells of the distal convoluted are tall and cuboidal and contain numerous mitochondria. Na^+,K^+-ATPase activity is higher than in any other segment of the nephron, being located in the basolateral membrane and providing the main driving force for ion transport. Reabsorption of sodium and chloride, with passive reabsorption of water, is the main function of the distal convoluted tubule (see later).

Collecting Duct

The collecting ducts are formed from approximately six distal tubules. These are successively joined by other tubules to form ducts of Bellini, which ultimately drain into a renal calyx. Two main cell types are found in the collecting duct: principal (light) cells and intercalated (dark) cells. Intercalated cells have a dark granular cytoplasm with high carbonic anhydrase activity but no Na^+,K^+-ATPase activity.

Juxtaglomerular Apparatus

Where the thick ascending limb of the loop of Henle passes very close to the glomerulus of its own nephron, the cells of the tubule and the afferent arteriole show regional specialization (see Figure 48-4). The tubule forms the macula densa; the arteriolar cells are filled with granules (containing renin or its inactive precursor, prorenin) and are innervated with sympathetic nerve fibers. This area, called the *JGA,* plays an important part in maintaining systemic blood pressure through regulation of the circulating intravascular blood volume and sodium concentration via the renin-angiotensin-aldosterone system (RAAS). The proteolytic enzyme renin is released primarily in response to decreased afferent arteriolar pressure and decreased intraluminal sodium delivery to the macula densa. Renin is an enzyme of the hydrolase class that catalyzes cleavage of the leucine-leucine bond in angiotensinogen to generate angiotensin I. Renin release from the macula densa is also influenced by nitric oxide, renal cortical prostaglandins (predominantly PGI_2), and the sympathetic nervous system. Angiotensin I is converted in the lungs by angiotensin-converting enzyme (ACE) to the potent vasoconstrictor and stimulator of aldosterone

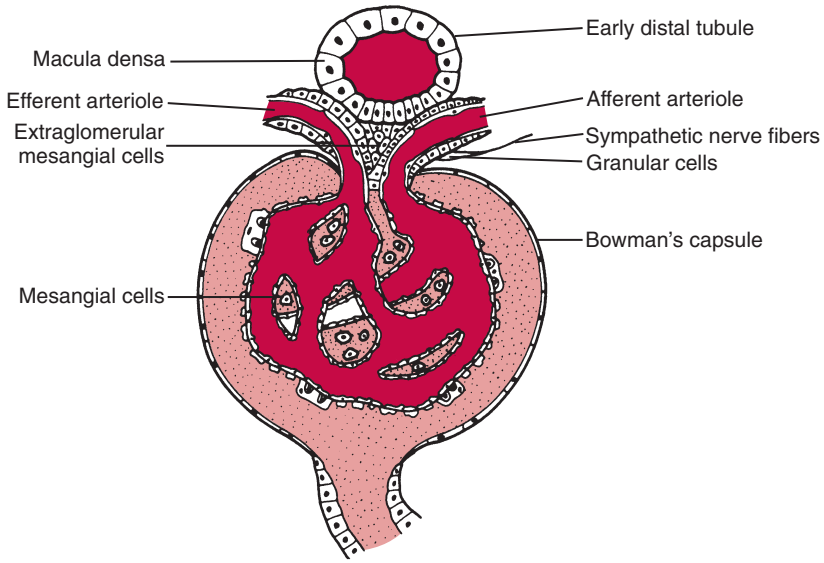

Figure 48-4 The juxtaglomerular apparatus. The beginning of the distal tubule (i.e., where the loop of Henle re-enters the cortex) lies very close to the afferent and efferent arterioles, and the cells of both the afferent arteriole and the tubule show specialization. The cells of the afferent arteriole are thickened, granular (juxtaglomerular) cells that are innervated by sympathetic nerve fibers. The mesangial cells are irregularly shaped and contain filaments of contractile proteins. Identical cells are found just outside the glomerulus and are termed *extraglomerular mesangial cells* or *Goormaghtigh cells*. *(From Lote CJ. Principles of renal physiology, 4th edition. London: Kluwer Academic Publishers, 2000:Chapter 2.)*

release, AII. Vasoconstriction and aldosterone release (with increased distal tubular sodium retention) act in concert with the other action of AII to increase the release of the nonapeptide ADH, and to increase proximal tubular sodium reabsorption, intravascular volume, and pressure. AII also has an inhibitory effect on renin release as part of a negative feedback loop.

Renal Interstitium

In a normal renal cortex, the interstitium is sparse (7 to 9% by volume) because the tubules lie very close together; however, a large proportion of the reabsorbed tubular fluid has to traverse a true interstitial space before entering the capillaries. The interstitium contains a variety of cell types, including lymphocytes and fibroblast-like cells.[361]

The medullary interstitium contains a further specialized cell, lipid-laden interstitial cells, which are arranged in a characteristic ladder-like pattern across the loops of Henle and the capillaries. The extracellular space is rich in glycosaminoglycans, resulting in a gelatinous matrix that contains various poorly characterized osmolytes, osmotically active molecules that help stabilize the high osmotic gradient essential to the countercurrent mechanism involved in the generation of hyperosmotic urine. The interstitium becomes very important in a variety of kidney diseases, and its expansion, as a consequence or cause of nephron loss, plays an important part in progressive kidney disease. Interstitial expansion includes cellular infiltration and increased interstitial matrix synthesis and interstitial fibrosis.

KIDNEY FUNCTION AND PHYSIOLOGY

The kidneys regulate and maintain the constant optimal chemical composition of the blood and interstitial and intracellular fluids throughout the body—the internal milieu—through integration of the major renal functions, namely, filtration, reabsorption, and excretion. Mechanisms of differential reabsorption and secretion, located in the tubule of a nephron, are the effectors of regulation (Table 48-2).

TABLE 48-2 Important Components of Kidney Function

Filtration	Preparation of an ultrafiltrate
Reabsorptive	Glucose, amino acids, electrolytes, proteins
Homeostatic	Extracellular volume, acid-base status, blood pressure, electrolytes
Metabolic	Synthetic: glutathione, glyconeogenesis, ammonia Catabolic: hormones, cytokines
Endocrine	Erythropoietin synthesis, activation of vitamin D, renin release

Excretory and Reabsorptive Functions

The *excretory function* of the kidneys serves to rid the body of many end products of metabolism and of excessive inorganic substances ingested in the diet. Waste products include the nonprotein nitrogenous compounds urea, creatinine, and uric acid; a number of other organic acids, including amino acids, are excreted in small quantities. Dietary intake contains a variable and usually excessive supply of sodium, potassium, chloride, calcium, phosphate, magnesium, sulfate, and bicarbonate. The efficiency of the homeostatic role of kidney function is illustrated by the way the sodium content of the body is maintained essentially constant, regardless of whether daily sodium intake is 1 or 150 mmol or more. Daily intake of water is also variable and may, on occasion, greatly exceed the requirements of the body. Under such circumstances, water becomes additional waste material requiring excretion. To achieve excretion of metabolic wastes and ingested surpluses without disrupting homeostasis, the kidneys must exercise both their *excretory* and *reabsorptive* functions.

Mechanisms for the regulation of electrolytes, nitrogenous wastes, and organic acids are similar, although not identical. For all, except potassium and hydrogen ions and a few organic acids, the maximal excretory rate is limited or established by their plasma concentrations and the rate of their filtration through the glomeruli. Bulk transfer of substances from blood to glomerular filtrate determines the initial mass on which the nephron must operate to produce and excrete urine. Thus the maximal amount of substance excreted in urine does not exceed the amount transferred through the glomeruli by ultrafiltration except in the case of those substances capable of being secreted by tubular cells. Depending on the activity of the renal tubular epithelial cells and their several reabsorptive capacities, excreted amounts of urinary constituents are in general less than the amounts filtered. Because of this general behavior, for many substances an estimate of the excretory capacity of the kidneys can be obtained by measuring the GFR or some variable that is closely related to it. The primary objective in evaluating renal excretory function is to detect quantitatively the degradation of normal capacities or the improvement of impaired ones.

Definitions

Urine is defined as a fluid excreted by the kidneys, passed through the ureters, stored in the bladder, and discharged through the urethra. In health, it is sterile and clear and has an amber color, a slightly acid pH (≈5.0 to 6.0), and a characteristic odor. In addition to dissolved compounds, it contains a number of cellular fragments and complete cells, derived from normal turnover of tubular cells, casts, and crystals (formed elements). Urinary casts are cylindrical proteinaceous structures formed in the distal convoluted tubule

and collecting ducts, which dislodge and pass into the urine, where they can be detected by microscopy.

Urination, also termed *micturition,* is the discharge of urine. In normal adults, adequate homeostasis is maintained with a urine output of 400 to 2000 mL/d. Alterations in urinary output are described as *anuria* (<100 mL/d), *oliguria* (<400 mL/d), and *polyuria* (>3 L/d or 50 mL/kg body weight/d). The most common disorder of urination is altered frequency, which may be associated with increased urinary volume or with partial urinary tract obstruction (e.g., in prostatic hypertrophy).

Formation of Urine—An Overview

The first step in urine formation is filtration of plasma water at the glomeruli. A net filtration pressure of about 17 mm Hg in the capillary bed of the tuft drives the filtrate through the glomerular membrane. The filtrate is called an *ultrafiltrate* because its composition is essentially the same as that of plasma, but with a notable reduction in molecules of molecular weight exceeding 15 kDa. Each nephron produces about 100 µL of ultrafiltrate per day. Overall, approximately 170 to 200 L of ultrafiltrate passes through the glomeruli daily. In the passage of ultrafiltrate through the tubules, reabsorption of solutes and water in various regions of the tubules reduces the total urine volume.

Transport of solutes and water occurs both across and between the epithelial cells that line the renal tubules. Transport is both active requiring energy and passive, but many of the so-called passive transport processes are dependent upon or secondary to active transport processes, particularly those involving sodium transport. All known transport processes involve receptor or mediator molecules, the activity of many of which is regulated by phosphorylation facilitated by protein kinase C or A. Their renal distribution has been shown to correlate with known regional functional activities, but the same transporters, or isoforms of them, can be found in other tissues, particularly the digestive tract. For instance, at least five independent proximal tubular transport processes may be noted for amino acids, including those for (1) basic amino acids plus cystine, (2) glutamic and aspartic acid, (3) neutral amino acids, (4) imino amino acids, and (5) glycine.[489] Inherited disorders of tubular transporters, discussed later in this chapter, may occur, as well as a well-known generalized disorder affecting all of the transport processes, causing Fanconi syndrome and resulting in decreased reabsorption of electrolytes and nutrients (e.g., glucose, amino acids).

Direct coupling of adenosine triphosphate (ATP) hydrolysis is an example of an active transport process. The most important enzymatic transporter in the nephron is Na^+ K^+-ATPase, which is located on the basolateral membranes of the tubuloepithelial cells, accounts for much of the renal oxygen consumption, and drives more than 99% of renal sodium reabsorption (Figure 48-5). Other examples of primary active transport mechanisms include a calcium-ATPase, an H^+-ATPase, and an H^+,K^+-ATPase. These enzymes establish ionic gradients, polarizing cell membranes and thus driving secondary transport processes.

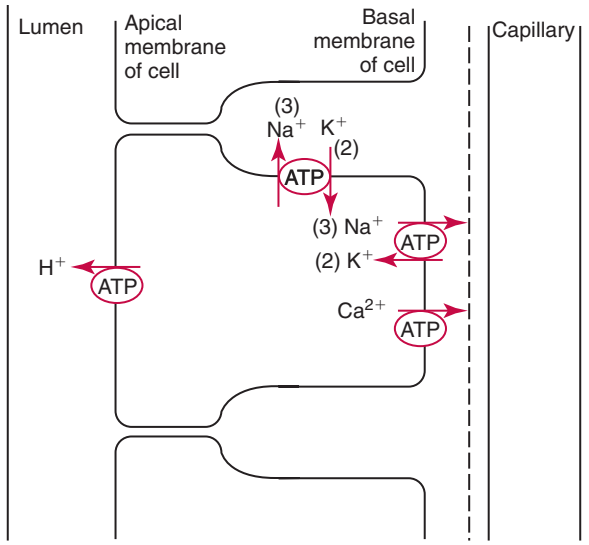

Figure 48-5 Tubular reabsorptive mechanisms: the major primary active transport processes in the proximal nephron. The renal tubular epithelium consists of a single layer of cells. At the luminal side, adjacent cells are in contact (the tight junction), whereas toward the basal side of the cells, there are gaps between adjacent cells (lateral intercellular spaces). *(From Lote CJ. Principles of renal physiology, 4th edition. London: Kluwer Academic Publishers, 2000:Chapter 4.)*

Many renal epithelial cell membranes also contain proteins that act as ion channels. For example, there is one for sodium that is closed by amiloride and modulated by hormones such as atrial natriuretic peptide (ANP). Ion channels enable much faster rates of transport than ATPases but are relatively fewer in number (e.g., ≈100 sodium and chloride channels vs. 10^7 Na^+,K^+-ATPase molecules per cell).

Different regions of the tubule have been shown to specialize in certain functions. The proximal tubule facilitates the reabsorption of 60 to 80% of the glomerular filtrate volume, including 70% of the filtered load of sodium and chloride, and most of the potassium, glucose, bicarbonate, calcium, phosphate, sulfate, and other ions—secreting 90% of the hydrogen ion excreted by the kidney (see Table 48-1). Glucose is virtually completely reabsorbed, predominantly in the proximal tubule, by a passive but sodium-dependent process that is saturated at a blood glucose concentration of about 180 mg/dL (10 mmol/L). Uric acid is also reabsorbed in the proximal tubule by a passive sodium-dependent mechanism, but an active secretory mechanism is present. Creatinine is secreted but only to a small extent—approximately 2.5 µmol/min.

Certain nonbiological compounds, such as phenolsulfonphthalein and *p*-aminohippurate, are secreted by the proximal tubule and have been used for the evaluation of renal tubular secretory capacity. When blood concentrations of

creatinine increase to above normal, creatinine is secreted in this region of the nephron. In the loop of Henle, chloride and more sodium without water are reabsorbed, generating dilute urine. Water reabsorption in the more distal tubules and collecting ducts is then regulated by ADH. In the distal tubule, secretion is the prominent activity; organic ions, potassium ions, and hydrogen ions are transported from the blood in the efferent arteriole into the tubular fluid.

Tubular epithelial cells synthesize a vast range of growth factors and cytokines in response to a variety of stimuli that can have both autocrine and paracrine effects. All cells secrete a variety of cell adhesion molecules that are essential for cellular attachment to the tubular basement membrane.

Regulatory Function

Electrolyte Homeostasis

A complex interplay has been noted between the tubular transport systems regulating individual electrolytes. For simplicity, we have considered each electrolyte individually and have restricted our discussion to the systems of major physiological, pharmacologic, and pathologic significance.

Sodium

Sodium reabsorption is required for the reabsorption of water and many solutes. The proximal tubule is highly permeable to sodium, and the net flux of reabsorption from the tubular lumen is achieved against a high backflux, particularly from paracellular* movement. Approximately 60% of filtered sodium is reabsorbed in the proximal tubule in an energy-dependent manner, driven by basolateral Na^+,K^+-ATPase pumps. Approximately 80% of sodium entering proximal tubular cells does so in exchange for hydrogen ion secretion, facilitated by apical Na-H exchangers. This process in turn permits bicarbonate reabsorption via carbonic anhydrases that are present in both the brush border and the intracellular compartment. A variety of apical sodium cotransporters also allow for reabsorption of other organic and inorganic solutes (e.g., chloride, calcium, phosphates, bicarbonate, sulfates,[406] glucose, urea, amino acids). Sodium transport activity is regulated by many factors, including protein kinase–dependent phosphorylation, which can increase both activity and channel numbers.

A further 30% of filtered sodium is reabsorbed in the thick ascending limb of the loop of Henle, where it is achieved by an apical, bumetanide-sensitive, 130 kDa, electroneutral, Na-K-2Cl cotransporter (NKCC2), itself driven by a favorable inward gradient generated by the basolateral Na^+,K^+-ATPase pump (Figure 48-6). NKCC2 is a kidney-specific member of a class of such channels found throughout secretory epithelia. Activation of these cotransporters appears, in part, to be a result of cell shrinkage. The distal tubule reabsorbs 5 to 8% of sodium via the apical thiazide-sensitive Na-Cl cotransporter (NCCT). Final sodium balance is achieved in the collecting duct via selective amiloride-sensitive, apical sodium channels (ENaCs) in exchange for potassium. ENaCs are controlled in part by the effects of aldosterone on the mineralocorticoid receptor (Figure 48-7).

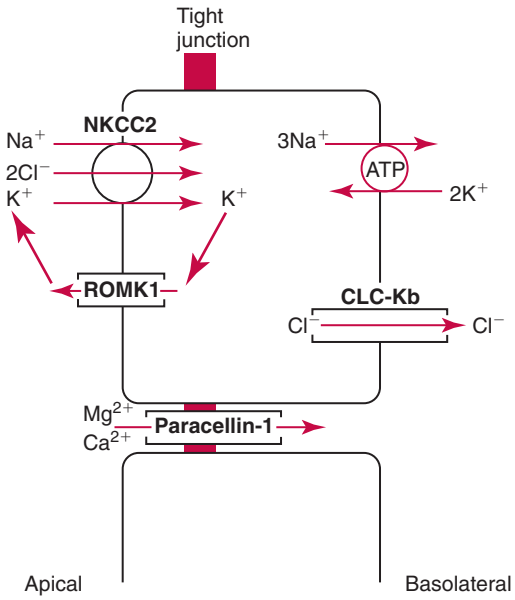

Figure 48-6 Schematic diagram showing the major pathways of solute reabsorption in the thick ascending limb of the loop of Henle. Sodium chloride is reabsorbed by the apical NKCC2 transporter. This electroneutral transport is driven by the low intracellular sodium and chloride concentrations generated by the basolateral Na^+,Ka^+-ATPase and the basolateral chloride channel CLC-Kb. The availability of potassium is rate-limiting for NKCC2, so potassium entering the cell is recycled back to the lumen via the ROMKI potassium channel. This potassium movement is electrogenic and drives paracellular resorption of Mg^{2+} and Ca^{2+} via paracellin-1. Mutations in NKCC2, ROMK1, or CLC-Kb cause Bartter's syndrome. Mutations in paracellin-1 lead to disruption of this paracellular pathway and the tubular disease known as *hypomagnesemic hypercalciuric nephrolithiasis.*[3] *(From Sayer JA, Pearce SHS. Diagnosis and clinical biochemistry of inherited tubulopathies. Ann Clin Biochem 2001;38: 459-70.)*

Potassium

Approximately 90% of daily potassium loss occurs via renal elimination. Potassium is freely filtered across the glomerulus and normally is almost completely reabsorbed in the proximal tubule. However, most regulatory mechanisms affect the loop of Henle, the distal tubule, and the collecting duct. Indeed, urinary losses can exceed filtered load, indicating the importance of distal secretion. Determinants of urinary potassium loss are dietary intake of potassium and plasma potassium concentration, acid-base disturbances (acidosis reduces potassium secretion and vice versa), circulating ADH concentration (ADH increases potassium loss[119]), tubular flow rate (increased flow rate increases potassium loss[240]), and aldosterone secretion (enhances potassium loss and increases

*Paracellular transport is that occurring between tubular epithelial cells and occurs by passive diffusion or by solvent drag.

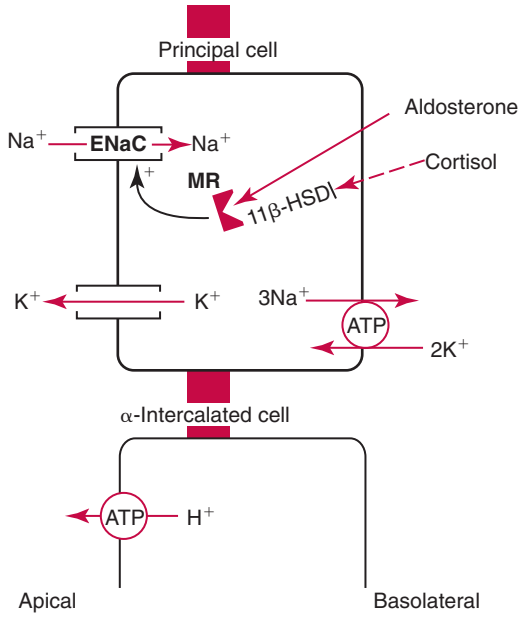

Figure 48-7 Schematic diagram showing the major pathways of solute reabsorption in the collecting duct. In principal cells, sodium reabsorption occurs through the amiloride-sensitive epithelial sodium channel (ENaC). Sodium reabsorption is influenced by the actions of aldosterone on the mineralocorticoid receptor (MR), with hyperaldosteronism producing an increase in channel activity. Cortisol, if permitted, will also bind to the MR, but a degree of specificity is maintained by 11β-hydroxysteroid dehydrogenase (11β-HSD), which inactivates cortisol to cortisone. Sodium uptake drives potassium secretion from principal cells and proton secretion from α-intercalated cells. In Liddle's syndrome, mutations lead to an increase in ENaC activity, with increased Na^+ reabsorption and consequent potassium and proton loss. In pseudohypoaldosteronism type Ia, loss-of-function mutations inactivate ENaC, whereas in pseudohypoaldosteronism type Ib, there are MR abnormalities. Both lead to reduced sodium entry via ENaC, causing salt wasting and decreased secretion of potassium and protons. Licorice causes hypertension and a hypokalemic metabolic alkalosis by inactivating 11β-HSD, allowing cortisol to act as a mineralocorticoid. *(From Sayer JA, Pearce SHS. Diagnosis and clinical biochemistry of inherited tubulopathies. Ann Clin Biochem 2001;38:459-70.)*

sodium retention).[153] Potassium ions are actively accumulated within tubular cells as a result of basolateral Na^+,K^+-ATPase activity, resulting in elevation of intracellular potassium concentration to above its electrochemical equilibrium. Several types of potassium channels exist that have a number of functions: (1) maintenance of a negative resting cell membrane potential, (2) regulation of intracellular volume, (3) recycling of potassium across apical and basolateral membranes to supply NKCC2 and enable sodium reabsorption, and (4) potassium secretion in the cortical collecting tubule.[32] As mentioned previously, potassium is reabsorbed with sodium by NKCC2 in the thick ascending limb of the loop of Henle, but it is recycled back into the lumen by the potassium-secreting channel, ROMK1, thus generating an electrical gradient that drives passive paracellular reabsorption of calcium and magnesium down their electrochemical gradient[3] (see Figure 48-6). ROMK1 is a pH-sensitive, membrane-spanning protein with several serine residues. At least two of these residues require phosphorylation by protein kinase A for the channel to be active.[32]

In the principal cells of the collecting duct, sodium reabsorption via ENaC is accompanied by movement of potassium into the lumen through potassium channels or through a K-Cl symporter* (see Figure 48-7).

Chloride

Approximately 60% of chloride is reabsorbed in the proximal tubule. In the early part of the proximal tubule, avid reabsorption of sodium in combination with glucose and amino acids occurs, creating a lumen-negative potential difference. The negative potential difference drives chloride reabsorption by diffusion through the paracellular pathway. Preferential reabsorption of glucose, amino acids, and bicarbonate in association with sodium in the early proximal tubule causes an increase in the luminal chloride concentration. This high chloride composition heralds the second phase of proximal chloride (and sodium) reabsorption: passive diffusion of sodium chloride via the paracellular pathway, and active reabsorption involving several antiporter† systems, by which chloride is exchanged for secretion of other anions (e.g., bicarbonate, formate, oxalate). In the thick ascending limb of the loop of Henle, further chloride reabsorption occurs in association with sodium via NKCC2. The concentration gradient is maintained by a basolateral chloride pump, CLC-Kb (see Figure 48-6).[239]

Calcium

Approximately 98% of filtered calcium is reabsorbed: 65 to 75% in the proximal tubule (via a paracellular pathway), 20 to 25% in the thick ascending limb of the loop of Henle, 10% in the distal tubule, and, finally, small amounts in the collecting ducts. Calcium reabsorption is predominantly a passive process linked to active sodium reabsorption. For example, in the thick ascending limb of the loop of Henle, paracellular calcium transport is driven by the potential difference created by ROMK1. Active processes, particularly in the distal tubule, tightly regulate the final amount of calcium excreted. Here, calcium reabsorption is transcellular, occurring against the existing electrochemical gradient, and is stimulated by parathyroid hormone (PTH). Following entry into the cell from

*A symporter is an integral membrane protein that is involved in movement of two or more different molecules or ions across a phospholipid membrane such as the plasma membrane in the same direction, and is therefore a type of cotransporter.

†An antiporter (also called exchanger or counter-transporter) is an integral membrane protein which is involved in secondary active transport of two or more different molecules or ions (i.e., solutes) across a phospholipid membrane such as the plasma membrane in opposite directions.

the lumen via an apical epithelial active transport mechanism (ECaC1), calcium binds to calbindin-D and is delivered to the basolateral membrane. Here it is extruded by a calcium-ATPase (PMCA1b) and an Na-Ca exchanger (NCX1). Transcription of messenger RNA coding for both ECaC1 and calbindin is stimulated by calcitriol [1,25$(OH_2)D_3$], possibly synthesized locally in the distal nephron and acting in a paracrine and autocrine fashion. A functional vitamin D response element has been identified in the promoter region of the calbindin-D gene, along with a putative site in the ECaC1 gene. ECaC1 is a pH-sensitive, 83 kDa protein with six transmembrane-spanning domains. Activation of the ion channel probably involves protein kinase C phosphorylation. Evidence indicates that stimulation of the renal calcium-sensing receptor by calcium in the tubular lumen can directly affect tubular reabsorption of calcium, independent of the effects of calciotropic hormones.[187]

Phosphate

Reabsorption of phosphate occurs predominantly in the proximal tubule and is mediated by a secondary active transport mechanism. Three families (types I, II, and III) of sodium-dependent, phosphate cotransporters have been identified, of which type IIa (NPT2a, SLC34A1), a 640 amino acid protein located in the apical plasma membrane, is thought to be the most physiologically important. NPT2a sodium-phosphate transporter is electrogenic (i.e., involves the inward flux of a positive charge), with three sodium ions and one phosphate ion (preferentially divalent) being transferred. Acute regulation of transport is achieved primarily by an alteration in the amount of NPT2a protein present in the apical membrane, with longer-term changes also involving increased transcription of the protein [e.g., in response to 1,25$(OH_2)D_3$]. Tonic amounts of NPT2a in the apical membrane are thought to be high, with regulation predominantly involving internalization of the protein. Increased intracellular movement of the channel from the plasma membrane to the lysosomes is believed to follow both protein kinase A and C phosphorylation initiated by PTH receptor binding.[429,430] Fibroblast growth factor 23 (FGF-23), is a 32 kDa phosphate-regulating peptide, largely produced by bone cells. It was discovered during the 1990s following studies of severe hereditary osteomalacia characterized by severe hypophosphatemia and inappropriate phosphaturia.[56] Its major action is the inhibition of sodium-coupled reabsorption of inorganic phosphate in the renal proximal tubule. Autosomal dominant hypophosphatemic rickets is due to a mutation in the *FGF-23* gene that results in a hyperstable form of this protein.[26] The current paradigm suggests that phosphate ingestion and/or hyperphosphatemia causes FGF-23 release into the circulation from skeletal osteocytes and osteoblasts and interacts with receptors within the kidney via a transmembrane protein, klotho, thereby inhibiting the sodium-coupled phosphate cotransporter in the proximal tubule (Na-Pi type IIa, or NPt2a) and causing phosphaturia. FGF-23 also inhibits 1α-vitamin D hydroxylase, leading to reduced calcitriolproduction. These effects will reduce plasma phosphate concentrations. FGF23 may act in concert with PTH by reducing expression of NPT2a at the proximal tubule brush border, hence promoting phosphaturia.[196] Efflux of phosphate across the basolateral membrane may involve an anion-exchange mechanism and/or a phosphate leak.

Normally, less than 20% of the filtered load of phosphate is excreted into the urine, but above a plasma phosphate concentration of approximately 3.6 mg/dL (1.2 mmol/L), increments in urinary phosphate excretion increase linearly with the filtered load, suggesting that there is T_m (tubular maximal uptake) for phosphate. The T_m for phosphate is decreased by increases in the circulating PTH concentration and the ratio of T_m for phosphate to GFR (T_mP/GFR). T_mP/GFR has been used as a test in the differential diagnosis of hypercalcemia. Although superseded in this context by modern PTH assays, it may be useful in the investigation of inherited disorders of tubular phosphate handling.[340]

Bicarbonate and Hydrogen Ion

The kidney plays a central role in the maintenance of acid-base homeostasis through reabsorption of filtered bicarbonate and secretion of ammonium and acid. The tubular mechanisms underlying these processes are discussed in Chapter 49.

Water Homeostasis

Approximately 180 L glomerular filtrate is formed each day. The unique physiology of the kidney enables approximately 99% of this to be reabsorbed in the production of urine with variable osmolality (between 50 and 1400 mOsmol/kg H_2O at extremes of water intake). Plasma membranes of all mammalian cells are water permeable but to variable degrees. In the kidney, different segments of the nephron show differing permeability to water, enabling the body to both retain water and produce urine of variable concentration. Water reabsorption occurs both isosmotically, in association with electrolyte reabsorption in the proximal tubule, and differentially, in the loop of Henle, distal tubule, and collecting duct in response to the action of ADH. Absorption of water depends on the driving force for water reabsorption (predominantly active sodium transport) and the osmotic equilibration of water across the tubular epithelium. The generation of concentrated urine depends upon medullary hyperosmolality; this in turn requires low water permeability in some kidney segments (ascending limb of the loop of Henle), whereas in other kidney segments (e.g., proximal tubule), there is a requirement for high water permeability. Differing permeability and enaction of hormonal control appear to be largely caused by differential expression along the nephron of a family of proteins known as the aquaporins (AQPs), which act as water channels.

At least 11 different mammalian AQPs have been identified, of which seven (AQP1, -2, -3, -4, -6, -7, -8) are expressed in the kidney.[320,321] Many of these have extrarenal expression sites as well (e.g., AQP1 may be important in fluid removal across the peritoneal membrane). Two asparagine-proline-alanine sequences in the molecule are thought to interact in

the membrane to form a pathway for water translocation. AQP1, which is found in the proximal tubule and the descending thin limb of the loop of Henle, constitutes almost 3% of total membrane protein in the kidney. It appears to be constitutively expressed and is present in both the apical and basolateral plasma membranes, representing entry and exit ports for water transport across the cell, respectively. Approximately 70% of water reabsorption occurs at this site, predominantly via a transcellular (e.g., AQP1) rather than a paracellular route. Water reabsorption in the proximal tubule passively follows sodium reabsorption, so that fluid entering the loop of Henle is almost isosmotic with plasma.

Urinary concentration is predominantly achieved by countercurrent multiplication in the loop of Henle (Figure 48-8).[364,383] The descending thin limb is very permeable to water, but the ascending limb and the collecting duct are not (the collecting ducts are also poorly permeable to urea). Fluid entering the loop of Henle is isotonic to plasma but is hypotonic on leaving it. The ascending limb has active sodium reabsorption driven by Na^+,K^+-ATPase with electroneutralizing transport of chloride—a combined process that can be inhibited by the so-called loop diuretics (e.g., furosemide; see discussion later in this chapter). In this section of the nephron, sodium reabsorption is not accompanied by water, creating a hypertonic medullary interstitium and facilitating water reabsorption from the anatomically adjacent descending limb. The descending limb cells are permeable to sodium chloride, which is cycled from the descending limb back to the ascending limb. Continuous flow along the loop generates an osmotic gradient at the tip of the loop that can reach 1400 mOsmol/kg H_2O. Approximately 5% of water is reabsorbed in the loop of Henle.

A further 10% of water reabsorption occurs in the distal tubule, with the remainder (>20 L/d) reabsorbed in the collecting ducts. Entry of water into the collecting duct cells occurs via apical AQP2 channels, with exit probably occurring via basolateral AQP3 (cortical and outer medullary collecting ducts) and AQP4 (inner medullary collecting ducts). AQP2 appears to be the primary target for ADH regulation of water reabsorption. AQP2 is stored in subapical vesicles in the collecting duct cells. In response to ADH stimulation, these vesicles are cycled through, and inserted into, the plasma membrane by a cytoskeletal, dynein-mediated transport process. Stimulation occurs following binding of ADH

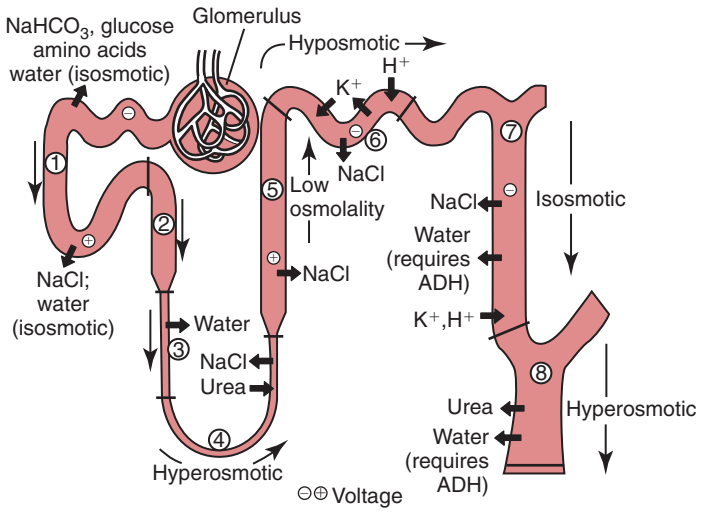

Figure 48-8 Countercurrent multiplication mechanism: schematic representation of the principal processes of transport in the nephron. In the convoluted portion of the proximal tubule *(1)*, salts and water are reabsorbed at high rates in isotonic proportions. Bulk reabsorption of most of the filtrate (65 to 70%) and virtually complete reabsorption of glucose, amino acids, and bicarbonate take place in this segment. In the pars recta *(2)*, organic acids are secreted and continuous reabsorption of sodium chloride takes place. The loop of Henle comprises three segments: the thin descending *(3)* and ascending *(4)* limbs and the thick ascending limb *(5)*. The fluid becomes hyperosmotic, because of water abstraction, as it flows toward the bend of the loop, and hyposmotic, because of sodium chloride reabsorption, as it flows toward the distal convoluted tubule *(6)*. Active sodium reabsorption occurs in the distal convoluted tubule and in the cortical collecting tubule *(7)*. This latter segment is water impermeable in the absence of antidiuretic hormone (ADH), and reabsorption of sodium in this segment is increased by aldosterone. The collecting duct *(8)* allows equilibration of water with the hyperosmotic interstitium when ADH is present. For additional details, see text.
(From Burg MB. The nephron in transport of sodium, amino acids, and glucose. Hosp Pract 1978;13:100. Adapted from a drawing by A. Iselin.)

tahir99-VRG & vip.persianss.ir

to a V_2 receptor in the basolateral plasma membrane of the principal cells of the collecting duct, which promotes a cyclic adenosine monophosphate (cAMP)/protein kinase A cascade, resulting in phosphorylation and activation of AQP2. ADH regulates the acute cellular water-retaining response (AQP2 trafficking) and its longer-term regulation via a conditioning effect on AQP2 gene transcription. The AQP2 gene has a cAMP response element that is involved in the long-term upregulation of AQP2 expression by ADH. It is likely that there are also ADH-independent regulatory pathways of AQP2 expression. Membrane insertion of AQP2 allows water to pass into the collecting duct cells under the influence of medullary hyperosmolality. Maintenance of medullary hyperosmolality depends upon efficient fluid removal, which is the function of the ascending vasa recta, a specialized medullary vasculature, and the close anatomic relations of all medullary constituents (see Figure 48-2). AQP2 expression is decreased in a variety of polyuric conditions (e.g., diabetes insipidus, lithium treatment, hypokalemia, hypercalcemia, urinary obstruction) and is increased in some water-retaining states (e.g., heart failure, cirrhosis, pregnancy).[321,396] A variety of V_2 receptor antagonists have been designed that block the actions of ADH. In contrast to diuretics, these agents promote the excretion of electrolyte-free water and have exciting therapeutic potential in water-retaining states.[396]

ADH also increases the permeability of collecting duct cells to urea, which is the major osmotically active component of luminal fluid in the distal tubule. Fluid of high urea concentration therefore enters the deepest layers of the medullary interstitium, passing down its concentration gradient, contributing to medullary hyperosmolality. Regulation of ADH excretion is of vital importance to fluid homeostasis. Normal plasma osmolality is maintained very tightly between 280 and 290 mOsmol/kg H_2O and is regulated by means of specific osmoreceptors found in the anterior hypothalamus. These receptors modulate the release of ADH and also affect thirst. ADH release may be stimulated by hypotension, hypovolemia, and vomiting independently of osmoregulation.

Endocrine Function

The *endocrine functions* of the kidneys may be regarded as primary, because the kidneys are endocrine organs producing hormones, or as secondary, because the kidneys are a site of action for hormones produced or activated elsewhere. In addition, the kidneys are a site of degradation for hormones such as insulin and aldosterone. In their primary endocrine function, the kidneys produce erythropoietin (EPO), prostaglandins and thromboxanes, $1,25(OH_2)D_3$, and renin. The importance of renin in the maintenance of systemic blood pressure was discussed previously (see earlier, "Juxtaglomerular Apparatus").

Erythropoietin

EPO is a large glycoprotein hormone (MW 34 kDa) containing 165 amino acids and is responsible for stimulating erythroid progenitor cells within the bone marrow to produce red blood cells. It is secreted chiefly by renal peritubular capillary endothelial cells in the adult and by the liver in the fetus. Physiologically, the kidneys sense a reduction in oxygen delivery to tissues by blood and release EPO, thereby stimulating erythropoiesis. Conversely, with a surplus of oxygen in blood traversing the kidneys, as in some forms of polycythemia, the release of EPO into blood is diminished. The use of recombinant human erythropoietin (rhEPO, epoetin) in the management of anemia of kidney disease is discussed later.

Prostaglandins and Thromboxanes

Prostaglandins and thromboxanes are synthesized from arachidonic acid by the cyclooxygenase (COX) enzyme system (see Chapter 27 for further details). The COX system is present in many parts of the kidney and has an important role in regulating the physiologic action of other hormones on renal vascular tone, mesangial contractility, and tubular processing of salt and water. Prostaglandins have a critical role in renal hemodynamics, control of tubular function, and renin release. The major renal vasodilatory prostaglandin is PGE_2, which is synthesized predominantly in the medulla. The major vasoconstrictor prostaglandin is thromboxane A_2, which is produced primarily within the renal cortex.[101] PGE_2 increases renal blood flow rate, inhibits sodium reabsorption in the distal nephron and collecting duct, and stimulates renin release.[101] These actions promote natriuresis and diuresis. In patients with chronic kidney disease (CKD), renal PGE_2 production is increased, representing a compensatory response to loss of nephron mass.[438] Vasodilatory prostaglandins are synthesized following stimulation with renal sympathetic adrenergic and AII-dependent mechanisms to offset or modulate vasoconstriction.[295] In the tubule, prostaglandins act as autocoids, exerting their effects locally, near the site of synthesis.

In pathophysiologic circumstances, including various forms of acute kidney injury, thromboxane A_2 and various prostaglandins may have a significant role in inflammation and alteration of vascular tone. The effects of nonsteroidal anti-inflammatory drugs (NSAIDs) on renal prostaglandin metabolism are considered later in this chapter. The lipoxygenase pathway, which leads to formation of leukotrienes, is also present within the kidneys, although the major source of leukotrienes in inflammatory disease of the kidneys is infiltrating white cells and macrophages.

$1,25(OH_2)D_3$

The kidneys are primarily responsible for producing $1,25(OH_2)D_3$ from 25-hydroxycholecalciferol as a result of the action of the enzyme 25-hydroxycholecalciferol 1α-hydroxylase found in proximal tubular epithelial cells. Regulation of this system is discussed in Chapter 52. The management of renal osteodystrophy is considered later in this chapter.

Glomerular Filtration Rate

The GFR is considered to be the most reliable measure of the functional capacity of the kidneys and is often thought of as indicative of the number of functioning nephrons. As

tahir99-VRG & vip.persianss.ir

a physiological measurement, it has proved to be the most sensitive and specific marker of changes in overall renal function. Measurement of GFR is discussed in Chapter 25.

The rate of formation of the glomerular filtrate depends on the balance between hydrostatic and oncotic forces along the afferent arteriole and across the glomerular filter. The net pressure difference must be sufficient not only to drive filtration across the glomerular filtration barrier but also to drive the ultrafiltrate along the tubules against their inherent resistance to flow. In the absence of sufficient pressure, the lumina of the tubules will collapse. This balance of forces can be expressed as follows:

$$\text{Rate of Filtration} = K_f\left(\left(P_{GCap} + \Pi_{BC}\right) - \left(P_{BG} + \Pi_{GCap}\right)\right)$$

where

K_f = (hydraulic permeability × surface area)
P_{GCap} = glomerular-capillary hydrostatic pressure
Π_{BC} = oncotic pressure in Bowman's capsule
P_{BC} = hydrostatic pressure in Bowman's capsule
Π_{GCap} = oncotic pressure in the glomerular capillary

Because the oncotic pressure in Bowman's capsule *(Π_{BC})* can be considered to be negligible (protein concentration is usually 10 to 100 mg/L), this equation becomes

$$\text{Rate of Filtration} = K_f\left(P_{GCap} - P_{BC} - \Pi_{GCap}\right)$$

Changes in K_f are caused by drugs and by glomerular disease, but it is also physiologically regulated. Mesangial cell contraction, which is thought to be the main mechanism, causes a reduction in K_f, tending to reduce GFR. Net P_{GCap} represents a balance between renal arterial pressure and afferent and efferent arteriolar resistance. Although an increase in arterial pressure will tend to increase P_{GCap}, the magnitude of the change is modulated by differential manipulation of afferent and efferent tone, which can result in minimal change to the P_{GCap}. When the renal blood flow is low, oncotic pressure can change as the plasma passes along the renal capillaries. As filtrate is removed, the oncotic pressure rises, and by the end of the capillary, the net filtration rate may become zero; thus GFR falls, and this limits the amount of filtrate that can be obtained from a given volume of plasma. The average ($P_{GCap} - P_{BC} - \Pi_{GCap}$) or net filtration pressure is only about 17 mm Hg. This pressure is sufficient to drive the filtration of 180 L of fluid per day, only because the K_f for glomerular capillaries is several orders of magnitude greater than for nonrenal capillaries.

Regulation of GFR

The factors involved in regulation of GFR are listed in Table 48-3. Autoregulation of renal blood flow and GFR is widely thought to be explained by the *myogenic theory.* This theory is based on the principle that an increase in wall tension of the afferent arterioles, brought about by an increase in perfusion pressure, causes automatic contraction of arteriolar smooth muscle, thus increasing resistance and keeping the flow constant despite the increase in perfusion pressure.

The *tubuloglomerular feedback mechanism,* involving the macula densa and release of the vasodilator adenosine, must also be considered. Although not fully understood, this mechanism appears to regulate GFR, with changes in renal blood flow as a secondary consequence. For individual nephrons, evidence indicates that each single nephron GFR (SNGFR) is influenced by the composition of the tubular fluid in the distal tubule, which in turn is influenced by the filtration rate. The macula densa is thought to sense the distal tubular sodium chloride content, its osmolality, or the rate at which sodium chloride is transported. The macula densa then signals the JGA via an uncertain mechanism to cause the release of adenosine and possibly AII and prostaglandins, which in turn affects vascular resistance.*

TABLE 48-3 Summary of Factors That Influence the Glomerular Filtration Rate (see text for explanation of terminology)

	Major Influencing Factors	Effect on GFR
Kf	Increased glomerular surface area due to relaxation of mesangial cells	Increase
	Decreased glomerular surface area due to contraction of mesangial cells	Decrease
P_{GCap}	Altered renal arterial pressure	
	Afferent dilation	Increase
	Afferent constriction	Decrease
	Efferent constriction	Increase
	Efferent dilation	Decrease
P_{BC}	Increased intratubular pressure (e.g., tubular obstruction)	Decrease
Π_{GCap}	Altered plasma oncotic pressure: increased	Decrease
	Altered renal blood flow: decreased	Decrease

The result of the combination of myogenic mechanisms and tubuloglomerular feedback is that the net filtration pressure or P_{GCap} is kept reasonably constant over a wide variety of systemic arterial pressures. It should be noted that renal blood flow and GFR change across this variety of systemic pressures but to a significantly smaller extent than would be predicted if these autoregulatory mechanisms were not in place.

Other factors influencing renal blood flow are indicated in Table 48-4. The afferent and efferent arterioles are richly supplied with renal sympathetic nerves. Epinephrine acts via α-adrenergic receptors, leading to constriction of both arterioles and causing a decrease in renal blood flow.

Nitric oxide (NO) has been identified as an important vasodilator produced by vascular endothelial cells. NO is synthesized from L-arginine and oxygen by nitric oxide synthetase (NOS), of which three isoenzymes are differentially located and regulated. Within the kidney are eNOS

*Vascular resistance is the resistance to flow that must be overcome to push blood through the circulatory system.

TABLE 48-4 Factors Altering Renal Artery Tone and Renal Blood Flow

Factor	Effect On		Effect On	
	Afferent Arteriole	Efferent Arteriole	RBF	GFR
Adenosine	Constriction	Dilation	N	N→NE
Angiotensin II	Constriction	Constriction	N	N
Epinephrine/norepinephrine	Constriction	Constriction	N	N→NE
Antidiuretic hormone (ADH)	Constriction	Constriction	NE	N→NE
Endothelin	Constriction	Constriction	NE	N→NE
Leukotrienes	Constriction	Constriction	NE	N→NE
Thromboxane A_2	Constriction	Constriction	NE	N→NE
Prostaglandins (PGE_2, PGI_2)	Dilation	Dilation	NE	NE
Nitric oxide	Dilation	Dilation	N	N
Atrial natriuretic factor	Dilation	Constriction	N	N→P
Dopamine	–	Dilation	N	N

GFR, Glomerular filtration rate; *N,* negative; *NE,* negligible; *P,* positive; *RBF,* renal blood flow.

(endothelial) and iNOS (inducible) isoenzymes. Activation of NOS has been shown to occur as a result of shear stress (e.g., increased arteriolar tone). A variety of physiologic vasoconstrictors are present, including acetylcholine, bradykinin, endothelin, and serotonin; a rise in intracellular ionized calcium is required for the vasoconstrictors. NO synthesis is now known to play an important role in the regulation of human vascular tone and has a crucial role in control of blood pressure and kidney function.[102,160,359] It has also been found in the macula densa and has been implicated in the regulation of renin release.

Age and the Kidney

Kidney function is not constant throughout life. In utero, urine is produced by the developing fetus from about the ninth week of gestation. Nephrogenesis is complete by approximately 35 weeks' gestation, although kidney function remains immature during the first 2 years of life. The kidney of the term infant receives approximately 6% of the cardiac output, compared with 25% in adults. Renal vascular resistance is relatively high, and the low renal blood flow is particularly directed to the medulla and inner cortex. The gradual increase in renal blood flow that occurs with increasing age is directed mainly to the outer cortex and is mediated by local neurohormonal mechanisms.[216] The GFR at birth is approximately 30 mL/min/1.73 m^2.[72] It increases rapidly during the first weeks of life to reach approximately 70 mL/min/1.73 m^2 by age 16 days.[72] Normal adult values are achieved by age 14 years. Tubular functions, including salt and water conservation, are also immature at birth. Birth is associated with rapid changes in kidney function, with a switch to salt and water conservation mediated by catecholamines, the renin-angiotensin system, ADH, glucocorticoids, and thyroid hormone.[72] The immaturity of the neonatal kidney contributes to the relatively common problems of water and electrolyte disturbances in infants. These disturbances are more likely to occur in premature infants, particularly those born before 35 weeks' gestation.

Aging is associated with a variety of structural changes in the kidney, which begin in early middle age, including decreasing kidney weight and number of glomeruli, with the cortical glomeruli being particularly affected.[110,222] Changes in the afferent and efferent arteriolar systems are evident, with formation of direct channels (shunts) between afferent and efferent arterioles in the medulla. Aging is also associated with the development of tubulointerstitial fibrosis, loss of tubular mass, and decreasing length of the proximal tubule.

Structural change is accompanied by functional changes, which in many respects are the reverse of those seen in early life. On average, GFR declines with age by approximately 1 mL/min/1.73 m^2/y over the age of 40 years.[11,92,375,459] Renal blood flow, particularly to the cortical area, also decreases with age, while the filtration fraction (i.e., GFR/renal plasma flow)[11] and renal vascular resistance[123,124] increase. Tubular function, such as the ability to concentrate urine and excrete a water and salt load, is decreased, and nocturnal polyuria is common. Renal salt conservation is impaired,[110] and the prevalence of albuminuria rises over the age of approximately 40 years.[95,213]

It is not known whether these changes are the result of a normal aging process (i.e., involutional) or whether they are caused by the interplay of pathology and age. Cumulative exposure to common causes of CKD such as (1) atherosclerosis, (2) hypertension, (3) heart failure, (4) diabetes,[65] (5) obstructive nephropathy, (6) infection, (7) immune insult, (8) nephrotoxins such as lead,[262] and (9) dietary protein[5,47] increases with age, and it is difficult to separate these effects from those of "healthy" aging. The decline in GFR with increasing age may be largely attributable to hypertension,[265,266] atherosclerosis,[222] or heart failure.[122] In the absence of these and other identifiable causes of kidney disease, many individuals have stable GFR as they age.

Loss of kidney function with aging appears to be heterogeneous and is not inevitable.[123,264] Kidney function may be well preserved in healthy older people, and assumptions with respect to GFR based solely on age could be erroneous.

tahir99-VRG & vip.persianss.ir

Conversely, attention to the common causes of CKD could preserve function in older people.[395] Kidney disease is more common among older people. Studies from England,[116] France,[217] and Iceland[281] have demonstrated a near exponential rise in CKD with age. Data from the United States on CKD prevalence show the prevalence of a GFR between 30 and 60 mL/min/1.73 m^2 to be 4.3% of the total noninstitutionalized population overall, but this rises to 25% among those over 70 years.[83] The prevalence may be even higher among institutionalized older people (e.g., 82% of a residential home population were identified as having a GFR <60 mL/min/1.73 m^2).[61] The incidence of acute kidney injury also increases with age.[230]

Glomerular and Tubular Protein Handling

Glomerular permselectivity to proteins is a function of the integrated actions of endothelial cells, the GBM, and the podocytes, although the exact contribution and importance of each is still a matter of some debate. A variety of methods have been used to study the permeability of the glomerular barrier, including urinalysis in vivo, micropuncture of single nephrons, isolated perfused kidneys, isolated glomeruli, isolated GBMs, and artificial membranes. All of these techniques have contributed to knowledge of glomerular permeability characteristics, and all have advantages and disadvantages. For example, micropuncture techniques may damage the barrier. These issues have been reviewed by Haraldsson and associates.[170] Additionally, a number of different markers, including endogenous and modified proteins, dextran, and Ficoll polymers, have been used to study glomerular permeability.[170]

Glomerular Sieving

The glomerular permeability of a molecule is expressed in terms of its glomerular sieving coefficient (GSC). Molecules smaller than approximately the molecular weight of inulin (5 kDa) are freely filtered. Therefore, inulin, urea, creatinine, glucose, and electrolytes all have a GSC = 1.0. Classic experiments in the 1970s used linear dextran chains of varying molecular weight and charge to study glomerular filtration characteristics. However, linear carbohydrate chains do not necessarily behave in the same manner as a globular protein of equal molecular weight or charge. For example, neutral dextran chains of 15 kDa (diameter 2.4 nm) have GSC = 1.0, whereas the smaller β_2-microglobulin (11.8 kDa, diameter 1.6 nm) has GSC = 0.7.[24] Linear molecules have higher GSC than globular proteins, hence theoretical glomerular pore dimensions based on dextran studies were overestimated. More recently, Ficoll polymers have been used. These are neutral, heavily cross-linked, sucrose-epichlorohydrin copolymers that behave as rigid hydrated spheres and are thought to behave more like globular proteins in their sieving behavior.[170]

As a result of such studies, some general conclusions can be drawn with respect to glomerular protein handling. The glomerulus acts as a selective filter of the blood passing through its capillaries, restricting the passage of macromolecules in a size-, charge-, and shape/configuration-dependent manner. Sieving coefficients (1) decrease as molecular size increases, (2) are lower for anionic proteins than for neutral proteins of equivalent size, and (3) are lower for globular rather than elongated proteins. Examples of the GSC for major urinary proteins are listed in Table 25-2.

The protein concentration in the glomerular filtrate has been measured in several animal models by direct glomerular puncture. The concentration of total protein found is in the range of several hundred mg/L (≈1% of plasma), with albumin concentrations varying from less than 40 to a few hundred mg/L. The filtered load of protein depends on the product of the GSC and the free plasma concentration; therefore the albumin load per nephron is much greater than that of the other filtered proteins.[24,275] In general, proteins larger than albumin (66 kDa, diameter 3.5 nm, charge −23) are retained by the healthy glomerulus and are termed high molecular weight proteins. However, lower molecular weight proteins are also retained to a significant extent.

Tubular Reabsorption

The final urinary concentration of proteins depends on the filtered load, but also on the efficiency of the proximal tubular reabsorptive process, in addition to any contribution of tubular secretion. Proteins are reabsorbed by receptor-mediated, low-affinity, high-capacity processes. Megalin (MW 600 kDa) and cubulin (MW 460 kDa) are endocytic, multiligand receptors that are important in protein reabsorption.[455] Megalin belongs to the low-density lipoprotein (LDL) receptor family, whereas cubulin is identical to the intestinal intrinsic factor–vitamin B_{12} receptor. In the kidney, both are localized in clathrin-coated pits in the apical brush border of renal proximal tubular cells and bind filtered proteins in a calcium-dependent process. Megalin appears capable of both binding and internalizing its ligands, whereas the cubulin-ligand complex requires megalin to be internalized. Some proteins such as albumin will bind to either receptor, whereas others are specific [e.g., transferrin binds to cubulin only, retinol-binding protein (RBP) and α_1-microglobulin to megalin only]. Once proteins have been internalized, they are transported by the endocytic vesicle and fuse with lysosomes. Proteolysis occurs, and the resultant amino acids are released into the tubulointerstitial space across the basolateral surface of the tubular epithelial cell. The membrane vesicles are then recycled to the brush border to complete the reabsorption cycle. In health, the reabsorptive mechanism removes 99% of the filtered protein, thus retaining most of the essential amino acid constituents for reuse.[24,162,275] Capture of filtered transport proteins is also important in conserving vitamin status (e.g., vitamin A associated with RBP).

The tubular reabsorptive process is saturable. Any increase in the filtered load [caused by glomerular damage, increased glomerular vascular permeability (e.g., inflammatory response), or increased circulating concentration of low molecular weight proteins] or decrease in reabsorptive capacity (caused by tubular damage) can result in increased urinary protein loss *(proteinuria)*.

tahir99-VRG & vip.persianss.ir

Tubular secretion of proteins also contributes to urinary total protein concentration; in particular, in health, Tamm Horsfall glycoprotein (THG) accounts for ≈50% of urinary total protein. THG (MW 200 kDa), a highly glycosylated acidic protein, is secreted into the tubular fluid only by the thick ascending limb and the early distal convoluted tubule and is thought to play a role in inhibiting kidney stone formation.[190,373] It is a major constituent of renal tubular casts, along with albumin and traces of other proteins. Investigation for increased urinary protein loss is mandatory in any patient with suspected kidney disease and was considered in Chapter 25.

Consequences of Proteinuria

It is increasingly accepted that proteinuria is not just a marker of, but contributes directly to, progression of kidney disease.[52,54] The accumulation of proteins in abnormal amounts in the tubular lumen may trigger an inflammatory reaction, which in turn may contribute to interstitial structural damage and expansion, and progression of kidney disease.[51] Increasing evidence suggests that megalin may not just be a scavenger receptor for albumin, but that it may have signaling functions that regulate cell survival. Excessive quantities of albumin in the tubular lumen may downregulate proximal tubular megalin expression, increasing cell sensitivity to apoptosis.[13] Evidence gathered from in vitro studies suggests that glomerular filtration of abnormal amounts or types of protein induces mesangial cell injury, leading to glomerulosclerosis, and that these same proteins can have adverse effects on proximal tubular cell function.[105] Numerous studies have demonstrated that proteinuria is a potent risk marker for progression of renal disease in both nondiabetic[202,346,377] and diabetic[48,189] kidney disease. Furthermore, reducing proteinuria slows the rate of progression of proteinuric kidney disease. This effect has been observed in clinical trials in patients treated with ACE inhibitors and angiotensin II receptor blockers (ARBs), given alone or in combination.[337,376] These drugs reduce protein excretion by reducing intraglomerular filtration pressure and possibly by stabilizing the glomerular epithelial cell slit diaphragm proteins.[6,276] Consequently, reduction of proteinuria is an important therapeutic target.[185,203,225]

PATHOPHYSIOLOGY OF KIDNEY DISEASE

Despite the diverse initial causes of injury to the kidney, progression of kidney disease leading to loss of function and ultimately to kidney failure is a remarkably monotonous process characterized by (1) early inflammation, followed by (2) accumulation and deposition of extracellular matrix, (3) tubulointerstitial fibrosis, (4) tubular atrophy, and (5) glomerulosclerosis. Proteinuria is thought to be one of the most important risk factors for progression of kidney disease (see earlier). Nephrons are also lost via toxic, anoxic, or immunologic injury that initially may occur in the glomerulus, the tubule, or both. Glomerular damage can involve endothelial, epithelial, or mesangial cells and/or the basement membrane.

The RAAS plays a pivotal role in many of the pathophysiologic changes that cause kidney injury and is an important therapeutic target (Figure 48-9).[380] Renal cells are able to produce AII in a concentration that is much higher than in the systemic circulation, and AII generates potentially toxic reactive oxygen species within renal cells affecting signal transduction. In addition, many profibrogenic and proinflammatory mediators are induced within the kidney by AII. Aldosterone has been reported to enhance profibrogenic processes. Inflammatory mediators released include cytokines, chemokines, and growth factors, such as TGF-β, monocyte chemoattractant protein-1 (MCP-1), interleukin-6 (IL-6), interferon-γ, or tissue necrosis factor-α (TNF-α); these inflammatory factors activate resident lymphocytes and macrophages and recruit additional cells from the peripheral circulation. Thus, cellular infiltration is a common but not

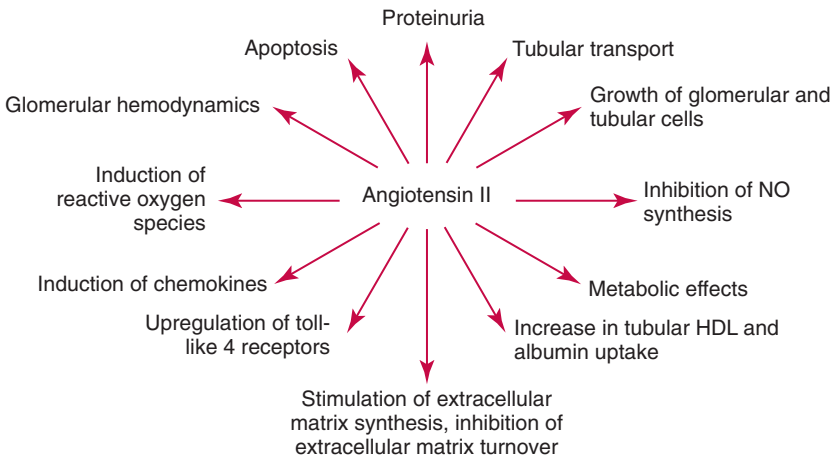

Figure 48-9 Role of angiotensin II in renal pathology. Angiotensin II is a cytokine with many effects on the kidney, clearly beyond its classical function as a hemodynamic mediator. *(From Ruster C, Wolf G: Renin-angiotensin-aldosterone system and progression of renal disease. J Am Soc Nephrol 2006;17:2985-91.)*

tahir99-VRG & vip.persianss.ir

universal finding in renal biopsy specimens. These activated cells can cause T cell–mediated cell lysis, activation, and proliferation of interstitial fibroblasts. Fibroblast activity results in increased extracellular matrix synthesis and eventually in glomerular and tubular fibrosis. Extracellular matrix expansion causes disruption of local blood flow, exaggerating regional ischemia, and a vicious cycle of inflammation, fibrosis, and cell death is propagated.

Elucidation of this common pathway is incomplete but is the focus of considerable research interest because novel therapies are required to reduce progression and ideally to reverse fibrosis. A strong relationship has been described for proteinuria and MCP-1–mediated interstitial damage in a prospective study of patients undergoing kidney biopsy for CKD.[104] In rodent models, anti–MCP-1 gene therapy reduced interstitial inflammation and fibrosis.[404] Increased production and activity of TGF-β have also been demonstrated in glomerular disease; this acts as a key mediator, along with AII, of fibrogenesis.[267] Data support the hypothesis that during tubulointerstitial fibrosis, α-smooth muscle actin-expressing mesenchymal cells might derive from the tubular epithelium via epithelial-mesenchymal transition (EMT) under the influence of TGF-β.[199] Strategies to block the process of EMT are being explored for future therapeutic targets in CKD. For example, an endogenous antagonist of TGF-β–induced EMT has been identified as bone morphogenic protein-7, a member of the TGF-β superfamily. Systemic administration of bone morphogenic protein-7 repaired severely damaged tubular cells in mice and reversed renal injury.[488]

The kidneys have considerable ability to increase their functional capacity in response to injury. Thus, a significant reduction in functioning renal mass (50 to 60%) may occur before the onset of any significant symptoms, or even before any major biochemical alterations appear. The most sensitive and specific measure of functional change, the GFR, can be reduced to less than 60 mL/min/1.73 m^2 before signs and symptoms of kidney failure will be observed. This increase in workload per nephron is thought to be an important cause of progressive renal injury.[486] A well-recognized hypothesis suggests that independent of primary renal injury, a point is reached in the decline in nephron number when further loss becomes inevitable and progressive as a consequence of a common pathway leading to interstitial fibrosis.[366]

Overview of Kidney Disease and Its Clinical Manifestations

Most often, kidney disease is detected opportunistically by measurement of blood pressure and urine testing and blood tests in asymptomatic individuals. Such testing can occur in the primary care setting or for health clearance purposes for insurance. Typical findings include isolated hematuria and isolated proteinuria. Kidney disease may also present with macroscopic hematuria, swollen ankles, headaches, and visual disturbances due to severe hypertension, or as a manifestation of systemic disease, such as in the vasculitides and systemic lupus erythematosus (SLE) (kidney diseases are discussed in greater detail later). Symptoms suggestive of advanced kidney disease include fatigue, nausea, vomiting, poor appetite, shortness of breath, fluid retention, poor memory, loss of libido, and itching. Unfortunately, as many as 30% of individuals present very late in their disease and may require urgent dialysis with no previous experience with the specialist nephrology service. These patients have a poor prognosis compared with patients who have been cared for in a multidisciplinary specialist environment for at least 1 year. Therefore, early recognition of kidney disease is of paramount importance to outcome.

Detection and diagnosis of kidney disease requires a detailed history to include current symptoms, past medical and family history, social history, and a full drug history. A focused examination may identify potential causes of kidney disease such as obstructive uropathy in which the bladder is easily palpable, or may indicate vascular disease associated with narrowing of the arteries supplying the kidneys (renal artery stenosis), systemic disease, or de novo kidney disease. Blood pressure measurement and urinalysis (see Chapter 25) are crucial baseline assessments. Examination of the skin may reveal evidence of advanced kidney disease with excoriations due to the intense itch that can occur. Signs of fluid overload can be seen in the ankles, or effusions may be noted in the chest. Abdominal examination may detect a palpable bladder, renal bruits, or enlarged kidneys. Fundoscopic examination is performed in hypertensive and diabetic patients to identify microvascular damage to the retina.

Kidney disease may present with heavy blood and protein detected in a sample of the urine—a so-called active urinary sediment. An acute "nephritic" syndrome may occur as the result of postinfectious glomerulonephritis, for example, following a streptococcal throat or skin infection. The patient presents with poor urine output, edema, hypertension and acute kidney failure, and brown discolored urine. This pattern of acute nephritis is commonly seen in the developing world and is relatively unusual in developed countries.

Proteinuria may be the only indicator of kidney disease in many people. Proteinuria, particularly if in excess of 1 g/d, is indicative of glomerular disease. Most cases of glomerular disease are chronic, and patients may be followed for many years with monitoring of GFR and quantification of proteinuria.

Kidney disease presenting as nephrotic syndrome is characterized by the triad of heavy proteinuria (typically defined as exceeding an arbitrary threshold of 3 g/d), hypoalbuminemia, and edema. It is almost always caused by glomerular disease as opposed to tubular proteinuria. Several distinct pathologic entities may cause nephrotic syndrome (and are discussed in detail later in the present chapter), including minimal change nephropathy, focal segmental glomerular sclerosis, and membranous nephropathy. Nephrotic syndrome can also be a manifestation of diabetic kidney disease (diabetic nephropathy). Amyloid light chain amyloidosis (AL-amyloid) is a relatively common cause of nephrotic syndrome in older people.

Kidney disease often accompanies systemic diseases such as diabetes mellitus, vasculitis, SLE, and disorders of

tahir99-VRG & vip.persianss.ir

immunoglobulin light chains. The whole spectrum of kidney involvement may be seen, including an active urinary sediment, isolated proteinuria or hematuria, nephrotic syndrome, and rapidly progressive kidney failure.

Imaging of the renal tract to include kidneys, ureters, bladder, and prostate gland is very important in many kidney diseases and provides useful information. It is mandatory in all cases of new acute kidney injury (AKI; see later) to identify size and symmetry of kidneys and to exclude obstruction to urine flow anywhere within the tract. Renal ultrasound, the imaging technique of choice in most cases, gives reliable data on the size of kidneys and evidence of obstruction where present. Additionally, underlying structural abnormalities such as polycystic kidneys, renal cysts and tumors, and anatomic and congenital malformations may be demonstrated. Renal ultrasonography is easy, cheap, noninvasive, and without risk. Intravenous urography/pyelography (IVU/IVP) is utilized in urologic practice mainly to identify kidney stone disease and to investigate structural disease of the urinary tract such as a transitional cell carcinoma of the ureter or bladder. Imaging of soft tissues with computed tomography (CT) scanning or magnetic resonance imaging (MRI) may also be necessary to identify structural abnormalities. Invasive investigations of the urinary tract, particularly in patients with obstruction and hematuria, include cystoscopic examination of the bladder lining under direct vision, which allows for selective cannulation of each ureteric orifice and imaging with x-rays following injection of radiocontrast medium (retrograde study). The location of the lesion in an obstructed kidney can be ascertained by percutaneous insertion of a catheter into the kidney via a nephrostomy and subsequent injection of contrast via the nephrostomy tube, with x-rays taken as the contrast is drained from the kidney into the ureter and bladder (antegrade study).

Nuclear medicine scintigraphy is used to identify scars or cortical defects within kidneys and to assess the differential function of each kidney relative to the other. In addition, patients with well-preserved kidney function who are suspected of having renal artery stenosis can be challenged with an ACE inhibitor, such as captopril. This investigation assesses whether the flow of the radioisotope alters significantly following captopril administration. Radioisotopes are also utilized in some cases when obstruction is suspected but cannot be reliably demonstrated on ultrasound scanning, or when the collecting system with the kidney is dilated to assess whether there is a functional obstruction. Excretion of the radioisotope is tested following administration of the loop diuretic furosemide.

In patients with suspected renal artery disease, direct examination of the blood supply is undertaken. This can be performed by direct selective renal angiography following x-ray screening of a fine-bore catheter inserted into the aorta via the femoral artery in the groin or the brachial artery approach at the elbow. Magnetic resonance angiography is proving a valuable tool in the noninvasive testing of patients for renovascular disease.

Despite all these investigations, it is occasionally necessary to perform a kidney biopsy. Biopsy typically is indicated in patients with (1) nephrotic syndrome, (2) moderate proteinuria in the presence of hematuria, (3) rapidly progressive disease, (4) AKI, and in patients with (5) CKD (see below) that is progressive despite attention to treatments targeted to preserve kidney function. A biopsy is taken from one kidney only following injection of local anesthetic. To minimize the risk of bleeding, the lower pole of the kidney is chosen, because the lower pole is away from the hilum, where the major blood vessels are present. The lower pole is identified using ultrasound scanning, and a semiautomatic needle device is placed on the capsule of the kidney and is released into the cortex and medulla. A sample of tissue is obtained, and light microscopy, immunofluorescence, or immunoperoxidase staining is performed, as well as electron microscopy. It should be emphasized that although approximately 13% of the adult population is estimated to have CKD,[84] only a minority of patients undergo a kidney biopsy. A kidney biopsy should be undertaken only for nonmalignant disease in a specialist nephrology setting. Histopathologic examination of the specimen confirms the diagnosis and gives some indication of prognosis and the need for specific treatment.

Classification of Kidney Disease

The terminology associated with kidney disease has been amended and is clarified here. Previously, renal failure was divided into (1) *acute renal failure* (ARF) and (2) *chronic renal failure* (CRF). These terms indicate the rate at which damage occurs, rather than the mechanism by which it occurs. Landmark guidelines developed in the United States by the National Kidney Foundation-Kidney Disease Outcomes Quality Initiative (NKF-K/DOQI)[315] attempted to evaluate, classify, and stratify CKD. These guidelines have been revised and updated by the Kidney Disease: Improving Global Outcomes (KDIGO) working group initiative[255] and the National Institute for Health and Clinical Excellence (NICE) in the United Kingdom[311] (Table 48-5).

The term *renal* has largely been replaced by *kidney* in reference to *chronic* disease, because it is more easily understood by patients and nonspecialists. The commonly used term, *acute renal failure (ARF),* has been replaced by *acute kidney injury (AKI). End-stage renal disease (ESRD)* is a U.S. federal government–defined term that indicates the need for long-term treatment by dialysis or transplantation. Each patient with ESRD is registered through the Medical Evidence form (2728), submitted by all dialysis and transplant providers. The term now includes both Medicare and non-Medicare populations. Kidney failure is defined by NKF-K/DOQI as a GFR of less than 15 mL/min/1.73 m^2. In the National Service Framework for Renal Services in the United Kingdom, the term *kidney failure* in the NKF-K/DOQI classification has been replaced by *established renal failure (ERF),* defined as "chronic kidney disease that has progressed so far that renal replacement therapy (RRT; i.e., dialysis and transplantation) is required to maintain life."[99]

tahir99-VRG & vip.persianss.ir

TABLE 48-5 Stages of Chronic Kidney Disease (CKD): Metabolic and Management Consequences

Stage*	Description	GFR, mL/min/1.73 m^2	Population Prevalence in the U.S., %[84]	Population Prevalence in the U.K., %[421]	Metabolic Consequences	Management
1†	Kidney damage with normal or increased GFR	>90	1.78	—	Hypertension more frequent than among patients without CKD	Diagnosis and treatment Treatment of comorbid conditions Slowing progression CVD risk reduction
2†	Kidney damage with mildly decreased GFR	60-89	3.24	—	• Hypertension frequent • Concentration of PTH starts to rise (GFR, 60-80)	Estimating progression
3‡	Moderately decreased GFR	30-59	7.69	9.19	• Hypertension frequent • Decrease in calcium absorption (GFR < 50) • More markedly increased PTH concentration • Reduced phosphate excretion • Malnutrition (reduced spontaneous protein intake) • Onset of left ventricular hypertrophy • Onset of anemia (erythropoietin deficiency)	Evaluating and treating complications

4	Severely reduced GFR	15-29	0.35	0.35	• As above but more pronounced, plus:
					  • Triglyceride concentrations start to rise
					  • Hyperphosphatemia
					  • Metabolic acidosis
					  • Tendency to hyperkalemia
					  • Decreased libido
						Preparation for RRT

5§	Kidney failure	<15	—	0.06	• As above but more pronounced, plus:
					  • Saline retention causing apparent heart failure
					  • Anorexia
					  • Vomiting
					  • Pruritus (itching without skin disease)
						RRT, if uremia present

CVD, Cardiovascular disease; *GFR,* glomerular filtration rate; *PTH,* parathyroid hormone; *RRT,* renal replacement therapy.

*The National Institute of Health and Clinical Excellence (NICE) has recommended that the suffix (p) should be used to denote the presence of proteinuria.[311]

†The diagnosis of stage 1 and 2 CKD requires additional evidence of kidney damage or disease (e.g., proteinuria).

‡NICE has recommended that stage 3 CKD should be subdivided into two subcategories defined by a GFR of 45 to 59 mL/min/1.73 m^2 (stage 3A) and a GFR of 30 to 44 mL/min/1.73 m^2 (stage 3B).[311]

§In the U.K. National Service Framework for Renal Services, the term *kidney failure* has been replaced by *established renal failure,* defined as "chronic kidney disease which has progressed so far that renal replacement therapy is needed to maintain life."[99]

Adapted from National Kidney Foundation. K/DOQI clinical practice guidelines for chronic kidney disease: evaluation, classification, and stratification. Am J Kidney Dis 2002;39:S1-266; Parmar MS. Chronic renal disease. BMJ 2002;325:85-90.

tahir99-VRG & vip.persianss.ir

Chronic Kidney Disease

Studies established to identify the incidence, causes, and complications of CKD have largely focused on advanced disease and kidney failure. Because the numbers of patients with ESRD continue to rise, with associated poor prognosis despite modern replacement therapies (e.g., 33% 5-year survival on dialysis) and an enormous healthcare cost (e.g., $23 billion total Medicare spending on ESRD in the United States in 2006),[79] it has been recognized that CKD is an important public health problem, emphasizing the need for early identification and treatment.[336] Historically, data obtained from epidemiologic surveys had been compromised by lack of consistent surrogate markers of kidney function to identify established disease. For example, serum creatinine, calculated creatinine clearance, and measured creatinine clearance were variously used. The NKF-K/DOQI published a definition of CKD partly in an effort to identify its early stages.[315] The guidelines have been widely distributed and have facilitated the undertaking of comparative studies and analysis. Criteria for the definition of CKD include the following: "kidney damage or GFR <60 mL/min/1.73 m^2 for at least 3 months." Kidney damage is defined as "pathologic abnormalities or markers of damage, including abnormalities in blood or urine tests or imaging studies."

The NKF-K/DOQI guidelines stratify CKD from stage 1 at the milder end of the spectrum to stage 5, with kidney failure or GFR less than 15 mL/min/1.73 m^2. Although the cutoff values between stages are somewhat arbitrary, the process may allow for consistency in prevalence reporting for epidemiologic studies, as well as focused treatment schedules for individual patients (see Table 48-5). In addition, it has been recognized that risk of cardiovascular disease and death associated with moderate kidney disease is increased, and therefore CKD alerts the physician to the need to modify relevant risk factors.[149] One of the concerns regarding classification is the high prevalence of CKD imposed by the classification system itself. In the United States, it is estimated that 27 million individuals have CKD, representing almost 1 in 7 adults.[84] Population samples from elsewhere indicate similar prevalence rates. Most individuals with CKD do not progress to ESRD, with prevalence rates of stage 3 CKD 10 to 20 times greater than the prevalence rates of stages 4 and 5.[207,474] In the NICE guideline, the classification system has been revised to include the presence or absence of albuminuria/proteinuria, and stage 3 has been subdivided into 3A (GFR 45 to 59 mL/min/1.73 m^2) and 3B (GFR 30 to 44 mL/min/1.73 m^2), on the basis of their differing epidemiologic and prognostic significance.[311] The prognostic value of proteinuria has been established in CKD and reveals a much higher probability of progression to ESRD (see earlier).[163] Since the introduction of the classification system, the documented prevalence of CKD has increased sharply, and recognition of the importance of CKD led to the introduction of new diagnostic codes during 2006 (ICD-9-CM diagnosis codes). The importance of early diagnosis of CKD is highlighted by the recognition that 40% of patients commenced on dialysis (so-called "incident" patients) in the United States during 2006 had not previously seen a nephrologist, and most individuals had not had a serum creatinine measurement within the previous year.[79]

The incidence and major causes of CKD in the United States, the United Kingdom, and Australasia were previously identified from community-based studies and registry databases, such as the U.S. Renal Data System (USRDS), the U.K. Renal Registry Report, and the Australia and New Zealand Dialysis and Transplant Registry (ANZDATA). As indicated, registry databases tend to highlight those patients who develop advanced CKD or ESRD requiring treatment with dialysis or transplantation. The incidence of less advanced stages of CKD and of ESRD among patients not accepted for RRT is less clear.

The annual acceptance rate for RRT is increasing worldwide and has done so for the past 2 decades. The annual acceptance rate in the United States during 2006 was 360 per million population (pmp), although much higher among African Americans and Native Americans (Figure 48-10),[79] and in the United Kingdom in 2007 was 109 pmp.[7] The age of patients accepted for RRT is increasing, with most new patients undergoing RRT within the ages varying from 66 to 74 years.[7] It should be noted that the incidence of ESRD increases with age. The prevalence rates of patients with ESRD are also increasing and reached 1600 pmp in 2006 in the United States.[79]

The main causes of CKD leading to kidney failure from 1990 to 2006 in the United States are indicated in Figure 48-11. As indicated, diabetes mellitus is the largest single cause of advanced CKD and accounts for almost 50% of new dialysis patients in the United States. Hypertension is the underlying diagnosis in around 25% of new dialysis patients and is particularly prevalent among African Americans. The myriad of kidney diseases, including glomerulonephritis, infection, and hereditary, systemic, interstitial, and obstructive conditions, as well as those of unknown origin, account for the remainder. In the United Kingdom, diabetic nephropathy as a cause of kidney failure is seen in approximately 20% of new patients.[7]

Ethnic origin also modifies risk of kidney disease.[115] The lifetime risk of developing ESRD in 20-year-old African American men and women respectively has been estimated to be 7.3% and 7.8%, compared with 2.5% in white men and 1.8% in white women.[231] Family history of kidney disease is also a risk factor for developing ESRD. For example, a ninefold increased risk for ESRD has been noted in the African American community for those individuals with a first-degree relative with ESRD.[135] Therefore, genetic influences may be involved in the development of kidney disease and in the rate of progression to ESRD.

In summary, the presence of kidney disease is easily identified through simple blood and urine testing. Subsequent diagnosis of the cause of kidney disease relies on medical history, examination, and laboratory and radiologic investigations and will be discussed in the relevant disease sections later in this chapter.

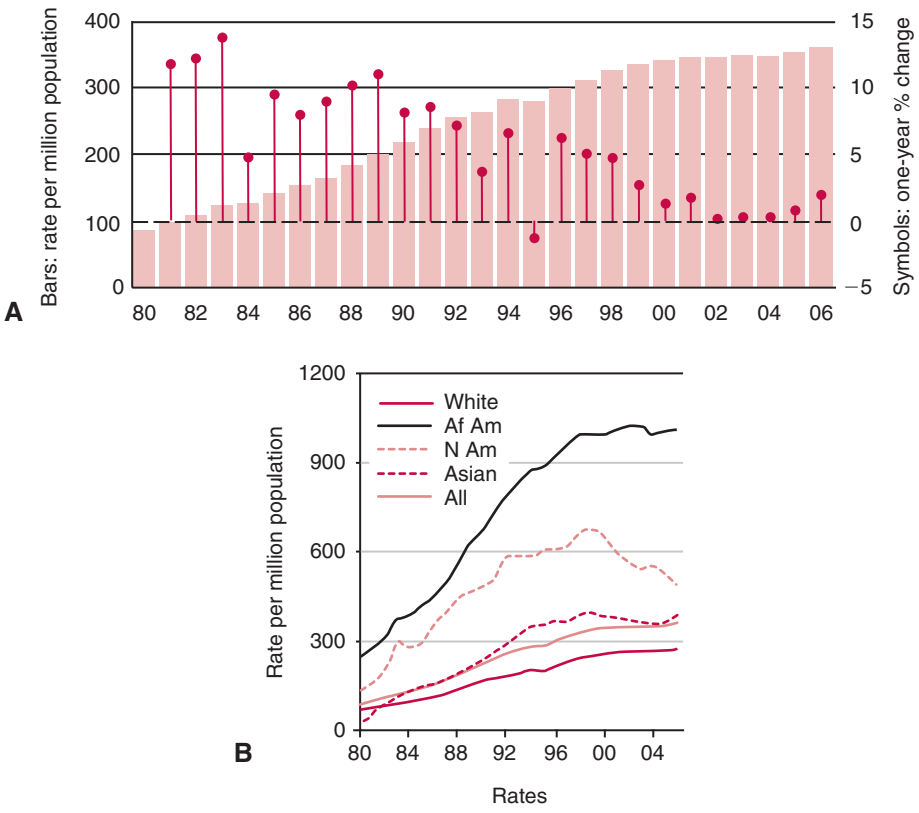

Figure 48-10 Changes in annual acceptance rate for renal replacement therapy (RRT) in the United States. The annual acceptance rate for incident end-stage renal disease (ESRD) patients reached 360 pmp up until 2006 (A: *bars*), although much higher rates for incident patients of approximately 1000 pmp (B) were recorded in African Americans. The percentage change in annual acceptance rate, shown in A, confirms a rise in 2006, compared with leveling of the incident rate during the early part of the decade. *(Reproduced from U.S. Renal Data System. USRDS 2008 annual data report: atlas of chronic kidney disease and end-stage renal disease in the United States. Bethesda, Md: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, 2008.[79])*

General Management of CKD

Complications of CKD that develop before the need for RRT are numerous (see Table 48-5) and include cardiovascular disease, metabolic acidosis, bone disease, and anemia. GFR cutoff values in the NKF-K/DOQI guidelines have been selected on the basis of limited data with respect to the relationship between complications and value of GFR. Additional studies may refine these values. Nevertheless, there is often a causal relationship between the burden of illness and the severity of CKD.

Rate of progression of CKD, irrespective of underlying cause, is dependent on both nonmodifiable factors, such as age, gender, race, and level of kidney function at diagnosis, and modifiable characteristics, including proteinuria, blood pressure control, and smoking. Progression and specific treatment options for diabetic and hypertensive nephropathy are discussed separately later in the chapter. The current discussion focuses on optimal treatment for nondiabetic CKD.

Lowering blood pressure and reducing proteinuria have been shown to ameliorate the progression of CKD. The Modification of Diet in Renal Disease (MDRD) study compared the rates of decline in GFR in 840 patients with various causes of CKD versus a "usual" or "low" blood pressure goal.[234] Patients with type 1 diabetes were excluded. Outcome data suggest that a low blood pressure goal had some beneficial effect in those patients with higher amounts of proteinuria.[194,234] The study supported the concept that proteinuria is an independent risk factor for progression of kidney disease. For patients with proteinuria greater than 1 g/d, the suggested target for mean blood pressure was 92 mm Hg (125/75 mm Hg).[346] The target blood pressure recommended by the seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) is 130/80 mm Hg for patients with diabetes or kidney disease.[73] Strong consensus among national and international renal, hypertension, and diabetes organizations has led to the recommendation of a target systolic blood pressure of less than 140 mm Hg (range 120-139 mm Hg) and diastolic blood pressure less than 90 mm Hg for most patients with CKD.[446] Whereas some evidence supports a

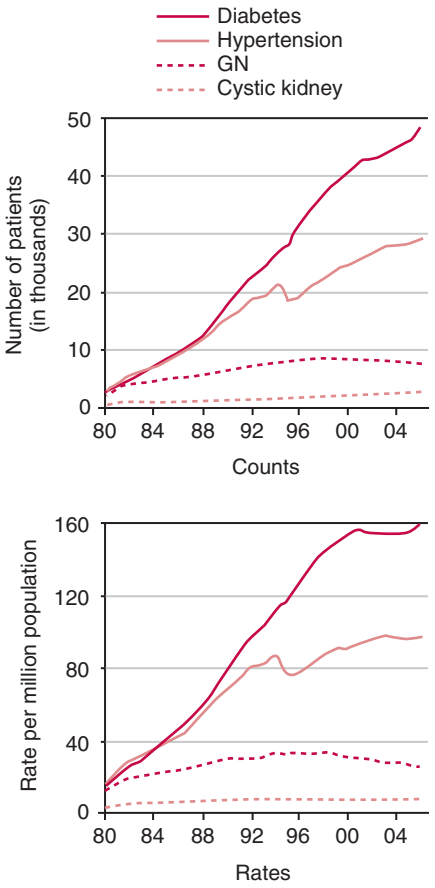

Figure 48-11 Trends in incident rates of end-stage renal disease (ESRD) by primary diagnosis in the United States. The number of patients with diabetes as the primary cause of ESRD reached 48,157 in 2006, 4.6% higher than the previous year, and 17.2% higher than in 2000. Incident rates for these patients have grown by 3.7% since 2000. The incidence of ESRD due to glomerulonephritis, in contrast, continues to fall—by 15.6% since 2000, to reach 26 pmp. In the *lower panel,* rates have been adjusted for age, gender, and race. *(Reproduced from U.S. Renal Data System. USRDS 2008 annual data report: atlas of chronic kidney disease and end-stage renal disease in the United States. lower target of less than 125/75 mm Hg in patients with more than 1 g/d of proteinuria, the concern is that lower blood pressure may be associated with adverse outcomes in some patients.

Data from the Third National Health and Nutrition Examination Survey (NHANES III) (1988-1994) reveal that among hypertensive individuals with an increased serum creatinine concentration, 75% were on antihypertensive treatment, and only 11% had their blood pressure reduced to lower than 130/85 mm Hg.[85]

ACE inhibitors are more effective than other antihypertensive drugs in slowing the rate of progression of proteinuric CKD,[146,289,376] although they do induce a mild decrease in GFR (<10 mL/min/1.73 m^2). It should also be noted that the evidence base for ACE inhibitor use in the setting of CKD may not be generalizable to older (>70 years), nonproteinuric adults, who form the majority of patients with CKD.[324] The development of hypotension, AKI, or hyperkalemia (plasma potassium concentration >5.5 mmol/L) should prompt discontinuation of the drug until other causes have been excluded. Short-term studies show that ARBs have effects on blood pressure and proteinuria that are similar to those of ACE inhibitors.

Low-nitrogen (protein) diets have been advocated from the early years of treatment of severe chronic uremia.[145] The very-low-protein diets tested in the MDRD study were of marginal benefit in these well-supervised patients with very low renal function, but are not well adhered to in practice, may lead to negative nitrogen balance, and are not recommended. Protein intake is restricted spontaneously to approximately 0.6 to 0.8 g/kg/d by uremic patients not receiving dietary advice.[195] To prevent malnutrition, patients receive professional dietary advice, with diets containing an increased proportion of protein and a total calorie content of up to 35 kcal/kg/d. The NHANES III has confirmed an association with reduced GFR and malnutrition in noninstitutionalized individuals studied in a cross-sectional survey of more than 5000 participants stratified according to GFR.[143]

In 2009, a relatively small trial demonstrated that bicarbonate supplementation slows the rate of progression of CKD.[94] General health measures, including cessation of cigarette smoking, should be encouraged.

Cardiovascular Complications of CKD

The spectrum of cardiovascular pathology predominant among patients with CKD (hypertensive cardiomyopathy, arrhythmias, heart failure, valvular disease, and peripheral vascular disease) differs from that predominant in the general population (atheromatous coronary artery disease).[12] The incidence of cardiovascular disease is seven- to tenfold greater in patients with CKD than in non-CKD age- and gender-matched controls.[467] By the time patients develop the need for RRT, there is an approximately 17 times greater risk of cardiovascular death or nonfatal myocardial infarction than among age- and sex-matched individuals without kidney disease.[12,126] Among patients treated by dialysis, the prevalence of coronary artery disease is approximately 40% and the prevalence of left ventricular hypertrophy (LVH) is approximately 75%.[127,405] Cardiovascular mortality, defined as death caused by (1) arrhythmias, (2) cardiomyopathy, (3) cardiac arrest, (4) myocardial infarction, (5) atherosclerotic heart disease, and (6) pulmonary edema, has been estimated to be approximately 9% per year in dialysis patients, accounting for 50% of deaths of all patients with ESRD. Even after stratification by age, gender, race, and the presence or absence of diabetes, cardiovascular mortality in dialysis patients is 10 to 20 times higher than in the general population (Figure 48-12).[130,384] Patients with ESRD should be considered in the highest risk group for subsequent cardiovascular events.

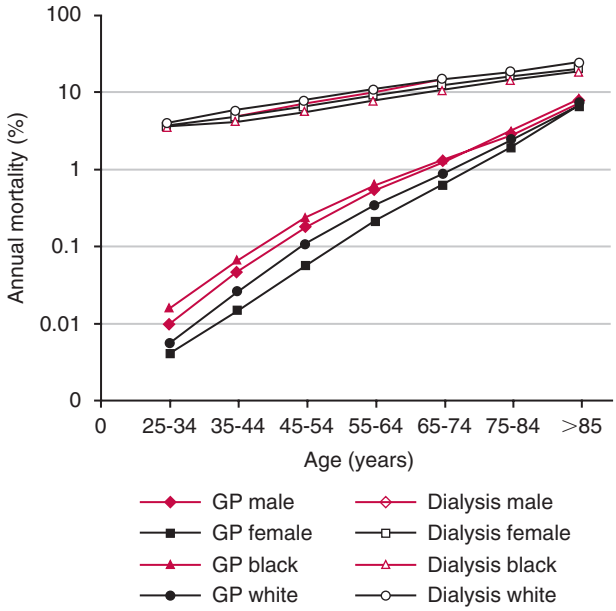

Figure 48-12 Cardiovascular disease mortality defined by death caused by arrhythmias, cardiomyopathy, cardiac arrest, myocardial infarction, atherosclerotic heart disease, and pulmonary edema in the general population (GP). Data from NCHS multiple cause of mortality data files compared with end-stage renal disease (ESRD) treated by dialysis. Data are stratified by age, race, and gender. *[From Foley RN, Parfrey PS, Sarnak MJ. Clinical epidemiology of cardiovascular disease in chronic renal disease. TABLE 48-6 Traditional and Chronic Kidney Disease (CKD)-Related Risk Factors for Cardiovascular Disease in CKD

Traditional risk factors for cardiovascular disease	Older age
	Male gender
	White race
	Hypertension
	Elevated LDL cholesterol
	Decreased HDL cholesterol
	Smoking
	Diabetes mellitus
	Menopause
	Sedentary lifestyle
	Family history
CKD-related risk factors for cardiovascular disease	Extracellular fluid overload
	Left ventricular hypertrophy
	Proteinuria
	Anemia
	Abnormal calcium and phosphate metabolism (vascular calcification)
	Dyslipidemia
	MIA syndrome
	Infection
	Thrombogenic factors
	Oxidative stress
	Elevated homocysteine
	Uremic toxins

LDL, Low-density lipoprotein; *HDL,* high-density lipoprotein; *MIA,* malnutrition inflammation atherosclerosis.

Risk factors for cardiovascular disease in CKD consist of a mixture of traditional and CKD-specific factors. Traditional risk factors such as diabetes, hypertension, and dyslipidemia are more likely in CKD patients.[467] In addition, many other risk factors are CKD related (Table 48-6).

Observational studies indicate that cardiovascular disease occurs at an early stage in CKD.[457] Thus among middle-aged men, a moderate increase in serum creatinine concentration [>1.5 mg/dL (>130 µmol/L)] was associated with an age-adjusted relative risk (RR) of 1.5 for coronary disease and 3.0 for stroke. Reduction of GFR is associated with increased risk of composite end points of cardiovascular death, myocardial infarction, and stroke.[286] Microalbuminuria and proteinuria have also been shown to be associated with increased risk of cardiovascular disease, cardiovascular mortality, and all-cause mortality.[2,45,88] These associations may arise because (1) CKD causes an elevated level of cardiovascular disease, (2) cardiovascular disease causes CKD, or (3) some other factor, such as diabetes and hypertension, causes both CKD and cardiovascular disease. Significantly, there are many more patients with stage 3 than stage 5 CKD (see Table 48-5). A longitudinal population study of 40,000 patients with stage 3 to 4 CKD in Northern California reported after a mean follow-up period of almost 4 years that the age-adjusted rate for development of ESRD in the white population was 0.67 per 100 person-years, whereas the rate for any cardiovascular event and death from any cause was 10.94 and 5.25 per 100 person-years, respectively.[345]

Two large prospective randomized controlled studies reported significant reductions in cardiovascular morbidity and mortality associated with ACE inhibitor treatment among patients at high risk for future cardiovascular events.[132,485] A secondary analysis of the Prevention of Events with ACE Inhibition (PEACE) trial data revealed a higher risk of death among patients with an estimated GFR of less than 60 mL/min/1.73 m^2 at baseline, and a significant reduction in all-cause mortality associated with ACE inhibitor treatment in this subgroup.[416] Whereas none of the studies already mentioned specifically included patients with CKD, and all excluded patients with severe renal impairment, these data do provide support for the notion that ACE inhibitor treatment reduces cardiovascular risk in high-risk patients. Because cardiovascular disease remains the most important cause of death among CKD patients, it seems reasonable to recommend ACE inhibitor or ARB treatment for reduction of cardiovascular risk and for slowing of CKD progression.

Left Ventricular Hypertrophy

Among dialysis patients, the prevalence of congestive heart failure is approximately 40%. Both coronary artery disease and LVH are risk factors for the development of heart failure. In practice, it is difficult to determine whether cardiac failure reflects left ventricular dysfunction or extracellular fluid volume overload. LVH is demonstrable early in the course of CKD, with the proportion of patients with LVH increasing as kidney function declines. Univariate analysis of a single-center cohort of CKD patients in Canada revealed that age, systolic blood pressure, and hemoglobin were significantly different between the groups with or without LVH.[258] For each 5 mm Hg increase in systolic BP, the risk of LVH increased by 3%. A fall in blood hemoglobin concentration of 1 g/dL increased the risk of LVH by 6%. A large prospective multicenter study confirmed progressive increases in left ventricular mass index (LVMI) over a 12-month period, with the incidence of new LVH at 10% per year.[259] Again, lower hemoglobin concentrations and higher systolic blood pressures were associated with left ventricular growth. Anemia has both direct and indirect effects on left ventricular function and growth. Cardiac output increases because of a combination of increased cardiac preload and a reduction in afterload. Such changes lead to ventricular remodeling, with initial left ventricular dilation followed by subsequent hypertrophy. In ESRD, other factors contribute to LVH, including hypertension, volume expansion, and the metabolic consequences of uremia, to which may be added the effects of diabetes.[125]

Dyslipidemia in CKD

Various dyslipidemias are associated with CKD.[291,362,467] The pattern of dyslipidemia in CKD differs from that seen in non-CKD. It is characterized by an accumulation of partially metabolized triglyceride-rich particles [predominantly very low-density lipoprotein (VLDL) and intermediate-density lipoprotein (IDL) remnants], due mainly to abnormal lipase function.[325] This causes hypertriglyceridemia and low high-density lipoprotein (HDL) cholesterol. Although total cholesterol concentration may be normal, there is often a highly abnormal lipid subfraction profile with a predominance of atherogenic small, dense LDL particles.[12] In a large cross-sectional analysis of 1047 hemodialysis patients in the Dialysis Morbidity and Mortality Study, only 20% of patients had low-risk lipid concentrations [i.e., LDL <130 mg/dL (3.36 mmol/L), HDL >40 mg/dL (1.03 mmol/L), and triglycerides <150 mg/dL (1.69 mmol/L)] (see http://www.kidney.org/professionals/KDOQI/guidelines_lipids/ii.htm#Table16, accessed on July 12, 2011). Low cholesterol was found to be associated with increased mortality, but this is probably a reflection of other conditions that lower cholesterol, such as inflammation and malnutrition ("reverse causality"). It is possible that other, nontraditional atherogenic lipoprotein abnormalities [e.g., lipoprotein (a) and oxidized LDL] are present in hemodialysis patients.[136,280] Similar profiles are seen in peritoneal dialysis patients.

Lipoprotein (a) concentrations are also increased in CKD. Baseline data from the Chronic Renal Impairment in Birmingham (CRIB) study confirmed dyslipidemia in early CKD.[467] Patients had lower HDL and LDL cholesterol and higher triglyceride concentrations.

The challenge to the nephrology community is to establish whether interventions to modify the pattern of dyslipidemia with lifestyle changes and drug treatment will preserve kidney function and reduce cardiovascular morbidity and mortality. At present, no large, adequately controlled trials are testing the hypotheses that treatment of dyslipidemia preserves kidney function. The major trials of intervention with statins [3-hydroxy-3-methylglutaryl-Co-enzyme A (HMG-CoA) reductase inhibitors] in the general population and those with established cardiovascular disease have been limited with reference to CKD, because patients with CKD have been excluded from trials as perceived to be too high risk for inclusion.[76,349] The Heart Protection Study randomly allocated 20,536 adults with coronary artery disease, occlusive disease of noncoronary arteries, or diabetes to simvastatin (40 mg) or placebo.[297] In a subgroup analysis of more than 1300 patients with serum creatinine concentration between 1.2 and 2.3 mg/dL (110 and 200 μmol/L), fewer major vascular events were reported in the simvastatin group.

Guidelines from the U.K. Renal Association[446] and NICE[311] recommend that statins should be considered for primary prevention in all patients with CKD, including dialysis patients, if their 10-year risk of cardiovascular disease is calculated as greater than 20% according to the guidelines of the Joint British Societies.[211] However, these risk calculations have not been validated in patients with kidney disease. The target total cholesterol should be less than 156 mg/dL (<4 mmol/L) or a 25% reduction from baseline; also, a fasting LDL cholesterol of less than 78 mg/dL (<2 mmol/L), or a 30% reduction from baseline, should be achieved, whichever is the greatest reduction in all patients. However, this guidance remains controversial.[82] At present there is no data to suggest that statins are of benefit in patients receiving dialysis. A major study, known as the 4D Study, investigated the use of atorvastatin in more than 1200 patients with type 2 diabetes mellitus undergoing hemodialysis and followed for a median period of 4 years. The study group concluded that atorvastatin had no statistically significant effect on the composite primary end point of cardiovascular death, nonfatal myocardial infarction, and stroke.[458] A 2009 study, called AURORA, evaluated the use of rosuvastatin in subjects on hemodialysis and failed to demonstrate any beneficial effects of statins on cardiovascular outcomes despite markedly reduced lipid concentrations.[117] Although these studies have limitations, the most likely explanation for the lack of benefit associated with statins is that patients on dialysis have a different type of cardiovascular disease than individuals with earlier stages of CKD.

The Study of Heart and Renal Protection (SHARP), evaluated the use of cholesterol lowering with simvastatin and ezetimibe in a broad variety of patients with CKD for benefit in terms of cardiovascular risk, but also amelioration of progression of CKD. This randomized double-blind placebo-controlled study of more than 9000 patients (including 3000

dialysis patients) has been reported.[12A] There were significant reductions in atherosclerotic endpoints including nonhemorrhagic stroke and arterial revascularization in the treated patients followed for a median of 4.9 years. In addition, a randomized controlled trial of proteinuric CKD patients receiving ACE inhibitors and ARBs reported additional benefit from treatment with atorvastatin in terms of reduction in proteinuria and progression of disease.[33]

Vascular Calcification

It has been known for many years that patients with kidney failure have vascular calcification. Serial x-ray studies and ultrasound imaging of large arteries confirm increased calcification in patients on dialysis over many years.[150] Studies from France have linked the presence of vascular calcification with reduced survival on dialysis.[35,36,158] Calcification of the major arteries occurs along the intimal lining of blood vessels in association with atheroma. However in CKD, medial and adventitial calcification also occurs, reducing the compliance of the vessel. Reductions in vessel compliance can be observed by measuring pulse wave velocities along major arteries such as the aorta. The pulse wave velocity is increased in stiff (less compliant) vessels, causing the rebound pulse wave to return more quickly to the heart during the cardiac cycle. Early rebound of the pulse wave places extra strain on the heart, leading to LVH.[35] Vascular calcification has been studied in both CKD and non-CKD populations using modern sophisticated imaging. Electron beam CT acquires serial sections of the aortic arch, the coronary vessels, and the aorta. Areas of calcification can be identified and allocated a calcium score (Agatston score).[1] This approach cannot distinguish between intimal and medial calcification, but in non-CKD patients, the higher the calcium score, the more predictive it is of stenotic vascular disease.[224,379] Dialysis patients as young as 20 years exhibit vascular calcification,[151] and calcium scores increased rapidly within several months when the scans were repeated.

The pathophysiology of vascular calcification in CKD patients is an exciting area of study, with many new developments and hypotheses. Vascular calcification was previously thought to be a passive process caused by precipitation of mineral from the circulation. However, it is increasingly recognized that vascular calcification is a tightly regulated process with true bone marrow, osteo/chondrocytic cells, cytokines, matrix proteins, and matrix vesicles characteristic of mature bone-forming cells (osteoblasts) within calcified vascular lesions.[394,401,442] Mineralization-regulating proteins are deposited at sites of vascular calcification. The generation of a matrix gamma-carboxyglutamic acid (Gla) protein knockout mouse, which exhibits extensive and lethal calcification and cartilaginous metaplasia of the media of all elastic arteries, has refocused attention on the role of Gla-containing proteins in vascular calcification.[401] A number of proteins, including matrix Gla protein, osteonectin, and osteoprotegerin, are constitutively expressed by vascular smooth muscle cells in normal media but are downregulated in calcified arteries. In calcified plaques, vascular smooth muscle cells express osteoblast-like gene expression profiles, as demonstrated by in situ hybridization,[442] and are able to transdifferentiate into osteo/chondrocytic cells in the arterial wall and to orchestrate bone formation and calcification in response to multiple factors such as hypertension, reactive oxygen species, advanced glycation end products, lipids, and inflammatory proteins. Identification of natural inhibitors of calcification in plasma, such as human fetuin-A [α_2-Heremans Schmid glycoprotein (AHSG)] and matrix-Gla protein, suggests that the vascular endothelium may be continually subjected to calcification stresses, and that regulatory systems break down in uremia. A cross-sectional study in hemodialysis patients demonstrated that AHSG concentrations were significantly lower in plasma of patients on hemodialysis than in healthy controls.[229]

The use of calcium-containing oral phosphate binders (see later) may be associated with increased risk of calcification.[151] The Treat to Goal study explored the use of a noncalcium, nonaluminum-containing phosphate binder, sevelamer hydrochloride, in 200 hemodialysis patients from Europe and North America.[68] This study demonstrated significant attenuation in the rate of calcification of vessels with sevelamer hydrochloride at 12 months. Patients were less likely to develop hypercalcemia and had lower plasma LDL cholesterol concentrations, but a tendency toward worsening acidosis was noted. Still other studies have identified a potential survival benefit for new ("incident") hemodialysis patients derived from treatment with sevelamer hydrochloride compared with calcium-based oral phosphate binders when treatment was provided for at least 18 months.[38] However, a study comparing sevelamer hydrochloride versus calcium-based binders in more than 2000 prevalent hemodialysis patients failed to show a significant difference between therapies in terms of all-cause mortality and cause-specific mortality.[424]

Disturbances in Calcium and Phosphate Metabolism

CKD is associated with complex metabolic disturbances in divalent ion and phosphate metabolism. Although this is commonly referred to as *renal osteodystrophy,* there has been a paradigm shift in terms of calcium, phosphate, and PTH management in patients receiving dialysis. The impetus for this change in approach has been recognition of the importance of the previously unheralded phosphate moiety in terms of increased risk of death in ESRD and the almost universal development of *cardiovascular calcification* (see earlier) that is seen in dialysis patients. It is likely that treatment of hyperphosphatemia in dialysis patients with calcium-based therapies may be contributing to vascular calcification; therefore these two problems are intricately linked. In an effort to clarify the terminology of renal metabolic bone disease, KDIGO proposed that the term *CKD-mineral and bone disorder* (CKD-MBD) should be used to describe the syndrome of biochemical, bone, and extraskeletal calcification abnormalities that occur in patients with CKD, and the term *renal osteodystrophy* should be used exclusively to define alterations in bone morphology, following bone biopsy, associated with CKD.[232]

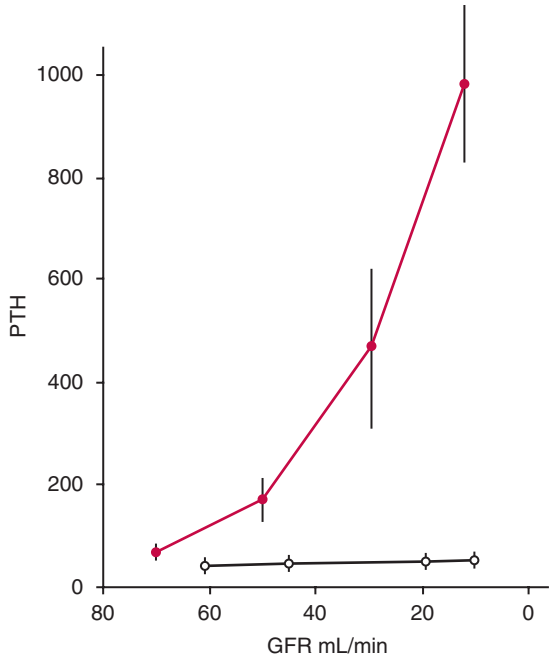

Figure 48-13 The relationship between parathyroid hormone (PTH) concentration and glomerular filtration rate (GFR) in two groups of dogs: those maintained on a normal phosphate diet *(closed circles)* and those maintained on a diet containing <100 mg of phosphate per day *(open circles)*. The vertical lines represent ±1 SEM. PTH is expressed in μEq/mL. *(From Slatopolsky E, Caglar S, Pennell JP, Taggart DD, Canterbury JM, Reiss E, et al. On the pathogenesis of hyperparathyroidism in chronic experimental renal insufficiency in the dog. J Clin Invest 1971;50:492-9.)*

As GFR declines, plasma phosphate concentration rises, resulting in reduced ionized calcium. The consequence of this is increased production of PTH by the parathyroid glands. PTH-producing cells are regulated tightly through complex feedback mechanisms to maintain normocalcemia (see Chapter 52). The calcium-sensing receptor (CaSR) is stimulated by calcium and has an inhibitory effect on PTH production.[50] In addition, phosphate has been reported to directly stimulate the production of PTH in vitro.[413] Elegant experiments on dogs with varying levels of induced kidney failure have confirmed the increase in PTH as GFR fell, with attenuation noted in animals fed a modified diet with very low concentrations of phosphate (Figure 48-13).[411] FGF-23 may stimulate PTH production. FGF-23 concentrations increase markedly in CKD (between 10 and 600 times higher than the normal range) and are correlated with predialysis phosphate concentrations, but not with bone mineral density.[448] Ongoing studies are evaluating the importance of this peptide in terms of skeletal resistance to PTH as seen in CKD patients.

In addition to hyperphosphatemia contributing to hypocalcemia, reduced 1α-hydroxylation of 25-hydroxycholecalciferol by the renal proximal tubular cells may lead to reduced production of calcitriol, the active form of vitamin D and a vitamin D receptor activator. Vitamin D is required in health to increase calcium absorption from the gut; it also increases phosphate absorption from the gut. PTH-producing cells in the parathyroid gland have receptors for vitamin D (VDRs). The VDR is a 427 amino acid peptide that is widely found in tissues, including parathyroid glands, intestine, and osteoblast-like cells. Binding of vitamin D to the VDR inhibits its PTH production. The result of these complex metabolic disturbances is secondary hyperparathyroidism. Increased secretion of PTH stimulates resorption of calcium and phosphate from the major calcium reservoir, the bone. Problems can develop early, and patients with a GFR of less than 60 mL/min/1.73 m^2 should be evaluated for these metabolic disturbances.[315] Secondary hyperparathyroidism classically causes bone changes consistent with osteitis fibrosa cystica. Bony erosions and intramedullary cysts are seen because of direct effects of PTH on osteoclasts and osteoblasts. Unchecked, this can lead to bone pain and fracture. Eventually, PTH secretion can become unhinged completely from feedback control; this autonomous production is called *tertiary hyperparathyroidism*. Severe secondary hyperparathyroidism is associated with hyperplasia of the glands and ultimately with nodular hyperplasia. These grossly enlarged glands tend to be resistant to medical therapies of secondary hyperparathyroidism, as they have significantly reduced expression of both the CaSR and VDR. In this setting, medical treatment has failed and parathyroidectomy is required. A severe and often terminal manifestation of long-standing ESRD is calcemic uremic arteriolopathy *(calciphylaxis)*. Calciphylaxis is characterized by calcium deposition within the arterioles of the microcirculation, leading to destruction of the vessel, and in turn causing necrosis of tissues, particularly the skin and adipose tissue on the legs and torso.

Adynamic bone in patients with CKD is characterized by low turnover and poor bone formation and is highly prevalent in CKD. It is much more common in older people and those with diabetes and malnutrition. Adynamic bone is associated with a low PTH concentration and abnormal calcium balance, hyperphosphatemia, and acidosis. Progression of CKD adds to the risk profile for adynamic bone, because 1,25-dihydroxyvitamin D becomes markedly reduced in advanced CKD.[257] The diagnosis of adynamic bone is ultimately made on bone biopsy, but patients are reluctant to undertake this procedure. Unfortunately, PTH alone does not correlate with bone biopsy findings. However, serum bone-specific alkaline phosphatase measured using an immunoassay technique has very good predictive value in separating high from low bone turnover, particularly in combination with PTH measurements. For example, low bone formation has been associated with bone-specific alkaline phosphatase activity less than 20 U/L and PTH less than 100 ng/L.[78] Although it has not proved to be associated with increased fracture risk in ESRD patients, dialysis patients with adynamic bone are less able to incorporate calcium into bone and are at increased risk of vascular calcification.[272] Excessive use of vitamin D analogs (e.g., alfacalcidol [1α-hydroxyvitamin D3]) is implicated in the high prevalence of adynamic bone in dialysis patients. However, recent data have revealed that this is less likely to occur with the synthetic vitamin D

TABLE 48-7 K/DOQI Target Guidelines for Serum Calcium, Phosphate, Calcium × Phosphate Product and Plasma PTH Concentrations in CKD Stages 4 and 5

Stage of CKD	Phosphate	Calcium (Corrected for Albumin)	PTH	Calcium × Phosphate Product
4	2.7 mg/dL-4.6* mg/dL (0.87 mmol/L-1.49* mmol/L)	Normal laboratory range	70-110* ng/L (7.7-12.1 pmol/L)	<55 mg^2/dL^2 (<4.51 $mmol^2/L^2$)
5	3.5 mg/dL-5.5 mg/dL (1.13 mmol/L-1.78 mmol/L)	8.4-9.5 mg/dL (2.10*-2.38* mmol/L)	150-300 ng/L (15-30 pmol/L)	<55 mg^2/dL^2 (<4.51 $mmol^2/L^2$)

Conversion to SI units:
Phosphate: mg/dL to mmol/L × 0.323.
Calcium: mg/dL to mmol/L × 0.25.
Calcium phosphate product: mg^2/dL^2 to $mmol^2/L^2$ × 0.0807.
PTH: ng/L to pmol/L × 0.1 (approx).
CKD, Chronic kidney disease; *K/DOQI,* Kidney Disease Outcomes Quality Initiative; *PTH,* parathyroid hormone.

receptor activator, paricalcitol (19-nor-1,25-dihydroxyvitamin D_2), which reduces bone resorption and intestinal calcium reabsorption, than with calcitriol or alfacalcidol.[412]

Bone disease in CKD is also complicated by the relatively high prevalence of hypogonadism in men on dialysis and the high prevalence of osteoporosis in postmenopausal women.

High concentrations of plasma phosphate are associated with increased mortality in hemodialysis patients.[37] In at least 50% of hemodialysis patients, the serum phosphate is greater than 6.0 mg/dL (1.9 mmol/L), and in 25% of patients, it is greater than 7.2 mg/dL (2.3 mmol/L). Higher corrected calcium and PTH concentrations are associated with death in hemodialysis patients. Patients with low phosphate concentrations are also at increased risk of death (RR of death increased by approximately 50% with phosphate <3 mg/dL) because low phosphate is associated with intercurrent illness and malnutrition. The U.K. Renal Association standard for midweek predialysis serum phosphate concentration is 3.3 to 5.6 mg/dL (1.1 to 1.8 mmol/L).[446] National guidelines were published in the United States by NKF-K/DOQI during 2003 (Table 48-7).[108] Achievement of these targets is variable between dialysis providers, with approximately 60% of patients within the phosphate target and 25% within the PTH target. As few as 8% of patients simultaneously achieve all four targets.[7]

Strategies to reduce phosphate concentrations are employed routinely in the treatment of patients on dialysis. Inorganic phosphate within the blood accounts for less than 0.1% of total body phosphate. Clearance of phosphate on intermittent hemodialysis is approximately one third of that seen with urea and is subject to postdialysis rebound because of efflux from the intracellular to the extracellular space. Phosphate is present in many foods and is linearly associated with protein ingestion. The recommended allowance of phosphate is reduced for patients on dialysis to around 800 mg/d. Treatment with vitamin D analogs increases gut absorption of phosphate from approximately 65 to almost 85%. The use of phosphate binders, taken with meals, is almost universal in dialysis patients; treatment may include calcium-containing and non–calcium-containing binders (Table 48-8). Prescribing of phosphate binders should be individualized for each patient because each binder has pros and cons. Recent interest has focused on the increased propensity to vascular calcification noted in those dialysis patients receiving calcium-containing phosphate binders. These binders reduce phosphate absorption to 30 to 40% and decrease serum phosphate concentrations. However, a 2009 systematic review of randomized controlled trials concluded that no evidence suggests that phosphate binders reduce all-cause or cardiovascular mortality compared with placebo.[318] Further, no survival advantages of newer phosphate-binding agents (sevelamer, lanthanum carbonate) over traditional calcium-based therapies were found.[318] In summary, patients on conventional three times weekly dialysis are in a net positive phosphate balance. It has been possible to normalize phosphate balance in patients treated by daily hemodialysis.[307]

Medical treatment strategies are designed to limit phosphate intake and normalize calcium. With the advent of vitamin D analogs, it has been possible to supplement vitamin D, resulting in increased plasma calcium concentrations and switching off of PTH production. Unfortunately, commonly used analogs, such as 1α-hydroxyvitamin D3, also lead to increased reabsorption of calcium and phosphate from the gut. In the setting of aggressive treatment with vitamin D analogs, hypercalcemia may develop that is associated with low, suppressed concentrations of PTH. Alternative vitamin D receptor activators, such as paricalcitol, are associated with improved survival in U.S. dialysis patients and have a lower incidence of treatment-related hyperphosphatemia and hypercalcemia than calcitriol.[288,431] The vitamin D receptor is ubiquitous, and its stimulation has wide-ranging effects on the cardiovascular and immune systems; this may explain the benefits of treatment in CKD patients over and above the effects on reducing PTH.[238]

A further development in the management of CKD-MBD has been the generation of calcimimetic agents such as cinacalcet.[8,263] Calcimimetics mimic calcium by directly stimulating the CaSR and can affect the molecular configuration of

TABLE 48-8 Summary of Currently Available Oral Phosphate Binders

Phosphate Binder	Advantages	Disadvantages
Aluminum salts	Calcium free High binder efficiency regardless of pH Cheap Moderate tablet burden	Risk of aluminum toxicity Requires frequent monitoring—extra cost
Calcium carbonate	Aluminum free Moderate binding efficacy Relatively low cost Moderate tablet burden Chewable	Calcium containing—potential risk of hypercalcemia and ectopic calcification Parathyroid hormone oversuppression Gastrointestinal side effects Efficacy pH dependent
Calcium acetate	Aluminum free Higher efficacy than calcichew/sevelamer Moderately cheap Lower calcium load than calcium carbonate	Calcium containing—potential risk of hypercalcemia and ectopic calcification, PTH oversuppression Gastrointestinal side effects Large tablets, nonchewable formulation
Sevelamer hydrochloride	Aluminum and calcium free No gastrointestinal absorption Moderate efficacy Reduces total and low-density lipoprotein cholesterol	Relatively costly High pill burden Large tablets, nonchewable formulation Gastrointestinal side effects Binds fat-soluble vitamins
Lanthanum carbonate	Aluminum and calcium free Minimal gastrointestinal absorption High efficacy across full pH range Chewable formulation Palatable Low tablet burden	Relatively costly Gastrointestinal side effects

PTH, Parathyroid hormone.

the CaSR to enhance its sensitivity to extracellular calcium.[263] Stimulation of the CaSR switches off PTH production selectively with no risk of increased phosphate absorption. Use of cinacalcet has increased the proportion of patients who reach the K/DOQI targets for CKD-MBD and has reduced the need for parathyroidectomy in patients with secondary hyperparathyroidism.[89] Prospective randomized controlled trials evaluating the effects of adding calcimimetics to standard therapy on cardiovascular outcomes and mortality are ongoing and include the Evaluation of Cinacalcet HCL Therapy to Lower CardioVascular Events (EVOLVE).

Aluminum Toxicity

A causative factor for renal bone disease, historically, has been aluminum intoxication (see Chapter 36). Aluminum concentrations in dialysis fluids were previously high, but with modern dialysis facilities, this is no longer such a problem. However, some dialysis patients are treated intermittently with aluminum-containing phosphate binders; therefore regular monitoring of blood aluminum concentration is recommended in such patients.[446] Aluminum accumulation has been associated with deposition along the mineralization surface of the osteoid and a low-turnover form of bone disease. Aluminum accumulation may be treated by infusions of the chelating agent desferrioxamine. Aluminum intoxication may be associated with neurologic disturbances characterized by dementia (dialysis dementia) and with a hypochromic microcytic anemia.

Anemia

The World Health Organization defines anemia, when the patient is at sea level, as a blood hemoglobin concentration of less than 13 g/dL in adult men and less than 12 g/dL in adult, nonpregnant women.[478] It is clearly established that anemia is inevitable as CKD progresses. Therapies are available to correct anemia; therefore it is mandatory that a patient with CKD should be assessed for anemia. The NKF-K/DOQI recommends that an estimated GFR of less than 60 mL/min/1.73 m^2 should be the cutoff value for determining the presence or absence of anemia.[314] The U.K. Renal Association recommends that anemia should be investigated in CKD when hemoglobin is less than 13 g/dL in adult males and postmenopausal females and less than 12 g/dL in premenopausal females.[446] In addition, CKD should be considered as a possible cause of anemia when the GFR is less than 60 mL/min/1.73 m^2. It is more likely to be the cause if the GFR is less than 30 mL/min/1.73 m^2 (<45 mL/min/1.73 m^2 in patients with diabetes) and no other cause (e.g., blood loss, folic acid or vitamin B_{12} deficiency) is identified. The prevalence of anemia increases as GFR declines. In the NHANES

III data set, the prevalence of anemia (defined as Hb <12.0 g/dL in men, Hb <11.0 g/dL in women) was 33% at a GFR of 15 mL/min/1.73 m^2 and 9% at a GFR of 30 mL/min/1.73 m^2.[83] CKD-related anemia occurs earlier in patients with diabetes and is highly prevalent among such patients.[109]

Detection is important because if left untreated, anemia causes many of the side effects of CKD, such as fatigue, breathlessness on exertion, intolerance to cold, and decreased exercise capacity. As indicated earlier, it is also a major factor in the high prevalence of cardiovascular disease in patients with CKD and contributes to the development of LVH. In patients on dialysis, large observational studies have clearly shown that anemia is associated with increased mortality rates and increased hospitalization.[81,269,274,482] In hemodialysis patients, hematocrit percentages of 33 to 36% (corresponding to hemoglobin concentrations of 11 to 12 g/dL) were associated with the lowest risk for all-cause and cardiac mortality[274]; these patients also had the lowest risk of hospitalization.[326,482]

Etiology of Anemia in CKD

The etiology of anemia in CKD is multifactorial. A major cause, however, is the loss of peritubular fibroblasts within the renal cortex that synthesize EPO. Failure of EPO production in the kidney leads to inappropriately low concentrations within the blood for the concomitant hemoglobin concentration. Other causes of anemia include absolute or functional iron deficiency, folic acid and vitamin B_{12} deficiencies, and chronic inflammation. Red cell survival may also be reduced. Hemodialysis patients tend to have more severe anemia than peritoneal dialysis patients because of greater blood losses and hemolysis.

Several national and international organizations such as NKF-K/DOQI,[317] the European Renal Association,[112] and NICE,[310] have published algorithms for the treatment of anemia in CKD and dialysis patients. The NICE guideline recommends that treatment should aim to maintain hemoglobin concentration between 10.5 and 12.5 g/dL in adults.[310] The NKF-K/DOQI Work Group recommends a slightly different target reference interval for hemoglobin of 11 to 12 g/dL, and that hemoglobin concentration should not exceed 13 g/dL.[317] The mainstays of treatment are iron supplementation and the use of erythropoiesis-stimulating agents (ESAs). Warnings, indications, precautions, and instructions for dosing and administration of ESAs are available from national regulatory agencies, including the U.S. Food and Drug Administration (FDA), and from product package inserts.

Assessment of Iron and Iron Supplementation

Iron status is assessed by measurement of serum ferritin and transferrin saturation. Transferrin saturation gives an indication of iron "delivery." Ferritin is used to represent iron stores. In patients with CKD, a serum ferritin concentration less than 100 μg/L is considered to suggest iron deficiency, and a serum ferritin of 100 to 200 μg/L in association with transferrin saturation less than 20% represents "functional" iron deficiency. Treatment of anemia in CKD requires adequate iron stores. A very high concentration of ferritin (>800 μg/L) may suggest iron overload (see Chapter 32). However, these indices have limitations (e.g., a high ferritin concentration is also generated by an inflammatory process; transferrin varies with nutritional state and is also influenced by inflammation). Clinical hematology laboratories may offer an automated estimate of the percentage of hypochromic red blood cells. A value above 10% is indicative of functional iron deficiency, and the target is less than 2.5%.[112]

Iron deficiency (absolute or functional) was the main cause of ESA resistance in the United Kingdom, but this has been resolved by iron replacement strategies. In hemodialysis patient populations, the inverse relationship between ESA dose and iron stores continues to maintain a linear relationship up to a mean ferritin of 500 μg/L. Parenteral iron is the treatment of choice for absolute and functional iron deficiency because oral iron has low efficacy in CKD. Parenteral iron can easily be administered during dialysis in patients receiving hemodialysis. Hemodialysis patients have additional iron losses from gastrointestinal bleeding, blood tests, and losses in dialysis lines that result in iron supplementation requirements that outstrip the capacity of the gut to absorb iron. Maintenance intravenous iron in hemodialysis patients greatly reduces ESA requirements and costs.[29] Maintaining iron stores at steady state in a hemodialysis population requires 50 to 60 mg/wk of intravenous iron.

In non–dialysis-treated CKD, a randomized study of intravenous iron versus oral iron in predialysis patients demonstrated a greater improvement in hemoglobin outcome in those on intravenous iron, but no difference in the proportion of patients who had to commence ESA after the start of the study.[450]

Nevertheless, oral iron is easy and cheap to prescribe and can be used as first-line iron supplementation in nondialysis patients. It is appropriate to treat patients who have not responded to, or have been intolerant of, oral iron with intravenous iron every 6 to 8 weeks to maintain serum ferritin greater than 100 μg/L.

Use of Erythropoiesis-Stimulating Agents

ESAs are synthetic versions of human EPO (rhEPO or epoetin) that are used to treat anemia. Following replenished iron stores and exclusion of other causes of anemia, the addition of ESAs is indicated for the treatment of CKD-related anemia. Measurement of serum EPO concentration is rarely indicated in the setting of renal anemia. The gene for human EPO was cloned in 1985, and epoetin was introduced into clinical practice shortly afterward.[200,475] ESAs are effective in correcting the anemia of CKD in 90 to 95% of patients. The most common side effect is hypertension; therefore blood pressure should be well controlled before treatment is introduced. Hypertension may develop or worsen in a quarter of patients. Failure to respond to treatment requires thorough investigation for many potential causes (Box 48-2). It is estimated that 3 million patients worldwide have received treatment with ESAs. A rare complication of ESA treatment is the generation of neutralizing antibodies to the ESA. These

BOX 48-2 Causes of Failure to Respond to Erythropoiesis-Stimulating Agents (ESAs)

Iron status
Occult blood loss
Vitamin B_{12} or folate deficiency
Infection and inflammation
Inadequate dialysis
Hyperparathyroidism
Aluminum toxicity
Patient adherence
Hypothyroidism
Primary disease activity
Transplant rejection
Malignancy
Pure red cell aplasia

antibodies stop bone marrow erythroid cells from producing mature red blood cells, so-called pure red cell aplasia.[62] If a case of pure red cell aplasia is proven, then no additional recombinant ESAs are administered.

Many clinical benefits are derived from correcting anemia with ESAs, including (1) improved exercise capacity,[294] (2) improved cognitive function,[287] (3) better quality of life,[306,367] and (4) increased libido. Much of the evidence has been taken from studies in dialysis patients. In patients with advanced CKD not yet on dialysis, small nonrandomized studies have suggested that regression of LVH is possible with partial correction of anemia with epoetin.[175,353] Patients who receive an ESA consistently over the 2 years before commencement of dialysis may have improved survival,[483] although larger prospective randomized trials have not confirmed these observations. Two important studies focused on patients not yet on dialysis. The Correction of Hemoglobin and Outcomes in Renal Insufficiency (CHOIR) study showed no benefit of higher hemoglobin concentration (13.5 g/dL vs. 11.3 g/dL) in CKD patients. Higher outcome target hemoglobin concentrations showed increased risk (using composite end points of death, myocardial infarction, and hospitalization for congestive cardiac failure) and no incremental improvement in quality of life.[407] The Cardiovascular Risk Reduction in Early Anaemia Treatment with Epoetin Beta (CREATE) study reported early correction of anemia to normal hemoglobin concentration (13 to 15 g/dL vs. 10.5 to 11.5 g/dL) but did not reduce the risk of cardiovascular events in patients followed for 3 years.[103] Indeed the hazards ratio for primary end points of death from any cause or death from cardiovascular disease consistently (but not significantly) favored the lower hemoglobin target group. LVH remained stable in both groups, and quality of life was significantly better in the higher hemoglobin outcome group.

A large randomized controlled trial has tested the hypothesis that normalization of anemia would have benefits in terms of morbidity and mortality for hemodialysis patients with New York Heart Association (NYHA) heart disease stage I to III.[30] Patients were randomized to normalization of anemia (618 patients and target hemoglobin concentration of 14 g/dL) or to the control group (615 patients and target hemoglobin concentration of 10 g/dL).

The study was terminated early because of a nonsignificant higher risk of death in the normalization group [RR 1.3, confidence interval (CI) 0.9 to 1.9]. These studies have been instructive in setting the current hemoglobin target of 10.0 to 12.0 g/dL and in recommending ESA dose adjustments when hemoglobin is less than 10.5 or greater than 11.5 g/dL, to balance benefit versus safety to patients.[446A]

The Uremic Syndrome

Uremia is defined as the excess within the blood of urea, creatinine, and other nitrogenous end products of amino acid and protein metabolism that are normally excreted in the urine. The *uremic syndrome,* the terminal clinical manifestation of kidney failure, is the group of symptoms, physical signs, and abnormal findings on diagnostic studies that result from failure of the kidneys to maintain adequate excretory, regulatory, and endocrine function.

Classic signs of uremia include (1) progressive weakness and easy fatigue, (2) loss of appetite followed by nausea and vomiting, (3) muscle wasting, (4) tremors, (5) abnormal mental function, (6) frequent but shallow respirations, and (7) metabolic acidosis. The syndrome evolves to produce stupor, coma, and ultimately death unless support is provided by dialysis or successful kidney transplantation. Regulation of body fluids is impaired in patients with uremia because of failure to excrete excess ingested fluid or to cope with fluid losses caused by vomiting or diarrhea. Patients also have difficulty excreting a salt load or retaining sodium when intake is low or vascular volume inadequate. Acid excretion is impaired, as is the ability to excrete nitrogenous metabolites from dietary sources. In relation to the stages of kidney disease defined by NKF-K/DOQI (see Table 48-5), kidney failure is present at a GFR ≤ 15 mL/min/1.73 m^2 (stage 5).[315] At this rate, signs and symptoms of uremia or the need for RRT is generally present. Biochemical characteristics of the uremic syndrome are summarized in Box 48-3. In addition to the consequences of reduced excretory, regulatory, and endocrine function of the kidneys, the uremic syndrome has several systemic manifestations—among them (1) pericarditis, (2) pleuritis, (3) disordered platelet and granulocyte function, and (4) encephalopathy—that have been difficult to explain.

For longer than 200 years, scientists have been studying the nature of uremia, but no single retained molecule has yet qualified for the title "uremic toxin," and many now agree that a variety of compounds are potential uremic toxins (Table 48-9). At least 90 organic compounds are known to be retained in uremia.[14,451] Many more still unidentified solutes are possibly retained and might exert systemic toxicity. Although urea was the first metabolite to be identified at increased concentrations in uremia, this does not appear to be responsible for the systemic manifestations of uremia. Urea is a 60 Da water-soluble compound that has the highest

BOX 48-3 Biochemical Characteristics of the Uremic Syndrome

Retained Nitrogenous Metabolites
- Urea
- Cyanate
- Creatinine
- Guanidine compounds
- "Middle molecules"
- Uric acid

Fluid, Acid-Base, and Electrolyte Disturbances
- Fixed urine osmolality
- Metabolic acidosis (decreased blood pH, bicarbonate)
- Hyponatremia or hypernatremia or hyperkalemia
- Hyperchloremia
- Hypocalcemia
- Hyperphosphatemia
- Hypermagnesemia

Carbohydrate Intolerance
- Insulin resistance (hypoglycemia may also occur)
- Plasma insulin normal or increased
- Delayed response to carbohydrate loading
- Hyperglucagonemia

Abnormal Lipid Metabolism
- Hypertriglyceridemia
- Decreased high-density lipoprotein cholesterol
- Hyperlipoproteinemia

Altered Endocrine Function
- Secondary hyperparathyroidism
- Osteomalacia (secondary to abnormal vitamin D metabolism)
- Hyperreninemia and hyperaldosteronism
- Hyporeninemia
- Hypoaldosteronism
- Decreased erythropoietin production
- Altered thyroxine metabolism
- Gonadal dysfunction (increased prolactin and luteinizing hormone, decreased testosterone)

concentrations of presently known uremic retention solutes in uremic plasma. Although its removal by dialysis is directly related to patient survival, the effects of urea on biological systems are not clear. Urea removal by dialysis is not necessarily representative of other molecules retained in the uremic syndrome, particularly protein-bound solutes such as *p*-cresol, or higher molecular weight molecules such as PTH and cystatin C.[319] Urea may be the source of other, more toxic moieties.[452] However, it is more likely that the syndrome is a result of the cumulative effect of many retained compounds, which may act as toxins and may have an effect on metabolism in general, for example, through enzyme inhibition or derangement in membrane transport. The decreased ability of the kidneys to degrade or eliminate hormones may also have a role.

TABLE 48-9 Potential Uremic Toxins

Toxin	Effect
Urea	At very high concentrations [>300 mg/dL (>50 mmol/L)] can cause headache, vomiting, and fatigue, carbamylation of proteins
Creatinine	Possibly affects glucose tolerance and erythrocyte survival
Cyanate	Causes drowsiness, hyperglycemia; a breakdown product of urea, it can cause carbamylation of proteins, altering protein function
Polyols (e.g., myoinositol)	Can cause peripheral neuropathy
Phenols	Can be highly toxic as they are lipid soluble and therefore can cross cell membranes easily
Middle molecules (e.g., atrial natriuretic peptide, cystatin C, delta sleep-inducing protein, IL-6, TNF-α, PTH)	Peritoneal dialysis patients clear middle molecules more efficiently than HD patients and show fewer signs of neuropathy than hemodialysis patients (many candidate molecules but none paramount)
β_2-Microglobulin	Causative agent in renal amyloid

HD, Hemodialysis; *IL-6,* interleukin-6; *PTH,* parathyroid hormone; *TNF-α,* tumor necrosis factor-alpha.

Acute Kidney Injury

AKI has largely replaced the older term *acute renal failure* and describes a sudden decline in kidney function over hours and days. AKI is an increasingly common and potentially catastrophic complication of systemic illness. Identifying the true incidence and prevalence of AKI has been difficult because of wide variation in the accepted definition of AKI. Several studies have reported multicenter experience with AKI in the intensive care unit setting and note wide variation in practice and outcomes.[69,299]

In 2003, a new classification of AKI was proposed that was based on the combination of susceptibility, nature and timing of insult, biomarker response, urine output, and end-organ consequences.[298] In recognition of the potential clinical importance of small changes in kidney function and the need to standardize definitions of AKI for clinical and research purposes, the RIFLE criteria were adopted by the Acute Dialysis Quality Initiative (ADQI), providing a graded definition of AKI severity.[226] The acronym RIFLE defines three grades of increasing severity of AKI (risk, injury, and failure) and two outcome variables (loss and end-stage renal disease). Grades of severity are established on the basis of change in serum creatinine concentration and decline in urine output

TABLE 48-10 Acute Kidney Injury Network (AKIN) Criteria for Acute Kidney Injury (AKI)*

AKIN Stage	Serum Creatinine Criteria	Urine Output Criteria
1	↑ SCr ≥ 0.3 mg/dL (26 µmol/L) *or* ↑ SCr ≥ 150-200% from baseline	<0.5 mL/kg/h for >6 h
2	↑ SCr > 200-300% from baseline	<0.5 mL/kg/h for >12 h
3	↑ SCr > 300% (>3-fold) from baseline *or* SCr ≥ 4 mg/dL (354 µmol/L) with an acute rise of ≥0.5 mg/dL (44 µmol/L) in ≤24 h *or* Initiation of renal replacement therapy (irrespective of stage at time of initiation)	<0.3 mL/kg/h for >24 h *or* Anuria for 12 h

*Only one criterion needs to be fulfilled to qualify for a stage.
SCr, Serum creatinine concentration.

from baseline. The most powerful tool to improve outcome in AKI is prevention, and the advantage of the RIFLE criteria is the definition of "risk," where it is envisaged that intervention may prevent injury and failure. In 2007, the Acute Kidney Injury Network (AKIN) proposed three stages of increasing disease severity (Table 48-10).[303] This expert working group, from all aspects of nephrology and critical care, modified the RIFLE criteria slightly to incorporate smaller changes in serum creatinine concentration into the definition of risk, because it was appreciated that small changes in kidney function can affect outcome. In essence, the AKIN has provided the following diagnostic criteria for AKI: (1) an abrupt (within 48 hours) reduction in kidney function, currently defined as an increase in serum creatinine concentration of 0.3 mg/dL (26 µmol/L); (2) an increase of 50% or greater (1.5-fold from baseline); or (3) a reduction in urine output (documented oliguria <0.5 mL/kg/h for >6 hours).

A prospective study of the initial hospital management of AKI confirmed that in almost 40% of cases, AKI was iatrogenic or preventable.[422] Early identification of intravascular volume depletion, use of nephrotoxic drugs, and early diagnosis of causative conditions can prevent AKI. Therefore, prompt administration of intravenous crystalloid solutions such as 0.9% sodium chloride may prevent further deterioration of AKI in many cases. Patients at risk for AKI include older persons; those with preexisting CKD, sepsis, diabetes, and heart disease; and those taking nephrotoxic drugs, particularly in the setting of hypovolemia. Fluid replacement requirements need careful monitoring and review of the patient, with emphasis on restoring an optimal circulatory volume without developing signs of fluid overload such as pulmonary edema. Additional monitoring may include use of a central venous pressure (CVP) line. Insertion of a CVP line is a specialist skill that requires cannulation of the internal jugular vein, ideally utilizing ultrasonic guidance facilities. However, where hypovolemia is clinically apparent, the priority is to resuscitate the patient with fluid, rather than delay treatment, by establishing invasive monitoring. The target CVP is 8 to 12 cm H_2O. A series of CVP measurements are useful for check response to fluids.

Clinical assessment of AKI should consider whether the precipitant is prerenal, intrarenal (intrinsic), or postrenal. The most common causes are listed in Box 48-4. Intrinsic AKI can be caused by primary vascular, glomerular, or interstitial disorders. It is therefore important that all patients presenting with AKI undergo urinalysis to test for infection, hematuria, and proteinuria. In most cases, the kidney lesion seen on histology is referred to as acute tubular necrosis (ATN). ATN is caused by ischemic or nephrotoxic injury to the kidney. In 50% of cases of hospital-acquired AKI, the cause is multifactorial. (The term *ATN* is somewhat misleading, insofar as necrosis per se is seldom seen, rather tubular *damage* occurs.) Although the pathogenesis is uncertain, a well-recognized clinical pattern is associated with the development of ATN, with anuria or oliguria and abnormalities indicating tubular dysfunction (Figure 48-14).[40] Necrosis of tubular cells need not be extensive, but obstruction by tubular casts, back-leak of glomerular filtrate through gaps in the tubular epithelium caused by cellular denudation, and primary reductions in GFR caused by altered intrarenal hemodynamics, known as tubuloglomerular feedback, may occur.[248] Direct vasoconstriction of glomerular capillaries in response to ischemic insults can also occur and may be mediated by AII, endothelin,[144,471] and serotonin.[453]

Urinary electrolyte measurements are seldom required or useful in the investigation of AKI. In practice, the treatment of prerenal AKI and ATN requires prompt and continued correction of hypovolemia, so urinary findings generally are not helpful.

Laboratory testing of blood is crucial in the management of AKI. Blood tests also assist in establishing the underlying diagnosis, and specific investigations are requested if kidney function has not improved following volume correction. An *acute renal screen* should clearly focus on most likely diagnoses and include the tests shown in Table 48-11.

The role of imaging in kidney disease is mentioned in Table 48-11, and exclusion of obstruction is important in AKI. Kidney biopsy is generally reserved for cases of AKI wherein an ultrasound scan has excluded obstructed kidneys, kidney sizes are maintained and the cause of AKI is otherwise unexplained, and an intrinsic pathology is suspected.

Metabolic acidosis is the most common acid-base disorder in patients with AKI. Reduced renal excretion of potassium and the effects of acidosis on the generation of extracellular

BOX 48-4 Causes of Acute Kidney Injury

Prerenal AKI
- Hemorrhage
- Diarrhea
- Postoperative fluid and blood losses
- Sepsis
- Acute cardiac failure

Intrinsic renal disease
- Tubular
- Glomerular
- Vascular

Any of the prerenal causes that are severe or that are not corrected promptly leading to ATN

Other causes of ATN
- Drug nephrotoxicity
- NSAIDs, ACE inhibitors
- Aminoglycoside antibiotics
- Amphotericin

TIN
- Allergic TIN associated with antibiotics and NSAIDs
- Sarcoidosis
- Pyelonephritis

Renal parenchymal disease
- RPGN (ANCA-associated vasculitides, Goodpasture's disease, SLE, other crescentic glomerulonephritides)
- Thrombotic microangiopathies
- Cryoglobulinemia

Myeloma

Miscellaneous
- Contrast nephropathy
- Poisoning
- Rhabdomyolysis
- Atheroembolism
- Urate nephropathy
- Hepatorenal syndrome

Vascular causes
- Aortic dissection
- Renal vein thrombosis

Postrenal AKI

Bladder outflow obstruction
- Benign and malignant prostate disease
- Invasive bladder carcinoma

Bilateral renal calculi or calculi within a single kidney

Retroperitoneal fibrosis

ACE, Angiotensin-converting enzyme; *AKI,* acute kidney injury; *ANCA,* antineutrophil cytoplasmic antibody; *ATN,* acute tubular necrosis; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *RPGN,* rapidly progressive glomerulonephritis; *SLE,* systemic lupus erythematosus; *TIN,* tubulointerstitial nephritis.

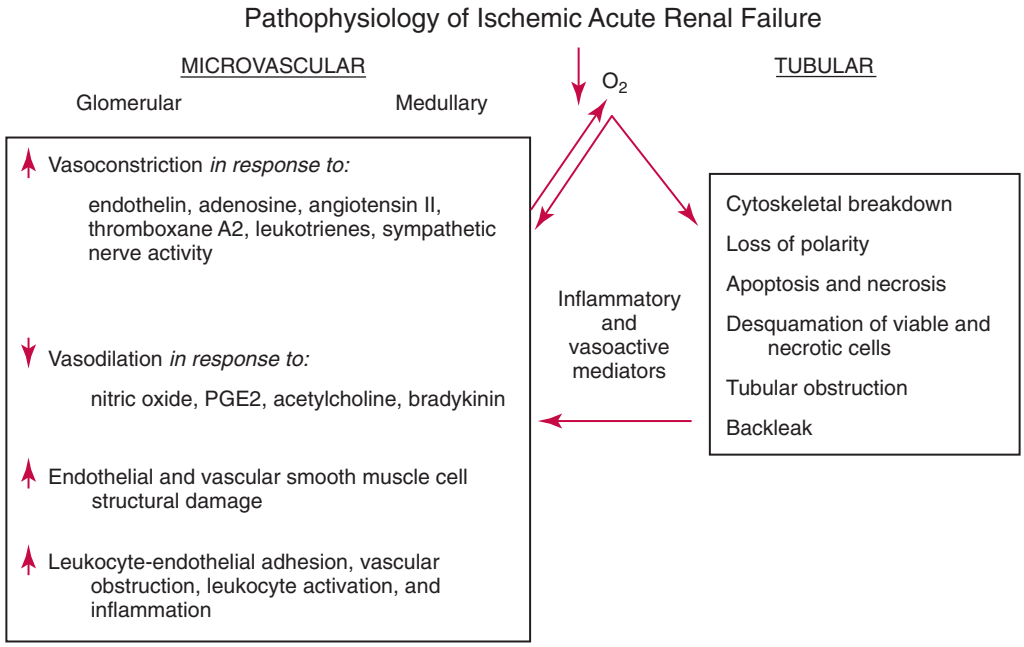

Figure 48-14 Pathogenesis of ischemic acute kidney injury. Hypoxic insults cause vascular responses and tubular damage. *(From Bonventre JV, Weinberg JM. Recent advances in the pathophysiology of ischemic acute renal failure. J Am Soc Nephrol 2003;14:2199-210.)*

TABLE 48-11 Investigation of Acute Kidney Injury (AKI)

Test	Indication/Comments
Urine Testing	
Urine reagent strip ("dipstick")	Hematuria and proteinuria may indicate glomerular origin
Red cell casts on microscopy	Not available universally: may need bedside microscope
Urine microscopy and culture	Identify urinary tract infection
Urine protein electrophoresis and immunofixation	
Blood Tests	
Baseline Studies	
Urea, electrolytes, creatinine, and calcium, phosphate, albumin	Check previous laboratory reports: AKI or AKI with preexisting CKD
Liver function tests	
Acid-base studies	Suspected multiorgan involvement or abnormal coagulation
Full blood count	Arterial blood gas or venous plasma bicarbonate concentration
Coagulation studies	Anemia, hemolysis, thrombocytopenia
	Evidence of intravascular coagulation; need to normalize if considering kidney biopsy and central line insertion
Selected Additional Investigations	
Blood culture	Any infection but especially endocarditis, severe pneumonia, or urinary tract sepsis
Creatine kinase	Very high in cases of muscle inflammation and necrosis (rhabdomyolysis)
Lactate dehydrogenase	If high, suspect renal infarction and consider hemolysis
Antineutrophil cytoplasmic antibodies	Vasculitides
Anti–glomerular basement membrane antibody	Anti–glomerular basement membrane disease
Antinuclear antibodies	Systemic lupus erythematosus
Anti-dsDNA antibodies, extractable nuclear antigens	Systemic lupus erythematosus
Low C4 complement	Systemic lupus erythematosus, atheroembolism, cryoglobulinemia
Cryoglobulin	Cryoglobulinemia
Urate	Urate nephropathy
Serum protein electrophoresis	Myeloma
Virology studies	Hepatitis serology, antistreptolysin O titer, human immunodeficiency virus
Imaging	
Chest x-ray	Pulmonary edema, pneumonia, effusions, malignancy, and granulomas
Abdominal x-ray (kidney, ureter, and bladder)	Renal stones
Renal tract ultrasound scan	Identify size and symmetry of kidneys
	Evidence of an obstructed system
	Small shrunken kidneys in advanced CKD
Computed tomography scan	Anatomy and perfusion
Magnetic resonance imaging	Angiography to identify renovascular lesions
Formal angiography	Critical renal artery stenosis
Kidney Biopsy	Reserved for patients with unexplained AKI in whom acute tubular necrosis is not suspected. It is anticipated that additional therapy such as steroids, cytotoxic drugs, and plasma exchange may be required.

CKD, Chronic kidney disease; *dsDNA,* double-stranded DNA.

potassium may lead to a very high concentration of potassium in the plasma. Severe hyperkalemia (serum potassium concentration >6.5 mmol/L) is associated with life-threatening cardiac arrhythmias. Emergency treatment of hyperkalemia should be instituted as necessary. Patients who have an abnormal electrocardiogram in the setting of high plasma potassium concentration, or a potassium concentration of 6.5 mmol/L or greater, should receive 10% calcium gluconate intravenously over 2 to 3 minutes through a large-bore peripheral venous cannula or a central line. This treatment stabilizes myocardial cells. However, calcium gluconate will not lower the potassium concentration. Infusion of high concentrations of glucose stimulates insulin secretion from the pancreas and uptake of potassium into the intracellular space. A fall in potassium concentration should be expected within 60 minutes. In addition, low-dose rapid-acting insulin can be administered with the glucose bolus. Serum potassium concentration should be monitored hourly until risk of a life-threatening cardiac event has passed and no evidence of potassium rebound is found. Blood glucose concentration should be monitored because hypoglycemia may occur following exogenous insulin. Again, care should be taken with 50% glucose infusions that good venous access is established, because extravasation can cause severe tissue necrosis.

When hyperkalemia persists despite appropriate medical measures, then RRT should be considered. Options for RRT include intermittent hemodialysis, peritoneal dialysis, and continuous renal replacement therapies (hemofiltration and hemodiafiltration) (see later). Continuous modalities are particularly appropriate for the intensive care unit setting in cases of multiple-organ failure. Continuous therapies are useful in the treatment of septic shock, cardiac failure, pancreatitis, and acute respiratory distress syndrome. They also allow the use of supplementary feeding, which is important in the oliguric patient with established AKI, in whom fluid is restricted to avoid overload.

If the patient survives, recovery usually will occur within days or weeks following removal of the initiating event. Uncomplicated AKI has a mortality rate of 5 to 10%,[186] although AKI complicating nonrenal organ system failure in the intensive care unit setting is associated with mortality rates approaching 50 to 70%, despite advances in dialysis treatment.[298]

The role of the clinical laboratory in assessment and monitoring of AKI is limited to assessment of electrolyte disturbance and fluid status, because during the recovery period, an initial polyuric phase occurs, as glomerular function recovers before tubular function recovers. This polyuric phase recedes after a few days to weeks, but careful monitoring is required to enable suitable fluid and electrolyte replacement.

Serum creatinine is the most widely used parameter for everyday assessment of GFR, but it has poor sensitivity and specificity in AKI because it lags behind both kidney injury and recovery. Several urinary and serum biomarkers of early tubular injury are being studied to assess whether injury can be detected before GFR is decreased.[77] These include urinary kidney injury molecule-1 (KIM-1), urinary neutrophil gelatinase-associated lipocalin (NGAL), urine IL-18, and serum cystatin C (see Chapter 25).

AKI Associated With Radiocontrast Media

Many procedures and tests that are undertaken within the hospital environment may contribute to the burden of AKI. In particular, intravascular administration of radiocontrast media during enhanced CT scanning and angiographic procedures accounts for many cases of AKI.[186] This is important as preventative strategies should be employed in patients with preexisting kidney disease, in patients with diabetes mellitus, and in those who are dehydrated and at increased risk of developing AKI when undergoing imaging. In 2003, 80 million doses of contrast media were administered worldwide.[223] Radiocontrast media are iodinated and may be ionic or nonionic. At concentrations required for angiography or CT scanning, the various agents used have differing osmolality. First-generation agents were ionic monomers with a very high osmolality with respect to plasma (e.g., 1500 to 1800 mOsmol/kg). Second-generation agents such as iohexol are nonionic monomers with a lower osmolality, although still higher than that of plasma (e.g., 600 to 850 mOsmol/kg). An iso-osmolal agent, iodixanol, has been introduced in 2003 (osmolality 290 mOsmol/kg). The use of iso-osmolar agents may lower the risk of AKI in high-risk diabetic patients undergoing angiography.[10] Preventative measures should be considered before a radiocontrast load is administered, regardless of the agent used. If possible, alternative investigations should be performed. However, when radiocontrast is required, the patient should be adequately hydrated with normal saline or isotonic sodium bicarbonate. An antioxidant, *N*-acetylcysteine, is commonly used to prevent contrast nephropathy following a reported benefit in reducing the incidence of AKI.[432] Reports of efficacy have been conflicting, but *N*-acetylcysteine is well tolerated and safe.[309] NSAIDs should be avoided because they interfere with vasodilator prostaglandins, causing increased renal vasoconstriction. The drug metformin should be discontinued at the time of the exposure to contrast in patients with diabetes.

DISEASES OF THE KIDNEY

Diabetic Nephropathy

Diabetes mellitus is a state of chronic hyperglycemia sufficient to cause long-term damage to specific tissues, notably the retina, kidney, nerves, and arteries (see Chapter 46). In 2000, the World Health Organization (WHO) estimated that 171 million people worldwide were affected by diabetes, with the prevalence set to reach 366 million by 2030.[479] In the United Kingdom, approximately 3% (1.9 million adults) of the population have diabetes. The WHO and national diabetes agencies have approved diagnostic criteria for diabetes based on venous plasma glucose concentrations.[479] In 2007, the Centers for Disease Control and Prevention in the United States took the unusual step for a noninfectious disease of classifying the increase in the incidence of diabetes as an epidemic.

Type 1 diabetes is due to autoimmune destruction of pancreatic islet β-cells, causing loss of insulin secretion. Type 2 diabetes is due to the combination of cellular resistance to insulin and β-cell failure. Tissue lesions are common to both types of diabetes, and chronic hyperglycemia (or a closely related metabolic abnormality) is responsible for diabetic complications including diabetic nephropathy.

Background

Diabetic nephropathy is a clinical diagnosis based on the finding of proteinuria in a patient with diabetes in whom there is no evidence of urinary tract infection. Overt nephropathy is characterized by protein loss greater than 0.5 g/d, approximately equivalent to albumin loss of greater than 300 mg/d. It is preferable to assess proteinuria as albuminuria because it is a more sensitive marker for CKD due to diabetes.[312,315] Albumin has been uniformly adopted as the "criterion standard" in evaluating diabetes-related kidney damage. The NKF-K/DOQI Work Group concluded that albumin should be measured to detect and monitor kidney damage in adults. Patients with urinary albumin loss of between 30 and 300 mg/d have so-called microalbuminuria (see Chapter 25).

Diabetic nephropathy is the most common cause of ESRD in the United States: the number of incident patients with diabetes as the cause of ESRD exceeded 48,000 during 2006—17.2% higher than in 2000 (see Figure 48-11).[79] Almost 200,000 people receiving RRT in the United States have diabetes as the cause of their ESRD, and this continues to rise steadily at around 2.5% per year.[79] Among patients who require dialysis, those with diabetes have a 22% higher mortality at 1 year and a 15% higher mortality at 5 years than patients without diabetes. Diabetic nephropathy as a cause of ESRD in the United Kingdom is seen in approximately 20% of new patients—a lower percentage than that of the United States and Europe.[7] In the United States, a number of objectives were developed for reducing threats to the health of the nation in the *Healthy People 2010* report. One of the objectives (HP 2010 Objective 4.7) is to reduce the incidence rate of ESRD caused by diabetes from 145 per million population to 78 per million people by 2010.[447] However, the overall rate for new cases of ESRD caused by diabetes was 153 pmp in 2008.[79,447A]

Diabetic nephropathy is clinically a very slowly developing condition, but ultrastructural evidence of glomerular damage has been found in renal biopsies taken from type 1 diabetic patients within a few years of their diagnosis.[18,65,120] In type 1 diabetes, early macroscopic changes include kidney enlargement and pallor. With disease progression, the kidneys become smaller. Type 2 diabetes is typified by variable kidney contraction caused by associated ischemia. On histologic examination, glomerular changes include diffuse mesangial sclerosis with accentuation of matrix and irregularly thickened basement membranes; sclerotic, acellular mesangial nodules (so-called Kimmelstiel-Wilson lesions); hyaline fibrin cap lesions around peripheral capillary loops; capsular drop lesions located within Bowman's capsule; and hyalinosis of arterioles.

Clinical progression is defined in terms of changes in rate of urinary albumin loss and decline in GFR and blood pressure changes (Table 48-12). In type 1 diabetes, it is unusual to develop microalbuminuria within the first 5 years of diagnosis, but it can occur anytime thereafter, and even after 40 years. Patients with type 1 diabetes and microalbuminuria will progress to overt nephropathy at an average rate of 20% over 5 years.[131] Long-term follow-up data on microalbuminuric patients confirm that 30% become normoalbuminuric (i.e., disease regression) and the rest remain microalbuminuric at 10 years.[59] Because the onset of type 2 diabetes is difficult to define, it is difficult to estimate the incidence of microalbuminuria, although 1% of patients in the United Kingdom have overt nephropathy at diagnosis. As albuminuria worsens and blood pressure increases, a relentless decline in GFR occurs.

Family studies of patients with type 1 diabetes have shown that diabetic siblings of patients with nephropathy have a fourfold risk of nephropathy compared with siblings without nephropathy. A family history of hypertension

TABLE 48-12 Development of Diabetic Nephropathy

Stage	Designation	Characteristics	Structural Changes	Glomerular Filtration Rate, mL/min/1.73 m^2	Blood Pressure, mm Hg
I	Hyperfunction	Hyperfiltration	Glomerular hypertrophy	>150	Normal
II	Normoalbuminuria	Normal albumin loss	Basement membrane thickening	150	Normal
III	Incipient diabetic nephropathy (microalbuminuria)	Increased albumin loss	Albumin loss correlates with structural damage and hypertrophy of remaining glomeruli	125	Increased
IV	Overt diabetic nephropathy	Clinical proteinuria	Advanced structural damage	<100	Hypertension
V	Uremia	Kidney failure	Glomerular closure	0-10	High

and cardiovascular disease may increase nephropathy rates.[41] However, the best available predictor for development of nephropathy is microalbuminuria, although cellular markers are being investigated—such as increased erythrocyte Na^+/Li^+ countertransporter and overactivity of the Na^+/H^+ antiporter.[23] Considerable work has been undertaken to look for genetic linkages with the development of nephropathy in diabetes.[393]

Pathophysiology

Observational studies have shown that sustained poor glycemic control is associated with a greater risk for development of nephropathy in both type 1 and type 2 diabetes.[100,235,362,444] The exact mechanism for hyperglycemic tissue damage probably includes (1) glycation of proteins, leading to the formation of advanced glycation end products (AGEs); (2) overactivity of the polyol pathway; and (3) generation of reactive oxygen species.[220] Polyols are sugar alcohols formed from their respective sugars under the action of aldose reductase. Glucose is preferentially shunted through the polyol pathway under hyperglycemic conditions, generating sorbitol that accumulates within cells. A key step linking glucotoxicity to cell dysfunction in diabetic nephropathy is the excess of extracellular matrix within the glomerulus and interstitium. A number of genes encoding matrix proteins in hyperglycemic conditions have been identified.[290] For example, transcription of the gene for TGF-β is stimulated by hyperglycemia, AGE, AII, and reactive oxygen species.[182,334,463]

One important consequence of glucose-stimulated TGF-β transcription is upregulation of the insulin-independent GLUT-1 transporter in mesangial cells. Glucose is transported to the cells through GLUT-1 and is metabolized mainly by the glycolytic pathway. Increased de novo synthesis of diacylglycerol results in the activation of protein kinase C and mitogen-activated kinases. Activation of these enzymes can lead to stimulation of certain genes, including TGF-β. Activation of TGF-β can induce the expression of GLUT-1, and these signaling pathways induce the expression of extracellular matrix proteins. The formation of AGE also generates reactive oxygen species, which can activate latent TGF-β.[290] Studies employing neutralizing anti–TGF-β antibodies have provided evidence that the prosclerotic and hypertrophic effects of high ambient glucose in cultured renal cells are largely mediated by autocrine production and activation of TGF-β.[198,491] These antibodies can reverse established nephropathy in animal models.[67,490] Furthermore, glomerular TGF-β mRNA is markedly increased in kidney biopsy specimens from patients with proven diabetic kidney disease, and blood and urine sampling across the renal vascular bed confirms net renal production of TGF-β in diabetic patients.[403] Treatment with the ACE inhibitor captopril lowers circulating TGF-β concentrations in patients with diabetic nephropathy.[402]

The receptor for AGE (RAGE) has been identified.[392] RAGE is selectively expressed in the glomerular epithelial cells (podocytes) and not in the mesangial cell or the glomerular endothelium.[427] Increased accumulation of AGE in diabetes engages podocyte RAGE and may lead to increased glomerular permeability.[466] Vascular hyperpermeability, a hallmark feature of diabetes, can be suppressed by inhibiting RAGE in the animal model of diabetes, the streptozotocin-treated rat.[461]

Studies of experimental diabetes in the rat suggest that hyperfiltration alone could cause glomerular changes; conflicting reports have described the effects in humans. Increased GFR could be a predictor of progression to microalbuminuria but is also a reflection of poor metabolic control. In the Diabetes Control and Complications Trial (DCCT),[100] no association was noted between hyperfiltration and subsequent development of microalbuminuria.[23] Systemic blood pressure is higher in patients with diabetes who subsequently develop microalbuminuria, although it is not clear which comes first. Tubulointerstitial fibrosis occurs in diabetic nephropathy, in addition to glomerulosclerosis. Decreased GFR correlates with interstitial and glomerular expansion.[469]

Treatment Strategies

The cornerstones of treatment for diabetic nephropathy consist of glycemic control, blood pressure control, particularly with drugs that block the RAAS, and management of cardiovascular risk.[100,140,327,444] Guidelines published by NICE in 2008 recommend negotiation and individual target setting of glycated hemoglobin (HbA_{1c}) of around 6.5%, while specifically avoiding highly intensive management to values less than 6.5%.[312] High blood pressure accelerates the progressive increase in albuminuria in patients with initially normal urinary albumin loss and accelerates loss of kidney function in those with overt nephropathy in type 2 diabetes.[15,169] The NKF Task Force on Cardiovascular Disease has recommended a target blood pressure of less than 125/75 mm Hg in diabetic kidney disease.[256] ACE inhibitors and ARBs slow the progression of diabetic kidney disease.[46,260,302,337] A trial that was reported in 2000 confirmed that even normoalbuminuric patients with type 2 diabetes should be managed with ACE inhibitors or ARBs to prevent cardiovascular events.[485] In addition to lowered systemic blood pressure, such patients have lowered glomerular capillary blood pressure and protein filtration.[176,487] ACE inhibitors and ARBs also reduce AII-mediated effects on glomerular permeability and cell proliferation and fibrosis[276,308] and should be incorporated into the treatment schedules of all patients with type 2 diabetes and those with type 1 diabetes and microalbuminuria. ACE inhibitors may exacerbate hyperkalemia in patients with advanced kidney disease and/or hyporeninemic hypoaldosteronism. In older patients with renal artery stenosis, they may cause a rapid decline in kidney function. A low sodium diet potentiates the antihypertensive and antiproteinuric effects of AII blockade in type 2 diabetes.[188] Patients should be encouraged to stop smoking cigarettes because smoking increases the risk of microalbuminuria.[329] Dyslipidemias should be managed as outlined for nondiabetic proteinuric CKD. For many years, the Steno Diabetes Center in Copenhagen, Denmark, has advocated multifactorial interventions in the

management of type 2 diabetes. For example, intensified interventions including tight glucose regulation, use of RAAS blockers, aspirin, lipid-lowering agents and lifestyle changes, were shown to reduce nonfatal cardiovascular disease among patients with type 2 diabetes[139] and subsequently beneficial effects with respect to vascular complications and on all-cause mortality.[138]

Hypertensive Nephropathy

Hypertension is second only to diabetes as a primary diagnosis of ESRD for incident patients commencing dialysis in the United States (see Figure 48-11).[79] The incidence is higher in older people and especially among the black population in the United States. Hypertension often develops as a consequence of CKD because of alterations in salt and water metabolism and activation of the sympathetic nervous and renin-angiotensin systems.[134,261] Hypertension can act as an accelerating force in the development of ESRD. As described earlier, treatment of hypertension to predefined target blood pressure values is critical in preventing progression to ESRD.[212,234,346] Various national and international guidelines on the treatment of hypertension have been published, although variability is evident among these recommendations. The JNC 7 report suggests that the risk of cardiovascular disease doubles for each increment in BP of 20/10 mm Hg, beginning at 115/75 mm Hg. The report identifies 120/80 mm Hg as normotension. All patients with hypertension (>140/90 mm Hg) should receive life-style change advice and antihypertensive medication if necessary.[73]

Hypertension is grouped with large vessel *renovascular disease* in the USRDS Annual Data Report database. Primary diseases of the renal arteries usually involve the origin of the renal arteries at the aorta (ostial lesions). Secondary diseases with hypertension and CKD with small vessel and intrarenal disease are referred to as *ischemic nephropathy.* A complex interplay occurs between renal artery stenosis and ischemic nephropathy. Atherosclerosis accounts for more than 90% of renal artery stenosis. The disease is progressive and may cause renal artery occlusion.[58] Prevalence increases with age and is associated with refractory hypertension, low body mass index, smoking, diabetes, and established vascular disease elsewhere. In general, as a marker of established cardiovascular disease, atheromatous renal artery stenosis is associated with a poor prognosis.[283] Diagnosis requires a high index of suspicion and is guided by radiologic examination of the renal arterial anatomy. Patients who receive ACE inhibitors and ARBs may develop AKI in the setting of severe bilateral renovascular disease or severe disease to a single functioning kidney. Kidney function should be carefully monitored following the introduction of these drugs, and a fall of GFR in excess of 15 to 20% should raise the suspicion of renovascular disease. The diagnosis is important to make because radiologic placement of intraluminal stents[39] is possible, and surgical repair can be performed to prolong vessel patency.[168] Patients are at risk, however, of atheroembolism following intervention.[398] A correctable atherosclerotic renal artery stenosis (ARAS) lesion is found in less than 1% of all hypertensive patients, so investigation has to be targeted to high-risk groups.

Renal artery stenosis in younger patients is characteristically due to fibromuscular dysplasia. The medial part of the artery is most commonly affected and presents radiologically as alternate bands of narrowing and dilatation, giving rise to a "string of beads" appearance. If the diagnosis is made, then hypertension can be cured following balloon angioplasty to the artery in at least 50% of cases.

Noninvasive imaging is readily available and includes CT angiogram and MRI angiography with gadolinium-based contrast media. A rare but potentially fatal disease, nephrogenic systemic fibrosis, has been described in patients with advanced kidney disease receiving gadolinium-based contrast media during MRI. Because many patients who are investigated for ARAS will have CKD, the approach to investigation has changed. Nephrogenic systemic fibrosis was first described in 2000 as a cutaneous scleromyxedema-like disorder in patients with ESRD.[87] Gadolinium-based contrast media are not recommended for patients with advanced renal impairment, particularly those on dialysis.[426]

Glomerular Disease

Glomerular disease is suggested clinically by the finding of blood and protein in the urine on urine reagent strip testing. Proteinuria greater than 1 g/d (≈0.88 g/g creatinine; ≈100 mg/mmol creatinine) in the absence of an overflow-type proteinuria such as myoglobinuria or light chain–related disease is invariably glomerular in origin. Although a detailed discussion of each glomerular disease is beyond the scope of this book, the most important diseases will be discussed to illustrate the spectrum of disease. Whereas the incidence of kidney failure in the Western world has increased dramatically over recent years, in the United States, the incidence rate due to glomerulonephritis has fallen (see Figure 48-11).[79] In the United Kingdom, glomerulonephritis accounts for 10% of new cases of established renal failure.[7]

Primary Glomerular Disease

Glomerulonephritis can be primary (affecting only the kidneys) or secondary (in which the kidneys are involved as part of a systemic process). Histopathologic classification of glomerulonephritis may appear slightly cumbersome but is readily simplified by consideration of the glomerular structures and cells that may be involved, and the presence or absence of immune complexes (Table 48-13). In essence, only three cell types are involved (endothelial, epithelial, and mesangial) plus the acellular GBM. The glomerular cells and the GBM have a limited range of response to injury, namely, proliferation, scarring (sclerosis), and GBM thickening. The term *focal* is used if less than half of the glomeruli are involved in the disease process as seen on light microscopy, whereas *diffuse glomerulonephritis* refers to cases in which all glomeruli are involved. Immune deposits identified following immunofluorescence or immunoperoxidase staining do not define whether a disease is focal or diffuse. Primary glomerular diseases that will not be considered further

TABLE 48-13 Overview of Some Primary Glomerular Diseases

Disease	Histologic Findings	Clinical Spectrum	Treatment	Prognosis
IgA nephropathy	• Focal mesangial cell proliferation on LM • IgA deposited within mesangial cells on IM	• Variable: incidental finding; episodes of macroscopic hematuria; proteinuria and declining GFR • Male preponderance • Peak incidence occurs in second and third decades of life • May be associated with systemic vasculitis in HSP	• Generic treatment targeting blood pressure and RAAS blockade • Selected cases receive corticosteroids and cytotoxic drugs	• Variable, but 30-40% progress to kidney failure over 20 years
Minimal change disease (MCD)	• Little evidence of cellular involvement on LM • Podocyte foot process effacement demonstrated on EM • No immune deposits	• Most common cause of nephrotic syndrome in children • Usually idiopathic • Relapsing and remitting course	• Oral corticosteroids and cytotoxic drugs	• Does not cause kidney failure • Significant side effects of immunosuppressant drugs
Focal segmental glomerulosclerosis (FSGS)	• Glomerular scarring and nonspecific trapping of immune complexes in scarred areas	• Common cause of nephrotic syndrome in adults • Congenital forms described • Secondary causes include collapsing variety seen in HIVAN	• Idiopathic disease requires corticosteroids and cytotoxic drugs in selected cases	• Nephrotic syndrome commonly refractory to treatment • 30-40% develop kidney failure at 10 years
Membranous nephropathy	• Thickened GBM with immune deposits in subepithelial GBM • Classically, "spikes" are seen along the GBM and represent new GBM squeezed between deposits	• Common cause of nephrotic syndrome • Secondary causes in 20% of cases	• Treat underlying condition • Idiopathic membranous • Treat generically and if progressive add immunosuppressive drugs	• Variable outcome: "rule of thirds" (see text)

include mesangiocapillary glomerulonephritis and hereditary nephritis (Alport's syndrome).

IgA Nephropathy

IgA nephropathy is an example of a focal glomerulonephritis with focal mesangial cell proliferation demonstrated by light microscopy. However, diffuse and global deposition of the immunoglobulin, IgA, can be demonstrated following immunostaining. It is the most common type of glomerulonephritis worldwide and has a particularly high prevalence around the Pacific rim, where it is commonly reported as an incidental finding in kidney biopsy specimens from potential kidney donors.[22] The disease tends to be slowly progressive (in terms of loss of kidney function) depending, as with most kidney

diseases, on the degree of proteinuria, kidney function at the time of diagnosis, and degree of interstitial fibrosis on kidney biopsy. Up to 50% of patients exhibit elevated concentrations of serum IgA, although diagnosis depends on kidney biopsy findings. Clinical presentation varies considerably from asymptomatic microscopic hematuria to macroscopic hematuria; proteinuria including nephrotic syndrome; and crescentic glomerulonephritis with kidney failure. Episodic macroscopic hematuria is seen in some patients at the same time as an upper respiratory tract infection. IgA nephropathy may also present with established proteinuria, renal impairment, and hypertension. Variation in clinical and histologic features leads to difficulty in reaching conclusions regarding treatment protocols that have been tested in clinical trials.

No treatment is available that specifically modifies mesangial deposition of IgA, and available options are limited to downstream immune and inflammatory events that may lead to scarring. Treatment options vary from tonsillectomy in patients with macroscopic hematuria associated with respiratory infection to no treatment in those with isolated microscopic hematuria or those with proteinuria of less than 1 g/d. In progressive disease, all patients are treated in a similar generic fashion as for most kidney diseases, including targeting blood pressure to less than 125/75 mm Hg and using comprehensive RAAS blockade to minimize proteinuria. Assessment of the impact of immunosuppressive therapy is compromised by the heterogeneity of the disease and the duration of a randomized controlled study with sufficient numbers to allow a conclusion. Nevertheless, a large Italian study with more than 10 years of follow-up data demonstrated benefit from oral corticosteroids in high doses for 6 months.[354,423] Cytotoxic therapy can be considered for rapidly progressing or vasculitic IgA.[17]

Nephrotic Syndrome

Nephrotic syndrome is defined as (1) heavy proteinuria (>3 g/d), (2) reduced serum albumin concentration, and (3) edema. In comparison with nephritic syndrome, nephrotic patients may exhibit an otherwise bland urinary sediment with little hematuria. Nephrotic syndrome can occur at any age from neonate to elderly. Although the underlying kidney disease tends to vary with age, in all cases the lesion is within the glomerulus and is associated with damage to the specialized visceral epithelial cells, the podocytes (see earlier). Proteinuria is a consequence of a reduction in the charge-selective properties of the filtration barrier, particularly the GBM, and of alterations in the slit diaphragms of interdigitating foot processes of adjacent podocytes (Figure 48-15).[91,365] Following the discovery of numerous genes and podocyte proteins that make up the slit diaphragm, the pathophysiology of glomerular proteinuria is beginning to be elucidated. The primary glomerular diseases that cause nephrotic syndrome have recently been termed *podocytopathies,* and a new

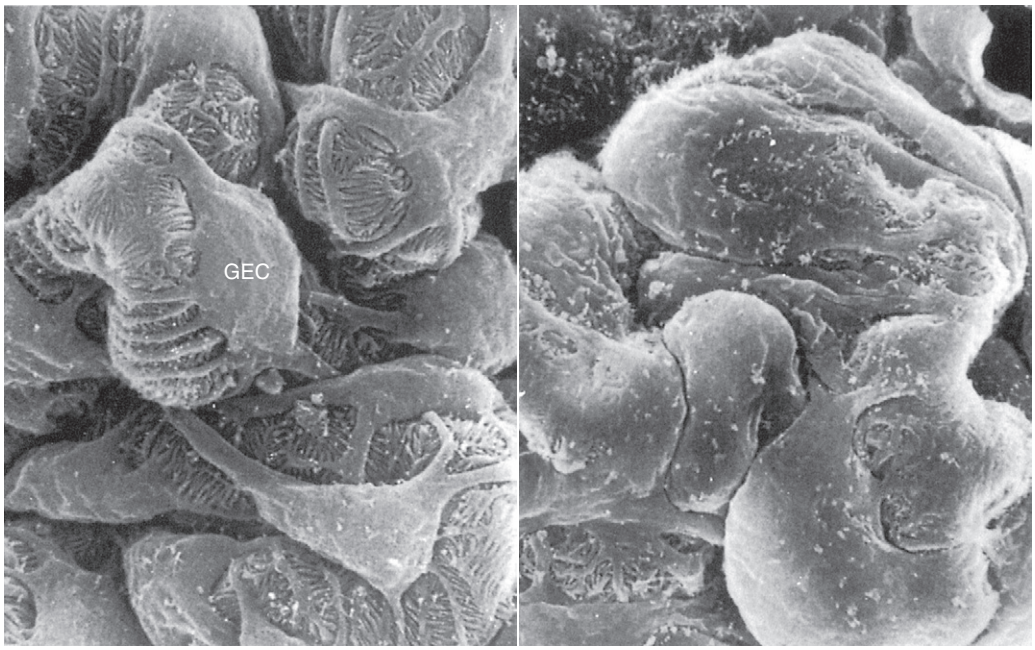

Figure 48-15 Graphic example of glomerular changes in nephrotic syndrome. Scanning electron microscopic view of glomerular epithelial podocytes from a vehicle-treated rat *(left)* and a puromycin aminonucleoside (PAN)-treated (180 mg/kg body wt) rat *(right)*. Note the extensive loss of podocyte foot processes, which occurs in response to PAN-induced nephrotic syndrome and illustrates the major cellular changes that can occur in nephrotic syndrome. *GEC,* Glomerular epithelial cell. *(From Ricardo SD, Bertram JF, Ryan GB: Antioxidants protect podocyte foot processes in puromycin aminonucleoside–treated rats. J Am Soc Nephrol 1994;4:1974-86.)*

classification scheme has been proposed that will identify diseases based on both morphology and etiology.[20]

The most common causes of nephrotic syndrome are minimal change disease (MCD), focal segmental glomerulosclerosis (FSGS), and membranous nephropathy (see later). Secondary causes are discussed separately and include diabetic nephropathy, amyloidosis, and SLE. A kidney biopsy is generally undertaken in all adult patients who present with nephrotic syndrome. Diagnosis is made only on kidney biopsy, and a biopsy is generally undertaken in all adult patients who present with nephrotic syndrome. Nephrotic syndrome is associated with significant morbidity regardless of cause, and patients with the disease have increased cardiovascular disease as the result of marked hyperlipidemia and increased risk of infection and thromboembolic disease. Between 10 and 40% of patients with nephrotic syndrome develop evidence of arterial and venous thromboemboli, particularly deep vein and renal vein thrombosis. Renal vein thrombosis may be unilateral or bilateral and may extend into the inferior vena cava. However, most cases of renal vein thrombosis have an insidious onset and produce no symptoms. Infrequently, patients develop acute renal vein thrombosis and present with signs of renal infarction, including flank pain and microscopic or gross hematuria. In addition, AKI may supervene in cases of nephrotic syndrome (Box 48-5), and prolonged proteinuria with a poor response to treatment may lead to kidney failure.

The management of nephrotic syndrome depends on the underlying glomerular lesion, although general principles apply in all cases (Box 48-6). In addition to general measures, specific treatment targeted at inducing remission from proteinuria usually requires a combination of immunosuppressive drugs, including corticosteroids and cytotoxic drugs.

MCD is the most common cause of nephrotic syndrome in children and young adults. The incidence of MCD is estimated at 1 to 5 cases per 100,000 children per year. It typically presents with severe edema and hypoalbuminemia, and urine testing confirms heavy proteinuria. Kidney function is normal, with little evidence of a reduced GFR. MCD does not progress to kidney failure, except in some cases of severe refractory disease that may be complicated by glomerular scarring lesions. Nephrotic syndrome in a noninfant child is assumed to be caused by MCD, and a kidney biopsy generally is not performed, because the condition typically is responsive to a trial of corticosteroids with remission within 2 weeks. Following the disappearance of proteinuria, or 1 week after remission is induced, the corticosteroid dose can be reduced and tapered slowly. An attempt to stop treatment may be indicated after 8 weeks. Longer duration of corticosteroid therapy significantly reduces the risk of relapse, and many centers will treat for a minimum of 12 weeks, particularly with a first episode of steroid-responsive nephrotic syndrome. Around 60% of steroid-responsive patients experience multiple relapses. Some of these patients can be managed with low-dose corticosteroids given daily or on alternate days, but relapses do occur, especially if intercurrent infection is present. In addition to the comorbidity associated with nephrotic syndrome, the burden of long-term exposure to corticosteroids and cytotoxic drugs has to be considered. Cyclophosphamide, azathioprine, and cyclosporine are reserved for refractory cases and can be used as corticosteroid-sparing agents with the aim of reducing relapse rates. Treatment with cyclophosphamide is limited to 8 to 12 weeks to reduce risk of gonadal toxicity, and the cumulative dose threshold whereby this risk increases significantly is 200 mg/kg in children.

The histologic lesion is by definition "minimal" when viewed on light microscopy. However, electron microscopy confirms disruption to the epithelial surface of the glomerular capillary. Podocyte foot processes are detached (effaced) from the GBM, conferring absence of the slit diaphragm, and therefore the final barrier to filtration fails (see Figure 48-15). The glomerular architecture is restored following prompt treatment with high-dose corticosteroids. In MCD, the onset of nephrotic syndrome is often preceded by an infection or allergic reaction, and it has been proposed that nephrotic syndrome may be the result of an exaggerated response to normal physiologic and immune mechanisms that increase proteinuria during infection. MCD does occur in adults who present with nephrotic syndrome. MCD occasionally complicates NSAID ingestion, and secondary MCD has been

BOX 48-5 Causes of AKI in Nephrotic Syndrome

- Acute tubular necrosis, usually in MCD and patients >50 years of age
- Minimal change disease with acute interstitial nephritis induced by NSAIDs
- Tubular injury in collapsing FSGS—idiopathic or associated with HIV infection
- Crescentic glomerulonephritis superimposed upon membranous nephropathy

FSGS, Focal segmental glomerulosclerosis; *HIV,* human immunodeficiency virus; *MCD,* minimal change disease; *NSAIDs,* nonsteroidal anti-inflammatory drugs.

BOX 48-6 Management of Nephrotic Syndrome

- Low-sodium diet
- Protein intake of 1.0 g/kg/d
- Fluid management: usually includes loop diuretics
- Thromboembolism prophylaxis: may include formal anticoagulation in high-risk patients (serum albumin <20 g/L or in nephrotic syndrome due to membranous nephropathy or mesangiocapillary glomerulonephritis)
- Vigilance for infection
- Treatment of hyperlipidemia with 3-hydroxy-3-methylglutaryl-Co-enzyme A (HMG)-CoA-reductase inhibitors (statins)
- Treatment of hypertension, primarily with RAAS blockade
- Supportive treatment of AKI
- Education and psychologic support for patients and relatives

AKI, Acute kidney injury; *RAAS,* renin-angiotensin-aldosterone system.

described in patients with malignancy (particularly Hodgkin's lymphoma).

Focal segmental glomerulosclerosis (FSGS) is the most important cause of the nephrotic syndrome in adults and remains a frequent cause in children and adolescents, particularly in the United States, Brazil, and many other countries.[161] Genetic studies in children with familial nephrotic syndrome have identified mutations in genes that encode important podocyte proteins.[44,228] Nephrin was the first slit diaphragm protein identified, and mutations in this transmembrane protein cause congenital (Finnish-type) nephrotic syndrome, which occurs with a frequency of 1/8200 live births in Finland. Among children with inherited nephrotic syndrome, other podocyte proteins (podocin, α-actinin 4, CD2-AP) have been described; all proteins are crucial to the interaction of the slit diaphragm with the podocyte cytoskeleton. Compelling evidence advocating a soluble permeability factor has been proposed as causing nephrotic syndrome in FSGS. Evidence includes experience in kidney transplantation, whereby FSGS may recur within hours of transplantation of a normal kidney into a recipient with FSGS.[387] The nature of the permeability factor remains unknown, but it can be removed by immunoabsorption to protein A and plasma exchange prior to transplantation.

Several disease processes lead to the description of FSGS on kidney biopsy and are shown in Box 48-7. Proteinuria in secondary FSGS, as in primary FSGS, reflects epithelial injury, although the mechanism is different. Following nephron loss, the remaining glomeruli undergo hypertrophy. Because podocytes are usually in a state of terminal differentiation and unable to replicate, the density of available foot processes to cover the enlarged glomerular surface is decreased. Focal areas of denudation from the GBM ensue, leading to proteinuria. Corticosteroids and other immunosuppressant drugs are not recommended for secondary forms of FSGS or for congenital forms. The treatment of primary disease causing nephrotic syndrome is typically a course of high-dose corticosteroids given for at least 6 months as tolerated. Remission of nephrotic syndrome is characterized by absence of proteinuria, loss of edema, and normalization of serum albumin concentration.

BOX 48-7 Causes of Secondary Focal Segmental Glomerulosclerosis

Glomerular hypertrophy/hyperfiltration
- Unilateral renal agenesis
- Massive obesity

Scarring due to previous injury
- Focal proliferative glomerulonephritis
- Vasculitis
- Lupus

Toxins (pamidronate)

Human immunodeficiency virus–associated nephropathy (HIVAN)

Heroin nephropathy

Membranous Nephropathy

The term *membranous nephropathy* reflects the primary histologic change noted on light microscopy: basement membrane thickening with little or no cellular proliferation or infiltration. Electron microscopy (EM) reveals electron-dense deposits across the glomerular basement membrane. The immune nature of these deposits is confirmed by immunostaining with immunoglobulins, and complement components are readily demonstrated. Idiopathic membranous nephropathy is a common cause of nephrotic syndrome, accounting for approximately 30% of adult cases. The clinical features are variable and are classically described as follows ("rule of thirds"): (1) a third of cases undergo spontaneous remission of proteinuria and recovery of kidney function; (2) a third of cases have nonprogressive disease but evidence of ongoing proteinuria; and (3) a third of cases continue to exhibit nephrotic syndrome and are at high risk of progressive kidney failure.

The clinical course therefore is difficult to predict at the onset of the disease, although 40% of patients develop kidney failure after 10 years. Patients generally are observed for 6 months to assess the likely natural history of the condition and are treated generically. In progressive cases and in those who have evidence of nephrotic syndrome for at least 6 months, a course of immunosuppressive drugs is indicated. Typical immunosuppressive schedules include high-dose corticosteroids, calcineurin inhibitors such as cyclosporine, and cytotoxic drugs (chlorambucil and cyclophosphamide).[350]

Secondary causes of membranous nephropathy are associated with a wide spectrum of diseases, including SLE, hepatitis B, falciparum malariae, malignancy, and drugs (e.g., gold, penicillamine, captopril). In comparison with idiopathic disease, the clinical outcome depends on the underlying disease process. Underlying malignancy has been thought to be responsible for up to 5 to 10% of cases of membranous nephropathy in adults; the risk is highest in patients older than 60 years of age. A solid tumor (such as carcinoma of the lung, colon, or prostate) is most often involved and usually is clinically obvious.[253]

Rapidly Progressive Glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is a heterogeneous group of disorders characterized by a fulminant clinical course that leads to kidney failure in only weeks or a few months. The clinical picture of RPGN is often preceded by a systemic illness for several months associated with general malaise, weight loss, breathlessness, upper respiratory tract abnormalities, and skin changes. Clinical examination may reveal nailfold infarcts affecting the fingernails and toenails and palpable purple lesions on the skin of the legs. In severe cases, a renal-pulmonary syndrome supervenes with kidney failure and alveolitis with associated pulmonary hemorrhage. In some cases, the condition may be limited to the kidneys (renal-limited vasculitis).

These syndromes are often characterized by focal glomerulonephritis with glomerular ischemia, infarction, and tissue

death (necrosis). Following release of inflammatory cytokines and chemokines from the necrotic capillaries the epithelial cells of Bowman's capsule proliferate. These cells lie on top of adjacent cells and form a partial circle around the inner rim of Bowman's capsule that is referred to as a *crescent*. Proliferating epithelial cells and macrophages eventually compress the glomeruli and obstruct the proximal convoluted tubules, thus severely compromising nephron function.

RPGN may be classified as idiopathic kidney disease or as a disease secondary to other conditions, such as infectious disease, multisystem disease, and occasionally an adverse reaction to medication. Anti-GBM antibodies may be present along the GBM in anti-GBM disease. Most commonly, however, there is no immunoglobulin deposition within the glomerulus (pauci-immune). Approximately 80% of patients with active pauci-immune necrotizing and crescentic glomerulonephritis have been shown to possess antineutrophil cytoplasmic antibodies (ANCAs), irrespective of the presence or absence of a concomitant systemic vasculitis. This strong association has allowed serologic discrimination of this type of glomerulonephritis from other types of RPGN. Wegener's granulomatosis, microscopic polyangiitis, and Churg-Strauss syndrome are small-vessel vasculitides characterized by an association with ANCAs.

ANCAs were first reported in 1982 in patients with pauci-immune serologic glomerulonephritis.[93] Three years later, ANCAs were detected by indirect immunofluorescence on human neutrophils in patients with active Wegener's granulomatosis.[449] Since 1989, two subtypes of ANCA have been described: cytoplasmic (C-ANCA) and perinuclear (P-ANCA), reflecting the patterns observed by indirect immunofluorescence microscopy using alcohol-fixed neutrophils as a substrate.[470] C-ANCAs are directed toward a plasma proteinase (PR3) in neutrophil primary granules and are associated with Wegener's granulomatosis, whereas the P-ANCA target antigen is usually myeloperoxidase (MPO) and is associated with microscopic polyangiitis.[113,322] Immunoassays have been used to measure anti-PR3 and anti-MPO antibody titers. Vasculitis or angiitis is an inflammatory reaction in the wall of any blood vessel that can have diverse clinical presentations. The exact sequence of events that triggers perivascular inflammation leading to injury is unclear, but ANCAs have been identified that have at least diagnostic and prognostic usefulness. ANCAs appear in the plasma of almost all patients with active and generalized disease and are useful in diagnosis of the disease and in monitoring response to therapy, because a falling titer of ANCA suggests response. Autoantibodies of other specificities in rheumatoid arthritis, SLE, and inflammatory bowel disease may mimic the P-ANCA pattern, and in isolation, the finding of P-ANCA has a low specificity for vasculitis. The International Consensus Statement on Testing and Reporting of Antineutrophil Cytoplasmic Antibodies (ANCA) was developed to optimize ANCA testing.[386] It requires that all sera are tested by indirect immunofluorescence examination of peripheral blood neutrophils and, where there is positive fluorescence, by immunoassays for antibodies against PR3 and MPO. Following this protocol, false-positive rates of less than 1% can be achieved. Testing will be further improved by standardization and use of common immunoassay methods.

Rapidly progressive glomerulonephritis accounts for 15% of patients presenting to specialist nephrology units for renal replacement therapy and therefore is an important disease category to be aware of, because if treatment is initiated early, independent kidney function can be restored, particularly if active lesions are seen on biopsy.[173] In addition to measurement of ANCA, C-reactive protein (CRP) is extremely helpful in assessment of the acute-phase reaction in active disease processes and is critical in helping to define disease remission. In patients in whom the CRP has returned to normal, disease remission is indicated; this prompts the clinician to reduce immunosuppressant treatment doses.[385]

Highly intensive immunosuppressive schedules are commenced in patients who present with RPGN. This *induction* phase of treatment is continued until the disease has remitted. Once remission is attained, a longer maintenance phase of treatment with less intensive schedules is commenced. In cases with a high index of suspicion on clinical grounds, treatment should begin empirically. Usually the diagnosis is made following a kidney biopsy and an ANCA or anti-GBM antibody test. High-dose oral prednisolone and oral or intravenous cyclophosphamide are given as standard baseline treatment. Adjunctive treatments that may be used routinely in severe cases include pulses of intravenous methylprednisolone (1 g/d for 3 days) or a series of plasma exchanges.[204] The rationale for these approaches is to switch off production of the antibody and attenuate the proinflammatory response to tissue damage. Patients are closely followed for many months for evidence of disease activity and signs of treatment-related toxicity. This involves monitoring of kidney function, full blood count, ANCA serology, and anti-MPO/PR3 titer, as well as CRP. Following remission of active disease, drug doses are tapered, and cyclophosphamide may be exchanged for azathioprine. Serologic testing for ANCA and measurement of CRP are performed prior to immunosuppressant dose reduction to ensure that the disease activity has abated. Plans for long-term follow-up are made, and treatment is expected to be ongoing for at least 3 to 5 years. Relapses may occur as immunosuppression is reduced or withdrawn. The untreated mortality of ANCA-associated vasculitis is 90% at 1 year. With current management strategies, the mortality rate has fallen to 20 to 30%. The elderly are most susceptible both to the disease and to treatment-related morbidities, particularly infection. Patients who require dialysis or ventilatory support for pulmonary involvement have a higher mortality rate.

Anti-GBM disease (Goodpasture's disease) affects 0.5 to 1 per million population per year in the United Kingdom. Serologic detection of anti-GBM antibodies is helpful for assisting diagnosis in cases of RPGN. In this process, the antigens are well characterized and the antibody is directed at the α3 chain of type IV collagen. The disease is characterized by a relative lack of prodromal illness; a very rapid deterioration in kidney function; and a poor prognosis if oliguria or anuria

should develop. The kidney biopsy typically demonstrates crescents in all the glomeruli ("100% crescents"), and each crescent is at a similar stage of development. The GBM stains positively with anti-GBM antibodies upon immunostaining in a linear pattern. In addition to renal involvement, lung basement membrane can be affected, leading to pulmonary hemorrhage (Goodpasture's syndrome). The environment plays a critical role in determining whether anti-GBM antibodies cause lung injury, because pulmonary hemorrhage occurs only in current cigarette smokers.

Systemic Lupus Erythematosus (SLE)

SLE is a chronic inflammatory disease of unknown cause that can affect the (1) skin, (2) joints, (3) kidneys, (4) lungs, (5) nervous system, (6) serous membranes, and/or (7) other organs of the body. The clinical course of SLE is variable and may be characterized by periods of remissions and chronic or acute relapses. Women, especially in their 20s and 30s, are affected more frequently than men. Renal involvement, termed *lupus nephritis,* occurs in up to 60% of adults with SLE. Lupus nephritis is especially common in African American and Hispanic patients in the United States.[21] Lupus nephritis may present variably from incidental hematuria and proteinuria, nephrotic syndrome, or a fulminating RPGN. Most patients with SLE (≈75%) develop an abnormal urinalysis or impaired kidney function during the course of the disease. A pathologic description is required to stage the disease process in lupus nephritis. The classification of lupus nephritis has been revised, and treatment is targeted depending on the stage of disease.[462] In general terms, pathologic findings include a spectrum from focal mesangial proliferation to diffuse global necrotizing glomerulonephritis. Membranous nephropathy may also be present. Detection of lupus nephritis involves urine testing for blood and protein and tests of kidney function. In addition, serologic testing for autoantibodies to nuclear antigens and measurement of complement components C3 and C4 are undertaken (Table 48-14). Significant hypocomplementemia and elevated anti-DNA titers suggest active disease. Combined use of corticosteroids and intravenous or oral cyclophosphamide has been the conventional treatment for diffuse proliferative lupus nephritis since the 1970s.[419] Treatment duration with cyclophosphamide is limited because of severe toxicity, including gonadal toxicity, hemorrhagic cystitis, bone marrow suppression, and carcinogenicity. Data from a 2009 study suggest that mycophenolate mofetil and corticosteroids can be as effective, but not superior to, intravenous cyclophosphamide for induction treatment for lupus nephritis.[9]

TABLE 48-14 Laboratory Investigation of Vasculitic Syndromes

Disease	Serologic Test	Antigens	Associated Laboratory Features
SLE	ANA including antibodies to dsDNA and ENA [including SM, Ro (SSA), La (SSB), and RNP]	Nuclear antigens	Leukopenia, thrombocytopenia, Coombs' test Complement activation: low serum concentrations of C3 and C4 Positive immunofluorescence using *Crithidia luciliae* as substrate Antiphospholipid antibodies (i.e., anticardiolipin, lupus anticoagulant, false-positive VDRL)
Goodpasture's disease	Anti-GBM antibody	Epitope on noncollagen domain of type IV collagen	
Small Vessel Vasculitis			
Microscopic polyangiitis	P-ANCA	MPO	↑ CRP
Wegener's granulomatosis	C-ANCA	Proteinase 3 (PR3)	↑ CRP
Churg-Strauss syndrome	P-ANCA in some cases	MPO	↑ CRP and eosinophilia
Henoch-Schönlein purpura	None		
Cryoglobulinemia			Cryoglobulins, rheumatoid factor, complement components, hepatitis C
Medium Vessel Vasculitis			
Classical PAN	None		↑ CRP and eosinophilia

ANA, Antinuclear antibodies; *ANCA,* antineutrophil cytoplasmic antibody; *C-ANCA,* cytoplasmic ANCA; *CRP,* C-reactive protein; *dsDNA,* double-stranded DNA; *ENA,* extractable nuclear antigens; *GBM,* glomerular basement membrane; *MPO,* myeloperoxidase; *P-ANCA,* perinuclear ANCA; *PAN,* polyarteritis nodosa; *RNP,* ribonucleoproteins; *SLE,* systemic lupus erythematosus; *VDRL,* Venereal Disease Research Laboratory.

Acute Nephritic Syndrome

This disorder is characterized by rapid onset of hematuria, proteinuria, reduced GFR, and sodium and water retention, with resulting hypertension and localized peripheral edema. Congestive heart failure and oliguria may also develop. In a number of patients with the acute nephritic syndrome, the pathologic process is related to recent group A α-hemolytic streptococcal infection of the pharynx or, less commonly, the skin. Only certain strains of streptococci are capable of inducing acute nephritis. A latent period averaging about 2 weeks exists between the time of streptococcal infection and clinical evidence of nephritis. In patients suspected of having acute poststreptococcal glomerulonephritis, evidence of recent infection may be found in increased titers of antibodies to streptococcal extracellular products: antistreptolysin O, antihyaluronidase, and anti–deoxyribonuclease-B. Serial measurements that document rising antibody titers against streptococcal antigens provide stronger evidence of recent infection than is provided by a single determination. Most patients have moderate reductions in total hemolytic complement activity (CH_{50}) and in the C3 component of the complement cascade. Typical poststreptococcal glomerulonephritis is now rare in developed countries, and a kidney biopsy may be performed in adult cases to establish the diagnosis pending serologic test results. A kidney biopsy of patients with poststreptococcal glomerulonephritis reveals diffuse involvement with enlarged hypercellular glomeruli infiltrated by polymorphonuclear leukocytes and monocytes. Electron microscopy reveals deposits, presumably immune complexes, on the epithelial side of the basement membrane. Abnormal laboratory results are usually present early in the course of acute nephritis. Hematuria, which may be gross ("cola-colored" urine) or microscopic, and proteinuria, usually <3 g/d, are almost always present. Red blood cell casts are highly suggestive of glomerulonephritis. These casts are commonly present in urine but are observed only if the specimen is fresh and acidic, centrifugation is light, and sediment (after decantation) is resuspended gently. Large numbers of hyaline and granular casts are common; waxy casts suggest a chronic process and should raise the possibility of acute exacerbation of a preexisting disease. Persistent and severe depression of C3 concentrations should suggest membranoproliferative glomerulonephritis, SLE, endocarditis, or other forms of sepsis. Although depressed concentrations of complement imply disease activity, they are not useful for grading the severity or determining the prognosis of the illness.

Other causes of acute nephritis include reactions to drugs, acute infection of the kidneys, systemic disease with immune complexes such as SLE, bacterial endocarditis, and finally disease in which the antigen is unknown but is possibly related to antecedent viral infection.

Interstitial Nephritis

A variety of chemical, bacterial, and immunologic injuries to the kidney may cause generalized or localized changes that primarily affect the tubulointerstitium rather than the glomerulus. This group of disorders is characterized by alterations in tubular function that, in advanced cases, may cause secondary vascular and glomerular damage. Interstitial nephritis, including chronic pyelonephritis, is the primary diagnosis, accounting for 3.8% of patients admitted onto dialysis programs in the United States[447] and 6.4% in the United Kingdom.[7] *Pyelonephritis,* the term associated with a bacterial infection that causes this kind of damage, is the most common of the interstitial nephritides.[435] Both acute and chronic types of pyelonephritis may occur; the acute type is most commonly associated with urinary tract infection (UTI). Acute pyelonephritis may develop into chronic pyelonephritis, usually as a result of a renal tract abnormality such as abnormal urethral valves. Interstitial nephritis is also associated with proteinuria that is less severe than in glomerular disease. In addition to conventional pyelonephritis, interstitial nephritis may present in acute and chronic forms and has many causes. Acute allergic interstitial nephritis presents with AKI and marked inflammation of the interstitium. Lymphocytes, polymorphonuclear cells, and eosinophils are prominent. The incidence is variable and depends on kidney biopsy practice. It may account for up to 7% of cases of AKI when an intrinsic kidney disease is diagnosed as opposed to purely toxic and/or ischemic acute tubular damage.[355] Higher values are likely in older people because of the increased incidence of drug reactions. A drug hypersensitivity reaction is the most common form of acute interstitial nephritis. Urinary findings may be normal, or decreased proteinuria and eosinophils may be seen on light microscopy. More than 100 different drugs have been implicated, but NSAIDs and β-lactam antibiotics are the drugs most commonly identified.[141] Nephrotic syndrome may accompany an acute interstitial nephritis associated with NSAIDs. Treatment is directed at removing any causative agent. Steroids are used to promote early resolution of the clinical course, although patients can develop chronic interstitial fibrosis.[397]

Sarcoidosis is a multisystem disorder associated with chronic granulomatous interstitial nephritis. Biochemical abnormalities include hypercalcemia, hypercalciuria, and increased serum ACE activity.[372] The condition may be effectively treated with steroids.

Prostaglandins and NSAIDs in Kidney Disease

NSAIDs block synthesis of prostaglandins by cyclooxygenase (COX) enzymes. Two isoforms of COX synthesize prostaglandins. COX-1 is a resident or constitutive form, and COX-2 is an inducible form that increases with disorders of inflammation.[399] NSAIDs are nonspecific inhibitors of both COX isoforms. Analgesic nephropathy is a common cause of kidney failure in many countries, causing 10% of such failures in Switzerland and Australia, but it is essentially a preventable condition for which monitoring of kidney function has proved useful. The incidence of this disease has decreased over the past decade as awareness has improved, and phenacetin was withdrawn from over-the-counter analgesic mixtures. In the United States, 1 in 5 citizens (50 million) report that they use an NSAID for an acute complaint.[468] Although most healthy individuals tolerate NSAIDs well, a study of the

very old (mean age, 88 years) demonstrated significant reduction of GFR within 1 week of ingestion of NSAIDs.[159] Renal blood flow, particularly within the medulla, is dependent on systemic and local production of vasodilatory prostaglandins, and analgesic-related kidney damage is seen mostly within the medulla, with late changes causing papillary necrosis and interstitial fibrosis. Hyperkalemia can develop as a consequence of reduced GFR or secondary to hyporeninemic hypoaldosteronism. In addition, NSAIDs can rarely cause nephrotic syndrome and drug-related acute allergic interstitial nephritis.

Monoclonal Light Chains and Kidney Disease

Immunoglobulin (Ig) molecules are formed in secretory B cells. The heavy chains α, β, γ, δ, and ε identify the antibody isotype, and light chains include peptide molecules that are called kappa (κ) and lambda (λ). A complete Ig molecule will contain either κ or λ. The proportion of Ig containing κ versus λ is 3:2 in humans. The molecular weight of light chains is approximately 23 kDa. Excess production of light over heavy chains appears to be required for efficient Ig synthesis, resulting in the release of free light chains into the circulation. In normal individuals, the small quantity of circulating polyclonal light chains is filtered by the glomerulus, and ≈90% is reabsorbed in the proximal tubule and degraded by proteases. Increased concentrations of filtered light chains lead to alteration in the proximal tubule cells, including prominent cytoplasmic vacuolation, loss of the microvillous border, and epithelial cell exfoliation.[382]

Light chains can deposit in the kidney as casts, fibrils, and precipitates or crystals, giving rise to a spectrum of disease including cast nephropathy, amyloid, light chain deposition disease, and the Fanconi syndrome. However, not all patients with excessive production of monoclonal light chains develop disease. Other promoters include dehydration, hypercalcemia, contrast medium, and NSAIDs. Evidence suggests that light chains are directly pathogenic.[415] The pattern of human renal injury associated with monoclonal light chains can be reproduced in mice injected intraperitoneally with large quantities of light chains isolated from patients with myeloma or light chain–associated amyloid (AL-amyloid).[237]

Myeloma or multiple myeloma is a neoplastic proliferation of secretory B cells (plasma cells) that produce excessive amounts of a monoclonal Ig (paraprotein)—so-called M protein, because of the characteristic peaks obtained from serum protein electrophoresis on agarose gel. A serum IgG greater than 2 g/dL (often much higher), or IgA or IgM greater than 10 g/dL, or the finding of an IgD or IgE paraprotein at any concentration suggests a malignant paraproteinemia. The clonal production of immunoglobulin is associated with excess or pure light chain production. In multiple myeloma, complete monoclonal Igs (usually IgG or IgA) are accompanied in the plasma by variable concentrations of free light chains that appear in the urine as Bence Jones proteins, named after Henry Bence Jones, who first described these in 1848. M proteins and light chains can be identified in the blood and/or the urine in 98% of patients with myeloma using protein electrophoresis and immunofixation. Immunoparesis, with reduction in nonparaprotein Ig, is characteristic of myeloma. The incidence of myeloma is 40 new cases per million population per year.[473] Myeloma is more common in men than in women, and the median age at presentation is 65 years.[242] It is the second most commonly diagnosed hematologic malignancy, with an annual incidence of 15,000 and a prevalence of 45,000 in the United States.[408]

Impairment of kidney function at presentation occurs in almost 50% of myeloma patients.[98,473] Although most recover following treatment for other factors contributing to renal impairment (e.g., dehydration, hypercalcemia, infection, nephrotoxic drugs), about 10% have severe renal involvement caused by the effects of light chains on the kidney. Severe kidney failure may occur in myeloma following deposition of light chains within tubules—so-called cast nephropathy (myeloma kidney). Cast nephropathy can present acutely, again precipitated by dehydration, hypercalcemia, or NSAIDs, or de novo in the absence of these factors. It occurs when the reabsorptive capacity of proximal tubule cells is exceeded by overproduction of light chains. In myeloma, light chain excretion can exceed 20 g/d. Casts are large and numerous and are found predominantly in the distal convoluted tubule and collecting ducts, causing obstruction to urine flow. They have a hard and fractured appearance with lamination visible on histologic examination of kidney biopsy specimens. Immunofluorescence confirms that casts are composed of monoclonal light chains and THG. Casts usually are stained exclusively with anti-κ or anti-λ antibodies. At biopsy, there is often an interstitial inflammatory infiltrate, and fibrosis and tubular atrophy can be extensive. Not all light chains induce cast formation. The ability of light chains to form casts is based on binding to THG.[373] Light chains interfere with proximal tubule cell function, and this promotes delivery to the distal tubule. A specific binding site for light chains has been identified on THG, and light chains with high affinity appear to be more likely to produce obstructing intratubular casts.[191]

Physicochemical determinants of binding of light chains to THG include the isoelectric point (pI) of the light chain. Those molecules with a pI above 5.1 (above the tubular fluid pH in the distal nephron) will have a net positive charge that may promote binding via charge interaction to anionic THG (pI, 3.2). Urinary alkalinization reduces binding of light chains to THG in animal models.[183] Nephrotoxicity may be determined by the ability of light chains to self-associate, leading to the formation of high molecular weight aggregates that are more likely to deposit in tissues, particularly in the setting of volume depletion.

The clinical features of myeloma include a normochromic normocytic anemia, bone pain with pathologic fractures (back or chest rather than extremities), and hypercalcemia in 20% of patients. Severe kidney failure may dominate the clinical picture, and 84% of patients studied retrospectively with severe renal impairment required dialysis.[197] Only 15% of these patients regained independent kidney function. Treatment has two main objectives: therapy is targeted at

predisposing factors for cast nephropathy as indicated, and chemotherapy is used to reduce the production of monoclonal antibodies and light chains from monoclonal plasma cells. Supportive therapy includes increased fluid intake where permissible to 3 L/d, treatment of hypercalcemia, treatment of infection, and withdrawal of NSAIDs. Anemia can be addressed by replacement with blood products or the use of ESAs. Skeletal complications are common in myeloma, and pathologic fractures occur in the setting of apparently trivial injury. Increased osteoclastic activity is mediated by IL-1, IL-6, TNF, and macrophage inflammatory protein-1α.[167] Bisphosphonates, which are specific inhibitors of osteoclastic activity, have beneficial effects in myeloma.[25] Bisphosphonates may exert direct antitumor effects on myeloma because they induce significant expansion of γδ-T cells in peripheral blood mononuclear cells, which exhibit specific cytotoxicity against myeloma cell lines in vitro.[241]

Chemotherapy can be considered as part of urgent treatment for patients with kidney involvement in myeloma. The aim is to reduce the concentration of free light chains. Chemotherapy with alkylating agents, such as melphalan, and combination treatment with cytotoxic agents and dexamethasone are the preferred initial treatment regimens, and doses and schedules are adjusted depending on the lrate of GFR. Combination chemotherapy results in partial responses but only rarely in complete remission.[4,155,277]

The disease is incurable and eventually relapses. Poor prognostic features in myeloma include increased serum concentrations of β_2-microglobulin, CRP, and lactate dehydrogenase, and abnormal cytogenetics (especially deletion of 13q). With modern, intensive therapy, including autologous hematopoietic stem cell transplantation, the median survival is 5 years. Refractory disease is associated with a short survival and requires salvage therapy. Development of the newer agents bortezomib and lenalidomide, in addition to the antiangiogenesis compound thalidomide,[328,409] has improved the outlook for relapsed disease. The rationale for use of thalidomide comes from observations that prominent bone marrow vascularization occurs in myeloma and correlates with markers of poor prognosis, and that plasma concentrations of angiogenic cytokines are elevated in myeloma. Clinical trials of thalidomide in myeloma were first described in 1965, and reduction in the paraprotein load and improved 1-year survival have been reported.[409,484] Significant side effects include thromboembolic disease and peripheral neuropathy, and the agent is highly teratogenic. Bortezomib is an inhibitor of the 26S proteosome (an intracellular organelle responsible for protein degradation). It causes rapid clonal cell reduction by inducing apoptosis, reversing drug resistance in myeloma cells, and blocking angiogenesis in vitro,[181] and has been demonstrated to be superior to dexamethasone for relapsed disease.[368]

In addition to chemotherapy, plasma exchange is often used in the treatment of myeloma cast nephropathy to acutely reduce free light chain load. There is a paucity of trial data,[209,492] but one prospective study of 29 patients demonstrated increased 1-year survival following plasma exchange treatment. Several early deaths in the control group render the data difficult to interpret.[492] Further study of 21 patients with myeloma and AKI demonstrated advantages of plasma exchange in patients with kidney failure severe enough to require dialysis.[209] The U.K. Renal Association and the U.K. Myeloma Forum are currently recruiting almost 300 patients to a national study of plasma exchange in myeloma cast nephropathy (Myeloma Renal Impairment Trial-MERIT). However, a study from Canada of 104 patients presenting with myeloma and AKI, randomized to five to seven plasma exchange treatments in addition to conventional treatment, showed no significant difference in the composite outcome of death, dialysis dependence, and GFR less than 30 mL/min/1.73 m^2 at 6 months.[75]

In cast nephropathy, glomerular filtration of *intact* light chains may occur. Excess production of monoclonal light chains (or rarely heavy chains) causes disorders in which *fragments* are deposited in the kidney and other tissues. Amyloidosis is a condition characterized by extracellular deposition of fibrils in an antiparallel β-pleated sheet arrangement. The type of amyloid is defined by the abnormal protein deposited. For example, in "primary amyloid" or "AL-amyloid," fibrils derived from the variable region of light chains are deposited in the tissue. Seventy-five percent are derived from the λ-light chain. Because it is the variable region that is deposited, it is often difficult to assess with immune reactants. Only 50% of AL-amyloid cases are stainable with commercially available antisera to κ and λ. The deposits are fibrillar in nature and bind to Congo red. Amyloid fibrils also bind to the serum amyloid P component, allowing noninvasive evaluation by radiolabeled serum amyloid P scanning.[174] The diagnosis of AL-amyloid can be suspected from the clinical findings of nephrotic proteinuria (>3.5 g/d) and serum or urinary paraprotein. However, 10 to 15% of patients with primary amyloid do not have a detectable serum or urinary paraprotein. Demonstration of a clonal excess of plasma cells on bone marrow biopsy may help with the diagnosis in those without detectable paraprotein. AL-amyloid has a poor prognosis, and mean survival is 18 months, with 50% of patients dying from cardiac failure. Treatment options are unsatisfactory, although prednisolone and melphalan may be tried.[243,244,410] Circulating free light chains can be detected by a nephelometric immunoassay in most patients with AL-amyloid, and patient outcome following treatment is improved if the concentration of free light chains can be reduced by 50%.[245]

The French Myeloma Group has published results of bone marrow or stem cell transplantation in AL-amyloid.[305] In a retrospective analysis of 21 patients treated with melphalan and stem cell transplantation, 43% died within 1 month, and the remainder had a favorable outcome.

Light chains may cause tubular dysfunction, especially of the proximal tubular cells. Characteristically, the light chain variable domain is resistant to degradation by proteases in lysosomes in the tubular cells. The variable domain fragments accumulate in proximal tubular cells, and clinical features include renal tubular acidosis and phosphate wasting.

Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is the second most common inherited monogenic disease (after familial hypercholesterolemia), with an estimated incidence of 1:1000. It is by far the most common inherited kidney disease; ≈12.5 million people worldwide are affected.[254] In the United Kingdom, ADPKD is responsible for 10% of new ESRD in patients younger than 65 years and 2.5% of incident patients over age 65 years.[7] The prevalence of the disease varies from 1 in 200 to 1 in 1000 of the population, but many cases, possibly up to 50%, remain clinically undiagnosed during life. Approximately 50% of ADPKD patients develop kidney failure by age 55 years.[137] It is therefore important to make the diagnosis in affected families and to monitor kidney function regularly. The intervals between estimations of GFR will depend on the stage of CKD, as with other progressive kidney diseases. An important clinical observation is the highly variable phenotype within families. The disease causes the development of multiple kidney cysts and extrarenal cysts occurring in the liver and pancreas. About 10% of ADPKD families have a strong family history of intracranial arterial aneurysm rupture. Hypertension is an early and frequent manifestation, and gross hematuria is a common presenting symptom. On the basis of effectiveness, cost, and safety, ultrasound is the imaging modality most commonly used to make the diagnosis. Screening for polycystic kidney disease is controversial, and age-dependent ultrasound diagnostic criteria for ADPKD have been developed. According to recent criteria, the presence of fewer than two renal cysts has a negative predictive value of 100% and is enough to exclude the disease in at-risk individuals who are 40 years of age and older.[342]

ADPKD is caused by mutations in the genes (*PKD1* and *PKD2*) that encode polycystin 1 and 2, which are located in primary cilia.[192,233,363] Mutations affecting *PKD1* are more prevalent than those of *PKD2* and tend to have a worse prognosis, with larger kidneys and earlier development of kidney failure. Genetic testing is not used routinely as a screening tool because current techniques identify only 70% of the hundreds of different *PKD1* and *PKD2* mutations.[152] The function of primary cilia is to act as flow sensors in the tubules, with flow-induced deformation resulting in calcium influx that leads to a proliferative cellular response mediated by intracellular cAMP. Animal model studies have demonstrated abnormalities in vasopressin and vasopressin receptors in ADPKD and these receptors may be therapeutic targets in the future. Other mutations include the *PKD2* mutation on chromosome 4 (110 kDa) and *APKD3,* for which the gene product and the chromosomal location remain unknown.[339] *PKD2* appears to be a more slowly progressive form of the disease.[172] The median age of onset of ESRD with *PKD2* is 15 years later than with *PKD1*. Also, a rare (incidence 1/20,000) autosomal recessive form of the disease may present in childhood.

Specific treatments for ADPKD in clinical practice are currently lacking. Generic treatment should include treatment of hypertension with ACE inhibitors and/or ARBs and maintaining a fluid intake of 2 to 3 L/d to reduce risk of kidney stone disease. Specific therapies, in development, are targeted at reducing cyst development and enlargement. Estimates of cyst volume can be determined using MRI techniques and changes documented over a relatively short period of time.[64] This has allowed the performance of clinical trials of novel drugs such as vasopressin receptor antagonists and other antiproliferative drugs such as sirolimus.[86]

Obstructive Uropathy

Benign prostatic hyperplasia (BPH) is one of the most common types of obstructive uropathy and is an almost universal finding in aging men.[296] For example, for men aged 50 years, the reported prevalence of BPH is 40%, and for men aged over 70 years, it is at least 75%.[27] No close relationship between the degree of enlargement and the symptoms experienced has been observed.[66] Among the most common symptoms are disorders of micturition, in particular increased frequency, and in many cases this progresses to bladder outflow obstruction. Between 10 and 40% of men with bladder outflow obstruction caused by BPH present in acute retention.[296] Approximately 5% of this group have high-pressure chronic retention of urine, which can result in upper urinary tract obstruction, and consequently CKD as a result of glomerular and tubular damage. Although medical treatments are available to decrease the rate of enlargement of the prostate, resection of the enlarged gland remains the most common surgical procedure performed on men. Urinary retention can be a chronic disorder, with acute exacerbations requiring bladder decompression by catheterization. If the obstruction is not removed by surgery, progressive kidney injury can occur as a result of backpressure along the urinary tract. It is important to identify those patients at risk of developing CKD, because failure to remove their enlarged gland can cause kidney failure. Obstruction can also occur because of kidney stones, which can cause bilateral or unilateral damage. In children, severe kidney damage can be caused by vesicoureteric reflux. One of the main complications of reflux, whether caused by obstruction or by an inherited defect, is the increased incidence of urinary tract infection. When the obstruction is relieved, the kidney often regains some independent function. A tendency toward slower progression to kidney failure has been noted in obstructive uropathy compared with other kidney diseases.

Tubular Disease

Types of tubular disease discussed in this section include renal tubular acidoses (RTAs) and inherited tubulopathies.

Renal Tubular Acidoses

The RTAs constitute a diverse group of inherited and acquired disorders affecting the proximal or distal tubule. They are characterized by a hyperchloremic, normal anion gap; metabolic acidosis; and urinary bicarbonate or hydrogen ion excretion inappropriate for the plasma pH. They may result from failure to retain bicarbonate or from inability of the renal tubules to secrete hydrogen ion. Typically, the GFRs in RTAs are normal or slightly reduced, and there is no retention of anions, such as phosphate and sulfate (as opposed to the

acidosis of kidney failure). Before attempting to understand the pathology of these conditions, the reader should ensure a good comprehension of normal renal acid-base (and ammonia) regulation (see Chapter 49).

Classification of RTAs is based on the biochemical expression and region of the defect, rather than on an understanding of the exact molecular defect. The three categories of RTA are distal (dRTA, type I); proximal (pRTA, type II); and type IV, which occurs secondary to aldosterone deficiency or resistance. [The term "type III RTA" (mixed proximal/distal defect) has been abandoned by some authors because it is not considered a separate entity.[343] It may arise as the result of a mutation in the gene coding for carbonic anhydrase type 2.[369]]

Distal RTA (Type I)

Type I dRTA occurs most often in infants (sometimes transiently) and young children, but it may also be encountered in adults, in whom it is more common than pRTA. Clinical features generally include metabolic acidosis, muscle weakness, nephrocalcinosis (i.e., diffuse, fine, renal parenchymal calcification), and urolithiasis (i.e., the formation of calculi in the urinary tract). The defect is an inability to secrete hydrogen ions in the distal tubule in the presence of a systemic acidosis. Several subtypes may be seen: urinary pH greater than 5.5 is a common feature.[343] Biochemical features typically include hypokalemia, hypocitraturia, and low urinary ammonium ion.

Classic (Hypokalemic, Secretory) dRTA. The molecular basis is not known but may include defects in the H-ATPase or H,K-ATPase transporters. dRTA may occur in association with a wide variety of conditions, including (1) an autosomal dominant condition (more common in females); (2) a sporadic, nonfamilial disease; (3) other genetic disorders (e.g., Wilson's disease); (4) dysproteinemias (e.g., hypergammaglobulinemia, cryoglobulinemia, amyloidosis); (5) disorders of calcium metabolism (e.g., primary hyperparathyroidism); and (6) a variety of autoimmune disorders (e.g., SLE, Sjögren's syndrome, primary biliary cirrhosis, thyroiditis). The pathogenesis of nephrocalcinosis and urolithiasis may be the result of decreased urinary citrate excretion secondary to cellular acidosis.

Back-leak dRTA. Although the kidney tubule retains the ability to secrete hydrogen ions, the gradient is not maintained because of back-diffusion. Typically, this occurs in association with specific drug treatments (e.g., amphotericin B).

Voltage-Dependent (Hyperkalemic) dRTA. This is due to failure to maintain an intraluminal negative potential that restricts hydrogen (and potassium) ion secretion; it may be seen with urinary tract obstruction, sickle cell disease, and treatment with amiloride or triamterene. Voltage-dependent (hyperkalemic) dRTA has many features in common with type IV RTA (see discussion later in this chapter). It is frequently associated with mild to moderate CKD, and hyperkalemia is caused in part by decreased GFR, in addition to decreased potassium excretion relative to the filtered load. In contrast to classic dRTA, potassium excretion cannot be increased in response to sodium sulfate (Na_2SO_4) administration, suggesting an isolated defect in hydrogen ion secretion. However, because hydrogen ion secretion is dependent on sodium reabsorption in the distal tubules, the primary defect could be impairment of distal tubular sodium reabsorption.

Incomplete dRTA. This is a less severe, normokalemic form, which may represent an early stage of overt dRTA. Some patients acidify urine at a submaximal rate, but at a rate that is generally sufficient to maintain acid-base balance. Potassium wasting, hypokalemia, and hyperchloremia generally are not present. However, when patients are stressed or are given an acid load test, their ability to excrete acid and to lower urine pH is suboptimal, and urinary pH may exceed 5.5.

Proximal RTA (Type II)

In pRTA the primary defect is failure of proximal tubular bicarbonate reabsorption. Proximal RTA may occur as an isolated defect (primary or sporadic type II pRTA) that occurs chiefly in infant males and is commonly associated with growth retardation, or that produces a generalized proximal tubular disorder (Fanconi syndrome). Proximal tubular bicarbonate reabsorption is still incompletely understood at the molecular level, but some candidate transporters associated with hereditary forms of pRTA are discussed by Ring and associates.[369] Most cases of pRTA are secondary to genetic disorders that affect the proximal tubule (e.g., cystinosis, fructose intolerance) or to acquired diseases including multiple myeloma, Sjögren's syndrome, and amyloidosis; heavy metal poisoning (lead, mercury, cadmium); drugs (e.g., ifosfamide); and renal transplant rejection. Drugs that act as carbonic anhydrase inhibitors (e.g., acetazolamide, topiramate) have also produced a pRTA condition. (Note that several of these disorders and agents also cause dRTA.) In pRTA the threshold for bicarbonate reabsorption is lowered (from a plasma concentration of 22 mmol/L to 15 mmol/L).[343] Once plasma bicarbonate falls below this threshold, filtered bicarbonate is reclaimed, and urinary pH generally will be less than 5.5. In pRTA, contrary to dRTA, nephrocalcinosis and nephrolithiasis are rarely observed, but metabolic bone disease is common. Other features of the Fanconi syndrome (e.g., glycosuria, aminoaciduria, hypophosphatemia, hypouricemia) are commonly present.

Selective Aldosterone Deficiency (Type IV RTA)

In type IV RTA failure of distal potassium and hydrogen ion secretion results from aldosterone deficiency or resistance due to a number of steroid or steroid receptor synthetic defects or from hyporeninemic hypoaldosteronism (e.g., due to diabetic nephropathy, tubulointerstitial disease, urinary obstruction, renal transplantation, or SLE). Hyperkalemia, although mild, is a usual manifestation. Type IV RTA associated with pseudohypoaldosteronism type 2 is thought to be due to a mutation in the *WNK* gene, which encodes a protein that interacts with several renal electrolyte transport systems (Table 48-15).[369]

TABLE 48-15 Characteristics of Some Inherited Tubulopathies*

Disorder [OMIM Number]	Protein Defect	Chromosome Localization	Inheritance	Clinical Features/Notes	Biochemical Features
Proximal Tubule					
Lowe's syndrome (oculocerebral dystrophy) [309000]	OCRL1	Xq26.1	XR	Hydrophthalmia, cataract, mental retardation, hyporeflexia, hypotonia, and progressive kidney failure; normotensive	Plasma: ↓K, ↓CO_2 Urine: ↑LMWP, ↑AA, ↑PO_4, ↑K
Wilson's disease [277900]	ATP7B	13q14.3-q21.1	AR	Liver disease or neurologic symptoms, or both, Kayser-Fleischer rings, normotensive	Plasma: ↑free copper, abnormal LFTs Urine: ↑copper excretion, ↑LMWP, ↑AA, ↑PO_4, ↑Glycosuria
Dent's disease (X-linked recessive hypophosphatemic rickets) [300009]	CLCN5	Xp11.22	XR	Nephrocalcinosis, nephrolithiasis, rachitic and osteomalacic bone disease, progressive kidney failure, normotensive	Plasma: ↓PO_4, N/↓K Urine: ↑LMWP, ↑AA, ↑K, ↑Ca, ↑PO_4, ↑Glycosuria
X-linked dominant hypophosphatemic rickets [307800]	PHEX	Xp22.2-p22.1	XD	Growth retardation, rachitic and osteomalacic bone disease, hypophosphatemia, and renal defects in phosphate reabsorption and vitamin D metabolism	Plasma: ↓PO_4, ↑ALP Urine: ↑PO_4
Loop of Henle					
Bartter's syndrome [601678] [241200] [607364] [602522]	NKCC2 (type I) ROMK (type II) ClC-Kb (type III, "classic") Barttin (type IV)	15q15-q21.1 11q24 1p36 1p31	AR AR AR AR	Polyuria, polydipsia, muscle weakness, hypovolemia, normotensive or hypotensive (all types). Maternal polyhydramnios, premature birth, perinatal salt wasting, nephrocalcinosis and kidney stones (types I and II), milder phenotype with normocalciuria (type III), sensorineural deafness, motor retardation, renal failure (type IV)	Plasma: ↑renin, ↓K, ↑CO_2, mild ↓Mg in some patients Urine: ↑Ca
Hypomagnesemic hypercalciuric nephrocalcinosis (magnesium-losing kidney) [248250]	PCLN1	3q27	AR	Nephrocalcinosis, renal failure, ocular/hearing defects, polyuria, polydipsia, recurrent urinary tract infections, recurrent renal colic, normotensive	Plasma: ↓Mg, ↑PTH Urine: ↑Ca, ↑Mg

Distal Tubule/Collecting Duct					
Liddle's syndrome [177200][†]	ENaC (activating)	16p13-p12	AD	Early, and frequently severe, hypertension, stroke	Plasma: ↓renin, ↓K, ↓Mg, ↑CO_2 Urine: ↑K
Pseudohypoaldosteronism type Ia [264350][†]	ENaC (inactivating)	12p13, 16p13-p12	AR	Presents in infancy with salt-wasting and hypotension. Cough, respiratory infections	Plasma: ↑renin, ↓Na, ↑K, ↓CO_2 Urine: ↑K
Pseudohypoaldosteronism type Ib [177735][†]	Mineralocorticoid receptor	4q31.1	AD	Presents in infancy with salt-wasting and hypotension. Milder than type 1a and remits with age	Plasma: ↑renin, ↓Na, ↑K, ↓CO_2 Urine: ↑K
Pseudohypoaldosteronism type II (Gordon's syndrome) [145260]	Unknown (?WNK)	1q31-q42 12p13 17q21-q22	AD	Hypertension (±muscle weakness, short stature, intellectual impairment). Correction of physiologic abnormalities by thiazide diuretics	Plasma: ↓renin, ↑K, ↓CO_2, ↑Cl Urine: ↓K
Gitelman's syndrome [263800]	NCCT	16q13	AR	Hypotension, weakness, paresthesias, tetany, fatigue, and salt craving. Presentation generally much later in life than in Bartter's, and hypocalciuria is typical	Plasma: ↑renin, ↓K, ↓Mg, ↑CO_2 Urine: ↓calcium:creatinine excretion ratio (useful in distinguishing Gitelman's and Bartter's) (*Note:* biochemically can mimic thiazide use)
X-linked nephrogenic diabetes insipidus type I [304800]	V2 receptor	Xq28	XR	Hyperthermia, polyuria, polydipsia, dehydration, inability to form concentrated urine, mental retardation if diagnosis delayed. Symptoms in infancy	Hyperosmolar plasma, dilute urine
Autosomal dominant nephrogenic diabetes insipidus type II [192340]	AQP2	12q13	AD and AR	Polyuria, polydipsia, dehydration, inability to form concentrated urine. Symptoms after first year of life	Hyperosmolar plasma, dilute urine

*Note: This list is not exhaustive. Some of the material in this table has been adapted from Sayer JA, Pearce SHS.[388] A useful resource for further information is the Online Mendelian Inheritance in Man (OMIM) Website, which may be searched using the OMIM numbers given in the table (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM).

[†]See Figure 48-7.

AA, Aminoaciduria; *AD,* autosomal dominant; *AR,* autosomal recessive; *LFTs,* liver function tests; *LMWP,* low molecular weight proteinuria; *XD,* X-linked dominant; *XR,* X-linked recessive.

Diagnosis of RTA

The finding of a hyperchloremic metabolic acidosis in a patient without obvious gastrointestinal bicarbonate losses (e.g., due to excessive diarrhea or small intestinal fistulas) and with no obvious pharmacologic cause should prompt suspicion of an RTA. The presence of suggestive clinical (e.g., nephrocalcinosis in dRTA) or biochemical (e.g., hypophosphatemia and hypouricemia as a result of proximal tubular wasting in pRTA) features should also be considered.

In addition to plasma electrolyte (including potassium) measurement, preliminary investigation should include measurement of urinary pH in a fresh, early morning urine sample. The finding of urine pH greater than 5.5 in the presence of systemic acidosis supports the diagnosis of dRTA, although it is not specific and will also be seen in types II and IV RTAs. If appropriate urinary acidification cannot be demonstrated, further investigation may involve assessing the ability of the kidneys to excrete an acid load (ammonium chloride load test) and to reabsorb filtered bicarbonate (fractional bicarbonate excretion). Additional details on the conduct and interpretation of these tests may be found in a review article.[343]

Treatment of RTA

Treatment of the RTAs is aimed at (1) correcting the biochemical disturbance and, where possible, underlying disorder; (2) improving growth in children; and (3) avoiding the development and progression of CKD. In both type I and II RTAs, bicarbonate is administered to correct the metabolic acidosis. Fludrocortisone and loop diuretics (see "Diuretics" section later) may be used to treat type IV RTA.

Inherited Tubulopathies

The inherited tubulopathies make up a heterogeneous set of disorders often characterized by electrolyte disturbances (see Table 48-15). Most are eponymous and have been described clinically for many years. However, enhanced understanding of the molecular biology of the tubular ion channel and transport pumps has delineated the mechanism of disease in many of these disorders. In addition to electrolyte disturbances (particularly of potassium), general reasons to suspect a tubulopathy include a familial disease pattern, renal impairment, nephrocalcinosis, and stone formation, especially if these should present at an early age. In cases in which a diuretic-sensitive channel is affected, these disorders will clearly mimic the effects of diuretic use (see discussion later in this chapter), and exclusion of covert use of diuretics is important. Although they are individually uncommon or rare, an awareness of these disorders is critical for the clinical biochemist when considering the potential differential diagnoses in patients presenting with electrolyte imbalances. A brief description of these disorders follows; for more detailed information, the reader is referred to the citation list, including several reviews on this subject.[341,388,389] This section should be considered in conjunction with the aforegoing description of tubular electrolyte handling (see "Electrolyte Homeostasis").

Bartter's Syndrome

This group of autosomal recessive disorders is characterized by (1) renal salt wasting; (2) polyuria; (3) polydipsia; (4) impaired urinary concentrating ability; (5) a hyperreninemic, hypokalemic metabolic alkalosis; and (6) a mild hypomagnesemia in some patients. Biochemically, the effects resemble those of loop diuretic use, but clinically, the phenotype is highly variable. This variability arises because of the fact that the syndrome encompasses defects of three different transporters/channels in the loop of Henle. The biochemical effects are predictable from knowledge of the function of these transporters and channels (see Figure 48-6).

Mutations in the genes encoding for NKCC2 (type I) or ROMK1 (type II) are associated with the more severe phenotype, including polyhydramnios, premature birth, life-threatening salt wasting in the perinatal period, and hypercalciuria. Patients with ROMK1 defects tend to have less severe hypokalemia.

The milder ("classic," type III) Bartter's syndrome is due to defects in the basolateral pump, CLC-Kb. Although the phenotype is extremely variable (neonatal, life-threatening presentations do occur), patients typically present in the first year of life with weakness and hypovolemia and normal urinary calcium excretion. Nephrocalcinosis and kidney stone formation usually are not features.

A fourth variant of Bartter's syndrome (type IV) has been described as due to a mutation in the gene coding for Barttin. Barttin is an essential subunit of CLC-Kb that influences its function and expression in the cell membrane. Bartter's syndrome type IV is characterized by severe, early-onset salt wasting, leading to polydramnios, premature birth, and inner-ear deafness.[239]

Gitelman's Syndrome

This autosomal recessive disorder is characterized by a hypokalemic, hyperreninemic, hypomagnesemic, metabolic alkalosis, but presentation is generally much later in life than with Bartter's syndrome, and hypocalciuria is typical. Clinical features include reduced blood pressure, weakness, paresthesia, tetany, fatigue, and salt craving.[19] The molar urinary calcium/creatinine excretion ratio can be useful in distinguishing between Gitelman's (≤0.20) and Bartter's (>0.20) syndromes.[31] The molecular defect is seen in the thiazide-sensitive NCCT transporter (see Figure 48-6), and the biochemistry can therefore mimic the effects of thiazide use (see "Diuretics" section later).

Liddle's Syndrome

This autosomal dominant disorder is characterized by a hypokalemic, hypomagnesemic metabolic alkalosis but, in contrast to Bartter's and Gitelman's syndromes, hypertension and hyperreninism also occur. The disease is due to activating mutations, which increase sodium transport through the ENaC channel with consequent enhanced kaliuresis (see Figure 48-7).

Pseudohypoaldosteronism Type I

This condition presents in infancy with salt wasting, hypotension, hyperkalemia, and significant hyperreninism and aldosteronism. Two different molecular mechanisms are causative. Type Ia (autosomal recessive) is caused by inactivating mutations of the *ENaC* gene, and type Ib (autosomal dominant) is caused by mutations in the mineralocorticoid gene. In both cases, sodium loss in the collecting duct is increased with consequent retention of potassium.

Dent's Disease

Dent's disease is an X-linked condition characterized by hypercalciuria and kidney stone formation, low molecular weight proteinuria, aminoaciduria, hypophosphatemia, and rickets.[481] The disease arises from single-base change mutations, of which approximately 60 have been described, in the gene coding for the tubular endosomal chloride channel CLC-5. The exact relationship between loss of function of this protein and the resulting Fanconi syndrome remains unclear, but CLC-5 appears to have an important role in proximal tubular endocytosis.[205] Although X-linked, a mild form of the disease can be seen in females because of lyonization. The related syndromes (1) X-linked recessive nephrolithiasis, (2) X-linked recessive hypophosphatemic rickets, and (3) Japanese idiopathic low molecular weight proteinuria are also all related to defects in CLC-5.[434]

Phosphate Disorders

Several disorders of tubular phosphate handling have been described, including X-linked dominant hypophosphatemic rickets (XLH; previously known as vitamin D–resistant rickets), autosomal dominant hypophosphatemic rickets, and acquired oncogenic hypophosphatemic osteomalacia. Our understanding of the molecular biology of these and other renal phosphate transport disorders has advanced greatly in recent years.[429]

Many other tubulopathies exist[341,388,389] and the features of some of these are described in Table 48-15.

Treatment With Diuretics

Diuretics are among the most widely prescribed drugs. They are used predominantly to treat hypertension and/or disorders associated with fluid overload. All diuretics act by interfering with tubular reabsorption of sodium and/or chloride, thereby promoting water loss from the peripheral circulation. Diuretics are taken up by tubular cells across the basolateral membrane by specific anion- (e.g., furosemide, thiazides) or cation- (e.g., amiloride, triamterene) exchangers and then are secreted into the lumen through a process that has not been fully elucidated.[389] Different classes of diuretics act at different sites along the nephron. A basic understanding of these processes is helpful in understanding both the potency of different diuretic classes and their importance in the investigation of electrolyte disorders, in particular hypokalemia. Many diuretics will cause hypokalemia to some degree, depending on potency, dose, duration of treatment, and the patient's underlying potassium balance.

Loop Diuretics

Loop diuretics act largely by blocking sodium and chloride reabsorption in the ascending limb of the loop of Henle. Because this is a site at which 30% of sodium reabsorption normally occurs, these are considered potent diuretics. Loop diuretics specifically inhibit NKCC2; therefore, they also have an effect on potassium handling in the ascending limb. Consequent changes in transepithelial potential result in a direct kaliuretic effect in this region,[153] causing hypercalciuria (see Figure 48-6). Loop diuretics also paralyze the macula densa segment, stimulating renin secretion and subsequent aldosterone release, promoting sodium reabsorption and potassium loss in the distal tubule, and so further exacerbating the kaliuresis. Most significantly, blockage of loop sodium reabsorption results in enhanced delivery of sodium ions to the distal tubule, where sodium is reabsorbed in exchange for potassium secretion.[153] The affinity of loop diuretics for NKCC2 is bumetanide>torasemide>piretanide>furosemide>azosemide.[154] The net effect of loop diuretics is that increased sodium chloride with associated water is lost from the body: potassium loss as a result of the various mechanisms described here means that hypokalemia is a common side effect.

Thiazide Diuretics

The benzothiadiazine group of compounds inhibits NCCT in the distal tubule. Because only 5 to 10% of sodium reabsorption occurs at this site, these agents are less potent than the loop diuretics, but hypokalemia is still common as a result of increased sodium delivery to the collecting duct. Thiazide diuretics also have secondary effects, resulting in increased calcium reabsorption, which may lead to hypercalcemia.[154]

"Potassium-Sparing" Diuretics

These diuretics act by reducing sodium reabsorption in the collecting duct, hence increasing potassium retention. Spironolactone acts as a competitive antagonist of aldosterone, blocking its stimulatory effects on sodium reabsorption via the mineralocorticoid receptor. Both amiloride and triamterene inhibit ENaC. The danger associated with this group of diuretics is that they can induce hyperkalemia; this is particularly likely to occur in patients with kidney disease.

Diabetes Insipidus

Primary functions of the kidney include conservation of water and production of a concentrated urine. A number of conditions are associated with disturbances of the renal concentrating mechanism, resulting in polyuria and an inability to produce hypertonic urine. General conditions giving rise to this picture include hypercalcemia, hypokalemia, and CKD. Specifically, diabetes insipidus is due to the absence of an ADH effect, caused by impaired or failed secretion (cranial or central diabetes insipidus) or lack of end-organ response to ADH (nephrogenic diabetes insipidus). A further disorder, psychogenic polydipsia, or compulsive water drinking can also present as diabetes insipidus. Polyuria is common to both diabetes insipidus and diabetes mellitus, but in diabetes insipidus, no hyperglycemia and no glycosuria are

present. These individuals may fail to concentrate urine even in response to fluid restriction or synthetic ADH as a result of medullary "washout"; sustained fluid ingestion destroys the hyperosmolality of the medulla, which may take some time to recover. Differentiation and the pathology of these three conditions are discussed in Chapter 53. It should be noted that a vast diuresis can be induced by consumption of excessive fluid volumes (e.g., among heavy beer drinkers).

Congenital nephrogenic diabetes insipidus is associated with defects that have been characterized at the molecular level (see Table 48-15).[34] Most (>90%) congenital nephrogenic diabetes insipidus patients have mutations in the *AVPR2* gene, which codes for the ADH V2 receptor. This results in an X-linked form of diabetes insipidus, with an estimated prevalence of 4 per 1 million males.[34] In less than 10% of cases, an autosomal recessive inheritance pattern is caused by mutations in the *AQP2* gene. It has been suggested that measurement of the urinary excretion of AQP may be useful diagnostically.[97,321] Downregulation of AQP2 has been observed in a variety of acquired forms of diabetes insipidus, including lithium treatment, hypokalemia, hypercalcemia, ureteric obstruction, and, in animal models, chronic kidney failure.[321] Acquired forms of diabetes insipidus are more common than congenital forms.

Assessment of Renal Concentrating Ability: Urinary Osmolality

Urinary concentration can be quantified by measuring specific gravity (see Chapter 25) or by measuring urinary osmolality. For most clinical purposes, measuring specific gravity is probably sufficient,[344] but urinary osmolality measurement is critical in the diagnosis of diabetes insipidus using the water deprivation test (see Chapter 53).

Urinary osmolality may vary widely, depending on the state of hydration. After excessive intake of fluids, for example, the osmotic concentration may fall to as low as 50 mOsm/kg H_2O, whereas in individuals with severely restricted fluid intake, concentrations of up to 1400 mOsm/kg H_2O can be observed. In individuals on an average fluid intake, values of 300 to 900 mOsm/kg H_2O are typically seen. If a random urine specimen has an osmolality greater than 600 mOsm/kg H_2O (or >850 mOsm/kg H_2O after 12 hours of fluid restriction), it generally can be assumed that the renal concentrating ability is normal.

In chronic progressive kidney disease, the concentrating ability of the tubules is diminished, and in ATN, the urinary osmolality, if there is urine output at all, approaches that of plasma. For a discussion on measurement of urinary and plasma osmolality, readers are referred to Chapter 28.

Renal Calculi

Nephrolithiasis is the disease condition associated with the presence of renal calculi. Renal calculi, commonly termed *kidney stones,* occur in the renal pelvis, the ureter, or the bladder. Calcification also occurs scattered throughout the parenchyma (nephrocalcinosis). Kidney stone formation is often considered to be a nutritional or environmental disease, linked to affluence, but genetic or anatomical abnormalities are significant. Approximately 5 to 10% of the population of the Western world are thought to have formed at least one kidney stone by the age of 70 years,[201,381] and the prevalence of kidney stones is increasing.[418] For most stone types, there is a male preponderance. The passage of a stone is associated with severe pain called *renal colic,* which may last for 15 minutes to several hours and is commonly associated with nausea and vomiting.[472] Kidney stone formation contributes to the development of CKD.[142,378]

Background

Chemically, urine contains many mineral salts that are present in concentrations that approach their solubility products at body temperature. Anyone who has seen a urine sample before and after refrigeration has witnessed the consequences of this in the massive crystal deposits that can form on cooling. Crystals are able to form spontaneously if the salt concentrations are high enough or, alternatively, may bind to organic material, acting as a "seed": hyaluronic acid, a large glycosaminoglycan, has been suggested as one such promoter of crystal formation.[454] Human urine contains a number of promoters of stone formation and a variety of inhibitors, the concentrations of which can be influenced by dietary and metabolic factors (Figure 48-16).

Initial diagnosis and investigation of stones require radiologic investigation to explore the degree of intrarenal calcification and papillary damage. Plain x-rays are undertaken at initial presentation, although it should be noted that urate and other purine stones and some cystine stones are radiolucent. An intravenous urogram or spiral CT scan may be performed to establish the presence and extent of urinary tract obstruction, intrarenal reflux, and ureteric dilation. Further investigation of the patient with kidney stones or suspected of being a stone former involves analysis of blood, urine, and the stone itself, should one be obtained.[177]

Small stones (<5 mm in diameter) pass spontaneously in the urine as "gravel."[472] Although surgical treatment to remove large staghorn calculi may still be necessary, the most common form of treatment is ultrasonic extracorporeal shock wave lithotripsy (ESWL),[358] which can be applied to stones between 5 mm and 2 cm in diameter. Although this allows noninvasive destruction of stones, the long-term sequelae of exposing the kidney to high-intensity sound waves have not been fully established.[142] Additionally, evidence is mounting that ESWL may be associated with higher recurrence rates than invasive treatment.[425] Percutaneous nephrolithotomy may be required if ESWL fails and also in the removal of cystine stones.

After treatment and successful removal of a stone, follow-up monitoring is required, as many patients will have recurrent disease: in the absence of medical treatment, the recurrence rate may be as high as 50% at 10 years.[268] The mechanisms responsible for multiple recurrences of kidney stones in only certain individuals are not completely understood. Factors involved include (1) urine flow (fluid intake); (2) excretion of excess quantities of stone components; (3) the

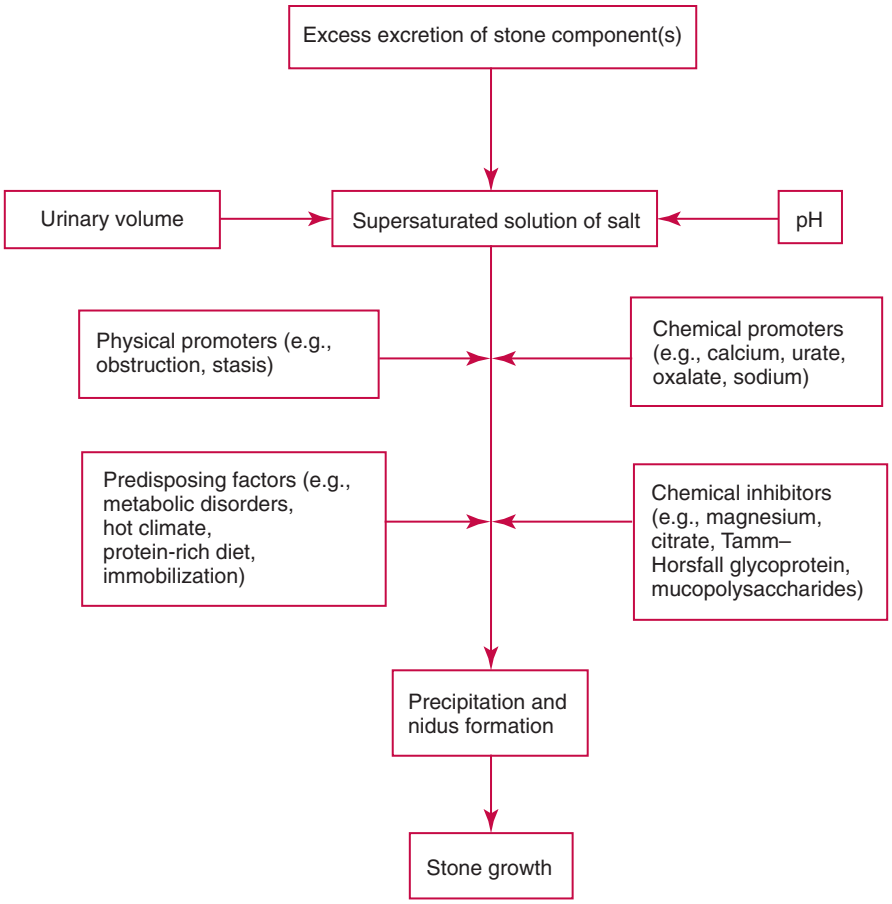

Figure 48-16 Diagrammatic representation of the interplay of factors involved in kidney stone formation. High or low pH may act as a promoter or inhibitor of stone formation depending on the stone type in question (e.g., calcium stone formation is favored by inadequate acidification, while urate is less soluble in acidic urine). Controversy exists as to whether formed stones become trapped as they pass through the nephron ("free particle theory"), or whether stone formation occurs at damaged sites on the tubule wall ("fixed particle theory").

relative absence of a substance, or substances, in the urine that inhibit stone formation; and (4) urinary pH (see Figure 48-16). The predominant risk factor is poor hydration, with concentrated urine further increasing the concentrations of the mineral salts, predisposing to crystallization. Urinary concentration at least partially explains the increased incidence of kidney stone disease in hot climates, for example, in the Gulf States.

Kidney Stone Analysis

A majority of kidney stones found in the Western world are composed of one or more of the following substances: (1) calcium oxalate with or without phosphate (frequency 67%); (2) magnesium ammonium phosphate (12%); (3) calcium phosphate (8%); (4) urate (8%); (5) cystine (1 to 2%); and (6) complex mixtures of these substances (2 to 3%).[381] These poorly soluble substances crystallize within an organic matrix, the nature of which is not well understood.

When available, analysis of the chemical constituents of stones may be useful in establishing the cause and in planning rational therapy. It complements and guides metabolic investigation of patients and may be particularly useful in identifying rare stone types (e.g., xanthine, dihydroxyadenine), artifacts (e.g., Munchausen syndrome), or drugs precipitating in the urinary tract, such as triamterene[417] and indinavir.[236] Conversely, it has been argued that stone analysis is not useful clinically,[178] because the stone material that is passed often does not represent the initial metabolic derangement. This is a result of the phenomenon known as *epitaxy,* whereby nonspecific stone material, typically arising as a result of urinary tract infection (e.g., struvite), may accumulate on a preexisting "metabolic" nidus, the latter of which may not be detected during stone analysis. Clearly, for stone analysis to be useful, it must be accurate. A variety of techniques have been used over the years. Traditionally, stones were crushed and solubilized, and the resulting solution analyzed (at several dilutions when appropriate) with the use of conventional qualitative or semiquantitative chemical methods. Such techniques require relatively large amounts of stone, may miss rare and artifactual material, and analytically often perform poorly.[381] More

sophisticated approaches including thermogravimetric analysis,[374] x-ray diffraction crystallography, and, particularly, infrared spectroscopy are preferred, a detailed description of the which is beyond the scope of this chapter.[28,180,221]

Metabolic Investigation of Kidney Stone Formers

Ensuring adequate fluid intake remains the cornerstone of management of stone disease. However, specific management of disease depending on the metabolic abnormality present is important, and a treatment rationale is emerging. Several misconceptions have arisen about the role of diet in stone formation, and optimal treatment at first may appear counterintuitive; some of these paradoxes are discussed here.

Further investigation of stone formers may be guided by knowledge of the type of stone formed. However, increasing use of lithotripsy means that often no stone material is available for analysis. Consequently, a management strategy that focuses on the cause of stone formation and is based on knowledge of blood and urinary composition is useful. Although historically, metabolic investigations have often been targeted at recurrent stone formers only, the increasing availability of simple assays for chemical risk factors and the health economic burden of renal colic suggest that they are likely to become more widespread.[178,357,428] However, in some instances, it is not possible to demonstrate a biochemical abnormality in stone-forming individuals beyond a persistently small urine volume.

A variety of metabolic screening strategies have been proposed in stone-forming patients.[177,179,381,437] The chosen strategy should balance convenience for the patient and the laboratory against ability to intervene therapeutically. For example, although THG is known to inhibit stone formation, in the absence of a specific treatment, there is little merit in measuring it. A reasonable approach would probably include measurement of plasma sodium, potassium, chloride, bicarbonate, creatinine, calcium, phosphate, and urate, together with 24-hour urinary volume, calcium, magnesium, phosphate, oxalate, urate, creatinine, sodium, citrate, and microbiology (to exclude infection). Additionally, urinary pH and cystine should be measured on a fresh, early morning urine sample. Some investigators have proposed complex "supersaturation indices" that combine the information obtained from these studies in a numeric index.[335,371,436] Metabolic evaluation should be undertaken at least 6 weeks after the episode of renal colic and ideally should be done on several occasions.[179] Evaluation is most informative when undertaken on an outpatient basis with patients pursuing their normal diet and lifestyle. A brief description of the role and measurement of these risk factors is given here, with focus predominantly on the investigation of calcium stone formers.

Calcium

Most of the stones formed in the Western world are composed of calcium, most commonly in association with oxalate, although calcium phosphate and urate may also be present, alone or in combination with calcium oxalate. As a consequence, urinary calcium measurement has served as the central investigation. However, the significant role of oxalate is increasingly appreciated, and this has resulted in changes to the optimal management of hypercalciuria. As a rough guide, calcium oxalate stones tend to suggest hyperoxaluria as the main cause, while calcium phosphate stones implicate hypercalciuria and/or failure to adequately acidify urine.[381] A strict definition of hypercalciuria is difficult because of significant overlap between stone-forming and non–stone-forming individuals, but a cutoff of 4 mg/kg body weight (0.1 mmol/kg) is useful.[55,477] Excretion in excess of this, the most common metabolic abnormality seen in calcium stone formers, is observed in up to 50% of patients.

Traditionally, some investigation strategies focused on whether patients demonstrated hypercalciuria while fasting *(renal hypercalciuria)* or in response to a calcium load *(absorptive hypercalciuria)*.[472] This classification was used as the basis of an investigative and treatment strategy in patients with absorptive hypercalciuria who have abnormally high intestinal calcium absorption compared with non–stone formers (possibly because of a relative increase in $1,25[OH]_2D_3$ concentration and/or changes in intestinal vitamin D receptor activity). Treatment in these patients focused on dietary modification of calcium intake. Patients with renal hypercalciuria are now thought not to have a renal transport defect, but to have increased turnover of skeletal calcium, although management of such patients may involve pharmacologic modification of renal calcium handling (e.g., thiazide diuretics).[472]

However, convincing evidence questions the usefulness of this classification and these therapeutic approaches. Dietary restriction of calcium now is generally regarded as ineffective, and actually counterproductive, as it results in an increase in intestinal oxalate absorption and increased risk of stone formation.[63,90] Further, patients with hypercalciuria are known to have reduced bone mineral density, and dietary calcium restriction may exacerbate a tendency toward osteopenia and/or osteoporosis.[439,465]

A more useful approach is to classify hypercalciuric patients into hypercalcemic or nonhypercalcemic causes. The former is most commonly due to primary hyperparathyroidism, which is seen in approximately 5% of stone formers. Treatment involves neck exploration and removal of the adenoma, although the risk of a stone recurring remains high for several years after parathyroidectomy.[304]

Nonhypercalcemic causes of hypercalciuria account for the majority of patients and generally are classified as idiopathic (although causes such as RTA, high sodium intake, and prolonged immobilization should be excluded). Most patients with idiopathic hypercalciuria appear to have a generalized acceleration of calcium transport, with increased absorption from the gut, increased mobilization from bone, and abnormal renal calcium conservation, all contributing to hypercalciuria.[477] In addition to increasing fluid consumption, idiopathic hypercalciuric patients appear to benefit from a diet that is low in animal protein and sodium.[42,370] Animal protein consumption increases the production of metabolic

acids, increasing urinary calcium and uric acid excretion and decreasing urinary citrate (see discussion later in this chapter).[55] High sodium excretion as a result of high consumption inhibits tubular reabsorption of calcium, with a consequent increase in risk of calcium stone formation. Sodium is easily measured in urine and represents a modifiable risk factor. Other therapeutic maneuvers that may be useful include using thiazide diuretics or alkaline citrate, reducing oxalate, and increasing fiber intake.[437] Some of these factors are discussed in greater detail in the following sections.

Magnesium

With calcium stone disease, magnesium is an inhibitor of stone growth. Magnesium forms complexes with oxalate that are more soluble than calcium oxalate. Increased urinary magnesium therefore inhibits stone formation.[165] Administration of magnesium has been shown to reduce enteral calcium absorption and has been proposed as a treatment for idiopathic hypercalciuric stone formers.[96] However, oral magnesium supplementation may have unpleasant side effects, and a positive benefit in terms of reducing stone recurrence has not been demonstrated.[437]

Urate

Some investigators believe that urate may potentiate calcium stone formation, although this perception is not universally accepted.[381] However, hyperuricosuria is common in calcium stone–forming patients, and treatment with allopurinol, by decreasing urate synthesis, reduces the rate of stone recurrence. Allopurinol treatment therefore is recommended for hyperuricosuric patients with calcium stone disease.[437] The formation and management of pure urate stones are discussed in Chapter 25.

Oxalate

Oxalate is an end product of metabolism, predominantly derived from breakdown of glyoxylate and glycine. The plasma concentration of oxalate is 1.0 to 2.4 mg/L (11 to 27 μmol/L), and it is excreted in the urine at a rate of 17.5 to 35.1 mg/d (200 to 400 μmol/d).[476] Only 10 to 15% of urinary oxalate is derived directly from dietary sources.[437] Intestinal oxalate absorption is increased when the availability of calcium in the intestine is reduced. Hyperoxaluria is a powerful promoter of calcium oxalate stone formation; indeed, it is more significant in this respect than calcium itself.[381]

Hyperoxaluria may occur as a result of excessive dietary intake, because of malabsorption and/or steatorrhea (enteric hyperoxaluria), or because of an inborn error of metabolism (primary hyperoxaluria). Enteric hyperoxaluria commonly occurs in association with inflammatory bowel disease and may contribute to an increased incidence of stone formation in such patients.[476] Fat malabsorption contributes to the formation of calcium–fatty acid complexes ("soaps") in the intestine, increasing the enteric concentration of unbound oxalate that is absorbed through the damaged bowel wall. Primary hyperoxaluria may be type 1 (glycolic aciduria) or type 2 (L-glyceric aciduria). Patients with type 1 disease present in the first decade of life with recurrent calcium oxalate nephrolithiasis. Inheritance is autosomal recessive and survival is poor. Type 2 disease is rarer and has been claimed to run a milder course, despite the passage of similarly high concentrations of urinary oxalate. The urinary excretion of oxalate may increase to approximately 60 mg/d (700 μmol/d) when a diet containing an excess of oxalate-rich foods is taken, and to as much as 260 mg/d (3 mmol/d) in patients with primary hyperoxaluria.

Ideally, urine for oxalate analysis should be collected into acid to prevent the crystallization of calcium oxalate crystals. Acidification also prevents ex vivo formation of oxalate from ascorbate—a cause of factitious hyperoxaluria in individuals ingesting excessive amounts of vitamin C.[171] A number of approaches to the measurement of urinary oxalate have been employed, including high-performance liquid chromatography (HPLC), enzymatic assays, and capillary electrophoretic methods.[184,251,347] The enzymatic methods employ the enzyme oxalate oxidase (EC 1.2.3.4. oxalate:oxygen oxidoreductase). With this method, the sample of urine is initially acidified to pH 1.8 (typically with 2 mmol/L HCl) to ensure complete solubilization of any calcium oxalate crystals. The oxalate is oxidized to carbon dioxide and hydrogen peroxide by oxalate oxidase, and the hydrogen peroxide is detected with horseradish peroxidase and is coupled with an oxygen acceptor reagent such as 3-dimethyl aminobenzoic acid and 3-methyl-2-benzothiazolinone hydrazone to yield an indamine dye that absorbs at 590 nm. A charcoal column pretreatment step to remove interferents from the urine has been used,[246] although this may not be necessary.[347] An alternative approach to the detection of hydrogen peroxide using catalase has been described. The oxalate oxidase is specific for oxalate; however, the peroxide detection reaction may suffer from interferences (e.g., turbidity in the catalase-mediated reaction, ascorbic acid, other reducing agents in the peroxidase-mediated reaction). The choice of oxygen acceptor will determine the potential for interference from compounds such as ascorbic acid.

A dietary history is important in the evaluation of calcium oxalate stone formers. Patients who are excreting large amounts of oxalate may be offered dietary advice to modify their risk of future stone formation. Foods rich in oxalate include beets, tea, spinach, sorrel, wheat bran, strawberries, rhubarb, blackcurrants, peanuts, and chocolate.[381,437,472] Paradoxically, epidemiologic evidence has actually demonstrated a protective effect of high tea consumption.[90] This has been attributed to the low bioavailability of oxalate in tea and the inhibition of tubular ADH action by caffeine. Patients may be treated with calcium carbonate, which binds oxalate in the gut, rendering it unavailable for absorption. Alternatively, pyridoxine (vitamin B_6) may be used; this increases the catabolism of oxalate to more soluble products.[472] It should be remembered that the use of calcium-lowering diets, once favored in the treatment of calcium stone formers, increases intestinal absorption of oxalate.

Citrate

Urinary citrate inhibits stone formation by forming soluble complexes with calcium. It is present in the diet in many fruits. Excretion [typically between 120 and 930 mg/d (0.6 and 4.8 mmol/d) for adult males and between 250 and 1160 mg/d (1.3 and 6.0 mmol/d) for adult females][381] is reduced in the calcium stone–forming population.[436] Urinary citrate measurement may be of value in the assessment of stone-forming risk, particularly in the setting of distal RTA, where the reduction in filtered bicarbonate appears to increase tubular reabsorption of citrate with consequent hypocitraturia.[166] Inadequate urinary acidification compounds the increased risk of calcium stone formation. Treatment with carbonic anhydrase inhibitors (e.g., acetazolamide,[332] topiramate[215,247]) mimics distal RTA with a consequent increase in stone risk. Hypocitraturia may also be seen in malabsorption and urinary tract infection. Administration of oral alkaline citrate increases urinary citrate concentration by increasing the pH of tubular cells. It has been shown to be effective in the treatment of nephrolithiasis,[333,437] although side effects are reported and compliance is poor.

Citrate is measured by gas chromatography, capillary electrophoresis,[184] or an enzyme-mediated reaction. Although methods using aconitase (EC 4.2.1.3) and isocitrate dehydrogenase (EC 1.1.1.42), or citrate lyase (EC 4.1.3.6) and oxaloacetate decarboxylase (EC 4.1.1.3), have been described, a method using the lyase together with malate dehydrogenase (EC 1.1.1.37) and lactate dehydrogenase (EC 1.1.1.27) is preferred. The combination of the two dehydrogenase pathways has been proposed to ensure that any oxaloacetate ion enzymatically decarboxylated is also measured. The enzyme-mediated decarboxylase pathway is less favored because of the poor stability of the enzyme. Using a reaction sequence that involves incubation of the sample with all constituents except the citrate lyase ensures that all endogenous oxaloacetate and pyruvate are removed. Analysis of serum involves a deproteinization step, and urine should be titrated to pH 8.0 before analysis. A typical incubation period is 10 to 15 minutes, and the citrate can be quantitated from the decrease in absorbance at 340 nm. A cheap, rapid, automated adaptation of this procedure, which does not require a deproteinizing step, has been described.[43]

Struvite Stones

Struvite stones (also called *triple phosphate* or *infection stones*) are composed of magnesium ammonium phosphate hexahydrate. The formation of such stones requires urinary tract infection with urea-splitting organisms; such stones therefore are more common in females and in certain patient populations (e.g., paraplegic individuals).[381] The risk of progression to CKD appears higher in patients who develop infection stones than in those with other forms of stone disease.[142]

Cystinuria

Cystinuria is an autosomal recessive condition in which excessive urinary excretion of cystine results from a defect in proximal renal tubular reabsorption. In the most common form of the disease, there is also excess excretion of the dibasic amino acids (lysine, ornithine, and arginine). These share the same renal tubular transporter, although their presence in excess in urine appears benign. More rarely, isolated cystinuria is seen. The reader should note that cystinuria should not be confused with cystinosis, which is a condition associated with intracellular accumulation of cystine but not with excess urinary excretion of cystine.

The normal urinary excretion of cystine has been reported to be 5 to 48 mg/d (40 to 400 μmol/d).[381] Its relatively low limit of solubility, 18 mg/dL (1500 μmol/L),[472] is exceeded in many patients with cystinuria,[381] resulting in the formation of hexagonal crystals and, ultimately, cystine stones. Cystine stones usually are seen only in homozygotes, although some evidence suggests that heterozygotes are at increased risk of stone formation.[147] Cystinuria may present at any age from infancy to old age, although presentation is most common in the second and third decades.

The finding of a cystine stone should prompt confirmation of cystinuria by urinary analysis.[381] It could be argued, however, that all stone formers should be screened for cystinuria; at least 10% of cystinuric individuals form stones in which cystine cannot be detected, presumably because of epistaxis.[301] The index of suspicion should be increased in patients who are relatively young stone formers and in those with a positive family history. Once a cystinuric patient is diagnosed, it is important to screen all members of the family, particularly to detect affected siblings.

Cystine can be measured in urine by using the cyanide-nitroprusside test, thin-layer chromatography, quantitative amino acid analysis with ion-exchange or liquid chromatographic techniques, or mass spectrometry. In the cyanide-nitroprusside test, cystine is split into two molecules of cysteine by cyanide. Sodium nitroprusside reacts with the free sulfide groups to give a magenta color. This test is hazardous and will give false-negative results in patients with acidified or infected urine, in those receiving penicillamine therapy, and in patients for whom the sodium nitroprusside solution is not fresh. Further, it cannot distinguish between cystine and homocystine or between heterozygote and homozygote cystinuric individuals. It is not useful when treatment is monitored for known cystinuric patients, who require quantitation of their urinary cystine output or concentration. In practice, amino acid analysis allows simultaneous quantitation of the dibasic amino acids, which may be helpful for characterizing the clinical phenotype. Quantitative amino acid analysis is described in Chapter 21.

Treatment of cystinuria is aimed at keeping cystine below its saturation point by maintaining high fluid intake, particularly at night. Other treatments include urinary alkalinization (cystine is more soluble in alkaline urine) and chelation with D-penicillamine. Quantitative analysis is an important adjunct for monitoring penicillamine therapy, which can be optimized on the basis of free cystine versus cystine/penicillamine disulfide. Penicillamine itself may cause glomerular damage; thus regular monitoring of urinary protein excretion is recommended.

Toxic Nephropathy

A wide variety of nephrotoxins exist in the environment, in some cases associated with particular occupations (e.g., heavy metals, such as cadmium and lead; see Chapter 36). Both glomerular and tubulointerstitial damage may result from exposure to toxins; detection of both requires biochemical monitoring of GFR/serum creatinine concentration and tubular and glomerular proteinuria. Anatomic, physiologic, and biochemical features make the kidney susceptible to insult from a variety of medicinal and environmental agents. Factors contributing to the sensitivity of the kidney include its large blood flow, the concentration of filtered solutes during urine production, and the presence of a variety of xenobiotic transporters and metabolizing enzymes. Toxic nephropathy commonly occurs as a result of decreased renal perfusion, because of precipitation within the tubule, or because of direct toxic effects at the proximal tubule. In some cases the conjugation of environmental chemicals (e.g., mercury, cadmium) to glutathione and/or cysteine targets these chemicals to the kidney, where inhibition of renal function occurs through a variety of mechanisms that are not completely understood. Although some drugs can cause kidney damage in the presence of normal renal function, a far greater variety of drugs can cause problems in patients with kidney disease, predominantly because of accumulation resulting from decreased renal elimination. The British National Formulary (www.bnf.org) has an appendix devoted to prescribing issues in the presence of renal impairment. A list of drugs and environmental toxins commonly known to cause kidney damage is given in Table 48-16.

RENAL REPLACEMENT THERAPY

Renal replacement therapy (RRT) includes dialysis procedures such as hemodialysis (HD), peritoneal dialysis (PD), continuous hemofiltration (HF), and continuous hemodiafiltration (HDF). These techniques are used to temporarily or permanently remove toxic substances from the blood when the kidneys cannot satisfactorily remove them from the circulation. In addition, kidney transplantation has become an effective form of RRT. Extensive laboratory support is required by an RRT program (Table 48-17).

Background

In 1861, Thomas Graham Bell in Glasgow, Scotland, carried out the first dialysis experiments (and coined the term *dialysis*), separating crystalloids and colloids in a solution. Bell predicted that this technique could have medical application, but this was not realized until nearly 100 years later in the work of Willem Kolff and then Belding Scribner, who made HD a feasible treatment in the early 1960s. Since that time, HD and more recently PD have extended the lives of many people, sometimes for up to 20 or 30 years.

Dialysis

Dialysis is the process of separating macromolecules from ions and low molecular weight compounds in solution based on the difference in their rates of diffusion through a semipermeable membrane, through which crystalloids can pass readily but colloids pass very slowly or not at all. Two distinct physical processes are involved: diffusion and ultrafiltration.

The timing of initiation of dialysis treatment is controversial and requires judgment, taking into account the treatment of metabolic consequences of advanced CKD, the comorbidities of the patient, and the accepted impact of dialysis treatment on quality of life. No absolute recommendation of commencement of dialysis based on GFR alone can be made, although commencement of dialysis is considered as GFR falls below 15 mL/min/1.73 m^2.[316] The USRDS reports the mean GFR on initiation of dialysis is 10 mL/min/1.73 m^2.[80]

Hemodialysis and Hemofiltration

HD is the technique most commonly used to treat advanced and permanent kidney failure. Clinically, it is considered the default therapy that is utilized in patients unsuitable for other modalities of PD and kidney transplantation. Operationally, it involves connecting the patient to a hemodialyzer, into which his or her blood flows. After filtration to remove wastes and extra fluids, the cleansed blood is returned to the patient. This is a complicated and inconvenient therapy requiring a coordinated effort from a healthcare team that includes the patient, nephrologist, dialysis nurse, dialysis technician, dietitian, and others.

Description

HD utilizes diffusive and convective mass transfer across a semipermeable membrane. The driving force for diffusion is the concentration gradient between blood and dialysate. Smaller solutes with larger concentration gradients give increased diffusion. The concentration gradient is maintained by using countercurrent flows and high flow rates. Heparinized blood is pumped in one direction across the membrane, and the recipient fluid, the dialysate, flows at a rate of 500 to 800 mL/min in the opposite direction, as shown in Figure 48-17. Water molecules and small molecular weight molecules are able to cross the membrane, while larger proteins and cellular elements are retained in the vascular space. Convection is the bulk movement of solvent and dissolved solute across the membrane, down a transmembrane hydrostatic pressure gradient. The most important functional part is the dialyzer membrane. Biocompatibility of the dialyzer membrane is an essential requirement because of high surface areas and long contact times. Patients are dialyzed in home-based or hospital-based units, with dialysis usually performed three times a week for sessions lasting between 3 and 5 hours. This dialysis schedule is largely empirical, insofar as it reconciles adequate treatment with breaks between treatments to provide the patient with a reasonable quality of life. Approaches to increase the dose of dialysis have been explored. These include short daily HD that entails a 2- to 3-hour dialysis on 6 days per week.[292] Alternatively, slow overnight dialysis for 5 to 7 nights has been employed. These regimens have been reported to improve outcome.[292,360,443]

TABLE 48-16 Toxic Nephropathy: Causes, Pattern, and Markers

Compound Category	Drug/Toxin	Type of Renal Injury/Pathology	Biomarkers/Notes
Antibacterial agents	Aminoglycosides (e.g., neomycin, gentamicin, tobramycin, amikacin)	Acute tubular necrosis and interstitial nephritis Nonoliguric AKI	Plasma: ↓K, ↓Mg, ↓Ca Urine: ↑LMWP, ↑glycosuria Nephrotoxicity major and common side effect
	Amphotericin	Initially distal tubular injury followed by medullary injury	Plasma: ↓K, ↑creatinine, dRTA
Antiviral/ antiprotozoal agents	Acyclovir	Nonoliguric AKI due to tubular obstruction and interstitial inflammation	Crystalluria and hematuria
	Pentamidine	Tubular toxicity	Plasma: ↓Mg, ↓Ca Urine: ↑Mg, ↑Ca
	Indinavir	Nephrolithiasis, irreversible kidney failure in some patients	Crystalluria and hematuria
Radiocontrast agents	(e.g., iothalamate, iodixanol)	Oliguric or nonoliguric AKI, generally reversible. Proximal tubular damage	↑plasma creatinine after contrast administration
Antitumor drugs	Cisplatin	Irreversible dose-related and cumulative kidney failure. TIN with heavy proteinuria. Often AKI	Urine: ↑Mg, ↑PO_4, tubular casts and ↑LMWP in early stages
	Methotrexate	Nonoliguric AKI. Tubular atrophy and interstitial fibrosis	Seen only in association with high-dose therapy
	Interleukin-2	Reversible AKI due to ↓RBF	Observed in up to 90% of cases of high-dose therapy
Other drugs	ACE inhibitors	Dramatic ↓GFR due to ↓efferent arteriolar tone	Especially in the setting of bilateral renal artery stenosis. ↑plasma creatinine and K
	5-Aminosalicylic acid (e.g., mesalazine, olsalazine)	Occasional ATN and irreversible kidney damage	Tubular proteinuria
	Cyclooxygenase (COX)-2 inhibitors	Probably a similar pattern of renal injury to NSAIDs (see below)	
	Lithium	Distal tubular damage with nephrogenic diabetes insipidus ± dRTA	
	Penicillamine	Membranous glomerulopathy with NS, occasionally AKI	Proteinuria
	NSAIDs	Several forms of nephropathy identified, including (1) hemodynamically mediated AKI, (2) TIN ± NS, (3) salt and/or water retention, (4) hyperkalemia, (5) CKD/ESRD ("analgesic nephropathy")	Depends on type of effect
Heavy metals	Cadmium	Subtle but irreversible TIN	Fanconi syndrome with RTA. ↑urinary metallothionein
	Gold	Membranous glomerulopathy but normal GFR maintained	Proteinuria <3.5 g/24 h
	Lead	Proximal tubular atrophy with interstitial fibrosis	Reversible Fanconi syndrome in children with acute poisoning. In lead workers, urinary proteinuria <2 g/24 h in association with ↑plasma urate, hypertension ± gouty arthritis
	Mercury	Proximal tubular damage with ATN	Urine: ↑LMWP

TABLE 48-16 Toxic Nephropathy: Causes, Pattern, and Markers—cont'd

Compound Category	Drug/Toxin	Type of Renal Injury/Pathology	Biomarkers/Notes
Other environmental agents	Hydrocarbons (e.g., paints, dry cleaning solvents)	ATN, chronic TIN, glomerulonephritis. Caused by renal cytochrome P450 metabolism of chloroform to toxic metabolites	Tubular proteinuria ± ↑plasma creatinine
	Paraquat, diquat	ATN secondary to ↓RBF due to shock and direct toxic effects of paraquat. Intrinsic kidney damage due to production of reactive oxygen species	↑plasma creatinine
Drugs used in transplantation	See Table 48-19.		

ACE, Angiotensin-converting enzyme; *AKI,* acute kidney injury; *ATN,* acute tubular necrosis; *CKD,* chronic kidney disease; *dRTA,* distal renal tubular acidosis; *ESRD,* end-stage renal disease; *LMWP,* low molecular weight proteinuria; *NS,* nephrotic syndrome; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *RBF,* renal blood flow; *TIN,* tubulointerstitial nephropathy.

TABLE 48-17 Laboratory Support for Dialysis Programs

Clinical Condition	Laboratory Tests
Acute Dialysis	
Dialysis disequilibrium	Urea and electrolyes, bicarbonate, calcium
Pyrexia	C-reactive protein, white cell count, blood cultures
Bleeding	Clotting screen, platelets
Chronic Dialysis Programs	
Anemia	Ferritin, transferrin saturation, B_{12}, folate Blood film, PTH, C-reactive protein
Sepsis	C-reactive protein, blood, urine specimens for microscopy, culture and sensitivity
Nutrition	Albumin, phosphate
Cardiovascular disease risk	Lipid profile
Dialysis-related amyloid	β_2-Microglobulin (not routinely measured)
CKD-MBD	Predialysis plasma calcium, phosphate (monthly in hemodialysis patients; 3-monthly in peritoneal dialysis patients) Alkaline phosphatase PTH (at least every 3 months) Aluminum in patients receiving aluminum-based phosphate binders (3-monthly)
Adequacy of hemodialysis as assessed by urea clearance	Predialysis and postdialysis urea
Sepsis, abdominal pain in peritoneal dialysis	Microscopy and culture of peritoneal dialysate
Adequacy of peritoneal dialysis as assessed by weekly small solute clearance	Dialysate creatinine, urea
Peritoneal membrane characteristics assessed by peritoneal equilibration test (PET)	Plasma and dialysate glucose and creatinine

CKD, Chronic kidney disease; *MBD,* mineral and bone disorder; *PTH,* parathyroid hormone.

HD relies on good vascular access to the circulation of the patient to enable blood to be pumped around the extracorporeal circuit at a rate in excess of 300 mL/min. Suitable vascular access was not achieved until the 1960s. Although Kolff at Groningen Hospital in the Netherlands performed the first dialysis experiments in humans in 1943, the problem of dialysis support with long-term vascular access was not solved until Scribner developed the arteriovenous cannula in 1960. This advance was followed by the development of the surgically created arteriovenous fistula (AVF), introduced by Brescia and coworkers in 1966, which provided permanent vascular access. The Dialysis Outcomes Practice Patterns

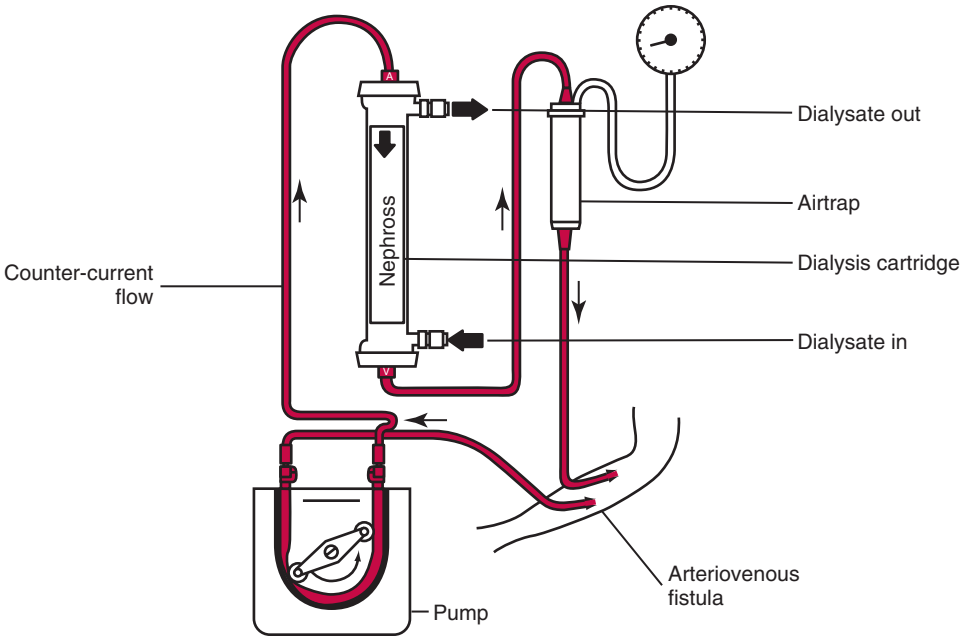

Figure 48-17 A hemodialyzer setup with inset flow diagram.

Study (DOPPS) confirmed a wide variation in how dialysis is achieved throughout the world. For example, most patients in Germany have an AVF as their main access, whereas in the United States, a fistula was used for access in only 13% of patients for their first dialysis in 2006,[79] reflecting suboptimal pre-ESRD care. AVF survival is longer in Europe than in the United States. However, coalition initiatives in 2011 exemplified by the "Fistula First" campaign and the K/DOQI Work Group have delivered service improvements with national AVF rates reported at 58.3% during April 2011.[120A] When used as a patient's first access, AVF survival is considered superior to arteriovenous grafts regarding time to first failure.

Conventional HD uses low-flux dialyzers, allowing diffusive but little convective solute removal. Middle molecule clearance is poor. HF is a convective treatment. Although middle molecule clearances are improved, small molecule clearance is poor. HF is used for continuous treatment in intensive care units in the management of AKI. High-flux HD using biocompatible membranes allows convective and diffusive solute removal. The use of very pure water is crucial in high-flux modes, because dialysis fluid is infused directly into the bloodstream by back-filtration. The Hemodialysis (HEMO) Study, a randomized clinical trial designed to determine whether increasing the dose of dialysis or using a high-flux dialyzer membrane alters major outcomes, concluded that patients undergoing HD three times weekly derived no major benefit from a higher dialysis dose than that recommended by current U.S. guidelines, or from the use of a high-flux membrane.[107] However, subgroup analysis suggested benefit in patients maintained on dialysis for longer than 3.7 years and in those with diabetes.[70] The Membrane Permeability Outcome (MPO) study group reported similar results,[271] and the K/DOQI recommends the use of high-flux membranes.[316]

HDF is HD in which fluid removal exceeds the desired weight loss, and fluid balance is maintained by the infusion of a sterile pyrogen-free solution. HDF offers the advantages of both HD and HF in a single therapy. The replacement fluid, previously supplied in autoclaved bags, is now generated "online" from concentrated bicarbonate, and 20 to 30 L of water is used per session.[252] The result is that HDF provides a 10 to 15% increase in urea clearance compared with HD along with increased middle molecule clearances. Water for online preparation of substitution solution should meet common standards for dialysis water regarding chemical contaminants, but should be of higher quality regarding microbiological contaminants. Online HDF has been used extensively in continental Europe over the past 20 years or so.

After several years of HD, patients may develop carpal tunnel syndrome and evidence of amyloid deposition. The main constituent of dialysis-related amyloid is β_2-microglobulin. Circulating concentrations of β_2-microglobulin can be as high as 30 to 40 mg/dL. Although no correlation is noted between β_2-microglobulin circulating concentration and risk of amyloidosis, evidence from the HEMO study indicates that concentrations are correlated with survival.[71] Retrospective data from Lombardy in Italy indicate that there is a 5% risk that carpal tunnel decompression surgery will be required after 8 years of extracorporeal therapy, and that a reduction in risk of 42% is seen in those patients treated by HDF and HF compared with conventional HD.[270] It is suggested that patients on PD are less prone to developing amyloidosis.

Fluid management on HD is crucial for patient well-being and survival. Because conventional dialysis is based on a thrice weekly schedule, fluid is accumulated by the patient between dialysis sessions. Many patients are anuric or at least oliguric; therefore unrestricted fluid intake would result in

fluid overload and complications of pulmonary edema and hypertension. Patients receiving HD are advised to restrict fluid intake to 1 L/d or so. This allowance is recommended to the individual patient by the dialysis nursing staff and the dietitian to ensure that adequate nutrition is maintained. Nevertheless many patients find the fluid restriction very difficult to maintain; therefore large weight gains between dialysis sessions are a common occurrence. During the dialysis session, the patient's "dry" or "target" weight is achieved. At dry weight, the fluid compartments are normal; this value is determined by gradually reducing weight until the patient is edema-free and reaches the point below which hypotension occurs on further fluid removal. The dry weight is difficult to reach in patients with abnormal cardiovascular responses, who may become hypotensive despite being relatively fluid replete.

When HD is begun, most patients have a small amount of residual renal function (RRF). This value of RRF may persist for many months and years; the volume of urine produced each day allows greater fluid intake and provides the benefit of reducing large fluctuations in body fluid volumes. RRF should be taken into consideration when dialysis prescriptions are adjusted. The K/DOQI Work Group 2006 updates include recommendations, as opposed to guidelines (opinion-based rather than evidence-based), for preserving RRF in patients receiving HD.[316]

Assessment of Adequacy of Hemodialysis

Assessment of adequacy of dialysis treatment for individual patients in the clinical setting includes consideration of the patient's well-being, cardiovascular risk, nutritional status, and degree of achievable ultrafiltration. It also includes estimates of a number of laboratory parameters, such as hemoglobin, phosphate, and albumin and clearance of the small solutes urea and creatinine. Although a full description of adequacy is beyond the scope of this text, a brief outline will be provided. Clearance of urea during a dialysis session (Kt/V) is calculated following determination of predialysis and postdialysis plasma urea concentrations, the time of the dialysis session, RRF, total clearance predicted from the dialyzer, and blood and dialysate flow rates. These variables are processed using computerized mathematical formulas. The Kt/V effectively describes the *power* of the dialysis session and continues to be valued as the most precise and accurate measure of dialysis.[316] A retrospective analysis of the National Cooperative Dialysis Study (NCDS) was the first study to identify a threshold in the value of Kt/V and survival in HD.[273] In practice, a simple calculation may be performed to obtain an estimate of dialysis adequacy: the urea reduction ratio (URR). The URR is the percentage fall in plasma urea attained during a dialysis session and is measured as follows:

$$[(\text{Predialysis }\{\text{urea}\} - \text{Postdialysis }\{\text{urea}\})/(\text{predialysis }\{\text{urea}\})] \times 100\%$$

Observational studies in populations of dialysis patients have shown that variations in URR are associated with major differences in mortality.[330]

Following publication of the HEMO study,[107] in 2006 the K/DOQI Work Group recommended that the target dose of delivered dialysis as calculated by Kt/V urea kinetic modeling was 1.4 per dialysis session. This dose is consistent with the target single pool Kt/V of approximately 1.4 set by the European Standards Group[111] and is roughly equivalent to a urea reduction ratio of 70% per dialysis for a patient receiving hemodialysis three times weekly.

Peritoneal Dialysis

Peritoneal dialysis (PD) is a type of dialysis in which dialysate is passed into the patient's peritoneal cavity, with the peritoneum employed as the dialysis membrane. It was first explored by Ganter in 1923 and initially showed poor results. The modern era of PD started in 1953, with intermittent irrigation of the peritoneal cavity with commercially prepared solutions and access achieved through a single disposable catheter (Figure 48-18). Popovich and coworkers in 1976 introduced the concept of portable equipment; this approach led to the use of continuous ambulatory peritoneal dialysis (CAPD),[351] a type of PD performed in ambulatory patients during normal activities. Peritoneal dialysis now accounts for 6.2% and 7.4% of the incident and prevalent dialysis populations in the United States—proportions that have continued to decline over the past decade from peaks of 13% and 11%, primarily as the result of an increase in HD capacity.[79] Use of PD varies between countries depending on access to HD. For example, in the United Kingdom, 21% of prevalent patients receive PD,

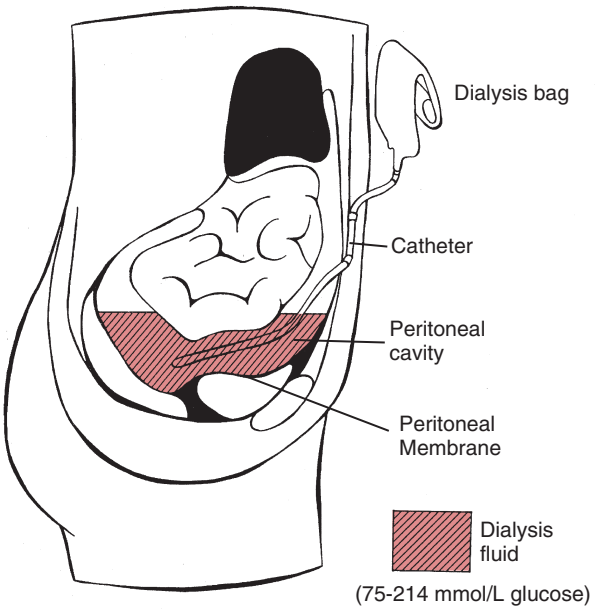

Figure 48-18 Diagrammatic sketch of peritoneal dialysis. *(Redrawn from Nolph KD. Peritoneal anatomy and transport physiology. In: Maher JF, ed. Replacement of renal function by dialysis, 3rd edition. Dordrecht, The Netherlands: Kluwer Academic Publishers/ Springer, 1989:Chapter 23.)* **To convert glucose concentration in mmol/L to mg/dL, multiply by 18.**

reflecting a percentage fall of 10% over 10 years, whereas in Mexico, 90% of patients receive PD.[338]

Description

Operationally, CAPD uses the patient's own peritoneal membrane (surface area ≈2 m^2), across which fluid and solutes are exchanged between the peritoneal capillary blood and the dialysis solution placed in the peritoneal cavity. Fluid removal (ultrafiltration) is achieved by using dialysis fluids containing high concentrations of dextrose acting as an osmotic agent; as dextrose passes across the peritoneal membrane, the rate of fluid removal decreases. Conventional therapies use four daily exchanges of approximately 2 L of fluid with approximately 10 L of spent dialysate generated, including ultrafiltration. RRF is critical to the success of PD because only a few milliliters per minute can contribute substantially to urea clearance and creatinine clearance (C_{Cr}), with each additional milliliter resulting in an extra 10 L of clearance per week. Practical reasons for opting for PD include (1) preservation of RRF and vascular access sites, (2) increased patient autonomy, (3) flexibility as to where the treatment can be administered, and (4) ease of self-treatment, with lower capital costs involved. The higher permeability of the peritoneal membrane provides good removal of β_2-microglobulin and may help to protect patients from the development of dialysis-related amyloid. Blood pressure control and extremes of fluid shifts are not as problematic as those that occur on conventional HD.

Automated PD is now widely available. It requires a programmable machine to regulate flow, dwell time, and drainage, and it may be performed at night. Solute clearance can be increased by leaving fluid in the peritoneum during the day and by performing an additional daytime exchange.

The main disadvantage of PD is the risk of infection causing peritonitis. Incidence rates of peritonitis have decreased over the years with the introduction of disconnect PD systems, improved training of patients with regard to meticulous hygiene, and microbiological surveillance protocols. The current standard from the U.K. Renal Association is that the peritonitis rate should be less than one episode per 18 patient months.[446]

Peritonitis typically presents with a cloudy dialysate effluent and abdominal pain. Additional features such as vomiting and a high temperature suggest serious infection. Blood and dialysate samples should be taken for urgent microbiological analysis and antibiotics administered via the dialysis catheter directly into the peritoneum. If antibiotic treatment fails, then the catheter is removed and the patient converted to HD. In most cases, the episode of peritonitis responds to treatment and PD can continue, although it is likely that repeated episodes will cause scarring and fibrosis of the peritoneal membrane with permanent loss of ultrafiltration. Long-term serious complications may occur, such as sclerosing encapsulating peritonitis caused by adhesions and peritoneal thickening encasing the peritoneal contents and causing bowel obstruction. This unusual condition is associated with increased frequency of peritonitis episodes and longer duration of PD.[16]

Assessment of Adequacy in PD

A series of clinical outcome reports have demonstrated that measures of PD solute removal (urea and creatinine) correlate with patient status and outcome.[249,284,400] In particular, a multicenter prospective cohort study of 680 incident CAPD patients [Canada-United States (CANUSA) Study] showed that a decrease of 0.1 in weekly urea clearance (defined by Kt/V_{urea}) was associated with a 5% increase in the RR of death.[74] Similarly, a decrease of 5 L/wk/1.73 m^2 of total C_{Cr} was associated with a 7% increase in the RR of death. As a consequence of these studies, national guidelines from the United Kingdom,[446] Australia,[60] and the United States[313] have set standards of dialysis adequacy in terms of small solute removal. An estimate of adequacy is performed in all patients within 6 to 8 weeks of commencement of dialysis. Additional studies should be performed at least every 6 months.[446]

Obtaining the weekly Kt/V_{urea} requires measurement of the volume of spent dialysate and urine for a complete 24-hour period. The concentration of urea in dialysate (D) compared with plasma (P) is calculated (the D/P ratio), and this value is then multiplied by the volume of the drained effluent to obtain an estimate of Kt. The calculation of "V," or the volume of distribution of urea, is derived from an estimate of total body water.[193,460] An estimate of weekly Kt/V_{urea} is simply the daily clearance multiplied by a factor of seven. These equations are used for both peritoneal and renal clearance, and the total weekly clearance is obtained by addition. Calculation of C_{Cr} is based on the following clearance (C) formula:

$$C = \frac{U\ (\text{or } D) \times V}{P}$$

where *U* is the concentration of creatinine in urine or dialysate, *V* is the mean daily drain volume or urine volume (measured in liters), and *P* is the concentration of creatinine in the plasma. The daily clearances obtained for both urine and dialysate are added together and multiplied by seven for the total weekly C_{Cr}. Current recommendations from the U.K. Renal Association include a combined urinary and peritoneal Kt/V_{urea} greater than 1.7/wk or a creatinine clearance greater than 50 L/week/1.73 m^2, which should be considered as reflecting minimal treatment doses. The dose should be increased in patients experiencing uremic symptoms.[446]

Compliance with complete collections is mandatory. To avoid sampling errors in patients who void infrequently, urine is collected over a 48 hour period. Dialysate sampling requires that all effluent bags obtained over a 24 hour period should be brought to the center renal unit; this can be difficult because the bags are heavy and bulky. Glucose concentrations in peritoneal dialysis bags may reach 3852 mg/dL (214 mmol/L): it is important that glucose interference in the dialysate creatinine measurement is corrected for when Jaffe assays are used[114] or minimized by the use of an enzymatic creatinine method.[250] An adjunct to assessment of adequacy in PD patients is the peritoneal equilibration test (PET),[441] which assesses peritoneal membrane transport characteristics in terms of creatinine clearance, glucose

absorption, and ultrafiltration. The results are used to select dialysis schedules appropriate to the transport characteristics of the patient.

Measurement of adequacy is burdensome, labor intensive, and prone to multiple measurement errors, particularly from volume measurements of urine and dialysate samples; laboratory errors in measurements of urea and creatinine in blood, urine, and dialysate; and finally adjustment of results to predict weekly clearance. Although dialysis center nursing staff and patients may collect the samples required for adequacy testing with the utmost diligence, the very complexity and number of measurements taken will lead to an accumulation of measurement errors. In the opinion of the authors of the NKF-K/DOQI Clinical Practice Guidelines for PD Adequacy, when properly performed, these measures are reproducible enough to be useful in routine clinical practice.[313] However, an alternative, simpler method for defining dialysis adequacy would be very useful in practice.

Malnutrition in Dialysis Patients

Dialysis patients with ESRD tend to have a poor appetite. In addition, protein metabolism is altered in the setting of chronic acidosis and low-grade inflammation. These factors in combination place patients at risk of protein and energy malnourishment. Nutritional screening is recommended in dialysis patients. Such screening may involve subjective global assessment, measurement of the body mass index, a recent history of weight loss, and the measurement of albumin. Serum albumin is often used as a marker of malnutrition, even though it is a relatively poor nutritional marker.[214] However, good evidence indicates that the lower the albumin concentration, the worse is the long-term prognosis.[128,129,330] An albumin concentration less than 3.5 g/dL (measured by a bromocresol green method) or less than 3.0 g/dL (bromocresol purple method) is indicative of undernutrition. Hypoalbuminemia is associated with increased markers of the acute-phase response, such as CRP.[331,420] Persistent elevation of CRP is common in dialysis patients and may occur in the absence of detectable infection. Episodes of peritonitis in PD patients cause significant albumin losses as the result of membrane leakage.

Kidney Transplantation

Kidney transplantation is the most effective form of renal replacement therapy, in terms of long-term survival and quality of life.[352] Data provided by the Organ Procurement and Transplantation Network reveal that 305,000 kidney transplants were performed in the United States between 1988 and June 2011. During 2010, 16,898 kidney transplants were performed in the United States, and more than 89,000 patients are on the waiting list for a kidney transplant.[328A] The median waiting time for a listed patient depends on his or her age. For example, for patients listed between 2003 and 2004, the median waiting time for a child aged 1 to 5 years was 361 days, and for an adult aged 35 to 49 years, 1807 days. Although patients with kidney failure should have equitable access to kidney transplantation, currently only 23% of adult patients on dialysis in the United Kingdom are on the active renal transplant waiting list. Waiting time spent on dialysis has been shown to be an important factor in determining mortality. In England and Wales, 45% of patients younger than 65 years were activated on the transplant list within 1 year of starting dialysis, and 66% were activated within 5 years. Evidence suggests that the very best outcomes are achieved following preemptive (i.e., before dialysis has become necessary) live donor transplants[285]; this has led to increased emphasis on preemptive transplantation, particularly in the United Kingdom following the National Service Framework for Renal Services, published in 2004.[99]

Since Joseph Murray in Boston performed the first successful transplant in 1954 from one twin to the other, progressive developments have occurred in this field of medicine. In 1959, Dameshek and Schwartz used 6-mercaptopurine (6-MP) in place of irradiation to precondition patients for bone marrow transplantation. Calne developed this work with the introduction of a safer derivative of 6-MP called azathioprine (AZA). By 1963, maintenance AZA and corticosteroids had become the standard regimen for kidney transplantation. Kidney transplant or "allograft" survival with these treatment protocols was approximately 40% at 12 months. In the late 1970s to early 1980s, cyclosporine was introduced and has since been the mainstay immunosuppressive regimen in combination with AZA and corticosteroids. Cyclosporine-based protocols led to fewer episodes of acute rejection and improved graft survival at 12 months to 80 to 90%. Tacrolimus, mycophenolate mofetil (MMF), sirolimus (Rapamycin), and everolimus (Ever) were developed for use in kidney transplantation in the mid- to late 1990s (see Chapter 35 for details on the individual drugs). Also, marked progress has been noted in the development and use of biological agents (monoclonal or polyclonal antibodies directed against immune response cellular targets) to suppress the immune response to a graft in human transplant recipients. All these advancements have led to increases in graft and patient survival, with 1-year graft survival of approximately 90% being the norm.[121,157] By contrast, long-term graft survival remains a major problem, with half of transplants failing within 14 years, usually as a result of chronic allograft injury or death with a functioning graft. Transplantation medicine provides a constant challenge to balance the immunologic risk of damage to the allograft (rejection) versus the well-being of the recipient, while avoiding excess immunosuppression that increases the likelihood of opportunistic infection and malignancy. In addition, many of the powerful immunosuppressive drugs have idiosyncratic side effect profiles.

Preoperative Assessment

The criteria for acceptance into a transplant program differ slightly from center to center, and it is easier to consider reasons for exclusion (Box 48-8). Two important psychologic issues remain to be considered: (1) the concept of organ receipt, and (2) the potential difficulty in complying with immunosuppressive therapies. Age is no longer a primary issue in an otherwise healthy individual; however, only 6% of

BOX 48-8 Exclusion Criteria for Consideration for a Kidney Transplant

Serious concomitant illness (particularly if likely to shorten life expectancy or to be exacerbated by immunosuppressive treatment)
- Active malignancy*
- Inoperable ischemic heart disease
- Severe chronic lung disease
- Active systemic infection (e.g., tuberculosis)
- Active immunologic disease
- Severe irreversible hepatic disease
- Severe peripheral vascular disease

Severe obesity [body mass index (BMI) >40 kg/m^2)
Lower urinary tract dysfunction not amenable to surgical repair
Substance abuse
Significant psychiatric disturbance

*Malignancy that has been treated with no evidence of recurrence is not an exclusion, provided the predefined remission period has elapsed.

BOX 48-9 Immunologic Aspects of Transplantation

Although a detailed description of the immunologic aspects of transplantation is beyond the scope of this chapter, a brief discussion follows to highlight the close collaboration between clinicians and the tissue typing laboratory, and to explore some of the recent advances in transplantation. The tissue type identifies an individual based on human leukocyte antigens (HLAs) expressed on cells. These antigens are coded by genes of the major (and minor) histo- (tissue) compatibility complex (MHC). Individuals who have received blood transfusions or previous transplants of nonidentical tissue and females who have had pregnancies develop antibodies to nonself HLA. These antibodies can be detected by analyzing the recipient serum against a panel of cells containing various HLA types. If a reaction is noted between donor cells and recipient serum in vitro, this is indicative of a potential positive cross-match between donor organ and recipient at the time of transplantation. All recipients are tested regularly by the tissue typing service. Highly sensitive individuals have a number of antibodies or an antibody to a common HLA type and typically have a longer waiting time for a suitable donor kidney. The definition of high sensitization varies, for example, panel-reactive antibody (PRA) >50%. PRA refers to the percentage of typical donors against which the patient has in vitro evidence of potentially toxic alloantibody. Highly sensitized patients form about 30% of those on the waiting list in the United States.[278]

ABO blood group incompatibility and HLA cross-match reactivity between donor organs and recipients result in an accelerated or "hyperacute" rejection of the nonself organ (allograft) and have been traditional barriers to transplantation. Recent developments have led to desensitization protocols to remove pre-formed antibodies from the plasma of potential recipients and have permitted transplantation across ABO and HLA barriers. This has permitted previously unsuitable potential live donors to donate. The outcome for recipients of desensitization programs is very encouraging, with 89% of allografts surviving at 22 months' follow-up in a single center.[279] Following transplantation, clinicians and the tissue typing laboratory must remain vigilant for the persistence or reappearance of antibodies that may mediate rejection of the allograft.

transplant recipients in the United Kingdom are over the age of 65.[445]

Laboratory assessment includes indicators of general operative health [e.g., electrolytes, acid-base status, clotting profile, full blood cell count, cross-matching (Boxes 48-9 and 48-10)]. In addition, a full screen for infectious diseases, particularly cytomegalovirus (CMV), Epstein-Barr virus, hepatitis B and C, varicella-zoster virus, and human immunodeficiency virus (HIV) status, is undertaken; these infections can be activated by immunosuppressive therapy.

The Operation

The donor kidney is usually placed extraperitoneally in the right or left iliac fossa. Anastomoses are constructed joining the transplant renal artery and vein to the recipient's respective iliac vessels. The ureter is joined to the bladder. The recipient native kidneys are left in situ in most cases. Living donor kidneys can be retrieved through open surgery or with the aid of laparoscopic techniques.

Postoperative Assessment

During the initial postoperative phase of 1 to 2 weeks, careful monitoring of serum creatinine and urine output is required to monitor graft function. Most grafts produce measurable amounts of urine within a matter of hours, and this is a clear sign of a functioning graft; however, in a certain proportion, perhaps 5 to 10% of cases, primary nonfunction is apparent. In this subgroup, continuing dialysis support is necessary. In some patients the condition resolves without treatment, but in others a percutaneous kidney biopsy may be necessary to establish whether the graft is still viable and what form of therapy should be initiated. In otherwise uncomplicated cases, the serum creatinine concentration falls rapidly postoperatively (Figure 48-19). Early allograft rejection episodes are suspected if the creatinine does not fall to the expected concentration, or if there is a rise of 10% in creatinine concentration. The differential diagnoses of graft dysfunction and complications that may ensue following transplant are summarized in Table 48-18. In the very early postoperative phase, in addition to rejection, graft dysfunction may be a consequence of delayed graft function, immunosuppressive drug toxicity, and acute tubular damage. Relative hypotension and dehydration may also contribute. Renal artery and venous thromboses are rare complications, and ureteric obstruction can be readily diagnosed using ultrasonography. Histologic examination of a transplant biopsy is necessary to aid diagnosis and treatment adjustment. Regular monitoring of kidney function, drug concentrations, and viral assay—particularly for CMV viremia and polyoma viruses such as BK virus— is mandated following kidney transplantation in many centers.

BOX 48-10 Laboratory Assessment of Potential Kidney Transplant Recipient*

Electrolytes, liver function tests, glucose, C-reactive protein
Acid-base status
Full blood cell count
Clotting profile
Cytomegalovirus (CMV)
Hepatitis B and C
Varicella-zoster virus (VZV)
Epstein-Barr virus (EBV)
Human immunodeficiency virus (HIV) 1 and 2
Toxoplasma
Syphilis serology
Blood group: ABO compatibility
Tissue typing: human leukocyte antigen (HLA)
Panel reactive antibodies (PRAs) (see Box 48-9)

*Tests of cardiac disease, vascular disease, and bladder function are also required in most cases.

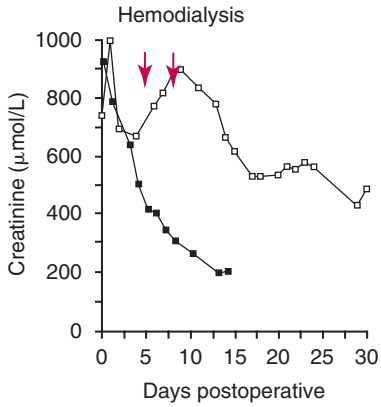

Figure 48-19 Post-transplantation biochemical profile. *Open squares* represent the course of a patient who experienced an early rejection episode (confirmed by biopsy, ↓) and requires initial hemodialysis support. *Solid squares* represent the typical profile of an uncomplicated transplant recipient. To convert creatinine concentration in μmol/L to mg/dL, multiply by 0.011.

Primary glomerular disease may recur following kidney transplantation, resulting in loss of the graft. An Australian study has confirmed the 10 year incidence of graft loss caused by recurrent glomerulonephritis as 8.4%.[49] Recurrence was the third most frequent cause of graft loss (chronic allograft nephropathy and death with a functioning graft were most common). As compared with the average for all recipients with a primary diagnosis of glomerulonephritis, FSGS (11.8%) and mesangiocapillary glomerulonephritis type 1 (10.2%) were most likely to recur, causing graft loss. In contrast, graft loss due to recurrent IgA and pauci-immune crescentic glomerulonephritis occurred in only 2% of patients at 10 years' follow-up.

Allograft Rejection

The immune response to the foreign graft (allograft) is very rapid, and allograft rejection may occur in response to nonidentical HLA molecules. A subtle rise in creatinine of approximately 10% in the first 3 months of a transplant may indicate a rejection episode. However, biopsy of the kidney transplant is necessary to confirm the cause of graft dysfunction and to identify the type of rejection that is occurring. A systematic classification system is employed ("Banff classification") to report transplant biopsy specimens.[414] The latest updates from the Banff report have increasingly recognized the importance of humoral (antibody-mediated) rejection as a cause of allograft failure during the whole life of the transplant. Rejection has classically been divided into cellular and vascular types, and typically has been qualified by the speed of onset of graft dysfunction and the time since transplant. This classification builds on this but incorporates antibody-mediated rejection (acute or chronic) and T cell–mediated rejection (again, acute or chronic). Advances in the diagnoses of humoral rejection have included identification of complement-fixing alloantibody along capillary walls within the transplant following the development of a stain for C4d product.[118] In addition, donor-specific anti-HLA antibodies can often be detected in the serum of the recipient during the course of the transplant and may predict graft dysfunction in some cases.[433,480] It is accepted that antibody- and T cell–mediated rejection may coexist as causes of immunologic damage to the allograft. Allograft rejection typically is treated by escalating immunosuppression schedules, and treatment may include antithymocyte globulin and/or high-dose corticosteroids.

Immunosuppression and Therapeutic Drug Monitoring

As mentioned earlier, the introduction of immunosuppressive drugs in the 1970s led to vast improvement in the success rate of kidney transplantation (see Chapter 35). However, currently used drugs have potentially numerous and serious side effects that are summarized in Table 48-19.

Following the introduction of cyclosporine in the 1980s, a dramatic increase in 1 year graft survival resulted from the reduction in the number of acute rejection episodes.[300] However, a number of important side effects have been observed. Nephrotoxicity was soon apparent in early clinical trials[57] and remains a major clinical problem. During the 1990s, tacrolimus was introduced and 1 year graft and patient survival rates were equivalent to those achieved with cyclosporine therapy, although rates of acute rejection episodes were lower.[148,293,348,440] Five-year follow-up data suggest improved graft survival with tacrolimus compared with cyclosporine.[456]

Sirolimus, in contrast to cyclosporine, does not cause nephrotoxicity, gingival hyperplasia, or tremor. However, patients treated with sirolimus have a higher incidence of thrombocytopenia, hyperlipidemia, and lymphocele formation.[218] Sirolimus and mycophenolate mofetil (MMF), both introduced during the late 1990s, have been studied in the

TABLE 48-18 Complications Following Kidney Transplantation

	Immediate Post Transplant	Early Post Transplant Period Until 3 Months	3-12 Months	After 1 Year	Comments
Surgical complications	Renal venous thrombosis, arterial thrombosis Pelvic lymphocele adjacent to the transplanted kidney Ureteric obstruction			Ureteric obstruction, renal artery stenosis	Increased incidence of lymphocele reported with sirolimus
Kidney	Acute tubular necrosis with delayed graft function				Dialysis treatment may need to be continued Transplant usually recovers following adjustment of CNI doses Electrolytes and creatinine should be measured daily
(a) Immunologic	Hyperacute rejection: occurs as a consequence of pre-formed antibodies in recipient serum to donor blood group or HLA antigens, resulting in graft failure. Plasma exchange may be initiated but transplant nephrectomy likely	Acute rejection in 20-60% of patients Associated with rise in serum creatinine concentration Confirmed on biopsy Pathologic description includes vascular and cellular infiltration by immune reactive cells Requires urgent treatment with high-dose corticosteroids	(i) Chronic allograft injury. Heralded by rising serum creatinine, proteinuria, and hypertension. Common cause of graft failure in the long term. Complex pathogenesis with a combination of donor-specific and recipient influences. Humoral (antibody-mediated) rejection increasingly recognized as contributing to immunologic injury. Transplant biopsy may show peritubular capillary stain for complement degradation product C4d (ii) Subclinical rejection not suspected from serum creatinine concentration. This is a pathologic diagnosis from transplant biopsy and is treated with high-dose corticosteroids		Transplant centers may perform biopsy protocols at 3, 6, and 12 months to guide therapy Clinical episode of rejection considered if serum creatinine concentration increases from baseline Monitor recipient serum for anti-HLA antibodies, particularly donor-specific antibodies Reduction in immunosuppression during maintenance phase of stable transplants
(b) Recurrent disease	Glomerular disease such as FSGS and MCGN may occur early and lead to graft failure		Risk of anti-GBM disease in patients with Alport's syndrome Familial hemolytic-uremic syndrome		Low risk of recurrent disease causing graft failure in diabetes and IgA nephropathy

Infection	Chest infection Urinary tract infection Septicemia	Opportunistic infections: PCP, CMV infection and reactivation. High-risk cases include donor-positive and recipient-negative for prior exposure to CMV (D+/D–) Prophylactic antiviral drugs recommended in high-risk patients Varicella-zoster virus, polyoma virus (BK virus nephropathy), candidiasis	CMV viremia in high-risk cases following discontinuation of prophylactic antiviral medication		Increased risk of infection in all patients receiving immunosuppression Patients advised to receive influenza vaccine annually and vaccination against pneumococcus Regular screening for viremia by PCR methods Routine staining of transplant biopsy specimens for SV40 to identify BK virus nephropathy C-reactive protein, urine microscopy, cultures performed Blood cultures Chest x-ray
Drug-related toxicity	See Table 48-19.				
Lymphoproliferative		PTLD Typically associated with EBV expression in patients exposed to highly potent immunosuppressive protocols	PTLD Includes non–EBV-related lymphoma	PTLD Includes non–EBV-related lymphoma	EBV-PCR CT/MRI scans of chest, abdomen, and pelvis Tissue diagnosis mandatory from lymph node and bone marrow Serum lactate dehydrogenase activity increased
Malignancy	Increased risk of nonmelanotic skin malignancy and solid organ malignancy in all patients				
Cardiovascular disease	Increased incidence of cardiovascular disease following transplantation. Death with a functioning graft is a common cause of "graft failure" Most transplant patients require treatment for hypertension and dyslipidemias				

CMV, Cytomegalovirus; *CNI,* calcineurin inhibitor; *CT,* computed tomography; *EBV,* Epstein-Barr virus; *FSGS,* focal segmental glomerulosclerosis; *GBM,* glomerular basement membrane; *HLA,* human leukocyte antigen; *Ig,* immunoglobulin; *MCGN,* mesangiocapillary glomerulonephritis; *MRI,* magnetic resonance imaging; *PCP, Pneumocystis carinii* pneumonia; *PCR,* polymerase chain reaction; *PTLD,* post-transplant lymphoproliferative disease; *SV40,* simian virus 40 (cross-reacts with BK virus).

TABLE 48-19 Noninfectious Complications of Immunosuppressant Drugs

Drug	Drug Dose	Target Therapeutic Range*	Toxicity Profile
Corticosteroids (e.g., prednisone)	Dose depends on weight of patient and time since transplant. Typically, 40 mg daily during first week and tapering to 5 mg at 6 months and withdrawal at 12 months	Not appropriate	Increased risk of developing diabetes mellitus Deterioration in diabetes control Osteopenia Osteoporosis Psychosis Fat redistribution Hypertension Dyslipidemia Cataracts Weight gain
Calcineurin Inhibitors			
Cyclosporine	Variable Depends on weight, time since transplant, and achieved drug concentration. Given in two divided doses and predose trough level measured in morning blood sample	200-300 µg/L for first 3-12 months. Thereafter aim for 100 µg/L	Nephrotoxicity Hypertension Neurotoxicity Hemolytic-uremic syndrome Tubular electrolyte abnormalities (hypophosphatemia, hypomagnesemia, hyperkalemia) Hirsutism Gingival hyperplasia Bone pain Dyslipidemia
Tacrolimus			As for cyclosporine, except no hirsutism or gingival hyperplasia Increased risk of diabetes mellitus Cardiomyopathy (children) Alopecia
Mycophenolate mofetil	Aim for 2 g daily in divided doses	Not routinely measured	Abdominal pain Diarrhea Myelosuppression
Sirolimus	Dose depends on weight and achieved drug level. The drug is administered once daily	Level depends on time since transplant. Typical early (<3 months) targets are 8-12 µg/L and thereafter 4-8 µg/L	Lymphocele (a fluid-filled collection near to transplanted kidney) Thrombocytopenia Hyperlipidemia
Azathioprine	Usual starting dose of 2 mg/kg body weight in a single daily dose	Levels not measured. Because the enzyme thiopurine methyltransferase (TPMT) metabolizes azathioprine, the risk of myelosuppression is increased in patients with low activity of the enzyme (although the enzyme level is not measured routinely: weekly monitoring of full blood counts is performed for several weeks following commencement of drug)	Myelosuppression Severe interaction if used with allopurinol (treatment for gout)

TABLE 48-19 Noninfectious Complications of Immunosuppressant Drugs—cont'd

Drug	Drug Dose	Target Therapeutic Range*	Toxicity Profile
Biological Agents			
Anti-CD25 monoclonal antibodies	Given at time of transplant and once thereafter		Very well tolerated
Basiliximab and daclizumab			
Polyclonal antithymocyte globulin (ATG) and antilymphocyte globulin (ALG), and monoclonal OKT3	Given in response to refractory rejection episodes in selected patients		Increased risk of malignancy, post-transplant lymphoproliferative disease Hypersensitivity reactions

*These are not recommendations but are illustrative and will vary between centers.

setting of cyclosporine withdrawal and cyclosporine-free strategies in kidney transplantation,* the hypothesis being that withdrawal or avoidance of cyclosporine would improve long-term outcomes because there is no nephrotoxic stimulus. It has been shown in a multinational study that withdrawal of cyclosporine within 3 months of transplantation is feasible.[208] Studies have also shown that sirolimus in combination with MMF is safe and is associated with low rates of acute transplant rejection at 12 months.[121]

These patients also received basiliximab, a monoclonal antibody to a specific target (CD 25) of T-cell activation that occurred in response to a nonidentical graft. However, the CEASAR study (Cyclosporin Sparing with Mycophenolate mofetil, daclizamab and Corticosteroids in Renal Allograft Recipients) found that use of MMF, corticosteroids, and daclizumab induction was associated with increased risk of rejection if cyclosporine was withdrawn by month 6 following the transplant, compared with continuation of low-dose cyclosporine.[106]

Cyclosporine is insoluble and is presented for clinical use as a microemulsion. It has a narrow therapeutic window, and in clinical transplantation it is important to monitor the blood concentration frequently. The most widely accepted practice is to monitor the "trough" blood concentration just before the next dose. Accepted trough concentrations vary from 100 to 300 μg/L (see Table 48-19). The highest concentrations are targeted during the induction phase of treatment for 2 to 3 months; subsequently, lower maintenance concentrations are desirable. The trough concentration within the blood may not provide a truly accurate guide to total drug exposure, because wide variation in absorption is seen over the first 2 to 4 hours following dosing.[210] This is important in that most of the pharmacodynamic effects of cyclosporine occur within 2 hours.[164] Studies from Canada suggest that trough concentrations do not reflect clinical outcomes in terms of acute rejection rates,[282] although high trough concentrations were associated with increased nephrotoxicity. A 2 hour drug (C-2) concentration correlated well with formal area under the curve measurements and is predictive of nephrotoxicity and acute rejection episodes. Among kidney transplant patients, the trough concentration of tacrolimus is well correlated with acute rejection episodes and nephrotoxicity.[227] Trough concentrations also guide sirolimus therapy (see Table 48-19).[219]

MMF is morpholinoethyl ester of mycophenolic acid (MPA), a potent and reversible inhibitor of inosine monophosphate dehydrogenase isoform 2 (IMPDH), and has become the single most used immunosuppressant in solid organ transplantation. Excellent results have been obtained with a fixed-dose regimen. IMPDH is a target for immunosuppression because lymphocytes depend on the de novo guanosine nucleotide synthesis pathway for DNA synthesis and cell division.[206] MMF, because it is a prodrug of MPA, is rapidly absorbed following an oral dose and is de-esterified to MPA, which is highly protein bound. Free MPA concentrations determine the amount of immunosuppressive activity, and this can be affected by hypoalbuminemia and renal insufficiency. Toxicity of MPA is manifested by bone marrow failure. Therapeutic drug monitoring of MPA is possible using HPLC and immunoassay techniques. However, it has not been established whether the extra effort of measuring MPA concentrations would improve clinical end points. Studies have been commenced to compare fixed dosing versus concentration-controlled MMF therapy; until these findings are reported, therapeutic drug monitoring of MPA has not been established in routine clinical practice.[356]

In summary, long-term graft failure is a major problem, and graft loss accounts for the return of increasing numbers of patients to dialysis. The most common cause of graft loss is death with a functioning graft. Kidney failure carries a considerable burden of cardiovascular morbidity. Although some risk factors, such as volume overload and anemia, are improved following transplantation, others, including dyslipidemia and hypertension, persist. The drugs used to prevent rejection can exacerbate these. Challenges to the nephrology

community are complex and include improving access to transplantation, reducing side effects of the powerful drugs used to prevent rejection, and reducing cardiovascular risk profiles for individual patients.

Simultaneous Pancreas-Kidney Transplantation

Patients with type 1 diabetes and stage 5 CKD with limited secondary complications of diabetes may be considered for simultaneous pancreas and kidney (SPK) transplantation. Patients (aged between 20 and 40 years) tend to be younger than kidney only recipients. Graft and patient survival rates were calculated for more than 3500 recipients of an SPK transplant in the United States from 1994 to 1997, based on data reported to the United Network for Organ Sharing (UNOS) renal registry database.[53] The 1 year graft survival rate was 90%, and patient survival was around 93%. At 5 years, graft survival was in excess of 70%, and patient survival 85%. These results compare favorably with those of cadaveric kidney only transplantation in diabetes. The main reason for the survival advantage of SPK over kidney only is the fact that younger donors and recipients are selected. A separate prospective observational study examined the impact of SPK transplant in terms of quality of life.[156] At 3 years, SPK patients report greater improvements than kidney only recipients in physical functioning, bodily pain, general health, and perception of improvements to secondary complications of diabetes.

The surgical technique for SPK involves whole organ pancreas transplantation with the duodenal segment draining into the urinary bladder through a duodenocystostomy. The kidney is attached as usual to the iliac vessels, and the donor ureter is inserted into the bladder separately. Alternatively, the pancreas can be drained enterically. This distinction is important because of the metabolic consequences outlined below. Postoperatively, blood glucose concentrations are monitored closely and intravenous insulin is given as necessary. Exocrine pancreatic secretion can be measured in the urine. The major fear is rejection and a number of parameters are monitored, including plasma glucose, amylase, lipase, and 12 or 24 hour urinary amylase. Because of high fluid, bicarbonate, and electrolyte losses into the urine, the need for supplementation is increased in SPK recipients. There is a long-term need for high-dose oral sodium bicarbonate supplementation in bladder-drained pancreatic transplantation because of exocrine secretory losses. Hyperamylasemia is common postoperatively and may or may not signify allograft rejection. Immunosuppressive schedules vary between centers and include induction therapy with monoclonal or polyclonal anti–T cell agents and a combination of the drugs outlined previously. Diagnosis of pancreatic rejection in the absence of a simultaneous kidney transplant is very difficult. Signs of rejection include fever, pain, hematuria, reduction of urinary amylase, and unexplained hyperglycemia. Organ scanning and biopsy are also used. However, the function of the kidney in SPK mirrors the pancreas; therefore immunosuppression can be tailored to the requirements of the kidney.

For patients with bladder drainage, enteric conversion may be required for refractory problems, such as dehydration, metabolic acidosis, chronic urethritis caused by trypsinogen activation, urinary tract infection, and recurrent reflux pancreatitis. Enteric conversion involves an anastomosis between the graft duodenal segment and the recipient small bowel.

CHAPTER 49

Physiology and Disorders of Water, Electrolyte, and Acid-Base Metabolism

Joshua L. Hood, M.D., Ph.D., and Mitchell G. Scott, Ph.D.

Adaptation to terrestrial life led to the evolution of physiologic systems to maintain the composition of the internal milieu of animals, including humans. These systems include a variety of chemical buffers and highly specialized mechanisms of the lungs and kidneys that work together to regulate water, electrolytes, and pH between intracellular and extracellular compartments. Perturbations in the dynamic equilibria that exist for water, electrolytes, and pH may arise from external (e.g., trauma, changes in altitude, ingestion of toxic substances) or internal (e.g., normal metabolism, disease state) sources. Endogenous correction of these imbalances may not always be adequate; at these times, the clinical laboratory can provide valuable information for guiding therapy.

TOTAL BODY WATER—VOLUME AND DISTRIBUTION

During gestation, ≈90% of fetal body weight is water.[22] Water is 80% of body weight for preterm infants and 70% for full-term infants. Water gradually decreases as percent of body weight, so that it accounts for 65% of body weight in older children, 60% in adolescents and adult males,[22] and ≈55% for adult females. After middle age, the percentage of body water falls to ≈50%. As depicted in Figure 49-1, approximately two thirds of total body water (TBW) is distributed into the intracellular fluid (ICF) compartment, and one third exists in the extracellular fluid (ECF) compartment. The ICF and ECF compartments are physically separated by the cellular plasma membrane. The ECF may be subdivided into interstitial (≈75% of ECF) and intravascular (≈25% of ECF) fluid compartments, which are separated by the capillary endothelium. The average adult has ≈5 L blood volume (intravascular compartment) and a plasma volume of ≈3.0 L when the hematocrit is ≈40%. Although other clinically relevant ECF compartments (e.g., cerebrospinal fluid,[31] urine) may be analyzed in the clinical laboratory, most laboratory tests used to determine hydration status and electrolyte and acid-base status are performed on samples from the *intravascular* compartment.

The minimum daily requirement for water can be estimated from renal (1200 to 1500 mL in urine) and "insensible" losses (≈400 to 700 mL due to evaporation from the skin and respiratory tract). Activity, environmental conditions, and disease all have dramatic effects on daily water (and electrolyte) requirements. However, on average, an adult must take in ≈1.5 to 2.0 L of water daily to maintain fluid balance. Because primary regulatory mechanisms are designed to first maintain *intracellular* hydration status, imbalances in TBW are initially reflected in the ECF compartment. Table 49-1 lists common causes and clinical manifestations of expansion and contraction of the ECF compartment.

WATER AND ELECTROLYTES—COMPOSITION OF BODY FLUIDS

The primary cationic (positively charged) electrolytes are sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and magnesium (Mg^{2+}), whereas the anions (negatively charged) include chloride (Cl^-), bicarbonate (HCO_3^-), phosphate (HPO_4^{2-}, $H_2PO_4^-$), sulfate (SO_4^{2-}), organic ions such as lactate, and negatively charged proteins. Electrolyte concentrations of the body fluid compartments are shown in Table 49-2. Na^+, K^+, Cl^-, and HCO_3^- in the plasma or serum are commonly analyzed in an *electrolyte profile,* because their concentrations provide the most relevant information about the osmotic, hydration, and acid-base status of the body. Although hydrogen ion (H^+) is a cation, its concentration is approximately 1 million–fold lower in plasma than the major electrolytes listed in Table 49-2 (10^{-9} mol/L vs. 10^{-3} mol/L) and thus is negligible in terms of osmotic activity.

Any increase in the concentration of one anion is accompanied by a corresponding decrease in other anions, or by an increase in one or more cations or both, as total electrical

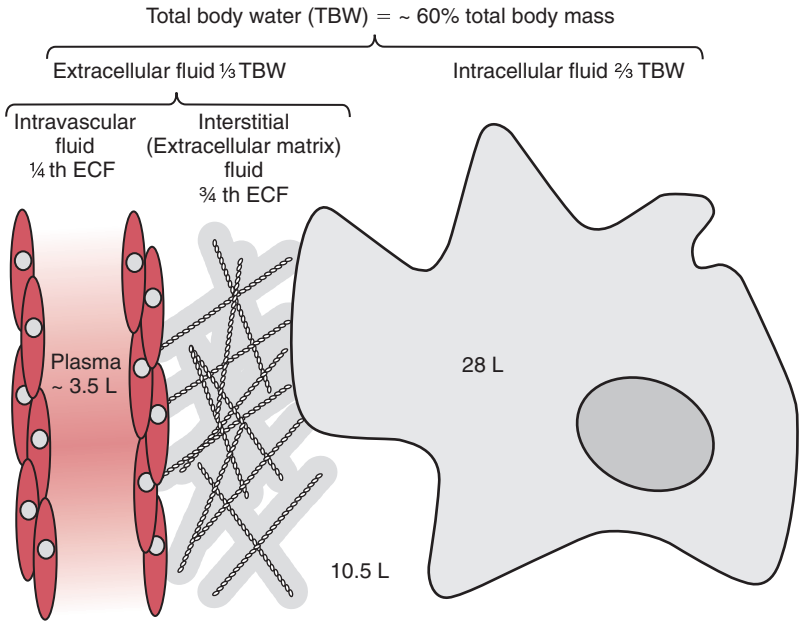

Figure 49-1 Volume and distribution of total body water. Note that the intracellular and extracellular fluid compartments (ICF and ECF, respectively) are separated by cellular plasma membranes, and within the ECF, interstitial and intravascular fluids are separated by the capillary endothelium (red cells). The volumes indicated represent water and not total volume. Endothelial cells = red; interstitial cell = gray; collagen matrix fibers = black cables.

TABLE 49-1 Causes and Clinical Manifestations of Changes in Extracellular Fluid (ECF) Volume

	Clinical Manifestations	Causes
ECF loss	Thirst, anorexia, nausea, lightheadedness, orthostatic hypotension, syncope, tachycardia, oliguria, decreased skin turgor and "sunken eyes," shock, coma, death	Trauma (and other causes of acute blood loss), "third-spacing" of fluid (e.g., burns, pancreatitis, peritonitis), vomiting, diarrhea, diuretics, renal or adrenal (i.e., sodium wasting) disease
ECF gain	Weight gain, edema, dyspnea (due to pulmonary edema), tachycardia, jugular venous distention, portal hypertension (ascites), esophageal varices	Heart failure, cirrhosis, nephrotic syndrome, iatrogenic (intravenous fluid overload)

TABLE 49-2 Electrolyte and Water Composition of Body Fluid Compartments*

Component	Plasma	Interstitial Fluid	Intracellular Fluid†
Volume, H_2O (TBW = 42 L)	3.5 L	10.5 L	28 L
Na^+	142	145	12
K^+	4	4	156
Ca^{2+}	2.4	2-3	0.3
Mg^{2+}	2	1-2	26
Trace elements	1	–	–
Total cations	155	–	–
Cl^-	103	114	4
HCO_3^-	27	31	12
$Protein^-$	16	–	55
Organic $acids^-$	5	–	–
HPO_4^{2-}	2	–	–
SO_4^{2-}	1	–	–
Total anions	154	–	–

*All electrolyte values are expressed in mEq/L of *fluid*. Because the H_2O content of plasma is ≈93% by volume, the corresponding electrolyte concentrations in plasma water are ≈10% higher. Note that the *molar concentration* of divalent ions is one half the depicted value.
†These values are derived from skeletal muscle.
TBW, Total body water.

neutrality must be maintained. Similarly, any decrease in the concentration of anions involves a corresponding increase in other anions or a decrease in cations, or both. In the case of polyvalent ions (e.g., Ca^{2+}, Mg^{2+}), it is important to distinguish between the substance concentration of the ion itself and the concentration of the ion charge. Thus although the concentration of total calcium ions in normal plasma is ≈2.5 mmol/L, the concentration of the total calcium ion *charge* is 5.0 mmol/L [also called 5 milliequivalents per liter (mEq/L)]. This law of *electrical neutrality* should not be confused with acid-base neutrality (pH = 7.0), where the activity of H^+ equals the activity of OH^-.

Extracellular and Intracellular Compartments

The extracellular compartment is composed of plasma and interstitial fluid.

Plasma

Plasma generally has a volume of 1300 to 1800 mL/m^2 of body surface and constitutes approximately 5% of the body volume (≈3.5 L for a 66 kg subject). Generally, total body volume is derived from body mass by using an estimated body density of 1.06 kg/L. Table 49-2 describes the electrolyte composition of plasma. The mass concentration of water in normal plasma is about 0.933 kg/L, depending on the protein and lipid content (see "Electrolyte Exclusion Effect" in Chapter 28). Thus a concentration of sodium in the plasma of 140 mmol/L would correspond to a molality of sodium in plasma water of 150 mmol/kg H_2O (140 mmol/L divided by 0.933 kg/L). The concentration of net protein ions in plasma is ≈12 mmol/L, with the charge mainly due to albumin, as the charge of globulins is negligible.[8]

Interstitial Fluid

Interstitial fluid is essentially an ultrafiltrate of blood plasma (see Figure 49-1). When all extracellular spaces except plasma are included, the volume accounts for about 26% (10.5 L) of the total body volume. Plasma is separated from the interstitial fluid by the endothelial lining of the capillaries, which acts as a semipermeable membrane and allows passage of water and diffusible solutes but not compounds of high molecular mass, such as proteins. The exchange of water between the interstitial and intravascular compartments is governed by Starling forces.[22] The Starling formula demonstrates that the net movement of fluid across a capillary membrane is a function of membrane permeability and differences in hydrostatic and oncotic pressures on the two sides of the membrane. The "impermeability" to proteins is not absolute, and in some pathologic conditions causing "shock," such as bacterial sepsis, the permeability of the vascular endothelium increases dramatically, resulting in leakage of albumin, a reduction in the effective circulating volume, and hypotension. If not aggressively treated with intravenous fluids and/or vasopressors, this condition can result in death as the result of decreased cerebral perfusion.

Intracellular Fluid

The exact composition of ICF is extremely difficult to measure because of the relative unavailability of cells free of contamination. Although erythrocytes are easily accessible, it would be incorrect to make any generalizations based on the composition of these highly specialized cells. Data for ICF (see Table 49-2), therefore, are considered only approximations. The ICF constitutes ≈66% of the total body volume (see Figure 49-1).

Reasons for Composition Differences of Body Fluids

The composition of ICF can differ markedly from that of ECF because of separation of these compartments by the cell membrane. The composition differences are a consequence of both the Gibbs-Donnan equilibrium and active and passive transport of ions.

Gibbs-Donnan Equilibrium

Two solutions separated by a semipermeable membrane will establish an equilibrium, so that all ions are equally distributed in both compartments, provided that the solutes can move freely through the membrane. At the state of equilibrium, the total ion concentration and therefore the total concentration of osmotically active particles are equal on both sides of the membrane.

If solutions on two sides of a membrane contain different concentrations of ions that cannot freely move through the membrane (e.g., proteins), distribution of diffusible ions (e.g., electrolytes) at the steady state will be unequal, but the sum of the concentrations of ions in one compartment is equal to the sum of ions in the other compartment (Gibbs-Donnan law). Also, the law of electrical neutrality is obeyed for both compartments. An example of the uneven distribution of an ion in two compartments with different protein content (nondiffusible ions) is the concentration of chloride ions in plasma and cerebrospinal fluid (CSF). As a result of increased selectivity of the blood-brain barrier against proteins, Cl^- ions are ≈15% higher in CSF to establish electrical and osmotic equilibrium.[31] Calculations that demonstrate these principles can be found in the first edition of this textbook.[27]

Cells that contain nondiffusible protein anions can withstand only a limited and temporary difference in osmotic pressure across the cell membrane. To some extent, cells adjust osmolality by producing "idiogenic osmoles" from the breakdown of macromolecules; this enhances resistance to cellular dehydration. Osmotic pressure is normally identical inside and outside the cells because the cell membrane can correct concentration differences by excluding some small ions through active, energy-requiring transport processes. If these processes cease, the cells will swell and eventually will burst (osmotic lysis).

Distribution of Ions by Active and Passive Transport

Examination of Table 49-2 reveals that the electrolyte compositions of blood plasma and interstitial fluid (both ECFs) are similar, but their compositions differ markedly from that

of ICF. The major ECF ions are Na^+, Cl^-, and HCO_3^-, but in ICF, the main ions are K^+, Mg^{2+}, organic phosphates, and protein. This unequal distribution of ions is due to active transport of Na^+ from inside to outside the cell against an electrochemical gradient. This process requires energy supplied by metabolic processes in the cell (e.g., glycolysis). An active sodium pump deriving its energy from adenosine triphosphate (ATP) is present in most cell membranes and frequently is coupled with transport of K^+ into the cell. The Na^+/K^+ pump is a heterodimer consisting of a catalytic transmembrane α-subunit that is about 1000 amino acid residues long, and an associated, smaller β-subunit.[13] The internal surface has a catalytic binding site for ATP and a binding site for Na^+. The external surface has a binding site for K^+.

In addition to the Na^+/K^+-ATPase, a ubiquitous Na^+-H^+ exchanger (often referred to as an *antiporter*) actively pumps H^+ out of the ICF in exchange for Na^+.[20] This exchanger is critical for maintaining intracellular pH homeostasis in many cell types. At least six different isoforms of this transmembrane protein have been identified, and regulation and tissue distribution of these differ.[20] Of particular importance is the role of this exchanger for acid-base regulation in renal tubular cells, as discussed later in this chapter.

ELECTROLYTES

Disorders of Na^+, K^+, Cl^-, and HCO_3^- will now be separately considered, even though disorders of electrolyte and water homeostasis need a systematic evaluation.[18]

Sodium

Disorders of Na^+ homeostasis can occur because of excessive loss, gain, or retention of Na^+, or as the result of excessive loss, gain, or retention of H_2O. It is difficult to separate disorders of Na^+ and H_2O balance because of their close relationship in establishing normal osmolality in all body water compartments. As described in detail in Chapter 48, the primary organ for regulating body water and extracellular Na^+ is the kidney. As a brief introduction to this section, it is important to remind the reader of the functions of healthy kidneys.

In the proximal tubules, 70 to 80% of filtered Na^+ is actively reabsorbed, with H_2O and Cl^- following passively to maintain electrical neutrality and osmotic equivalence. In the descending loop of Henle, H_2O, but not electrolytes, is passively reabsorbed because of the high osmotic strength of interstitial fluid in the renal medulla. In the ascending loop of Henle, Cl^- is reabsorbed actively, with Na^+ following. At the level of the distal tubule, the first of the two primary Na^+/H_2O regulating processes occurs. Here, aldosterone stimulates the cortical collecting ducts to reabsorb Na^+ (with water following passively) and secrete K^+ (and to a lesser extent, H^+) to maintain electrical neutrality. Aldosterone is produced by the adrenal cortex in response to angiotensin II derived via the action of renin. The secretion of renin by renal juxtaglomerular cells is stimulated by low chloride, by β-adrenergic activity, and by low arteriolar pressure.[26] Thus when the kidneys are hypoperfused (as occurs when blood volume decreases, or when the renal arteries are obstructed), the distal tubules, under the influence of aldosterone, reclaim Na^+.

Further water regulation in the kidney occurs from the distal tubule through the collecting duct, where tubular permeability to H_2O is under the influence of antidiuretic hormone (ADH) (see Chapters 48 and 53). ADH (also called vasopressin) is released by the posterior pituitary under the influence of baroreceptors in the aortic arch and of hypothalamic chemoreceptors that are responsive to circulating osmolality, which is primarily a reflection of Na^+ concentration. When blood volume is decreased, or when plasma osmolality is increased, ADH is secreted, tubular permeability to H_2O increases via aquaporins, and H_2O is reabsorbed in an attempt to restore blood volume or to decrease osmolality. In contrast, when blood volume is increased or osmolality decreased, ADH secretion is inhibited, and more H_2O is excreted in the urine (diuresis).

Besides the kidney, the body's only other mechanism for restoring Na^+/H_2O homeostasis is ingestion of H_2O. Thirst is stimulated by decreased blood volume or by a hyperosmotic condition. It is important to remember that receptors that influence renal handling of Na^+ and H_2O, and thirst, sense changes only in the intravascular blood volume and not the total ECF. Furthermore, laboratory assessment of water and electrolyte disorders is made primarily from the blood volume (plasma). As discussed in subsequent sections, the clinician must assess the status of TBW and blood volume before interpreting laboratory values in the diagnosis of water and electrolyte disorders. The physical findings of these disorders are every bit as important as the laboratory values (see Table 49-1).

Hyponatremia

Hyponatremia is defined as a decreased plasma Na^+ concentration (<130 to 135 mmol/L). Hyponatremia typically manifests clinically as nausea, generalized weakness, and mental confusion at values <120 mmol/L, ocular palsy at <110 mmol/L, and severe mental impairment at between 90 and 105 mmol/L.[25] The rapidity of development of hyponatremia influences the Na^+ concentrations at which symptoms develop [i.e., clinically apparent symptoms may manifest at higher Na^+ concentrations (≈125 mmol/L) when hyponatremia develops rapidly].[25] It is important to note that symptoms are due to changes in osmolality rather than to the Na^+ concentration per se. Central nervous system (CNS) symptoms are due primarily to movement of H_2O into cells to maintain osmotic balance and subsequent swelling of CNS cells.

Hyponatremia can be hypo-osmotic, hyperosmotic, or isosmotic. Thus, measurement of plasma osmolality is an important initial step in the assessment of hyponatremia. Of these, the most common form is hypo-osmotic hyponatremia. Figure 49-2 describes an algorithm for laboratory measurements and physical examination findings in the differential diagnosis of plasma Na^+ <135 mmol/L.

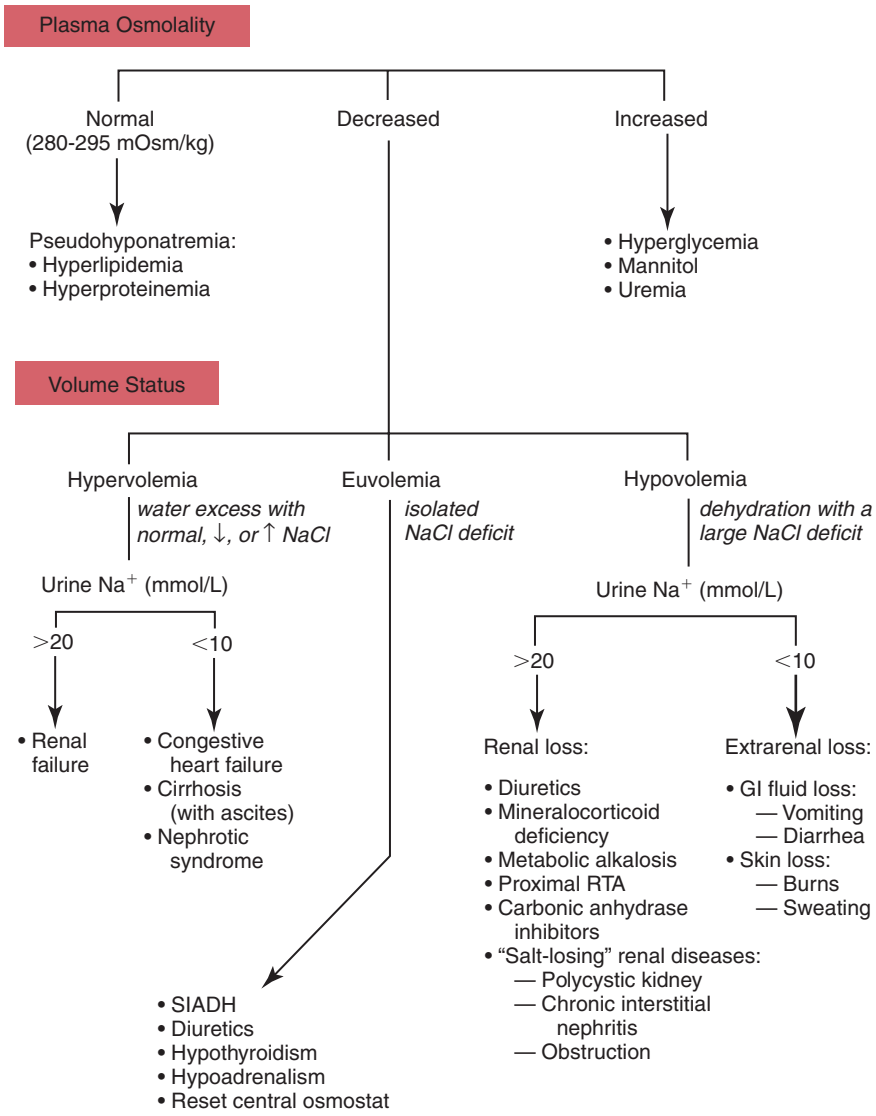

Figure 49-2 Algorithm for the differential diagnosis of hyponatremia. *(Modified from Kirkpatrick W, Kreisberg R. Acid-base and electrolyte disorders. In: Liu P, ed. Blue book of diagnostic tests. Philadelphia: WB Saunders, 1986:239-54.)*

Hypo-Osmotic Hyponatremia

Typically, when plasma Na^+ concentration is low, calculated or measured osmolality will also be low. This type of hyponatremia can be due to excess loss of Na^+ *(depletional hyponatremia)* or increased ECF volume *(dilutional hyponatremia)*. Differentiating these initially requires clinical assessment of TBW and ECF volume by history and physical examination.

Depletional hyponatremia (excess loss of Na^+) is almost always accompanied by loss of ECF water, but to a lesser extent than Na^+ loss. This occurs because thirst leads to ingestion of water, which obviously is more hypotonic than the lost fluids. Hypovolemia is apparent in the physical examination (orthostatic hypotension, tachycardia, decreased skin turgor). If urine Na^+ is low (generally <10 mmol/L), the loss is extrarenal (see Figure 49-2), as the kidneys are properly retaining filtered Na^+ in response to aldosterone, which is stimulated by hypovolemia. Causes of extrarenal loss of Na^+ in excess of H_2O include losses from the gastrointestinal tract or skin (see Figure 49-2).

Alternatively, if urine Na^+ is elevated in this setting (generally >20 mmol/L), renal loss of Na^+ is likely. Renal loss of Na^+ occurs with (1) osmotic diuresis, (2) use of diuretics (inhibit reabsorption of Cl^- and Na^+ in the ascending loop), (3) adrenal insufficiency (no aldosterone or cortisone prevents distal tubule reabsorption of Na^+), or (4) salt wasting nephropathies, as can occur with interstitial nephritis and tubular recovery after acute tubular necrosis or obstructive nephropathy. Renal loss of Na^+ in excess of H_2O can also occur in metabolic alkalosis from prolonged vomiting, because increased renal HCO_3^- excretion is accompanied by Na^+ ions. In this case, urine sodium is elevated (>20 mmol/L), but urine chloride remains low. In proximal renal tubular acidosis (RTA), bicarbonate is lost because of a defect in

HCO_3^- reabsorption, and Na^+ is coexcreted to maintain electrical neutrality.

Dilutional hyponatremia is a result of excess H_2O retention and often can be detected during the physical examination as edema. In advanced renal failure, water is retained because of decreased filtration and H_2O excretion. When ECF is increased but the blood volume is decreased, as occurs in congestive heart failure (CHF), hepatic cirrhosis, or nephrotic syndrome, a vicious cycle is established. The decreased blood volume is sensed by baroreceptors and results in increased aldosterone and ADH, even though ECF volume is excessive. The kidneys reabsorb Na^+ and H_2O in response to increased aldosterone and ADH in an attempt to restore the blood volume, but this simply results in further increases in ECF and further dilution of Na^+.

In hypo-osmotic hyponatremia with a normal volume status, the most common causes are the syndrome of inappropriate ADH (SIADH), primary polydipsia, and hypothyroidism (see Figure 49-2). SIADH is usually a result of ectopic or otherwise "inappropriate" ADH production arising from a variety of conditions[6] (see Chapters 48 and 53) and results in excessive H_2O retention. SIADH is often diagnosed when urine osmolality is greater than plasma osmolality, *but only when renal, adrenal, and thyroid function are normal*. In cortisol insufficiency, hyponatremia can occur as a result of increased cortisol-releasing hormone, which stimulates vasopressin release.[29] Hypothyroidism impairs free H_2O excretion. Finally, euvolemic hyponatremia can be found in polydipsia when water intake is greater than the renal capacity to excrete excess H_2O. This is most often the result of psychiatric illness, but diseases that cause hypothalamic disorders, such as sarcoidosis, may also cause polydipsia by altering the thirst reflex (see Figure 49-2).

Hyperosmotic Hyponatremia

Hyponatremia that occurs in the presence of increased quantities of other solutes in the ECF is the result of an extracellular shift of water or an intracellular shift of Na^+ to maintain osmotic balance between ECF and ICF compartments. The most common cause of this type of hyponatremia is severe hyperglycemia (see Figure 49-2). As a general rule, Na^+ is decreased by ≈1.6 to 2.4 mmol/L for every 100 mg/dL increase in glucose above 100 mg/dL.[30] Correction of hyperglycemia will restore normal blood Na^+.

Isosmotic Hyponatremia

If the measured Na^+ concentration in plasma is decreased, but measured plasma osmolality, glucose, and urea are normal, the most likely explanation is pseudohyponatremia caused by the *electrolyte exclusion effect* (see Chapter 28). This occurs when Na^+ is measured by an indirect ion-selective electrode (and flame photometry in the past) in patients with severe hyperlipidemia. It can also occur when osmotically active agents such as mannitol and glycine are used in irrigation fluids for transurethral resection of the prostate (TURP) and endometrial ablation.

Hyponatremia must be corrected cautiously because too rapid correction can lead to brain demyelination. The pons is particularly sensitive to this, and rapid correction can lead to central pontine myelinolysis. Current recommendations are to increase Na^+ by 0.5 to 2.0 mmol/L/h and not to exceed a total increase in Na^+ greater than 18 to 25 mmol over 48 hours.[30] The rate of recommended Na^+ increase is dependent on symptoms and length of time the patient is hyponatremic.

Hypernatremia[1]

Hypernatremia (plasma Na^+ >150 mmol/L) is always hyperosmolar. Symptoms of hypernatremia are primarily neurologic (because of neuronal cell loss of H_2O to the ECF) and include tremors, irritability, ataxia, confusion, and coma.[25] As with hyponatremia, the rapidity of development of hypernatremia will determine the plasma Na^+ concentration at which symptoms occur. Acute development may cause symptoms at 160 mmol/L, although in chronic hypernatremia, symptoms may not occur until Na^+ exceeds 175 mmol/L. In chronic hypernatremia, the intracellular osmolality of CNS cells will increase to protect against intracellular dehydration. Because of this, rapid correction of hypernatremia can cause dangerous cerebral edema, as CNS cells will take up too much water if the ICF is hyperosmotic when normonatremia is achieved.[25]

In many cases, the symptoms of hypernatremia may be masked by underlying conditions. Indeed, most cases of hypernatremia occur in patients with altered mental status or in infants, both of whom may have difficulty in rehydrating themselves despite a normal thirst reflex. Thus, hypernatremia rarely occurs in an alert patient with a normal thirst response and access to water.

Hypernatremia arises in the setting of (1) hypovolemia (excessive water loss or failure to replace normal water losses), (2) hypervolemia (a net Na^+ gain in excess of water gain), or (3) normovolemia. Again, assessment of TBW status by physical examination and measurement of urine Na^+ and osmolality are important steps in establishing a diagnosis (Figure 49-3).

Hypovolemic Hypernatremia

Hypernatremia in the setting of decreased ECF is caused by renal or extrarenal loss of hypo-osmotic fluid, leading to dehydration. Thus once hypovolemia is established by physical examination, measurement of urine Na^+ and osmolality is used to determine the source of fluid loss. Patients who have large extrarenal losses will have concentrated urine (often >800 mOsmol/L) with low urine Na^+ (<20 mmol/L), reflecting a proper renal response to conserve Na^+ and water to restore ECF volume. Extrarenal causes include diarrhea, skin losses (burns, fever, or excessive sweating), and respiratory losses coupled with failure to replace the water. When gastrointestinal loss is excluded, and the patient has normal mental status and access to H_2O, a hypothalamic disorder (tumor or granuloma) should be suspected, because the

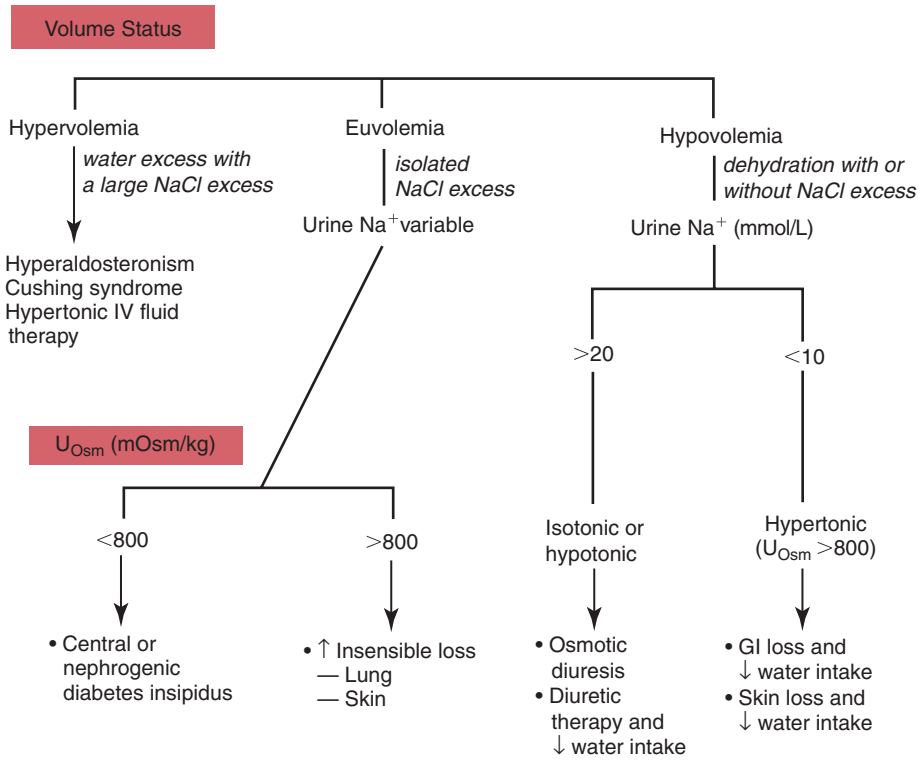

Figure 49-3 Algorithm for the differential diagnosis of hypernatremia. *(Modified from Kirkpatrick W, Kreisberg R. Acid-base and electrolyte disorders. In: Liu P, ed. Blue book of diagnostic tests. Philadelphia: WB Saunders, 1986:239-54.)*

normal thirst response should always replace insensible water losses.[25]

Normovolemic Hypernatremia

Hypernatremia in the presence of normal ECF volume is often a prelude to hypovolemic hypernatremia. Insensible losses through the lung or skin again must be suspected and are characterized by concentrated urine as the kidneys conserve water. Another cause of normovolemic hypernatremia is water diuresis, which is manifested by polyuria (see Figure 49-3). The differential for polyuria (generally defined as >3 L urine output/d) is a water or solute diuresis. Solute diuresis is exemplified by the osmotic diuresis of diabetes mellitus and generally is characterized by urine osmolality >300 mOsmol/L and hyponatremia (see previous discussion in this chapter). Water diuresis, a manifestation of diabetes insipidus (DI), is characterized by dilute urine (osmolality <250 mOsmol/L) and slight hypernatremia.[25] DI can be central or nephrogenic.[21] Central DI is due to decreased or absent ADH secretion resulting from head trauma, hypophysectomy, pituitary tumor, or granulomatous disease. Nephrogenic DI is due to renal resistance to ADH as a result of drugs (e.g., lithium, demeclocycline, amphotericin, propoxyphene); sickle cell anemia and Sjögren syndrome, which affect collecting duct responsiveness to ADH; or, more rarely, mutant ADH receptors.[2] Central DI usually is treated with vasopressin, whereas nephrogenic DI is treated by discontinuing the drug or providing easy access to water, which will maintain normonatremia.

Hypervolemic Hypernatremia

The presence of excess TBW and hypernatremia indicates a net gain of water and Na^+, with Na^+ gain in excess of water (see Figure 49-3). This rare condition is observed most commonly in hospital patients receiving hypertonic saline or sodium bicarbonate.

Potassium

The total body potassium of a 70 kg subject is ≈3.5 mol (40 to 59 mmol/kg), of which only 1.5 to 2% is present in the ECF. Nevertheless, plasma K^+ is often a good indicator of total K^+ stores, unless abnormal K^+ is due to abnormal cellular shifts. Disturbance of K^+ homeostasis has serious consequences. For example, a decrease in extracellular K^+ (hypokalemia) is characterized by muscle weakness, irritability, and paralysis. Plasma K^+ concentrations less than 3.0 mmol/L are often associated with marked neuromuscular symptoms and indicate a critical degree of intracellular depletion. At lower concentrations, tachycardia and cardiac conduction defects are apparent by electrocardiogram (flattened T waves) and can lead to cardiac arrest.[25]

High extracellular K^+ (hyperkalemia) concentrations may produce symptoms of mental confusion, weakness, tingling, flaccid paralysis of the extremities, and weakness of the respiratory muscles.[25] Cardiac effects of hyperkalemia include bradycardia and conduction defects evident on the electrocardiogram as prolonged PR and QRS intervals and "peaked" T waves. Prolonged severe hyperkalemia >7.0 mmol/L can lead to peripheral vascular collapse and cardiac arrest. Symptoms are almost always present at K^+ concentrations >6.5 mmol/L. Concentrations >10.0 mmol/L in most cases are fatal, but as with Na^+, symptoms vary with the rapidity of onset.

Hypokalemia

Causes of *hypokalemia* (plasma K^+ <3.5 mmol/L) are classified as redistribution of extracellular K^+ into ICF, or true K^+ deficits, caused by decreased intake or loss of potassium-rich body fluids (Figure 49-4).

Redistribution

Intracellular redistribution of K^+ is illustrated by the fall in plasma K^+ that occurs following insulin therapy for diabetic hyperglycemia when cells take up K^+ as a consequence of glucose transport. Redistribution hypokalemia is also a feature of alkalosis, in which K^+ moves from ECF into cells as increased H^+ alters activity of the Na^+/K^+-ATPase. In addition, renal conservation of H^+ in the distal tubule occurs at the expense of K^+. Hypokalemia is highly prevalent in cancer patients. Pseudohypokalemia is a feature of acute leukemia. The elevated white blood cell count can cause time-dependent transport of K^+ into leukemic cells after the blood sample is drawn. Additionally, use of myelopoietic growth factors following chemotherapy can lead to rapid K^+ uptake by new cells.[17] Other causes of hypokalemia in cancer patients include tumors (small cell lung, pheochromocytoma, islet cell, medullary thyroid) that produce adrenocorticotropic hormone (ACTH), resulting in increased cortisol and renal

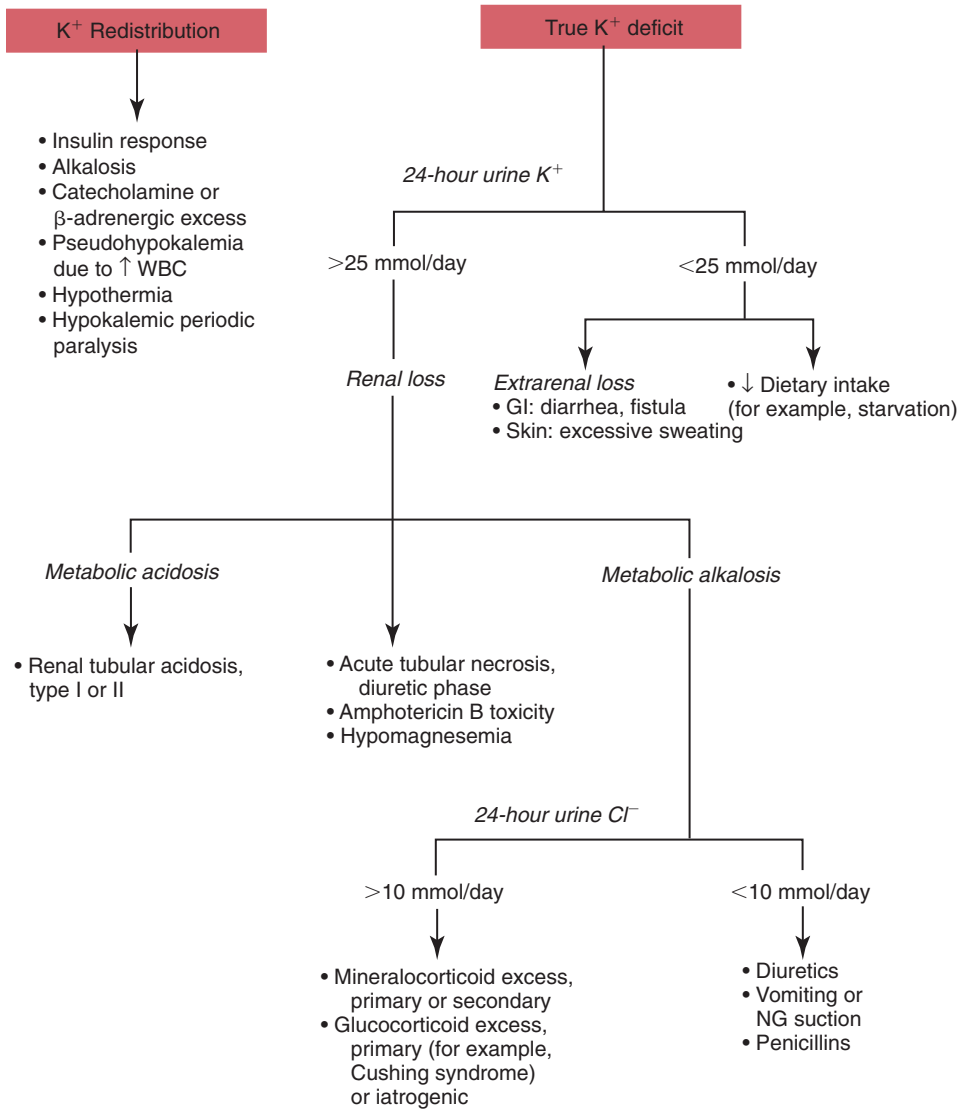

Figure 49-4 Algorithm for the differential diagnosis of hypokalemia. *(Modified from Kirkpatrick W, Kreisberg R. Acid-base and electrolyte disorders. In: Liu P, ed. Blue book of diagnostic tests. Philadelphia: WB Saunders, 1986:239-54.)*

loss of K^+. Other causes of intracellular redistribution are listed in Figure 49-4.

True Potassium Deficit

Hypokalemia reflecting true total body deficits of K^+ can be classified into renal and nonrenal losses, based on daily excretion of K^+ in the urine (see Figure 49-4). If urine excretion of K^+ is <30 mmol/d, it can be concluded that the kidneys are properly functioning and are attempting to reabsorb K^+ as appropriate in a hypokalemic setting. The cause may be decreased K^+ intake or extrarenal loss of K^+-rich fluid. Situations of decreased intake include chronic starvation and postoperative intravenous fluid therapy with K^+-poor solutions. Gastrointestinal loss of K^+ occurs most commonly with diarrhea and loss of gastric fluid through vomiting or prolonged nasogastric suction.

Urine excretion exceeding 25 to 30 mmol/d in a hypokalemic setting is inappropriate and indicates that the kidneys are the primary source of lost K^+. Renal losses of K^+ may occur during the diuretic (recovery) phase of acute tubular necrosis and during states of excess mineralocorticoid (primary or secondary aldosteronism) or glucocorticoid (Cushing syndrome) when the distal tubules increase Na^+ reabsorption and K^+ excretion. Renal loss of K^+ is also caused by thiazide and loop diuretics.[16] In addition to redistribution of K^+ into cells in an alkalotic setting, K^+ can be lost from the kidneys in exchange for reclaimed H^+ ions. This cause of true hypokalemia will be evident in low urine Cl^- and an alkaline urine. In cancer patients, increased renal K^+ loss is due to chemotherapy (e.g., cisplatin)-induced nephron and tubular damage.[17]

Hyperkalemia

Hyperkalemia (plasma K^+ >5.0 mmol/L) is a result of (singly or in combination) (1) redistribution, (2) increased intake, or (3) increased retention. In addition, preanalytical conditions—such as hemolysis, thrombocytosis (>10^6/μL), and leukocytosis (>10^5/μL)—have been known to cause marked pseudohyperkalemia, as described in detail in Chapter 28 (Figure 49-5).

Redistribution

The transfer of intracellular K^+ into ECF invariably occurs in acidosis as K^+ shifts outward as the result of pH-induced changes in Na^+/K^+-ATPase activity. As a general rule, K^+ concentrations can be expected to rise 0.2 to 0.7 mmol/L for every 0.1 unit drop in pH. When acidosis is corrected, normokalemia will be restored rapidly. Extracellular redistribution of K^+ may also occur in (1) tissue hypoxia; (2) insulin deficiency (e.g., diabetic ketoacidosis); (3) massive intravascular hemolysis; (4) severe burns; (5) violent muscular activity, as in status epilepticus; (6) rhabdomyolysis; and (7) tumor lysis syndrome. Finally, important iatrogenic causes of redistribution hyperkalemia include digoxin

toxicity and β-adrenergic blockade, especially in patients with diabetes or on dialysis.[25]

Potassium Retention

When glomerular filtration or renal tubular function is decreased, hyperkalemia may be precipitated by intravenous infusion of K^+. When renal function is normal, overtreatment with K^+ solutions is unlikely to produce hyperkalemia, because renal capacity is more than adequate to excrete the excess K^+. Indeed, in the absence of severe renal failure, hyperkalemia is seldom prolonged. Decreased excretion of K^+ in moderate and acute renal disease and end-stage renal failure (with oliguria or anuria) are the most common causes of prolonged hyperkalemia (see Figure 49-5). Hyperkalemia occurs along with Na^+ depletion in adrenocortical insufficiency (e.g., Addison disease) because diminished Na^+ reabsorption results in decreased tubular K^+ secretion. Drugs that block the production of aldosterone, such as inhibitors of angiotensin-converting enzyme (ACE inhibitors; e.g., lisinopril), nonsteroidal anti-inflammatory drugs, and angiotensin II receptor blockers, may also cause hyperkalemia. Excess administration of potassium-sparing diuretics that block distal tubular K^+ secretion (e.g., triamterene, spironolactone) commonly causes hyperkalemia.[11] In cancer patients, hyperkalemia can be caused by adrenal insufficiency due to metastases to the adrenal glands, nephrotoxic chemotherapy agents (e.g., mitomycin-C, methotrexate, platinum compounds), postrenal obstruction, or tumor lysis syndrome.[17] Treatment of hyperkalemia includes agents that increase cellular uptake of K^+ such as calcium gluconate, glucose and insulin, sodium bicarbonate, and β_2-adrenergic agonists. Potassium can be removed from the circulation with the use of K^+-losing diuretics, cation-exchange resins, and finally hemodialysis.[17]

Chloride

In the absence of acid-base disturbances, Cl^- concentrations in plasma generally will follow those of Na^+. However, determination of plasma Cl^- concentration is useful in the differential diagnosis of acid-base disturbances and is essential for calculating the anion gap. Fluctuations in serum or plasma Cl^- have little clinical consequence, but do serve as signs of an underlying disturbance in fluid or acid-base homeostasis.

Hypochloremia

In general, causes of hypochloremia will parallel causes of hyponatremia. Persistent gastric secretion and prolonged vomiting result in significant loss of Cl^- and ultimately in hypochloremic alkalosis and depletion of total body Cl^- with retention of HCO_3^-. Respiratory acidosis, which is accompanied by increased HCO_3^-, is another common cause of decreased Cl^- with normal Na^+.

Hyperchloremia

Increased plasma Cl^- concentration, similar to increased Na^+ concentration, occurs with dehydration, prolonged diarrhea with loss of sodium bicarbonate, DI, and overtreatment with normal saline solutions, which have a Cl^- content of 154 mmol/L. In fact, mounting evidence suggests that use of saline (NaCl) solution for maintenance, intraoperative, and resuscitative therapy can result in a host of hyperchloremia-induced side effects.[10] Thus, there is a movement among the surgical community toward more physiologic solutions such as Ringer's lactate and Hartmann's solution.[10] A rise in Cl^- concentration may also be seen in respiratory alkalosis because of renal compensation for excreting HCO_3^-.

Bicarbonate

The total carbon dioxide (CO_2) content of plasma consists of carbon dioxide dissolved in an aqueous solution (dCO_2), CO_3 loosely bound to amine groups in proteins (carbamino compounds), HCO_3^-, and very small quantities of CO_3^{2-} ions and carbonic acid (H_2CO_3). Bicarbonate ions make up all but ≈2 mmol/L of the total carbon dioxide of plasma. Alterations in HCO_3^- and CO_2 dissolved in plasma are characteristic of acid-base imbalances.

ACID-BASE PHYSIOLOGY

Normal metabolic processes result in the production of large amounts of carbonic acid and lesser amounts of sulfuric, phosphoric, and other acids. For example, during a 24 hour period, a person weighing 70 kg disposes of about 20 mol of carbon dioxide (the volatile form of carbonic acid) through the lungs, and about 70 to 100 mmol (or ≈1 mmol/kg) of nonvolatile acids (mainly sulfuric and phosphoric acids) through the kidneys. These products of metabolism are transported to the lungs and kidneys via the ECF and blood with no appreciable change in the ECF pH, and with only a minimal difference between arterial (pH 7.35 to 7.45) and venous (pH 7.32 to 7.38) blood. This is accomplished by the buffering capacity of blood and by respiratory and renal regulatory mechanisms.

Acid-Base Balance and Acid-Base Status

A description of acid-base balance involves an accounting of the carbonic (H_2CO_3, HCO_3^-, CO_3^{2-}, and CO_2) and noncarbonic acids and conjugate bases in terms of input (intake plus metabolic production) and output (excretion plus metabolic conversion) over a given time interval. The acid-base status of body fluids is typically assessed by measurements of total CO_2, plasma pH, and PCO_2, because the bicarbonate/carbonic acid system is the most important mammalian buffering system.

The following clinical terms are used to describe acid-base status. *Acidemia* is defined as an arterial blood pH <7.35, and *alkalemia* indicates an arterial blood pH >7.45. *Acidosis* and *alkalosis* refer to pathologic states that often lead to acidemia or alkalemia. For example, in common acid-base disorders such as lactic acidosis and diabetic ketoacidosis, intermediate organic acids (lactic acid and β-hydroxybutyric acid, respectively), which normally are metabolized to carbon dioxide and water, may accumulate to a significant extent, resulting in acidemia. Additionally, more than one type of pathologic process can occur simultaneously, giving rise to a mixed

acid-base disturbance, in which the blood pH may be low, high, or within the reference interval. To understand how these and other perturbations of acid-base metabolism affect human physiology, it will be necessary to examine briefly the concepts of acids, bases, pH, and buffers in relation to the relevant systems that function to maintain normal acid-base balance in the human body.

Acid-Base Parameters—Definitions and Abbreviations

Acids are chemical substances that can donate protons (H^+ ions) in solution, and *bases* are substances that accept protons. Strong acids readily give up H^+, whereas strong bases readily accept H^+. Thus the conjugate base of a strong acid is a weak base and vice versa.

pH and pK

The pH of a solution is defined as the negative logarithm of the hydrogen ion activity ($pH = -\log aH^+$). Thus *pH is a dimensionless quantity,* such that a decrease in one pH unit represents a tenfold increase in H^+ activity. Potentiometric determinations of blood pH measure H^+ activity and not H^+ concentration, although the activity is assumed to equal the concentration. The average pH of blood (7.40) corresponds to a hydrogen ion concentration of 40 nmol/L, but this assumes an activity coefficient of 1. The relationship between hydrogen ion activity and pH is illustrated in Figure 49-6. This relationship is inverse and is obviously nonlinear. Expressing the acidity of blood in terms of its hydrogen ion concentration in nanomoles per liter (nmol/L) has the advantage of avoiding logarithmic transformations when acid-base calculations are performed. Even though it would be consistent with how other ion concentrations are expressed, this method has not gained widespread use in the United States.

The p*K* (also, p*K′* and pK_a) represents the negative logarithm of the ionization constant of a weak acid (K_a), that is, the p*K* is the pH at which an acid is half dissociated, existing as equal proportions of acid and conjugate base. Thus acids have p*K* values <7.0, whereas bases have p*K* values >7.0. The lower the p*K*, the stronger the acid, and the higher the p*K*, the stronger the conjugate base. For example, the p*K* of lactic acid is 3.86, and that of ammonium ion NH_4^+ is 9.5. The high pK for the ammonium ion indicates that this species prefers to hold onto its proton, rather than dissociating into NH_3 and H^+.

The pH of plasma may be considered to be a function of two independent variables: (1) the PCO_2, which is regulated by the lungs and represents the acid component of the carbonic acid/bicarbonate buffer system, and (2) the concentration of titratable base (base excess or deficit, which is defined later), which is regulated by the kidneys. The plasma total CO_2 (bicarbonate) concentration generally is taken as a measure of the base excess or deficit in plasma and ECF, although conditions exist in which it may not accurately reflect the true base excess or deficit.

Bicarbonate and Dissolved CO_2

Bicarbonate is the second largest fraction (behind Cl^-) of plasma anions (≈25 mmol/L). Conventionally, it is defined to include (1) plasma bicarbonate ion (HCO_3^-), (2) carbonate ion (CO_3^{2-}), and (3) CO_2 bound in plasma carbamino compounds (Figure 49-7). At the pH of blood, the plasma carbonate concentration is ≈25 μmol/L, which is ≈ 1/700 to 1/1000 of the total bicarbonate fraction. CO_2-bound carbamino compounds (RCNHCOOH) are 0.2 mmol/L in plasma and 1.5 mmol/L in erythrocytes. Actual bicarbonate ion concentration is not measured, but rather is calculated from the

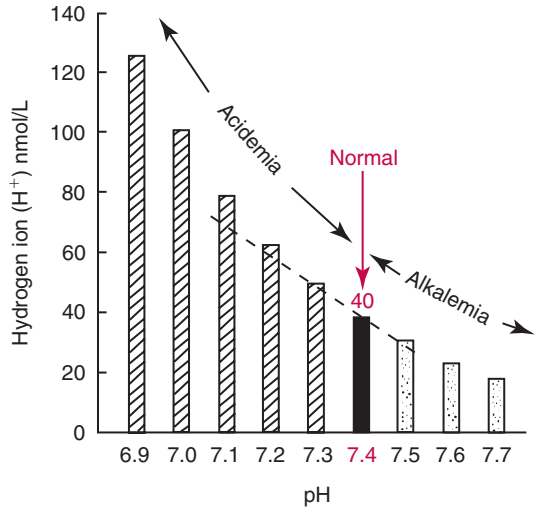

Figure 49-6 Relationship of pH to hydrogen ion concentration. A *broken line* is drawn to emphasize the (approximate) linear relationship between hydrogen ion concentration and pH over the pH range of 7.2 to 7.5. *(From Narins RG, Emmett M. Simple and mixed acid-base disorders: a practical approach. Medicine 1980;59:161-87.)*

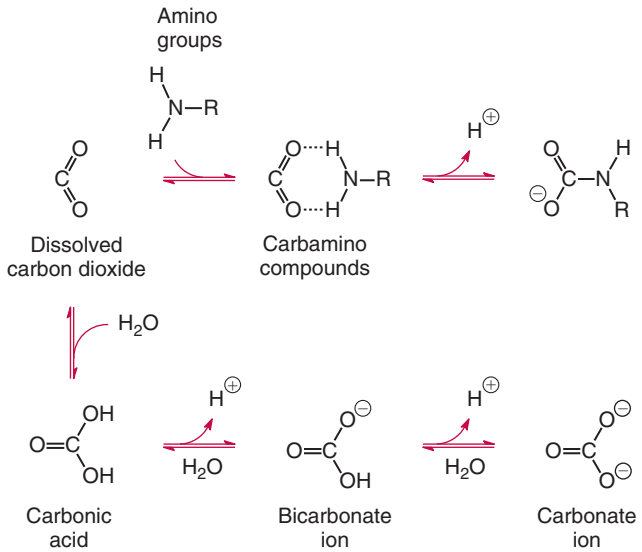

Figure 49-7 Reactions of CO_2 with water and amino groups. Hydrogen bonding is indicated by a *dotted line*. The carbamino acid is fairly strong (—R—NH—COOH → H^+ + R—NH—COO^-).

Henderson-Hasselbalch equation as described later (and discussed in detail in Chapter 28). Also as described in Chapter 28, the analyte usually measured in plasma is total CO_2, which includes bicarbonate and dissolved CO_2 (dCO_2). At the pH of the blood, the amount of dissolved CO_2 is 700 to 1000 times greater than the amount of carbonic acid (H_2CO_3); therefore $cdCO_2$ is the term used to express their combined concentration. It is calculated from the solubility coefficient of CO_2 in blood at 37 °C (α = 0.0306 mmol/L per mm Hg) multiplied by the measured PCO_2 in mm Hg. Thus at a PCO_2 of 40 mm Hg, $cdCO_2$ is 1.224 mmol/L (0.0306 mmol/L × 40 mm Hg). This $cdCO_2$ value can then be used, in the Henderson-Hasselbalch equation, to calculate the total bicarbonate concentration.

Henderson-Hasselbalch Equation

The Henderson-Hasselbalch equation is described in detail in Chapter 28. However, it is important to review this equation here because it enhances understanding of pH regulation of body fluids as it relates to compensatory mechanisms of the body in acid-base disturbances. The equation derived in Chapter 28 can also be written as follows:

$$\text{pH} = 6.1 + \log \frac{c\text{HCO}_3^-}{c\text{dCO}_2}$$

where $cdCO_2$ is equal to α (0.0306 mmol/L per mm Hg) PCO_2 and 6.1 is the pK' for the carbonic acid/bicarbonate system. An alternative expression useful for approximating cH^+ in blood is as follows:

$$c\text{H}^+ = K \times \frac{P\text{CO}_2}{c\text{HCO}_3^-}$$

where K = 24 (nmol/L)(mmol/L)(mm Hg^{-1}).

The average normal ratio of the concentrations of bicarbonate and dissolved carbon dioxide in plasma is 25 (mmol/L)/1.25 (mmol/L) = 20/1. It follows then that any change in the concentration of bicarbonate or dissolved CO_2 relative to each other must be accompanied by a change in pH. Such changes in this important ratio can occur through a change in $cHCO_3^-$ (the renal component) or in PCO_2 (the respiratory component). Clinical conditions characterized as *metabolic* disturbances of acid-base balance are classified as primary disturbances in $cHCO_3^-$. Those characterized as *respiratory* disturbances are classified as primary disturbances in $cdCO_2$ (PCO_2). Various compensatory mechanisms attempting to re-establish the normal ratio of $cHCO_3^-/cdCO_2$ may result in changes in bicarbonate concentration, dissolved CO_2 concentration, or both. Application of the Henderson-Hasselbalch equation to human acid-base physiology can be illustrated by a lever-fulcrum (teeter-totter) diagram (Figure 49-8).

Buffer Systems and Their Role in Regulating the pH of Body Fluids

A buffer is a mixture of a weak acid and a salt of its conjugate base that resists changes in pH when a strong acid or base is added to the solution. If concentrations of the acid and base components of a buffer are equal, the pH will equal the pK.

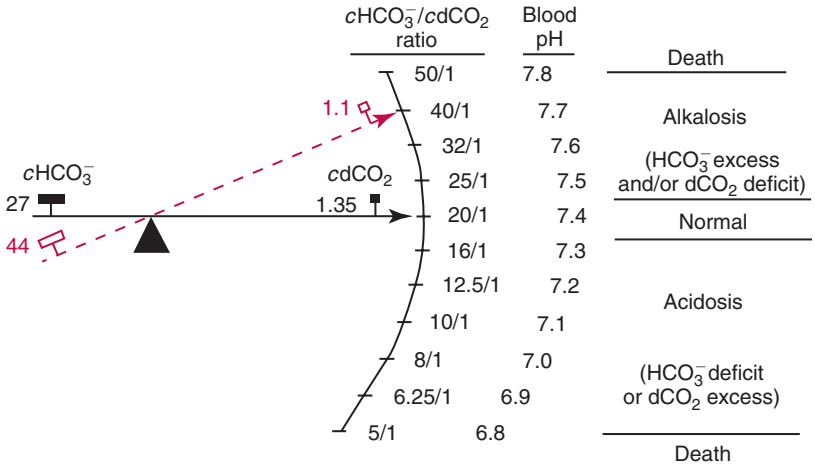

Figure 49-8 Scheme demonstrating the relation between pH and the ratio of bicarbonate concentration to the concentration of dissolved CO_2. If the ratio in blood is 20:1 ($cHCO_3^-$ = 27 mmol/$cdCO_2$ = 1.35 mmol/L), the resultant pH will be 7.4, as demonstrated by the *solid beam*. The *dotted line* shows a case of uncompensated alkalosis (bicarbonate excess) with a bicarbonate concentration of 44 mmol/L and a $cdCO_2$ of 1.1 mmol/L. The ratio therefore is 40:1, and the resultant pH is 7.7. In a case of uncompensated acidosis, the pointer of the balance would point to a pH between 6.8 and 7.35, depending on the $cHCO_3^-/cdCO_2$ ratio. *[From Weisberg HF. A better understanding of anion-cation ("acid-base") balance. Surg Clin North Am 1959;39:93-120.]*

Generally, buffers work best at resisting pH changes in the interval ±1 pH unit of its p*K*, that is, buffers work best when the ratio of acid/base is within the range of 10:1 to 1:10. Buffers are also more effective at higher concentrations, so that a 10 mmol/L buffer solution is more effective than a 1.0 mmol/L solution.

The action of buffers in the regulation of body pH can be explained by using the bicarbonate buffer system as an example. If a strong acid is added to a solution containing HCO_3^- and H_2CO_3, the H^+ will react with HCO_3^- to form more H_2CO_3, and subsequently CO_2 and H_2O. The hydrogen ions are thereby bound, and the increase in the H^+ concentration will be minimal.

$$H^+ + HCO_3^- \rightleftharpoons H_2CO_3 \rightleftharpoons CO_2 + H_2O$$

Bicarbonate/Carbonic Acid Buffer System

The most important buffer of plasma is the bicarbonate/carbonic acid pair. Initially, one might not think that this buffer would be very effective because its p*K* is 6.1, whereas normal plasma pH is 7.4, which is outside the general limits for good buffering capacity. Also note that the normal bicarbonate/dCO_2 ratio is 20:1, which is outside the 10:1 or 1:10 ratio at which buffers work best. However, the effectiveness of the bicarbonate buffer is based on the fact that the lungs can readily dispose of or retain CO_2, and that other than hemoglobin and other serum proteins, it is present at higher concentrations than other buffers. In addition, the renal tubules can increase or decrease the rate of reclamation of bicarbonate from the glomerular filtrate (see Chapter 48). The importance of the relatively high concentration of bicarbonate (relative to H^+) becomes apparent when one considers that at normal plasma pH, 5 mmol/L of lactate (p*K* ≈3.86) generates ≈5 mmol/L of H^+ ion, which is remarkable given that a normal H^+ ion concentration is only 40 nmol/L. The buffer value (β) is defined as the amount of base required to cause a change in pH of one unit. The buffer value of the bicarbonate buffer in plasma is 55.6 mmol/L. Derivation of this value is attained by taking partial differentials of the Henderson-Hasselbalch equation, which is presented in detail in the second edition of this textbook.[28]

Phosphate Buffer System

At a plasma pH of 7.4, the ratio $cHPO_4^{2-}/cH_2PO_4^-$ is 4:1 (pK′ = 6.8). The total concentration of this buffer in both erythrocytes and plasma accounts for about 5% of the nonbicarbonate buffer value of plasma. Organic phosphate, however, in the form of 2,3-diphosphoglycerate (present in erythrocytes in a concentration of about 4.5 mmol/L), accounts for about 16% of the nonbicarbonate buffer value of erythrocytes.

The phosphate buffer reacts with acids and with bases as follows:

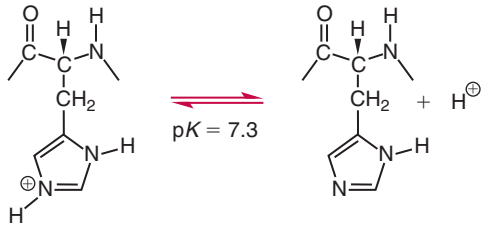
$$HPO_4^{\oplus\oplus} + H^{\oplus} \rightarrow H_2PO_4^{\oplus}$$

$$H_2PO_4^{\oplus} + OH^{\ominus} \rightarrow HPO_4^{\oplus\oplus} + H_2O$$

This system is most important in the titration and excretion of acids in urine.

Plasma Protein Buffer System and Plasma Base Excess

The buffer value (β) of the nonbicarbonate buffers of plasma totals about 7.7 mmol/L at pH 7.40 and a normal plasma protein concentration of 72 g/L. Proteins, especially albumin, account for the greatest portion (>90%) of the nonbicarbonate buffer value of plasma. The most important buffer groups of proteins in the physiologic pH range are the imidazole groups of histidines (p*K* ≈7.3). Each albumin molecule contains 16 histidines.



The significance of nonbicarbonate buffers of plasma can be illustrated by the chemical reactions during CO_2 equilibration:

$$CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow HCO_3^{\ominus} + H^{\oplus}$$

$$HPr \rightarrow H^{\oplus} + Pr^{\ominus}$$

where the HPr/Pr^- system represents all nonbicarbonate buffers. Because the purpose of this buffer system is to maintain cH^+ constant, for each molecule of HCO_3^- that is generated, one molecule of nonbicarbonate buffer base disappears. Thus in alkalosis, the cH^+ from CO_2 equilibration falls, and an excess of nonbicarbonate buffer base is the result. As follows, there is a consumption or negative excess of this buffer base in acidosis.

Plasma base excess is defined as the initial concentration of titratable base when the plasma with strong acid or base is titrated to pH (Std) = 7.4 at PCO_2 = 40 mm Hg and 37 °C. The equation for the CO_2 equilibration curve of plasma and for calculation of *plasma base excess* can be written as follows:

$$\Delta cHCO_3^-(P) = [-\beta Pr \times \Delta pH(P)] + \Delta cB'(P)$$

where $\Delta cHCO_3^-$ = actual HCO_3^- minus the standard HCO_3^- of 24.5 mmol/L, ΔpH = measured pH minus 7.40, and $\Delta cB'(P)$ is the plasma base excess.

Hemoglobin Buffer System and Whole Blood Base Excess

The buffer value (β) of the nonbicarbonate buffers of erythrocyte fluid is about 63 mmol/L at pH 7.20, for an erythrocyte hemoglobin concentration of 21 mmol/L (33.8 g/dL). Hemoglobin accounts for the major part (53 mmol/L), with the remainder being caused mainly by 2,3-diphosphoglycerate (2,3-DPG). The imidazole groups of hemoglobin are quantitatively the most important buffer groups.

As in plasma, CO_2 equilibration of whole blood depends on the buffer value of nonbicarbonate buffers. Thus CO_2 equilibration in whole blood is dependent on hemoglobin concentration and also on pH and oxygenation status. It is

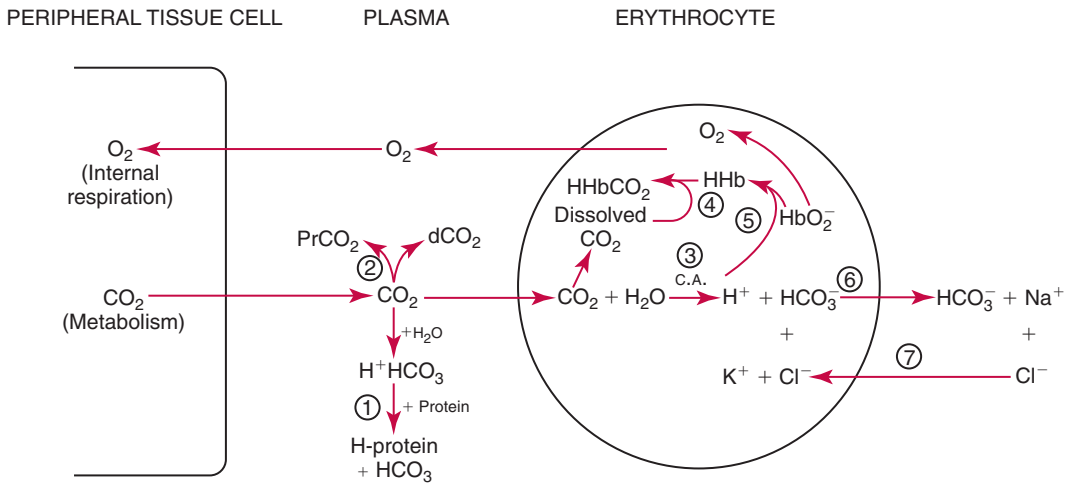


Figure 49-9 Scheme demonstrating the isohydric and chloride shift. The *encircled numbers* refer to the reactions described in the text. For details, see text.

possible to derive an approximate equation for whole blood CO_2 equilibration and calculation of *whole blood base excess* as follows:

$$\Delta c\mathrm{HCO_3^-}(\mathrm{P}) = -\beta \times \Delta \mathrm{pH}(\mathrm{P}) + \frac{\Delta c\mathrm{B'}(\mathrm{B})}{\zeta}$$

where

- $\Delta c\mathrm{HCO_3^-}$ = measured plasma $c\mathrm{HCO_3^-}$ (P) − 24.5 mmol/L $\mathrm{HCO_3^-}$
- ΔpH = measured pH − the standard pH of 7.40
- $\Delta c\mathrm{B'}(\mathrm{B})$ = the *whole blood base excess* [i.e., the concentration of titratable base when the blood is titrated with strong acid or base to pH = 7.40 at $P\mathrm{CO_2}$ (Std) and 37 °C]
- $\beta = \beta_m\mathrm{Hb} \times c\mathrm{Hb}(\mathrm{B}) + \beta\mathrm{Pr}$, where $\beta_m\mathrm{Hb}$ is the molar buffer value of hemoglobin (2.3 mol/mol), $c\mathrm{Hb}(\mathrm{B})$ is the substance concentration of hemoglobin (Fe) in the blood (unit: mmol/L), and βPr is the buffer value of the plasma proteins (7.7 mmol/L)
- $\zeta = 1 - c\mathrm{Hb}(\mathrm{B})/c_{\mathrm{ref}}$, where c_{ref} is an empirical parameter (43 mmol/L).

This equation for *whole blood base excess* (known as the Van Slyke equation[23,24]), together with the Henderson-Hasselbalch equation, provides the simplest algorithm for calculation of various acid-base variables. The buffer value of HHb is slightly lower than that for O_2Hb at pH ≈6.5 but higher at pH ≈7.8. This is due to a decrease in the p*K* value of the "oxygen-linked" acid-base groups of Hb (C-terminal histidine and N-terminal valine) when HHb is oxygenated. When oxygenated, H^+ ions are liberated from Hb—a phenomenon called the *Haldane effect*. For additional details on the Haldane effect, see Chapter 31 of the second edition of this textbook.[28]

Isohydric and Chloride Shift

Because of continuous production of carbon dioxide within tissue cells, there is a concentration gradient for carbon dioxide from cells to plasma and thus to erythrocytes. Despite this, all buffer systems discussed previously interact together through a phenomenon known as the *isohydric Cl– shift,* which keeps the $c\mathrm{dCO_2}$ and $c\mathrm{H^+}$ (pH) essentially constant between arterial and venous blood. A small portion of the carbon dioxide entering the plasma stays as dissolved carbon dioxide, thus the slightly higher $P\mathrm{CO_2}$ of venous blood. Most reacts with water to form carbonic acid that dissociates into H^+ and $\mathrm{HCO_3^-}$. The increased amount of H^+ is buffered by plasma buffers (Figure 49-9, reaction 1). Another small portion combines with the amino groups of proteins and forms carbamino compounds (Figure 49-9, reaction 2). The normal concentration of carbamino compounds in the plasma is about 0.2 mmol/L. Most of the carbon dioxide enters the erythrocytes and reacts with water to form carbonic acid. This reaction is catalyzed by the enzyme carbonic anhydrase (CA) and proceeds at a relatively high rate (Figure 49-9, reaction 3). Some CO_2 remains as dissolved CO_2, and some combines with Hb to form $HbCO_2$ (Figure 49-9, reaction 4).

The carbonic acid formed in reaction 3 initially increases the H^+ concentration. The pH change, however, is fully or partially compensated by the release of oxygen from O_2Hb, which involves the conversion of stronger acid (O_2Hb) into weaker acid (HHb) that then readily accepts the H^+. For each mole of O_2 released, the hemoglobin binds about 0.5 mol of H^+ ion. Furthermore, the HHb binds significantly more CO_2 in the form of carbamino-CO_2 than does oxyhemoglobin; thus an additional fraction of CO_2 is transported in this form. The oxygen released from O_2Hb moves from the erythrocytes through the plasma into the peripheral tissue cells.

Remaining hydrogen ions formed in reaction 3 are buffered by the nonbicarbonate buffers of the erythrocyte fluid, whereas the concentration of $\mathrm{HCO_3^-}$ increases to the same extent that the concentration of Hb anion falls. The transformations described so far (Figure 49-9, reactions 1 through 5) are referred to as the *isohydric shift* (i.e., a shift in which the hydrogen ion concentration remains unchanged).

However, the equilibrium between plasma and red cells has been disturbed by this isohydric shift. The concentration of HCO_3^- has increased relatively more in the erythrocytes than in the plasma; the pH of plasma has fallen relatively more than the pH of erythrocytes; and the nondiffusible ion concentration in the erythrocytes has fallen because of the increase in protonation of hemoglobin. The membrane potential of the erythrocytes therefore becomes less negative, and the distribution of all diffusible ions must change with the new membrane potential. The ion shifts that occur rapidly include movement of HCO_3^- out of the erythrocytes and movement of Cl^- into the erythrocytes to provide electrochemical balance. This shift of chloride ions is referred to as the *chloride shift* (Figure 49-9, reactions 6 and 7). As a result of these ion fluxes, the concentration of chloride in venous plasma is about 1 mmol/L lower than that in arterial plasma.

In the alveoli, low PCO_2 and high PO_2 cause a reversal of reactions 1 through 7, as shown in Figure 49-9.

Respiratory Mechanism in the Regulation of Acid-Base Balance

In addition to supplying O_2 to tissue cells for normal metabolism, the respiratory mechanism contributes to maintenance of normal body pH through elimination or retention of CO_2 in metabolic acidosis and alkalosis, respectively.

Respiration

Exchange of O_2 and CO_2 in the lungs between alveolar air and blood is called *external respiration,* in contrast to internal respiration, which occurs at the tissue level. At inspiration, muscular contraction expands intrathoracic volume and creates a fall in intrapulmonary pressure. Atmospheric air is drawn into the bronchial tree, which terminates at the alveoli, where the exchange of gases between alveolar air and pulmonary blood occurs. Expiration takes place passively as the elastic tissues of the lungs and chest wall rebound and the intrathoracic volume is decreased. Loss of elasticity of the lungs and destruction of the alveolar membranes are basic pathologic mechanisms underlying many pulmonary diseases.

Peripheral venous blood reaches the pulmonary circulation from the right ventricle of the heart and is *arterialized* in the capillaries of the lungs by uptake of O_2 and loss of CO_2. Pulmonary venous blood then returns to the left ventricle by way of the left atrium and is pumped through the aorta to the peripheral tissues. In the capillaries of peripheral tissues, the arterial blood releases O_2 to the tissue cells and takes up CO_2.

In a resting state, the respiration rate is normally 12 to 15 breaths/min. For an average-sized adult with a tidal volume of about 0.5 L, 6 to 8 L of air is moved per minute in either direction. Physical activity increases ventilation. Involuntary increases in rate and depth of respiration are regulated by the medullary respiratory center in the brainstem, which is stimulated by central chemoreceptors located on the anterior surface of the medulla oblongata and by peripheral chemoreceptors located in the carotid arteries and aorta. Peripheral chemoreceptors are stimulated by a fall in pH caused by accumulation of CO_2 or by a decrease in PO_2. Central chemoreceptors are stimulated only by a decrease in pH of the CSF.

The normal response to these chemical receptors that drive respiration can be perturbed by a pathologic condition in the circulatory or respiratory system. Such patients may require assisted ventilation that uses a mechanical device to provide gas mixtures via an endotracheal tube. Adjustments of gas mixtures and rates of mechanical ventilation depend greatly on the results of laboratory blood gas and pH determinations.

Exchange of Gases in the Lungs and Peripheral Tissues

Diffusion of O_2 and CO_2 across alveolar and cell membranes is governed by gradients in the partial pressure of each gas (Figure 49-10). Dry air inspired at a pressure of 1 atm (760 mm Hg) consists of 21% O_2 (PO_2 ≈160 mm Hg), 0.03% CO_2 (PCO_2 ≈0.25 mm Hg), 78% nitrogen, and ≈0.1% other inert gases. As inspired air passes over the moist mucous membranes of the upper respiratory tract, it is warmed to 37 °C, becomes saturated with water vapor, and mixes with air in the respiratory tree, resulting in partial pressures of ≈150 mm Hg for O_2, ≈0.3 mm Hg for CO_2, ≈47 mm Hg for H_2O, and ≈563 mm Hg for nitrogen. Further mixing with alveolar air results in partial pressures at the alveolar membrane of ≈105 mm Hg for O_2, ≈40 mm Hg for CO_2, and ≈47 mm Hg for H_2O. Venous blood on the opposite side of the alveolar membrane has PO_2 ≈40 mm Hg and PCO_2 ≈46 mm Hg. Thus the gradient for O_2 is inward, toward the blood, and for CO_2, it is outward, toward the alveoli. CO_2 removal is so efficient that the PCO_2 in expired air is more than 100 times the PCO_2 in inspired air (see Figure 49-10). In arterial blood, the PO_2 is slightly lower than in alveolar air (90 to 100 vs. 105 mm Hg) as the result of shunting of about 5% of blood that does not equilibrate.

At the arterial end of capillaries of peripheral tissues, the PO_2 at 95 mm Hg is substantially higher than the average PO_2 at the surface of tissue cells (20 mm Hg), and the PCO_2 at 40 mm Hg is substantially lower than that in the cells (50 to 70 mm Hg). Thus in the tissue capillary, the gradient for O_2 is inward to the cell; for CO_2, it is outward to the capillary blood. The arteriovenous difference in partial pressures is approximately 60 mm Hg for O_2 and 6 mm Hg or less for CO_2. This difference in arteriovenous PO_2 is one indicator of the efficiency of O_2 extraction in the passage of blood through the capillaries. During passage through the tissues, the concentration of total oxygen falls on average 2.3 mmol/L, whereas the concentration of total CO_2 of blood rises about 2.0 mmol/L.

Respiratory Response to Acid-Base Perturbations

Most metabolic acid-base disorders develop slowly, within hours in diabetic ketoacidosis and months in chronic renal disease. The respiratory system responds immediately to a change in acid-base status, but several hours may be required

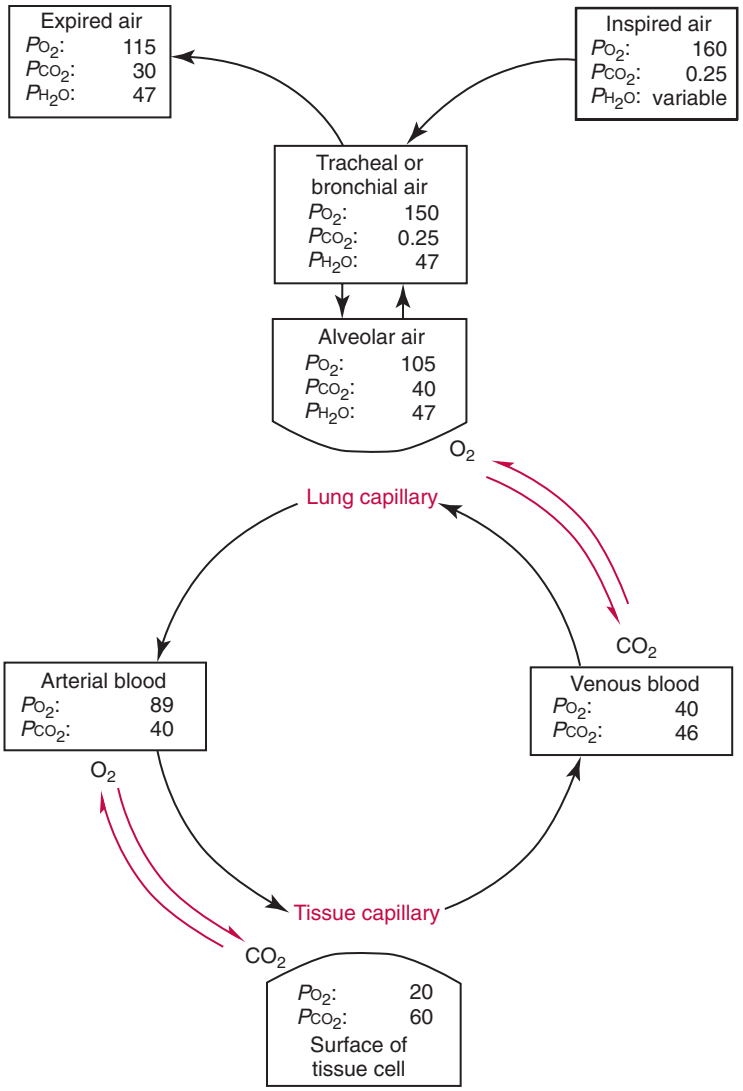

Figure 49-10 Partial pressures of oxygen and carbon dioxide in air, blood, and tissue. Values shown are approximations in mm Hg and are calculated assuming a 5% shunt. *Red arrows* show directions of gradients. *(Modified from Tietz NW. Fundamentals of clinical chemistry, 3rd edition. Philadelphia: WB Saunders, 1987.)*

for the response to become maximal. The maximum response is not attained until both central and peripheral chemoreceptors are fully stimulated. For example, in the early stages of metabolic acidosis, plasma pH decreases, but because H^+ ions equilibrate rather slowly across the blood-brain barrier, the pH in CSF remains nearly normal. However, because peripheral chemoreceptors are stimulated by decreased plasma pH, hyperventilation occurs, and plasma PCO_2 is decreased. When this occurs, the PCO_2 of the CSF decreases immediately because CO_2 equilibrates rapidly across the blood-brain barrier, leading to a rise in pH of the CSF that inhibits the central chemoreceptors. As plasma bicarbonate gradually falls because of acidosis, bicarbonate concentration and pH in the CSF will also eventually fall. At this point, stimulation of respiration becomes maximal from both central and peripheral chemoreceptors.

The reverse is true when a patient with metabolic acidosis is treated with HCO_3^-. When the pH in plasma increases as the result of HCO_3^- administration, stimulation of the peripheral chemoreceptors returns to normal. However, because of slow equilibration of HCO_3^- between plasma and CSF, the central chemoreceptors continue to be stimulated and the patient continues to hyperventilate. Respiration does not return to normal until normal acid-base balance in the CSF is restored.

Renal Mechanisms in the Regulation of Acid-Base Balance

The average pH of plasma and of the glomerular filtrate is ≈7.4, whereas the average urinary pH is ≈6.0, reflecting the renal excretion of nonvolatile acids. Various functions of the kidneys respond to different alterations in acid-base status. In

the case of acidosis, excretion of acids is increased and that of base is conserved; in alkalosis, the opposite occurs. The pH of the urine changes correspondingly and may vary in *random* specimens from pH 4.5 to 8.0. This ability to excrete variable amounts of acid or base makes the kidney the final defense mechanism against changes in body pH.

The various acids produced during metabolic processes are buffered in the ECF at the expense of HCO_3^-. Renal excretion of acid and conservation of HCO_3^- occur through several mechanisms, including (1) Na^+-H^+ exchange, (2) production of ammonia and excretion of NH_4^+, and (3) reclamation of HCO_3^-.

Na^+-H^+ Exchange

Nearly all mammalian cells contain a plasma membrane ATP-hydrolyzing protein capable of exchanging sodium ions for protons—the so-called Na^+-H^+ exchanger (Figure 49-11). In 2002 it was reported that at least six isoforms of the Na^+-H^+ exchanger (NHE-1 through NHE-6) are differentially expressed in a wide variety of tissues.[20] In the renal tubules, NHE-1 and NHE-3 appear to be the predominant isoforms that extrude H^+ ions into the tubular fluid in exchange for Na^+ ions.

Na^+-H^+ exchange is enhanced in states of acidosis and is inhibited in alkalosis. Both NHE-1 and NHE-3 are transcriptionally upregulated in response to acidotic states.[20] The proximal tubules, however, cannot maintain an H^+ gradient of more than ≈1 pH unit, whereas the distal tubules cannot maintain 1 of more than ≈3 pH units. Thus maximum urine acidity is reached at ≈pH 4.4. In type I and type IV RTA, this exchange process is defective and may lead to a decrease in blood pH. In type I RTA, an increase in urinary pH is often noted.

Potassium ions compete with H^+ in the renal tubular Na^+-H^+ exchanger. If the intracellular K^+ level of renal tubular cells is high, more K^+ and less H^+ are exchanged for Na^+. As a result, the urine becomes less acidic, thereby increasing the acidity of body fluids. If K^+ is depleted, more H^+ ions are exchanged for Na^+; the urine becomes more acidic and the body fluids more alkaline. Thus hyperkalemia contributes to acidosis and hypokalemia to alkalosis. Because the body's compensatory mechanism against metabolic alkalosis is relatively ineffective, K^+ depletion alone can result in a metabolic alkalosis.

Renal Production of Ammonia and Excretion of Ammonium Ions

Renal tubular cells are able to generate ammonia from glutamine and other amino acids derived from muscle and liver cells according to the following reaction:

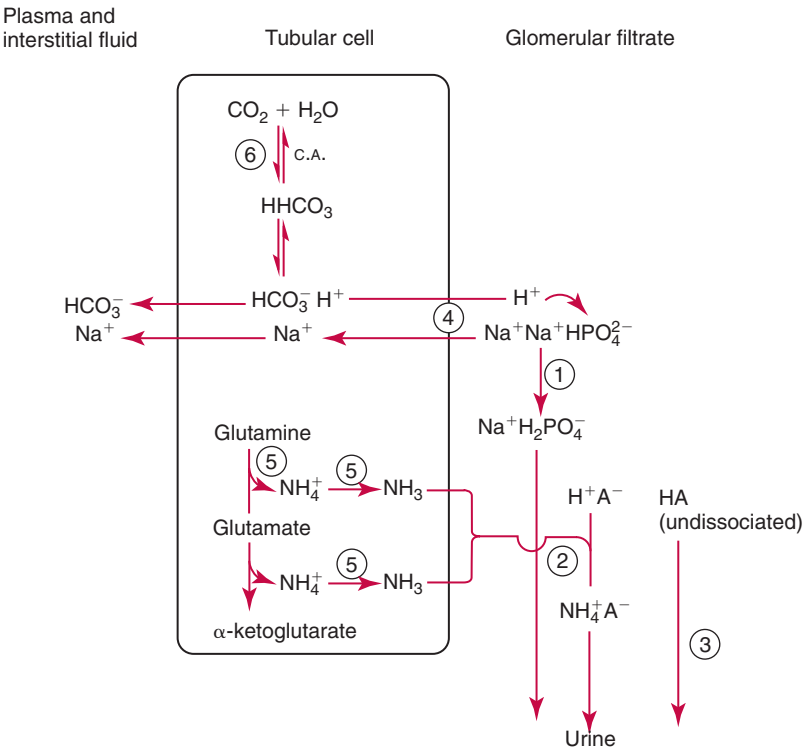

Figure 49-11 Hydrogen ion excretion, sodium hydrogen ion exchange, and ammonia production in the renal tubules. Key: *1*, conversion of HPO_4^{2-} to $H_2PO_4^-$; *2*, reaction of hydrogen ions with NH_3; *3*, excretion of undissociated acids; *4*, Na^+-H^+ exchange; *5*, NH_3 production; and *6*, synthesis of carbonic acid from CO_2.

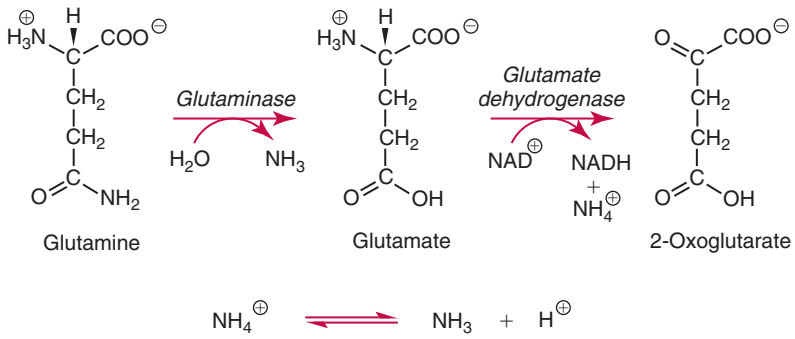

The ammonium ion produced dissociates into ammonia and hydrogen ions to a degree dependent on the pH (see Figure 49-11). At normal blood pH, the ratio of NH_4^+ to NH_3 is about 100 to 1. Ammonia is a gas that diffuses readily across the cell membrane into the tubular lumen, where it combines with hydrogen ions to form ammonium ions (see Figure 49-11). At the acid pH of urine, the equilibrium between NH_4^+ and NH_3 shifts markedly to the left (≈10,000 to 1), strongly favoring formation of NH_4^+. The NH_4^+ formed in the tubular lumen cannot easily cross cell membranes and thus is trapped in the tubular urine and excreted with anions such as phosphate, chloride, or sulfate. In normal individuals, NH_4^+ production in the tubular lumen accounts for the excretion of ≈60% (30 to 60 mmol) of the hydrogen ions. Finally, the α-oxoglutarate produced in this reaction is converted to bicarbonate (up to 270 mmol/d) that helps to replenish bicarbonate neutralized by metabolic acid production. The amount of H^+ excreted bound to NH_3 can be measured as NH_4^+. The H^+ required for NH_4^+ formation may be present in the glomerular filtrate or may be generated within tubular cells by carbonic anhydrase synthesis of carbonic acid from CO_2 (see Figures 49-11 and 49-12). These hydrogen ions are secreted into the tubular lumen through the Na^+-H^+ exchangers (see Figure 49-11).

Excretion of H^+ as $H_2PO_4^-$

H^+ secreted into the tubular lumen by the Na^+-H^+ exchanger may also react with HPO_4^- to form $H_2PO_4^{2-}$ (see Figure 49-11). This process depends on the amount of phosphate filtered by the glomeruli and the pH of urine. Under normal physiologic conditions, ≈30 mmol of H^+ is excreted per day as $H_2PO_4^-$. Acidemia increases phosphate excretion and thus provides additional buffer for reaction with H^+. A decrease in the glomerular filtration rate (GFR), as observed in renal disease, results in a decrease in $H_2PO_4^-$ excretion. The secretion of H^+ and the subsequent reaction with $H_2PO_4^-$ allow the removal of one H^+ with no significant decrease in urinary pH. As a result, the pH gradient is not greatly affected and more H^+ can be secreted into the tubules, whereas more Na^+ is reabsorbed and conserved.

Reclamation of Filtered Bicarbonate

The unmodified glomerular filtrate has the same concentration of HCO_3^- as does plasma; however, with increasing acidification of proximal tubular urine, the HCO_3^- concentration is decreased. Excreted H^+ reacts with HCO_3^- (catalyzed by carbonic anhydrase, in the brush border of the proximal tubular cells) to form H_2CO_3 and subsequently CO_2 and H_2O (see Figure 49-12).

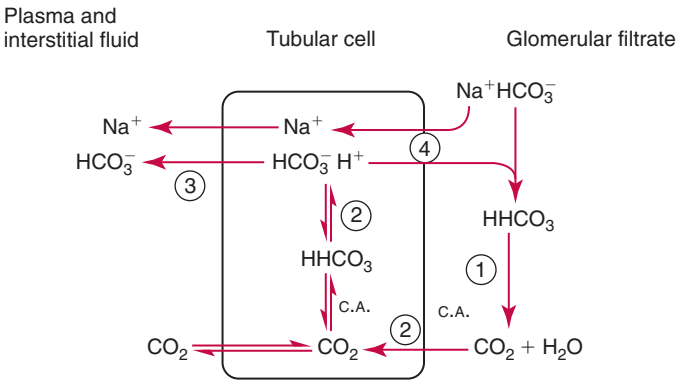

Figure 49-12 Key: *1*, Formation of CO_2 from bicarbonate in the tubular fluid; *2*, formation of H^+ and HCO_3^- from CO_2 in the tubular cell; *3*, new generation of HCO_3^-; and *4*, Na^+-H^+ exchange.

This increase in urinary CO_2 causes carbon dioxide to diffuse across the tubular cell membrane into the tubular cell, where it reacts with H_2O in the presence of *cytoplasmic* carbonic anhydrase to form H_2CO_3 and subsequently H^+ and HCO_3^- (see Figure 49-12). Thus reclamation of bicarbonate consists in fact of diffusion of CO_2 into tubular cells and its subsequent conversion to HCO_3^-. The increase in HCO_3^- helps to maintain or restore a normal pH in the circulation. Normally, ≈90% of filtered HCO_3^- (or about 4500 mmol/d) is reclaimed in the proximal tubule, which parallels Na^+ reabsorption. Thus for each mmol H^+ secreted into the tubular fluid, 1 mmol Na^+ and 1 mmol HCO_3^- enter the tubular cell and return to the general circulation. When plasma HCO_3^- concentration increases above ≈28 mmol/L, the capacity of the proximal and distal tubules to reclaim HCO_3^- is exceeded, and HCO_3^- is excreted in the urine. Type II RTA is caused by a decreased ability to reabsorb HCO_3^- in the proximal tubules, leading to a decrease in blood pH.

CONDITIONS ASSOCIATED WITH ABNORMAL ACID-BASE STATUS AND ABNORMAL ELECTROLYTE COMPOSITION OF THE BLOOD[5,19,25]

Many pathologic conditions are accompanied by acid-base and electrolyte disturbances in the blood. Abnormalities in acid-base status of the blood are always accompanied by characteristic changes in electrolyte concentrations in the plasma. Hydrogen ions cannot accumulate without concomitant accumulation of anions, such as Cl^- or lactate, or without exchange for cations, such as K^+ or Na^+. Consequently, the electrolyte composition of blood serum or plasma is often determined along with measurements of blood gases and pH to assess acid-base disturbances.

Acid-base disturbances are traditionally classified as (1) metabolic acidosis, (2) metabolic alkalosis, (3) respiratory acidosis, or (4) respiratory alkalosis. In simple, straightforward acid-base disorders, the laboratory parameters observed for these groups are shown in Table 49-3. However, interpretation of laboratory values to classify these disorders is rarely straightforward because of compensatory responses by the respiratory and renal systems in attempting to correct the imbalance.

Causes of acid-base disorders, resulting laboratory values, and compensatory responses are discussed here in the traditional categorization of these disorders. However, it is often difficult to remember which disorders fall into which categories, so it is common for mnemonic devices or tables to be used to facilitate description of these disorders. A useful and more logical approach is to realize that an acidosis can only occur as the result of one (or a combination) of three mechanisms: (1) increased addition of acid, (2) decreased elimination of acid, and (3) increased loss of base. Similarly, alkalosis occurs only by (1) increased addition of base, (2) decreased

TABLE 49-3 Classification and Characteristics of Simple Acid-Base Disorders

	Primary Change	Compensatory Response	Expected Compensation
Metabolic			
Acidosis	$\downarrow cHCO_3^-$	$\downarrow PCO_2$	$PCO_2 = 1.5\ (cHCO_3^-) + 8 \pm 2$ PCO_2 falls by 1 to 1.3 mm Hg for each mmol/L fall in $cHCO_3^-$ Last 2 digits of pH = PCO_2 (e.g., if PCO_2 = 28, pH = 7.28) $cHCO_3^-$ + 15 = last 2 digits of pH ($cHCO_3^-$ = 15, pH = 7.30)
Alkalosis	$\uparrow cHCO_3^-$	$\uparrow PCO_2$	PCO_2 increases 6 mm Hg for each 10 mmol/L rise in $cHCO_3^-$ $cHCO_3^-$ + 15 = last 2 digits of pH ($cHCO_3^-$ = 35, pH = 7.50)
Respiratory			
Acidosis			
Acute	$\uparrow PCO_2$	$\uparrow cHCO_3^-$	$cHCO_3^-$ increases by 1 mmol/L for each 10 mm Hg rise in PCO_2
Chronic	$\uparrow PCO_2$	$\uparrow cHCO_3^-$	$cHCO_3^-$ increases by 3.5 mmol/L for each 10 mm Hg rise in PCO_2
Alkalosis			
Acute	$\downarrow PCO_2$	$\downarrow cHCO_3^-$	$cHCO_3^-$ falls by 2 mmol/L for each 10 mm Hg fall in PCO_2
Chronic	$\downarrow PCO_2$	$\downarrow cHCO_3^-$	$cHCO_3^-$ falls by 5 mmol/L for each 10 mm Hg fall in PCO_2

Modified from Narins RG, Gardner LB. Simple acid-base disturbances. Med Clin North Am 1981;65:321-46.

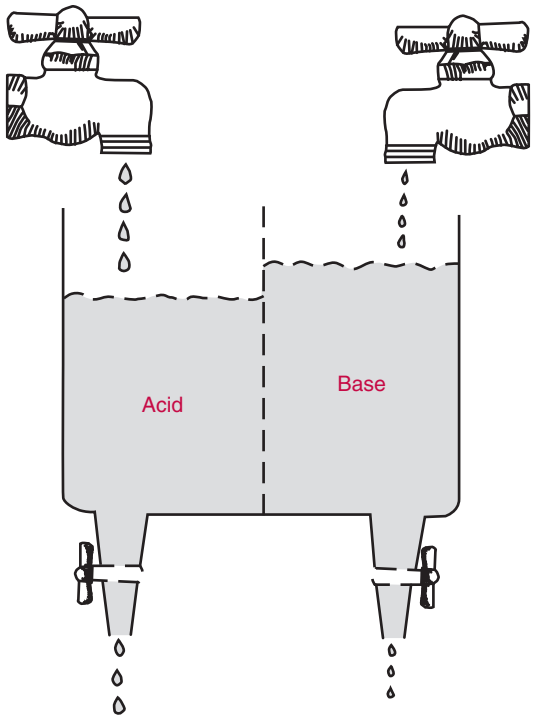

Figure 49-13 Simple depiction of the body as a two-vat system of acid and base. At equilibrium, input and output from each "vat" are equal. *(From Dufour DR. Acid-base disorders. In: Dufour DR, Christenson RH, eds: Professional practice in clinical chemistry: a review. Washington, DC: AACC Press, 1995:604-35.)*

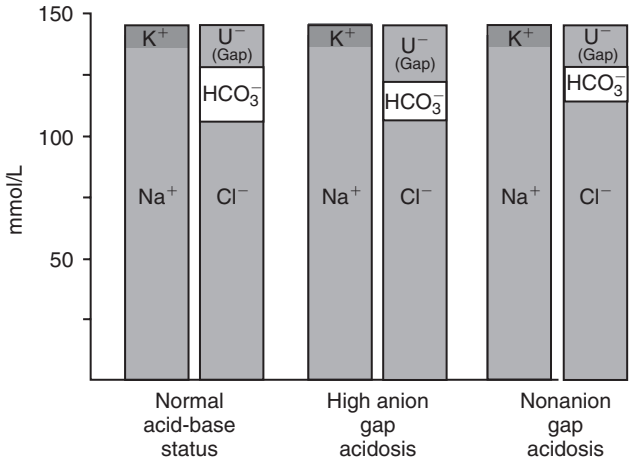

Figure 49-14 Simple "Gambelgram" depiction of normal gap, anion gap acidosis, and nonanion gap acidosis. Cations, Na^+ and K^+, are in left bar for each condition, whereas measured (Cl^- and HCO_3^-) and unmeasured (U^-) anions are in right bar for each condition.

elimination of base, and (3) increased loss of acid. Dufour has illustrated this simple concept by depicting the body as a two-tank vat, one of acid and one of base, with inputs and outputs for each vat (Figure 49-13).[5] In the normal setting, these inputs and outputs are balanced; an acid-base disorder then involves a perturbation in the input or output of these body reservoirs, as is discussed in the next section.

Metabolic Acidosis (Primary Bicarbonate Deficit)

Metabolic acidosis is readily detected by decreased plasma bicarbonate (or a negative extracellular base excess)—the primary perturbation in this acid-base disorder. Causes include the following:

1. Production of organic acids that exceeds the rate of elimination (e.g., production of acetoacetic acid and β-hydroxybutyric acid in diabetic ketoacidosis and of lactic acid in lactic acidosis). Bicarbonate is "lost" in the buffering of excess acid.
2. Reduced excretion of acids (H^+) as occurs in renal failure and some RTAs, resulting in an accumulation of acid that consumes bicarbonate.
3. Excessive loss of bicarbonate due to increased renal excretion (decreased tubular reclamation) or excessive loss of duodenal fluid (as in diarrhea). Plasma $cHCO_3^-$ falls; the fall is associated with a rise in the concentration of inorganic anions (mostly chloride) or, rarely, a concomitant fall in the sodium concentration.

When any of these conditions exists, the ratio of $cHCO_3^-/cCO_2$ is decreased because of the primary decrease in bicarbonate. The resulting drop in pH stimulates respiratory compensation via hyperventilation, which lowers PCO_2 and thereby raises the pH.

Increased Anion Gap Acidosis (Organic Acidosis)

Metabolic acidoses are classified as those associated with an increased anion gap or a normal anion gap (Table 49-4). The concept of the *anion gap* was originally devised as a quality control rule when it was noted that if the sum of Cl^- and HCO_3^- values was subtracted from the Na^+ values [$Na^+ - (Cl^- + HCO_3^-)$], the difference, or "gap," averaged 12 mmol/L in healthy subjects.[14] This *apparent* gap is due to unmeasured anions (e.g., proteins, SO_4^{2-}, $H_2PO_4^{2-}$) that are present in plasma. In reality, unmeasured cations (calcium, magnesium, organic cations) should be included in the equation with sodium and potassium, but their concentration in the blood is relatively small compared with circulating sodium levels. It is important to note that infrequently, low serum anion gaps (<2 mEq/L) can occur. Laboratory error is the most common cause, but bromide, lithium, or iodide intoxication or use of polymyxin B can also lead to a low anion gap, as can low albumin/increased immunoglobulin in cirrhosis and monoclonal gammopathies.[14] The anion gap is increased in many patients with a metabolic acidosis. Indeed, the presence of an elevated anion gap is often the first indication of a metabolic acidosis and should be assessed in the electrolyte profiles of all patients.[14] The gap is also slightly increased in the absence of acidosis by very low calcium, magnesium, or potassium levels, because lower levels of these "unmeasured" cations will result in lower levels of anions (Figure 49-14).

TABLE 49-4 Conditions of Metabolic Acidoses With High and Normal Anion Gaps

Etiology	Retained Acids	Other Laboratory Findings
High AG*		
Methanol toxicity	Formate	↑Osmolal gap (>15 mOsmol/kg)
Uremia of renal failure	Sulfuric, phosphoric, organic	↑BUN† and serum creatinine
Ketoacidoses		
Diabetes mellitus	Acetoacetate and β-hydroxybutyrate	↑Plasma and urine glucose
Ethyl alcohol toxicity		†Osmolal gap (>15 mOsmol/kg)
Starvation		
Paraldehyde toxicity		
Isoniazid or iron toxicity, also ischemia	Organic, mainly lactate	Isoniazid and iron act as mitochondrial poisons
Lactic acidosis	Lactate	
Ethylene glycol toxicity	Hippurate, glycolate, oxalate	↑Osmolal gap (>15 mOsmol/kg), urine oxalate crystals
Salicylate toxicity	Salicylate, organic	Respiratory alkalosis
Normal AG		
Gastrointestinal fluid loss	Primary loss of bicarbonate	
Severe diarrhea		Hypokalemia
Pancreatitis		K^+ variable
Intestinal fistula		
Renal tubular acidoses (RTAs)		
Proximal (type II) RTA		Urine pH <5.5, with K^+ normal or low
Distal (type I) RTA		Urine pH >5.5 with hypokalemia (usually)
Type IV RTA		Urine pH <5.5 with hyperkalemia

*Although there is considerable variability, the anion gap is often >25 mmol/L in these conditions, with the exception of uremic renal failure.
†Blood urea nitrogen (reference interval: 8 to 25 mg/dL, or ≈3.0 to 9.0 mmol/L).

All anion gap metabolic acidoses, besides inborn errors of metabolism, can be explained by one (or a combination) of eight underlying mechanisms listed here according to the common mnemonic device MUDPILES (see Table 49-4). The physiologic basis for the anion gap in these conditions is the consumption of bicarbonate in buffering excess acid. Cl^- values remain normal when the excess acid is any other than HCl, because lost bicarbonate is replaced by unmeasured anions.

Methanol

Although nontoxic itself, methanol is metabolized by the liver to formaldehyde and formic acid. Accumulation of this acid leads to metabolic acidosis with a high anion gap and to clinical symptoms of optic papillitis ("snowfield" blindness), retinal edema, and ultimately blindness caused by optic nerve atrophy and neurologic defects that may lead to coma. Methanol and other ingested alcohols such as ethylene glycol, ethanol, and isopropanol will increase the osmolality of plasma. Thus in the presence of a high anion gap acidosis, determination of the osmolal gap (see Chapter 28) will help determine the source of the unmeasured anion[4] and will suggest specific toxicologic analyses.[4]

Uremia of Renal Failure

Loss of functional renal tubular mass results in decreased ammonia formation, decreased Na^+-H^+ exchange, and decreased GFR. All lead to decreased acid excretion (see Chapter 48). Acidosis usually develops if GFR falls below 20 mL/min. Serum creatinine and blood urea nitrogen levels usually are elevated and are used as an estimate of the degree of renal damage or, more appropriately, as an estimate of remaining functional renal capacity.

Diabetes or Ketoacidosis

The pathogenesis of ketoacidosis is discussed in detail in Chapter 46. Ketoacids such as β-hydroxybutyrate and 2-oxoglutarate accumulate and represent the unmeasured anions. Accumulation of these "ketone bodies" causes a decrease in HCO_3^-, a normal serum chloride, and a high anion gap. Ketoacids also accumulate in states of starvation and alcoholic malnutrition.

Paraldehyde Toxicity

Paraldehyde toxicity may develop after chronic paraldehyde ingestion. The pathogenesis is poorly defined, but the acidosis may actually be a ketosis (nitroprusside negative)

with β-hydroxybutyric acid as the main acidic product. Patients with paraldehyde toxicity have a pungent, apple-like odor to their breath.

Isoniazid, Iron, or Ischemia

These seemingly unrelated causes of high anion gap acidosis share a common feature: the accumulation of organic acids, with a predominance of lactic acid. Thus the "three I's" actually represent special cases in the general category of lactic acidosis, which is described next. Both isoniazid, an antimycobacterial agent commonly used in the treatment or prophylaxis of tuberculosis, and iron toxicity involve the production of toxic peroxides that act as mitochondrial poisons and interfere with normal cellular respiration. In addition, isoniazid may be hepatotoxic, leading to significant liver damage and impairment of lactate clearance.[16]

Tissue ischemia may result from many causes; in general, hypoperfusion leads to hypoxia of cells, resulting in anaerobic metabolism with accumulation of organic (mainly lactic) acids.

Lactic Acidosis

Lactic acid, present in blood entirely as the lactate ion (pK = 3.86), is an intermediate of carbohydrate metabolism that is derived mainly from muscle cells and erythrocytes (see Chapter 26). It represents the end product of anaerobic metabolism and is normally metabolized by the liver. Therefore, the blood lactate concentration is affected by the rate of production and the rate of metabolism, both of which are dependent on adequate tissue perfusion. An increase in the concentration of lactate to >3 mmol/L with the associated increase in H^+ is considered lactic acidosis.

Lactic acidosis caused by severe tissue hypoxia is seen in severe anemia, shock, cardiac arrest, and pulmonary insufficiency. Severe oxygen deprivation of tissue blocks aerobic oxidation of pyruvic acid in the tricarboxylic acid cycle, resulting in the reduction of pyruvate to form lactate. Extreme deterioration of the cellular oxidative process is associated with marked tachypnea, weakness, fatigue, stupor, and finally coma. Conditions at these later stages are frequently irreversible, even when treatment for acidosis and hypoxia is instituted. A short-lived lactic acidosis is often observed following grand mal seizures. If the origin of lactate (e.g., seizure, hypoxic tissue) can be rectified, lactate is rapidly metabolized to CO_2, which then is eliminated by an intact respiratory system.

Lactic acidosis is also caused by (1) drugs and toxins such as ethanol, methanol, or isoniazid (see previous discussion); (2) acquired and hereditary defects in enzymes involved in gluconeogenesis; (3) disorders such as uremia, liver failure, tumors, and seizures; (4) anesthesia; and (5) abnormal intestinal bacteria producing D-lactate. Most common methods for lactate do not detect D-lactate acidosis; this form of lactic acidosis should be considered in patients with "short-bowel" syndromes or following other GI surgeries resulting in "blind loops."[12]

Alcohol taken in excess tends to prevent the metabolism of lactate in the liver, because oxidation of ethanol to acetaldehyde competes for the NAD^+ necessary for conversion of lactate to pyruvate.

During exercise, lactate levels may increase significantly, from an average normal concentration of ≈0.9 mmol/L to ≈12 mmol/L. However, under normal conditions, the lactate is rapidly metabolized to CO_2, so the "acidosis" is only transient as hyperventilation eliminates the CO_2.

Lactate in spinal fluid normally parallels blood levels. In cases of biochemical alterations in the central nervous system, however, CSF lactate values change independently of blood values. Increased CSF lactate levels may be seen in intracranial hemorrhage, bacterial meningitis, epilepsy, and other CNS disorders.[31]

Ethylene Glycol

Ingested ethylene glycol is metabolized primarily to glycolic and oxalic acids. Its metabolism leads to an acidosis with high anion and osmolal gaps. Accumulation of toxic metabolites may also contribute to lactic acid production that further contributes to the acidosis. Precipitation of calcium oxalate and hippurate crystals in the urinary tract may lead to acute renal failure. Clinically, patients develop a variety of neurologic symptoms that may lead to coma. The minimal lethal dose of ethylene glycol is ≈100 mL for an average 70 kg adult.

Salicylate Intoxication

Acidosis generally occurs with blood salicylate concentrations above 30 mg/dL. Salicylate, itself an unmeasured anion, alters peripheral metabolism, leading to the production of various organic acids without dominance of any specific acid. These processes eventually result in a metabolic acidosis with a high anion gap. Salicylate also stimulates the respiratory center to increase the rate and depth of respiration, resulting in a low PCO_2 and mixed respiratory alkalosis and metabolic acidosis.

Normal Anion Gap Acidosis (Inorganic Acidosis)

In contrast to high anion gap acidoses, in which bicarbonate is consumed from buffering excess H^+, the cause of acidosis in the presence of a normal anion gap is the loss of bicarbonate-rich fluid from the kidney or the gastrointestinal tract. As bicarbonate is lost, more Cl^- ions are reabsorbed with Na^+ or K^+ to maintain electrical neutrality, so that hyperchloremia ensues (see Figure 49-14). Normal anion gap acidosis can be divided into *hypokalemic, normokalemic,* and *hyperkalemic* acidoses, which can be helpful in the differential diagnosis of this type of disorder (see Table 49-4 and subsequent section on type IV RTA).

GI Losses

Diarrhea may cause acidosis as a result of loss of Na^+, K^+, and HCO_3^-. One of the primary exocrine functions of the pancreas is production of HCO_3^- to neutralize gastric contents on entry

into the duodenum. If the water, K^+, and HCO_3^- in the intestine are not reabsorbed, a hypokalemic, normal anion gap metabolic acidosis will develop. The resulting hyperchloremia is due to replacement of lost bicarbonate with Cl^- to maintain electrical balance.

Renal Tubular Acidoses, Types I and II

These syndromes are characterized predominantly by loss of bicarbonate due to decreased tubular secretion of H^+ (distal or type I RTA) or decreased reabsorption of HCO_3^- (proximal or type II RTA).[15] Because the major urine-acidifying power of the kidneys rests in the distal tubules, proximal and distal RTAs may be differentiated by measurement of urine pH after administration of acid. In proximal RTA, urine pH becomes <5.5, whereas in distal RTA, the distal tubules are compromised and urine pH is >5.5.[15]

Carbonic Anhydrase Inhibitors

Acetazolamide is the most commonly used drug in this class of therapeutic agents. It is rarely used as a mild diuretic. More often, it is used for urine alkalinization and in patients suffering from open-angle glaucoma or acute mountain (altitude) sickness.[11] Inhibition of carbonic anhydrase causes wasting of Na^+, K^+, and HCO_3^- in the proximal tubules and represents a pharmacologically induced proximal RTA.

Hyperkalemic Normal Anion Gap Acidosis (RTA Type IV)

Failure of the kidneys to synthesize renin, failure of the adrenal cortex to secrete aldosterone, and renal tubular resistance to aldosterone are the most common causes of this type of acidosis (often called type IV RTA). It inhibits Na^+ reabsorption, and both K^+ and H^+ are thus abnormally retained. The result is decreased renal ammonia formation and therefore decreased elimination of H^+. Hyperkalemia is also usually present.

Compensatory Mechanisms in Metabolic Acidosis

The buffer systems of the blood (mainly the bicarbonate/carbonic acid buffer) minimize changes in pH. In acidoses, the bicarbonate concentration decreases to yield a ratio of $cHCO_3^-/cdCO_2$ of less than 20:1. The respiratory compensatory mechanism responds to correct the ratio with increased rate and depth of respiration to eliminate CO_2. Table 49-3 depicts expected compensation in acidoses and alkaloses and corresponding laboratory values.

Respiratory Compensatory Mechanism

The decrease in pH in metabolic acidosis stimulates hyperventilation (Kussmaul respiration), which results in the elimination of carbonic acid as CO_2, a decrease in PCO_2 (hypocapnia), and thus a decrease in $cdCO_2$. There is also a decrease in $cHCO_3^-$ that is smaller than that in $cdCO_2$. For example, the ratio of $cHCO_3^-/cdCO_2$ might be 16:1.28 (12.5:1) for a pH of 7.2 before compensation, and 14.5:0.9 (16:1) for a pH of 7.30 after compensation (see Figure 49-8).

Renal Compensatory Mechanism

If possible, the kidneys respond to restore the normal pH through increased excretion of acid and preservation of base (increased rate of Na^+-H^+ exchange, increased ammonia formation, and increased reabsorption of bicarbonate). When the renal compensating mechanisms are functioning, urine acidity and ammonia are increased. The total amount of H^+ excreted may be as great as 500 mmol/d. As a result, $cHCO_3^-/cdCO_2$ will increase, for example, to 22:1.1 (20:1) for a pH of 7.40. *This is a fully compensated metabolic acidosis,* because the pH has returned to normal; however, acidosis still exists because a process that consumes HCO_3^- persists. Physiologically, a normal pH suggests that the acidosis is overcompensated.

Laboratory Findings in Metabolic Acidosis

Bicarbonate concentrations have been used to empirically estimate pH and PCO_2. For pH, 15 is added to the determined bicarbonate concentration for an estimate of the decimal digits of pH. For example, a patient who has been acidotic for at least 12 to 24 hours and has a bicarbonate of 10 mmol/L (10 + 15 = 25) will have an estimated pH of 7.25. Another common estimator of proper compensation is that the PCO_2 will equal the last two digits of the pH. If a respiratory acidosis was superimposed on a preexisting metabolic acidosis, the PCO_2 would be higher than expected by this estimate.

Electrolytes are also altered depending on the cause of metabolic acidosis. In diabetic ketoacidosis, the increase in the fraction of organic acids caused by increased ketone body production is reflected by a decrease in plasma bicarbonate and sometimes in chloride. Plasma Na^+ and K^+ are also decreased because of the associated polyuria and coexcretion of these cations with acetoacetate and β-hydroxybutyrate. Furthermore, because of the high glucose, a dilutional effect occurs as a result of the osmotically induced increase in vascular volume. When glucose concentration is decreased following insulin treatment, water leaves the vascular compartment, and Na^+ concentration is increased. Serum potassium concentrations, however, may be normal or even high, despite severe total body depletion of K^+; the serum concentration represents a balance struck between the amount of K^+ lost in the urine, the amount of K^+ shifted from cells into ECF, and the degree of dehydration.

Metabolic Alkalosis (Primary Bicarbonate Excess)

Alkalosis occurs when excess base is added to the system, base elimination is decreased, or acid-rich fluids are lost (Box 49-1). Any of these can lead to a primary bicarbonate excess, such that the ratio of $cHCO_3^-/cdCO_2$ becomes greater than 20:1. For instance, a primary increase in bicarbonate to 48 mmol/L will alter the $cHCO_3^-/cdCO_2$ to 48:1.5 (32:1) for a pH of 7.6 (see Figure 49-8). The patient will hypoventilate to raise PCO_2, thereby lowering the pH toward normal. However, hypoxia usually prevents the patient from achieving a PCO_2 greater than 55 mm Hg. Above pH 7.55, tetany may

BOX 49-1 Conditions Leading to Metabolic Alkalosis

Chloride-Responsive (Urine Cl^- <10 mmol/L)
Contraction alkaloses
- Prolonged vomiting or nasogastric suction
- Pyloric or upper duodenal obstruction
- Prolonged or abusive diuretic therapy (loop diuretics)
- Dehydration

Posthypercapnic state
Cystic fibrosis (systemic ineffective reabsorption of Cl^-)

Chloride-Resistant (Urine Cl^- >20 mmol/L)
Mineralocorticoid excess
- Primary hyperaldosteronism (adrenal adenoma or, rarely, carcinoma)
- Bilateral adrenal hyperplasia
- Secondary hyperaldosteronism
- Congenital adrenal hyperplasia [due to adrenal enzyme deficiencies in cortisol production (11β- or 17α-hydroxylase)]

Glucocorticoid excess
- Primary adrenal adenoma (Cushing syndrome)
- Pituitary adenoma secreting ACTH (Cushing disease)
- Exogenous cortisol therapy
- Excessive licorice ingestion

Bartter syndrome (defective renal Cl^- reabsorption)

Exogenous Base
Iatrogenic
- Bicarbonate-containing intravenous fluid therapy
- Massive blood transfusion (sodium citrate overload)
- Antacids and cation-exchange resins in dialysis patients
- High-dose carbenicillin or penicillin (associated with hypokalemia)

Milk-alkali syndrome

develop, even in the presence of a normal serum total calcium concentration. The cause of the tetany is a decreased concentration of ionized calcium due to increased binding of calcium ions by albumin. Measurement of urine Cl^- can be helpful, as causes of metabolic alkalosis fall into Cl^- responsive, Cl^- resistant, and exogenous base categories (see Box 49-1 and Figure 49-4).

Cl^- Responsive Metabolic Alkalosis

Most causes of Cl^- responsive metabolic alkalosis occur as a result of *hypovolemia* (see Box 49-1). When the ECF is severely depleted, the resulting acid-base disorder is often referred to as *contraction alkalosis.* Hypovolemia will result in increased reabsorption of Na^+, along with increased HCO_3^- absorption and excretion of K^+ and H^+. Urine Cl^- will be less than 10 mmol/L, as both the available Cl^- and HCO_3^- are reabsorbed with Na^+. Urine Na^+ is not useful for classifying metabolic alkalosis because an obligatory loss of Na^+ will occur when filtered HCO_3^- exceeds reclamation. Common causes of contraction alkalosis include prolonged vomiting or nasogastric suction, pyloric or upper duodenal obstruction, and the use of certain diuretics. Following prolonged vomiting or gastric suction, excessive loss of hydrochloric acid from the stomach and *hypovolemia* may occur. In this hypochloremic, hypovolemic setting, the kidneys preferentially reabsorb Na^+ to restore volume, and excess bicarbonate is reabsorbed in the absence of sufficient Cl^- to maintain electrical neutrality. In addition, H^+ and K^+ are secreted in exchange for Na^+. Urine Cl^- will be less than 10 mmol/L in this setting (see Figure 49-4). Treatment consists of replacing TBW with water and NaCl tablets or saline infusion.

Diuretic Therapy

Prolonged administration of certain diuretics has been known to cause an alkalosis similar to that observed in a hypovolemic setting. Most common are those acting on the ascending limb of the loop of Henle [e.g., furosemide (Lasix)] that block sodium, potassium, and chloride reabsorption.[11] The resulting increase in Na^+ concentration reaching the distal convoluted tubule, particularly when combined with activation of the renin-angiotensin-aldosterone axis, leads to increased urinary excretion of K^+ and H^+. Loss of K^+ with furosemide is much greater than with thiazides. Continued abuse or unmonitored use of loop diuretics can lead to volume contraction and a contraction alkalosis. This is commonly seen among patients using diuretics for the purpose of weight loss.

Cl^- Resistant Metabolic Alkalosis

This condition is far less common than Cl^- responsive metabolic alkalosis and is almost always associated with an underlying disease (primary hyperaldosteronism, Cushing syndrome, or Bartter syndrome) or with excess addition of exogenous base. In these conditions, urine Cl^- will usually be greater than 20 mmol/L.

In states of adrenocortical excess (endogenous or pharmacologic, primary or secondary), K^+ and H^+ are "wasted" by the kidneys as a consequence of increased Na^+ reabsorption stimulated by elevated aldosterone or cortisol. The attendant hypokalemia often further contributes to the alkalosis and should be treated with K^+ replacement therapy. The decreased tubular K^+ concentration stimulates NH_3 production and thus renal H^+ excretion as NH_4^+. This is accompanied by enhanced HCO_3^- reabsorption (see Figures 49-3 and 49-12). Diseases in which endogenous mineralocorticoids, glucocorticoids, or both are elevated include primary and secondary hyperaldosteronism, bilateral adrenal hyperplasia, pituitary ACTH-producing adenoma (Cushing disease), and primary adrenal adenomas producing glucocorticoids (Cushing syndrome) or aldosterone.

Excessive licorice ingestion may cause a form of Cl^- resistant alkalosis. Black licorice contains glycyrrhizic acid, which inhibits the enzyme 11-β hydroxysteroid dehydrogenase, which catalyzes the conversion of cortisol to cortisone.[7] The excess cortisol exerts a mineralocorticoid effect on the distal tubule aldosterone receptors.

Finally, a rare cause of Cl^- resistant metabolic alkalosis is a genetic (autosomal recessive) defect in Cl^- reabsorption

within the thick ascending limb of the loop of Henle—a condition known as Bartter syndrome.[3]

Exogenous Base

Examples in this category include citrate toxicity following massive blood transfusion, aggressive intravenous therapy with bicarbonate solutions, and ingestion of large quantities of antacids in the treatment of gastritis or peptic ulcer *(milk-alkali syndrome).*[9] The latter is far less commonly seen since the introduction and now widespread use of H_2-receptor antagonists and proton pump inhibitors.

Compensatory Mechanisms in Metabolic Alkalosis

The compensatory mechanisms for metabolic alkalosis include both respiratory compensation and, if physiologically possible, renal compensation. The increase in pH depresses the respiratory center, causing retention of carbon dioxide (hypercapnia), which in turn causes an increase in cH_2CO_3 and $cdCO_2$. Thus the ratio of $cHCO_3^-/cdCO_2$, which was originally increased, approaches its normal value, although the actual concentrations of both $cHCO_3^-$ and $cdCO_2$ remain increased. The kidneys respond to the state of alkalosis by decreased Na^+-H^+ exchange, decreased formation of ammonia, and decreased reclamation of bicarbonate. This response is blunted, however, in conditions of hypokalemia and hypovolemia.

Laboratory Findings in Metabolic Alkalosis

Plasma values for $cHCO_3^-$, $cdCO_2$, and PCO_2, and therefore the plasma total CO_2 concentration, are increased, and the ratio of $cHCO_3^-/cdCO_2$ is high. In uncomplicated metabolic alkalosis, the PCO_2 is increased by ≈6 mm Hg for each 10 mmol/L rise in $cHCO_3^-$. A higher than expected PCO_2 may indicate superimposed respiratory acidosis. The extent of increase in pH in uncompensated metabolic alkalosis can be estimated by adding 15 to the $cHCO_3^-$ to give the last two digits of the pH. If the $cHCO_3^-$ is 35 mmol/L, the estimated pH would be 7.50 (35 + 15 = 50). In cases of prolonged vomiting, Cl^- (and sometimes K^+) concentrations are low because of loss of these ions through the vomitus. Protein values may be increased owing to dehydration, and if food intake is inadequate, formation of ketoacids may increase the organic acid fraction. In cases of excessive administration of $NaHCO_3$, Na^+ levels are increased.

In patients with adequate renal function, urinary pH values are usually increased as the result of decreased excretion of acid and increased excretion of bicarbonate. Urinary ammonium values are decreased because of decreased formation of ammonium in the tubules. In K^+ depletion, H^+ is preferentially exchanged for Na^+ and the pH of the urine may be low. This is called *paradoxical aciduria.*

Respiratory Acidosis

Any condition that decreases elimination of carbon dioxide through the lungs results in an increase in PCO_2 (hypercapnia) and dCO_2 (respiratory acidosis). Thus respiratory acidosis occurs only through decreased elimination of CO_2. Causes of decreased CO_2 elimination (Box 49-2) are classified as acute or chronic. Alternatively, these conditions may be separated into those caused by factors that directly depress the respiratory center (such as centrally acting drugs, CNS trauma, or infection) and those that affect the respiratory apparatus or cause mechanical obstruction of the airways. Chronic obstructive pulmonary disease is the most common cause. Rebreathing, or breathing air high in CO_2 content, may also cause a high PCO_2. An increase in PCO_2 results in an increase in $cdCO_2$ (and thus H_2CO_3, which dissociates to H^+ and HCO_3^-), which in turn causes a decrease in the $cHCO_3^-/cdCO_2$ ratio [e.g., the ratio may be 28:1.7 (16:1) for a pH of ≈7.30; see Figure 49-8]. Doubling of PCO_2 will cause a fall in pH of about 0.23 when other factors remain constant.

BOX 49-2 Conditions Leading to Respiratory Acidosis

Factors That Directly Depress the Respiratory Center
Drugs such as narcotics and barbiturates
Central nervous system (CNS) trauma, tumors, and degenerative disorders
Infections of the CNS such as encephalitis and meningitis
Comatose states such as cerebrovascular accident due to intracranial hemorrhage
Primary central hypoventilation

Conditions That Affect the Respiratory Apparatus
Chronic obstructive pulmonary disease (most common cause)
Severe pulmonary fibrosis
Status asthmaticus (severe)
Disease of the upper airways such as laryngospasm or tumor
Pulmonary infection (severe)
Impaired lung motion due to pleural effusion or pneumothorax
Adult respiratory distress syndrome
Chest wall disease and chest wall deformity
Neurologic disorders affecting the muscles of respiration

Others
Abdominal distention, as in peritonitis and ascites
Extreme obesity (pickwickian syndrome)
Sleep disorders such as sleep apnea

Compensatory Mechanisms in Respiratory Acidosis

Compensation for respiratory acidosis occurs immediately via buffers, and over time via the kidneys and, if possible, the lungs. Excess carbonic acid present in blood is buffered to a great extent by the hemoglobin and protein buffer systems[8] (see Figure 49-9). Buffering of CO_2 causes a slight rise in $cHCO_3^-$. Thus in the immediate posthypercapnic state, this compensation may appear as a metabolic alkalosis (see Box 49-1). The kidneys respond to respiratory acidosis similarly to the way that they respond to metabolic acidosis, namely, with (1) increased Na^+-H^+ exchange, (2) increased ammonia formation, and (3) increased reclamation of

bicarbonate. In a partially compensated chronic respiratory acidosis at steady state, the plasma pH is returned about halfway toward normal as compared with the acute (uncompensated) situation. Renal compensation is not effective before 6 to 12 hours and is not optimal until 2 to 3 days. In chronic respiratory acidosis, such as occurs in patients with chronic obstructive pulmonary disease (COPD), full renal compensation may be seen even in those patients with very high PCO_2 (>50 mm Hg). However, patients with severe COPD often present with a superimposed metabolic alkalosis arising from a variety of causes, such as prolonged administration of diuretics.

The increase in PCO_2 stimulates the respiratory center, resulting in an increased pulmonary rate and depth of respiration, provided that the primary defect is not in the respiratory center. Elimination of carbon dioxide through the lungs results in a decrease in $cdCO_2$; thus the ratio of $cHCO_3^-/cdCO_2$ and pH approach normal.

Laboratory Findings in Respiratory Acidosis

Plasma $cdCO_2$, PCO_2, $cHCO_3^-$, and therefore $ctCO_2$ are elevated in respiratory acidoses. Because of an increase in $cdCO_2$, the ratio of $cHCO_3^-/cdCO_2$ is decreased, resulting in a decreased pH. In the acute phase, $cHCO_3^-$ will increase by ≈1 mmol/L for each 10 mm Hg rise in PCO_2. If respiratory acidosis persists, the change will be ≈3.5 mmol/L, mainly as a result of renal compensation. For every 15 mm Hg increase in PCO_2, pH decreases in the *acute* phase by ≈0.10 pH unit, and in *chronic* conditions by slightly less than 0.05 pH unit. For example, if the PCO_2 increases acutely by 30 mm Hg, the pH drops to ≈7.20. The same PCO_2 increase in a chronic condition results in a pH of ≈7.31. The plasma chloride decreases as plasma bicarbonate increases. Hyperkalemia may occur but is not as predictable as in some forms of metabolic acidosis. For every 0.1 unit decrease in pH, there is generally an inverse change of 0.6 mmol/L in K^+. Urinary acidity and ammonium content are increased as the kidney attempts to compensate.

Respiratory Alkalosis

A decrease in PCO_2 (hypocapnia) and the resulting primary deficit in $cdCO_2$ (respiratory alkalosis) are caused by an increased rate and/or depth of respiration. Therefore, the basic cause of respiratory alkalosis is excess elimination of acid via the respiratory route. Excessive elimination of carbon dioxide reduces the PCO_2 and causes an increase in the $cHCO_3^-/cdCO_2$ ratio. The latter shifts the normal equilibrium of the bicarbonate/carbonic acid buffer system, reducing the hydrogen ion concentration and increasing the pH. This shift also results in a decrease in $cHCO_3^-$, which somewhat ameliorates the change in pH. Analogous to causes of respiratory acidosis, causes of respiratory alkalosis can be classified as those with a direct stimulatory effect on the respiratory center and those due to effects on the pulmonary system. These and some additional conditions underlying respiratory alkaloses are listed in Box 49-3.

BOX 49-3 Factors Causing Respiratory Alkalosis

Nonpulmonary Stimulation of Respiratory Center
Anxiety, hysteria
Febrile state
Gram-negative septicemia
Metabolic encephalopathy (e.g., due to liver disease)
Central nervous system infection such as meningitis, encephalitis
Cerebrovascular accident
Intracranial surgery
Hypoxia [e.g., severe anemia, high altitudes (acute condition)]
Drugs and agents such as salicylates, catecholamines, and progesterone
Pregnancy, mainly third trimester (↑ progesterone?)
Hyperthyroidism

Pulmonary Disorders*
Pneumonia
Pulmonary emboli
Interstitial lung disease
Large right-to-left shunt (PCO_2 <50 mm Hg)
Congestive heart failure
Respiratory compensation after correction of metabolic acidosis

Others
Ventilator-induced hyperventilation

*The severe stages of some of these disorders may be associated with respiratory acidosis if elimination of CO_2 is severely impaired.

Compensatory Mechanisms in Respiratory Alkalosis

The compensatory mechanisms respond to respiratory alkalosis in two stages. In the first stage, erythrocyte and tissue buffers provide H^+ ions that consume a small amount of HCO_3^-. The second stage becomes operational in prolonged respiratory alkalosis and depends on renal compensation as described for metabolic alkalosis (decreased reclamation of bicarbonate).

Laboratory Findings in Respiratory Alkalosis

In this condition, $cdCO_2$, PCO_2, $cHCO_3^-$, and thus total CO_2 concentration all decrease. The ratio of $cHCO_3^-/cdCO_2$ is increased, causing an increase in pH. During the acute phase, $cHCO_3^-$ falls by 2 mmol/L for each 10 mm Hg decrease in PCO_2 (i.e., if the PCO_2 falls by 20 mm Hg, $cHCO_3^-$ is decreased by 4 mmol/L). For the same 20 mm Hg decrease in PCO_2, the (H^+) will decrease by 16 nmol/L.

If the original cH^+ was 40 nmol/L, it would now be 24 nmol/L (40 − 16 = 24), which corresponds to a pH of 7.61 (see Figure 49-6). Finally, individuals living at high altitudes chronically hyperventilate owing to hypoxia and have PCO_2 values lower than those seen at sea level.

CHAPTER 50

Liver Disease

*D. Robert Dufour, M.D., F.C.A.P., F.A.C.B.**

The liver has a central and critical biochemical role in the (1) metabolism, (2) digestion, (3) detoxification, and (4) elimination of substances from the body. All blood from the intestinal tract initially passes through the liver, where products derived from digestion of food are processed, transformed, and stored. These include amino acids, carbohydrates, fatty acids, cholesterol, lipids, vitamins, and minerals (see Chapters 21, 26, 27, and 31 respetcively). Most major plasma proteins (with the exception of immunoglobulins and von Willebrand factor) are mainly or exclusively synthesized in the liver. The liver responds to multiple hormonal and neural stimuli to regulate the blood glucose concentration. Not only does it extract glucose from blood for use in generating energy, it also stores dietary glucose as glycogen for later use. The liver is also the major site for gluconeogenesis, which is critical for maintaining blood glucose in the fasting state. The liver is central in lipid metabolism; it extracts and processes dietary lipids, and it is the principal site of cholesterol, triglyceride, and lipoprotein synthesis. Another major liver function is the synthesis of bile acids from cholesterol with secretion of these compounds into the bile, facilitating the absorption of dietary fat and fat-soluble vitamins. The liver is also the primary site of metabolism of both endogenous substances and exogenous compounds, such as drugs and toxins. This process, known as *biotransformation,* converts lipophilic substances to hydrophilic ones for subsequent elimination. The liver is a major site of catabolism of hormones, and thus participates in regulation of plasma hormone concentrations. The liver is also involved in hormone synthesis, producing such hormones as insulin-like growth factor 1, angiotensinogen, hepcidin, thrombopoietin, erythropoietin, and the prohormone 25-OH vitamin D. Many of these hepatic functions may be assessed by laboratory procedures to gain insight into the integrity of the liver.

As a large organ, the liver shares with many other organs the ability to perform its functions with extensive reserve capacity. In many cases, individuals with liver disease maintain normal function despite extensive liver damage. In such cases, liver disease may be recognized only by using tests that detect injury. Most commonly, this is accomplished by measuring plasma activities of enzymes found within liver cells, released in somewhat specific patterns with different forms of injury. Chronic liver injury often involves fibrosis in the liver; markers of the fibrotic process might be indicators of degree of injury. Chronic damage is often due to chronic inflammation; cytokines alter the pattern of liver protein production, allowing detection of inflammation (although not necessarily that involving the liver). Some proteins are produced in increased amounts with liver regeneration and neoplasm; such markers may be useful in detecting liver cell proliferation.

The chapter begins with a discussion of the anatomy and biochemical functions of the liver. Various disease states that involve the liver are then discussed. The chapter concludes with a discussion of the use of laboratory test results in recognizing and characterizing patterns of liver injury.

ANATOMY OF THE LIVER

The adult liver weighs approximately 1.2 to 1.5 kg. It is located beneath the diaphragm in the right upper quadrant of the abdomen and is protected by the ribs and held in place by ligamentous attachments.

Gross Anatomy

The liver is divided into left and right anatomic lobes by the falciform ligament, an anterior extension of the peritoneal folds that connects the liver to the diaphragm and the anterior abdominal wall (Figure 50-1). Two smaller lobes are found on the posterior surface (caudate lobe) and the inferior surface (quadrate lobe) of the right lobe. Riedel's lobe, an anatomic extension of the right lobe of the liver, consists of a projection that may feel like a mobile tumor in the right abdomen.

The liver has a dual blood supply. The portal vein, which carries blood from the spleen and nutrient-enriched blood from the gastrointestinal (GI) tract, supplies approximately 70% of the blood supply; the hepatic artery, a branch of the celiac axis, provides oxygen-enriched arterial blood. Each supplies approximately half of the oxygen reaching the liver, making it highly resistant to infarction. Ultimately, these two blood supplies merge and flow into the sinusoids that course

The author gratefully acknowledges the original contributions by Drs. Keith G. Tolman and Robert Rej upon which portions of this chapter are based.

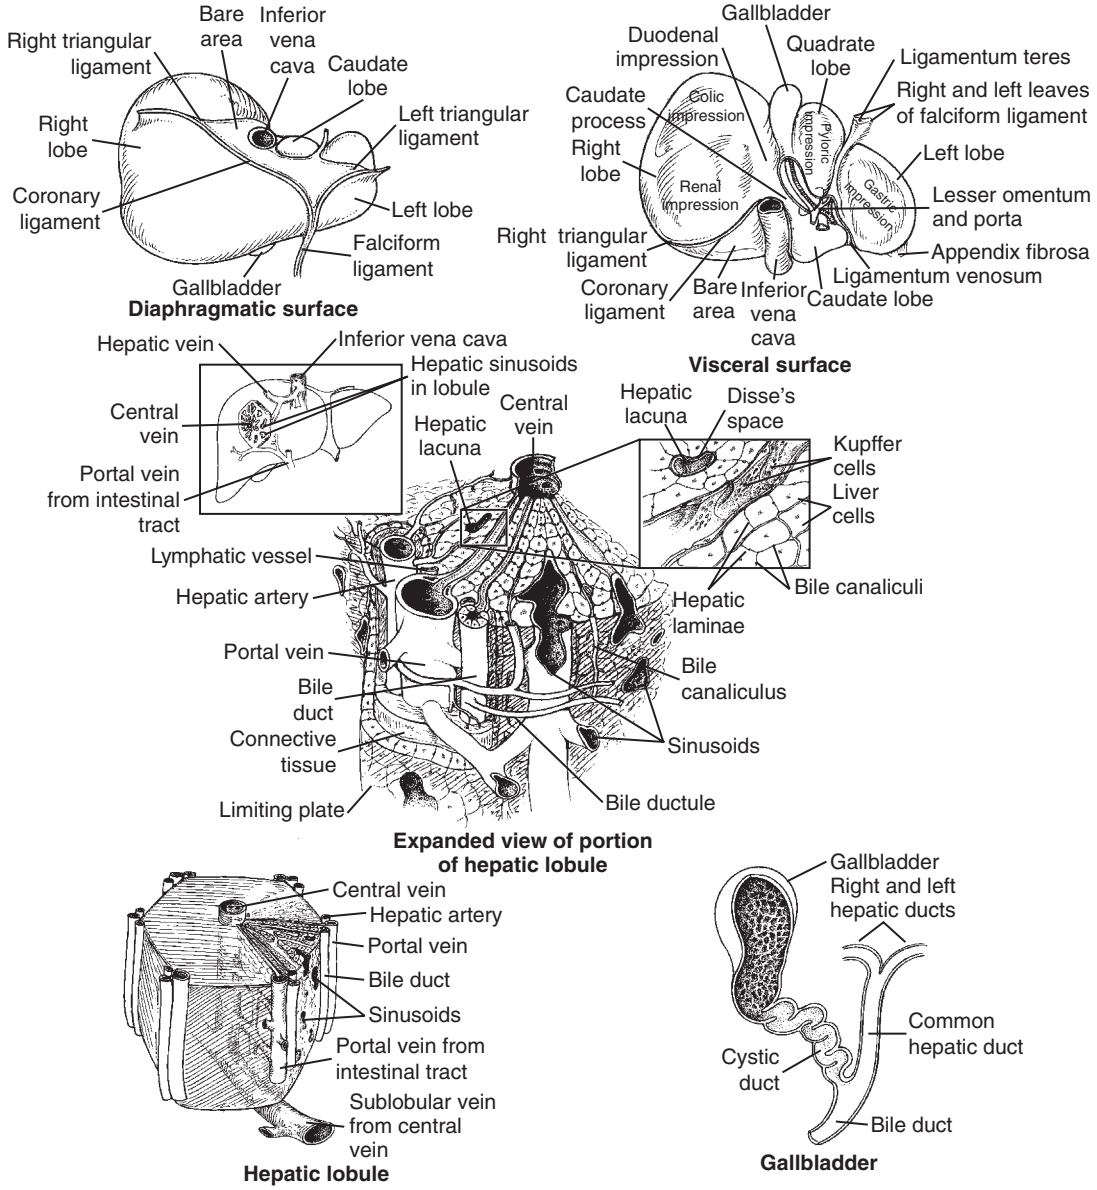

Figure 50-1 Structure of the liver. *(From Dorland's illustrated medical dictionary, 30th edition. Philadelphia, Pa: WB Saunders, 2003, plate 26.)*

between individual hepatocytes. Venous drainage from the liver ultimately converges into the right and left hepatic veins, which exit on the posterior surface of the liver and join the inferior vena cava near its entry into the right atrium.

The liver is covered by an anterior reflection of the peritoneum known as *Glisson's capsule*. Other extensions of the peritoneum form ligaments that hold the liver in place. Internal extensions of the capsule provide an internal supporting framework that divides the liver into lobules and ultimately surrounds blood vessels and nerves. One of the ligaments, the ligamentum teres, is the vestigial remnant of the umbilical vein; it connects the umbilicus to the inferior border of the liver. When portal hypertension occurs, the umbilical veins may reopen, leading to venous dilation around the umbilicus (termed *caput medusae*).

The nerve supply to the liver comes from the vagus and phrenic nerves and the sympathetic ganglia originating from cell bodies in the spinal cord that are located between the seventh and tenth thoracic vertebrae. These merge to accompany the hepatic artery and bile ducts throughout the liver.

Biliary drainage originates at the bile canaliculi; these grooves between adjacent hepatocytes form ductules that merge to create the intrahepatic bile ducts, which ultimately join to form the right and left hepatic bile ducts, which exit from the liver at the porta hepatis and combine to form the common hepatic duct. The hepatic duct is joined by the cystic duct draining the gallbladder to form the common bile duct (see Figure 50-1). The common bile duct then enters the duodenum (usually with the pancreatic duct) at the ampulla of Vater. The duodenal portion of the common bile duct is

surrounded by longitudinal and circular muscle fibers that form the sphincter of Oddi. This musculature relaxes when the gallbladder contracts, allowing bile to enter the duodenum; in its normally contracted state, the sphincter prevents reflux of acidic duodenal contents into the bile duct. The gallbladder, located on the undersurface of the right lobe of the liver, is the site for storage and concentration of bile, a complex mixture of bile salts and waste products. In the adult, it averages about 10 cm in length and has a capacity of 30 to 50 mL of bile. Hormonal stimuli initiated by food ingestion cause contraction of the muscular wall of the gallbladder, releasing bile salts into the intestine to facilitate digestion of fat.

Microscopic Anatomy

The functional anatomical unit of the liver is the acinus, adjacent to the portal triad (which consists of a branch of the portal vein, hepatic artery, and bile duct). Each acinus is a diamond-shaped mass of liver parenchyma that is supplied by a terminal branch of the portal vein and of the hepatic artery and is drained by a terminal branch of the bile duct. The blood vessels radiate toward the periphery, forming sinusoids, which perfuse the liver and ultimately drain into the central (terminal) hepatic vein (Figure 50-2). The sinusoids are lined by fenestrated endothelial cells (allowing free filtration of blood) and phagocytic Kupffer cells (see Figure 50-1). The Kupffer cells are derived from blood monocytes. They contain lysosomes with hydrolytic enzymes that break down phagocytized foreign particles, such as bacteria. They also have immunoglobulin and complement receptors and are the main site for clearance of antigen-antibody complexes from blood. Kupffer cells secrete interleukins, tumor necrosis factor, collagenase, prostaglandins, and other factors involved in the inflammatory response.

Hepatocytes are the major functioning cells in the liver and are responsible for about 70% of liver mass and perform most of the metabolic and synthetic functions of the liver. Two other cell types are found in small numbers within the liver. The *stellate cells* (sometimes referred to as *Ito cells*) are located between the endothelial lining of the sinusoids and the hepatocytes within a small cleft referred to as the *space of Disse.* In their normal, quiescent state, stellate cells serve as a site of storage for fat-soluble vitamins, particularly vitamin A. When stimulated, stellate cells are morphologically and functionally transformed. They synthesize collagen and are the cells responsible for fibrosis and, eventually, cirrhosis. They also synthesize nitric oxide, which helps to regulate intrahepatic blood flow. *Oval cells,* found near the portal areas around small bile passages, are believed to be liver stem cells involved in regeneration of hepatocytes and bile ducts after liver injury.[268]

The blood supply to each acinus consists of three zones (Figure 50-3). Zone 1, the area immediately adjacent to the portal tract, is enriched with lysosomes and mitochondria.

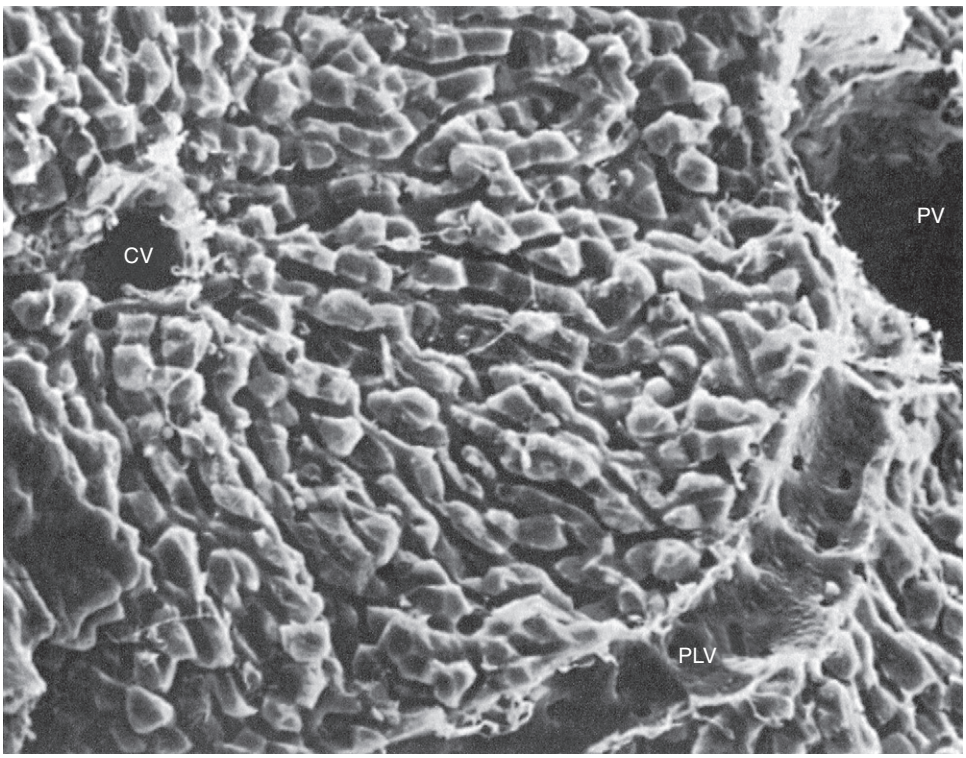

Figure 50-2 A low-magnification scanning electron micrograph depicting a portion of a liver lobule from a rat liver. *CV,* Central vein; *PLV,* perilobular venules; *PV,* portal vein. *(From Zakim O, Boyer TD. Hepatology: a textbook of liver disease, 3rd edition. Philadelphia, Pa: WB Saunders, 1996:9.)*

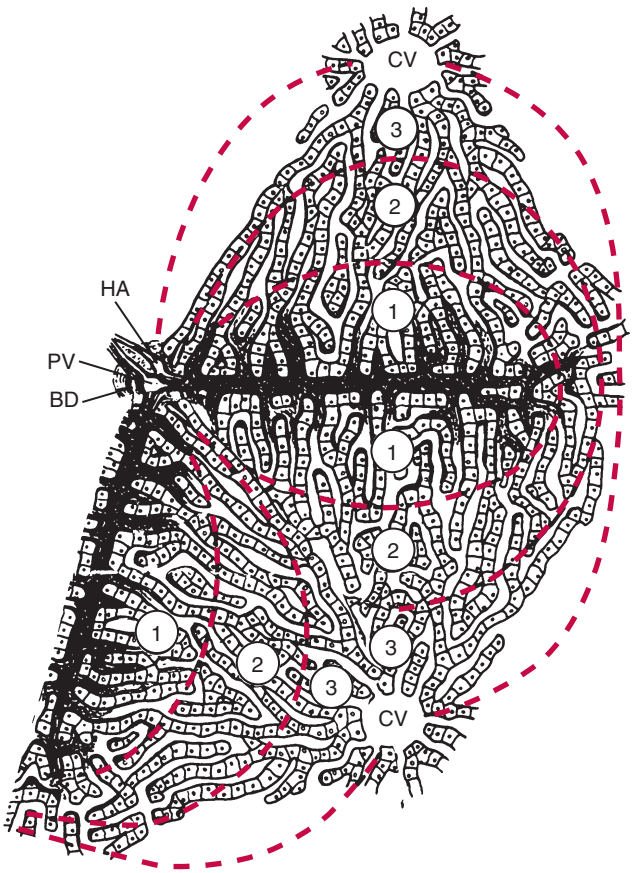

Figure 50-3 Blood supply of the simple liver acinus. ***Zones 1, 2,*** **and** ***3*** **indicate corresponding volumes in a portion of an adjacent acinar unit. Oxygen tension and the nutrient level in the blood in sinusoids decrease from zone 1 through zone 3.** ***BD,*** **Bile duct;** ***CV,*** **central vein;** ***HA,*** **hepatic artery;** ***PV,*** **portal vein.** *(From Zakim O, Boyer TD. Hepatology: a textbook of liver disease, 3rd edition. Philadelphia, Pa: WB Saunders, 1996:10.)*

The periphery of the acinus, zone 3, is enriched with endoplasmic reticulum, is very active metabolically, and has relatively low oxygen tension. This area is most susceptible to injury, although zone 1 appears to be involved in protecting the liver from external injury and providing a base for hepatic regeneration.

Ultrastructure of the Hepatocyte

Hepatocytes contain a well-developed organelle substructure (Figure 50-4). Mitochondria, which constitute approximately 18% of hepatocyte volume, are the sites of oxidative phosphorylation and energy production. They contain enzymes involved in the citric acid cycle and in β-oxidation of fatty acids. The rough endoplasmic reticulum is the site of synthesis of many proteins, including albumin, coagulation factors, enzymes (e.g., glucose-6-phosphatase), and triglycerides. The smooth endoplasmic reticulum contains microsomes that are involved in bilirubin conjugation, detoxification (cytochrome P450–dependent isoenzymes), steroid synthesis, cholesterol synthesis, and bile acid synthesis. Several microsomal enzymes, including γ-glutamyltransferase, are induced by many drugs and inhibited by others. This is the site of most drug metabolism and many important drug interactions.

Peroxisomes are found near the smooth endoplasmic reticulum and contain oxidases that use molecular oxygen to modify a variety of substrates, leading to the production of hydrogen peroxide. They also contain catalase, which decomposes hydrogen peroxide. Peroxisomes catalyze the β-oxidation of fatty acids with chain lengths from 7 to 18. Approximately 5 to 20% of the metabolism of ethanol also occurs in the peroxisomes. Lysosomes are dense organelles that contain hydrolytic enzymes that act as scavengers. Deposition of iron, lipofucsin, bile pigments, and copper occurs in the lysosomes. The Golgi apparatus lies near the canaliculus and is involved in the secretion of various substances, including bile acids and albumin.

BIOCHEMICAL FUNCTIONS OF THE LIVER

The liver is involved in various excretory, synthetic, and metabolic functions. Clinical laboratories perform numerous tests that are useful in the biochemical assessment of these functions.

Hepatic Excretory Function

Organic compounds of both endogenous and exogenous origin are extracted from the sinusoidal blood, biotransformed, and excreted into the bile or urine. Assessment of this excretory function provides valuable clinical information. The most frequently used tests involve the measurement of plasma concentrations of endogenously produced compounds, such as bilirubin and bile acids, and determination of the rate of clearance of exogenous compounds, such as aminopyrine, lidocaine, and caffeine.

Bilirubin

Bilirubin is the orange-yellow pigment derived from heme, mainly as a product of red blood cell turnover. It is extracted and biotransformed in the liver and excreted in bile and urine. The chemistry, biochemistry, and analytical methodsology for bilirubin and related compounds are discussed in Chapter 32; a brief overview of factors relevant to an understanding of liver disease is included here.

Bilirubin is transported from sites of production (mainly the spleen), loosely bound to albumin, in its native, unconjugated form. Bilirubin is transported across the hepatocyte membrane and is rapidly conjugated with glucuronic acid to produce bilirubin glucuronides, which are then excreted into bile by an energy-dependent process. This process is highly efficient, and bilirubin conjugates are detectable in normal plasma only with the use of highly sensitive techniques. In the presence of bilirubin monoglucuronide, albumin (and other proteins) can be postsynthetically modified by covalent attachment to lysine residues. In the case of albumin, this produces a protein-bound form termed *biliprotein* or δ-*bilirubin*. Increases in conjugated bilirubin or δ-bilirubin are highly specific markers of hepatic dysfunction (except in

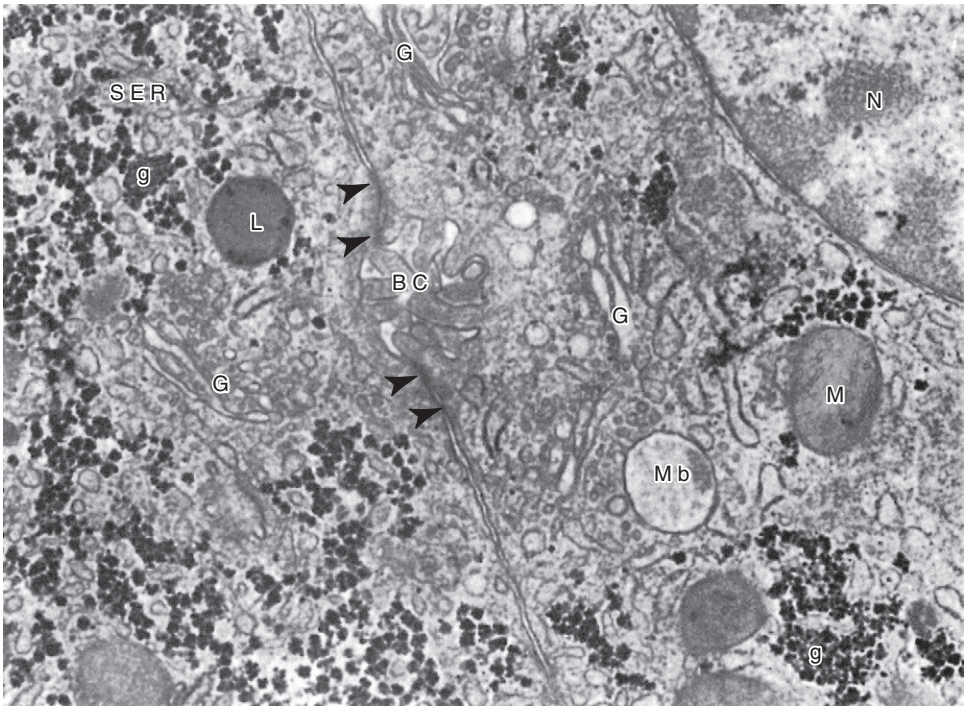

Figure 50-4 Portions of two human liver cells showing the relationship of the organelles and a typical bile canaliculus (BC). *Arrowheads* indicate light junctions. *G,* Golgi; *g,* glycogen; *L,* lysosome; *M,* mitochondria; *Mb,* microbody; *N,* nucleus; *SER,* smooth endoplasmic reticulum. *(From Zakim O, Boyer TD. the presence of rare inherited disorders that impair excretion of conjugated bilirubin, such as Dubin-Johnson syndrome). In the intestinal tract, bilirubin glucuronides are hydrolyzed and reduced by bacteria to form colorless *urobilinogens,* which undergo an enterohepatic circulation. A small fraction (2 to 5%) escapes the liver and is excreted in urine. In the colon, urobilinogens spontaneously oxidize to stool pigments stercobilin, mesobilin, and urobilin.

Increased plasma bilirubin typically is classified as primarily indirect (an approximation of unconjugated bilirubin) or direct (an approximation of the sum of conjugated bilirubin and biliprotein). Increased indirect bilirubin indicates overproduction of bilirubin, usually caused by hemolysis, or decreased metabolism by the liver [primarily caused by congenital defects involving uridine 5′-phosphate (UDP)-glucuronyl transferase]. With severe liver injury, as occurs with fulminant hepatic failure and end-stage cirrhosis, liver disease may cause primarily unconjugated hyperbilirubinemia. Increased urine urobilinogen occurs when bilirubin delivery to the intestinal tract is increased (as with hemolysis, or following recovery from hepatitis or obstruction), or when liver clearance is decreased, as occurs in portal hypertension.

Increased direct bilirubin generally results from functional or mechanical impairment in bilirubin excretion from the hepatocyte. Increased conjugated bilirubin is found in most cases of acute hepatitis and cholestasis (stoppage or suppression of the flow of bile); the percentage of direct bilirubin is similar in both types of liver disease.[42] Urine bilirubin reflects increased plasma concentrations of conjugated bilirubin. With resolution of liver disease, conjugated bilirubin is rapidly cleared, and biliprotein may become the only form present; urine bilirubin is typically absent in such circumstances. Increased conjugated bilirubin is rarely seen with congenital defects in bilirubin excretion, such as Dubin-Johnson syndrome, and with impaired bilirubin excretion, as occurs in sepsis or other acute illness.

Bile Acids

Regulation of bile acid metabolism is a major function of the liver. Alterations in bile acid metabolism are usually a reflection of liver dysfunction. Cholesterol homeostasis is in large part maintained by the conversion of cholesterol to bile acids and subsequent regulation of bile acid metabolism. Bile acids themselves provide surface-active detergent molecules that facilitate both hepatic excretion of cholesterol and solubilization of lipids for intestinal absorption. Bile acid homeostasis requires normal terminal ileum function to absorb bile acids for recirculation (enterohepatic circulation). Alterations in hepatic bile acid synthesis, intracellular metabolism, excretion, intestinal absorption, or plasma extraction are reflected in derangements of bile acid metabolism.

Chemistry

Four major bile acids are known. Cholic acid and chenodeoxycholic acid, the primary bile acids, are synthesized in the liver. The sequence of reactions involved in the synthesis of

Clinical implications of bile acid metabolism. In: Silverberg M, Daum F, eds. Textbook of pediatric gastroenterology, 2nd edition. Chicago, Ill: Year Book Medical Publishers, 1988:72-89. By permission of Mosby, Inc.)*

cholic acid from cholesterol is shown in Figure 50-5. To date, nine inborn errors of bile acid synthesis have been identified; these can present with neonatal hepatitis, fat malabsorption, or neurologic defects that can progress to chronic liver disease or liver failure and death.[192] The primary bile acids are metabolized (by bacterial 7-α-dehydroxylase) in the intestinal lumen to the secondary bile acids—deoxycholic acid and lithocholic acid. Bile acids (at their carboxylic acid) are conjugated in the liver with the amino acid glycine or taurine. This decreases passive absorption in the biliary tree and proximal small intestine, but permits conservation through active transport in the terminal ileum. Approximately 0.1 to 0.6 g of bile acids is lost in the feces daily.

Because they possess both polar and nonpolar regions, molecules of bile acids are able to solubilize biliary lipids. Such molecules align at water-lipid interfaces and reduce surface tension, acting as detergents. In an aqueous solution, bile acids aggregate to form small polymolecular aggregates ≈5 nm in diameter called *micelles,* which are capable of incorporating cholesterol and phospholipids to form mixed micelles. Micellar solubilization of these water-insoluble constituents maintains cholesterol in solution. In the intestinal lumen, dietary cholesterol and the products of triglyceride digestion (predominantly free fatty acids and monoglycerides) are incorporated into mixed micelles. Micelles deliver lipolytic products to the mucosal surface. To carry out these functions, a critical micellar bile acid concentration of ≈2 mmol/L is necessary. Bile acids are thus important for ensuring the solubility of cholesterol (a major component of most gallstones) in bile and dietary lipids (including fat-soluble vitamins) in the intestinal lumen.

Clinical Significance of Bile Acids

In view of the multiple processes involved in bile acid synthesis, conjugation, and excretion, and in its hepatic and intestinal uptake, several potential sites for primary or secondary disturbances have been identified (Box 50-1). With hepatocyte dysfunction (as occurs in many liver disorders), decreased

BOX 50-1 Disturbances in Bile Acid Metabolism

Defective bile acid synthesis
- *Inherited* defects in bile acid synthesis
- *Acquired* defects in bile acid synthesis secondary to liver disease

Extrahepatic bile duct obstruction
Bile acid malabsorption
Defective uptake or altered intracellular metabolism

bile acid synthesis results in low primary bile acid concentrations and a decreased ratio of primary to secondary bile acids in plasma; in addition, decreased extraction from plasma often leads to increased concentrations of bile acids, particularly in the nonfasting state. With cholestatic disorders, decreased delivery of primary bile acids to the intestine with resulting decreased secondary bile acid production causes an increased ratio of primary to secondary bile acids, as well as increased total bile acid concentrations. With intestinal disease (including bypass operations that may be performed to treat obesity), increased fecal loss of bile acids leads to decreased concentrations of both primary and secondary bile acids and, often, a decrease in cholesterol caused by increased need for bile acid synthesis. Although bile acid concentrations are abnormal in many situations, they add little to standard tests of liver function and are rarely used in clinical medicine.

Analytical Methods

Analytical techniques used to quantify total or individual bile acids in biological fluids include (1) gas-liquid chromatography (GLC), (2) high-performance liquid chromatography (HPLC), (3) enzymatic assay, (4) radioimmunoassay (RIA), (5) enzyme-linked immunosorbent assay (ELISA), and (6) tandem mass spectrometry (MS/MS).

Hepatic Synthetic Function

The liver has extensive synthetic capacity and plays a major role in the regulation of protein, carbohydrate, and lipid metabolism (see Chapters 21, 26, and 27). A bidirectional flux of precursors and products, such as glucose, amino acids, free fatty acids, and other nutrients, occurs across the hepatocyte membrane. Normal blood glucose concentrations are maintained during short fasts by the breakdown of hepatic glycogen and during prolonged fasts by hepatic gluconeogenesis. The primary sources of carbon atoms for gluconeogenesis are amino acids derived from muscle proteins. To a lesser extent, lactate (produced in skeletal muscle and erythrocytes) and glycerol (obtained from hydrolysis of triglycerides) also serve as substrates for gluconeogenesis. In humans, the oxidation of odd-numbered fatty acids yields propionyl-CoA, which can be converted to glucose. However, the formation of glucose in this manner is not quantitatively significant. Protein, triglyceride, fatty acid, cholesterol, and bile acid synthesis also occurs within the liver.

Protein Synthesis

The liver is the primary site of the synthesis of plasma proteins (see Chapter 21). Synthesis occurs in the rough endoplasmic reticulum of hepatocytes, followed by release into the hepatic sinusoids. Although disturbances of protein synthesis occur as a consequence of impaired hepatic function, a variety of other factors may affect plasma protein concentrations. These include (1) decreased availability of amino acids (malnutrition, maldigestion, and malabsorption), (2) catabolic states (hyperthyroidism, Cushing's syndrome, burns, postsurgery recovery), (3) protein-losing states (nephrotic syndrome and protein-losing enteropathy), (4) actions of cytokines (decrease in transport proteins such as albumin, transferrin, and lipoproteins, but increase in inflammatory response modifiers such as α_1-antitrypsin, ceruloplasmin, and α_2-macroglobulin), (5) action of hormones (such as growth hormone, cortisol, estrogen, androgens, and thyroid hormones) to increase or decrease production of specific proteins, and (6) congenital deficiency states (Wilson's disease and α_1-antitrypsin deficiency). In addition, the liver has a significant reserve capacity, preventing protein concentrations from decreasing unless liver damage is extensive. In addition, many liver proteins have relatively long half-lives, such as albumin at approximately 3 weeks. For this reason, the sensitivity and specificity of protein concentrations for diagnosis of liver disease are far from ideal.

The patterns of plasma protein alterations seen in liver disease depend on the type, severity, and duration of liver injury. For example, in acute hepatic dysfunction, usually little change is seen in the plasma protein profile or the total plasma protein concentration; with fulminant hepatic failure or severe liver injury, concentrations of short-lived hepatic proteins (such as transthyretin and prothrombin) fall quickly and become abnormal, whereas proteins with longer half-lives are normal or minimally changed. In cirrhosis, concentrations of liver-synthesized plasma proteins and immunoglobulins decrease and increase, respectively. Serial determination of plasma proteins provides prognostic information, for example, worsening of prothrombin time during acute hepatitis suggests a poor prognosis.

Plasma Proteins

Albumin. Albumin, the most commonly measured serum protein, is synthesized exclusively by the liver. The rate of synthesis varies, depending on hormonal environment, nutritional status, age, and other local factors. In inflammatory conditions, interleukin (IL)-6 inhibits albumin synthesis but induces synthesis of acute-phase response proteins. With liver disease, hypoalbuminemia is noted primarily in cirrhosis, autoimmune hepatitis, and alcoholic hepatitis. The mechanism is multifactorial. In cirrhosis, hepatic synthesis of albumin may be decreased, normal, or increased. Loss of albumin into ascitic fluid seems responsible for the decrease in albumin in many cases. One important consideration in measurement of albumin is the inaccuracy of dye-binding methods in patients with liver disease. Although bromocresol green measurements tend to overestimate

albumin concentration at low concentrations,[293] bromocresol purple methods give falsely low values in patients with jaundice because of interference of bilirubin at the site of binding.[207]

Transthyretin. This protein has a short half-life of 24 to 48 hours, making it a sensitive indicator of current synthetic ability. Transthyretin is typically decreased in cirrhosis (among other conditions) as a result of decreased synthesis. It is more commonly used as a measurement of nutritional status.

Immunoglobulins. Immunoglobulins are commonly increased in cirrhosis, autoimmune hepatitis, and primary biliary cirrhosis but are normal in most other types of liver disease. Immunoglobulin (Ig)G is increased in autoimmune hepatitis and cirrhosis; IgM is increased in primary biliary cirrhosis. IgA tends to be increased in all types of cirrhosis. None of these findings are specific, and they are seldom used in the diagnosis of liver disease.

Ceruloplasmin. This protein is decreased in Wilson's disease, cirrhosis, and many causes of chronic hepatitis, but may be increased by inflammation, cholestasis, hemochromatosis, pregnancy, and estrogen therapy. It is discussed in greater detail under Wilson's disease.

α_1-Antitrypsin. This protein, which is the major serine protease inhibitor (serpin) in plasma, is decreased in homozygous deficiency and cirrhosis and is increased by acute inflammation. It is discussed in greater detail later in this chapter under the heading "α_1-Antitrypsin Deficiency."

α-Fetoprotein. This protein, a normal component of fetal blood, falls to adult concentrations by 1 year of age. Mild increases are seen in patients with acute and chronic hepatitis and indicate hepatocellular regeneration. It is present at higher concentrations in hepatocellular carcinoma (HCC) and is discussed in greater detail later and in Chapters 21 and 24.

Coagulation Proteins

The coagulation proteins that are synthesized in the liver are listed in Table 50-1. These proteins interact to produce a fibrin clot (see Chapter 59). Inhibitors of the coagulation system, including antithrombin, protein C, and protein S, are also synthesized in the liver. Some of the coagulation factors (II, VII, IX, and X) require vitamin K for post-translational carboxylation within the hepatocyte. Proteins C and S are also carboxylated by a vitamin K–dependent enzyme. Activated protein C in plasma inhibits coagulation by inactivating factors V and VIII. Parenchymal liver disease of sufficient severity to impair protein synthesis or obstructive liver disease sufficient to impair intestinal absorption of vitamin K is therefore a potential cause of bleeding disorders. Because of the great functional reserve of the liver, failure of hemostasis usually does not occur except in severe or long-standing liver disease.

Prothrombin time (PT) measures the activity of fibrinogen (factor I), prothrombin (factor II), and factors V, VII, and X. Because all of these factors are made in the liver and several are vitamin K dependent, a prolonged PT often indicates the presence of significant liver disease. In cholestasis, vitamin K deficiency may cause an increase in PT. In this case, the coagulation abnormality is corrected within a few days by parenteral injection of 10 mg of vitamin K. In contrast, if PT is prolonged because of hepatocellular disease, factor synthesis is decreased and administration of vitamin K does not typically correct the problem. PT is also prolonged in some patients with liver disease because of the presence of dysfibrinogenemia, an abnormal form of fibrinogen that does not clot normally, and that may predispose to thrombosis.[188]

*Protein synthesized in liver.
†Synthesis requires vitamin K.

The method for reporting PT in liver disease remains controversial. PT measures the time to clot after exposure of plasma to tissue factor. Reagents differ in the amount of tissue factor present; in patients on warfarin, clotting times are more greatly prolonged when lower amounts of tissue factor and other reagents that stimulate clotting are in the reagents. This makes a reagent more sensitive to clotting factor abnormalities, but makes standardization of results between laboratories difficult. The International Normalized Ratio (INR) was developed by the World Health Organization (WHO) and the International Committee on Thrombosis and Hemostasis (ICTH) for reporting the results of blood coagulation (clotting) tests. All results are standardized using the international sensitivity index (ISI) for the particular thromboplastin reagent and instrument combination used to perform the test. In practice, it requires determination of the ISI based on the slope of the relationship between prothrombin time using the reagent and that using a reference method in patients on warfarin. The INR is then calculated as follows:

$$INR = \left[\frac{\text{PT (patient)}}{\text{PT (geometric mean of normal)}}\right]^{ISI}$$

INR has been found to standardize interpretation of PT measurements between laboratories in those taking warfarin.

Unfortunately, INR does not have the same relationship to impairment of clotting in individuals with liver disease.[216,235] The apparent explanation lies in the mechanism of clotting factor deficiency in liver disease and warfarin administration. Although liver disease inhibits synthesis of clotting factors, warfarin impairs vitamin K–dependent carboxylation, impairing the ability of the factors to bind calcium. These noncarboxylated clotting factors (termed proteins induced by vitamin K antagonists, or PIVKAs) appear to act as inhibitors of coagulation; thus when lower amounts of tissue factor are present, clotting times are more prolonged.[235] In contrast, in liver disease, factor deficiency is due to impaired factor synthesis, and no PIVKAs are present (except in HCC, as discussed later in this chapter). This leads to lesser increases in PT in individuals with liver disease and underestimation of the degree of clotting impairment when reagents with low ISI are used. Studies have shown that calculation of a different ISI using plasma samples from patients with liver disease can standardize PT results with different reagents,[33,454] but to date, such "liver ISI" information is not readily available to laboratories.

Lipid and Lipoprotein Synthesis

The liver plays a key role in the metabolism of lipids and lipoproteins (see Chapter 27). On a daily basis, approximately 33% of the fatty acids originating from adipose tissue enter the liver, where they undergo esterification into triglycerides or are oxidized. Oxidation is favored in the fasting state and esterification is favored in the nonfasting state. Excessive esterification results in "fatty liver," a disorder in which excess triglycerides are deposited in large vacuoles that displace other cellular components. Most cholesterol is endogenously synthesized in the liver. It and cholesterol of dietary origin enter the hepatic pool, where they are converted to bile acids, incorporated into lipoproteins, or used in the synthesis of liver cell membranes. The relative rates of secretion of bile acids, cholesterol, and lecithin are important factors in the pathogenesis of cholesterol gallstones.

Urea Synthesis

Patients with end-stage liver disease may have low concentrations of urea in plasma (see Chapter 48). The rate of urea excretion in urine is lower than in healthy individuals. In addition, plasma concentrations are elevated for the urea precursors—ammonia and amino acids. Lower specific activities of enzymes involved in urea synthesis are also seen. These findings suggest that patients with liver disease have an impaired ability to metabolize protein nitrogen and to synthesize urea. The rate of hepatic urea synthesis also depends on exogenous intake of nitrogen and on endogenous protein catabolism.

Hepatic Metabolic Function

A recurring theme is the central importance of the liver in metabolic and regulatory pathways. The functional expression of the complex, integrated organelle structure includes the metabolism of drugs (activation and detoxification) and the disposal of exogenous and endogenous substances, such as galactose and ammonia. In addition, metabolic abnormalities due to specific, inherited enzyme deficiencies can affect the liver. A classic example is galactosemia. In this condition, congenital absence of galactose-1-phosphate uridyltransferase allows accumulation of the toxic metabolite galactose-1-phosphate, which causes injury to the liver, brain, and kidneys.

Ammonia Metabolism

Biochemistry and Physiology

The major source of circulating ammonia is the GI tract. Plasma ammonia concentration in the hepatic portal vein is typically fivefold to tenfold higher than that in the systemic circulation. It is derived from the action of bacterial proteases, ureases, and amine oxidases on the contents of the colon and from the hydrolysis of glutamine in both the small and large intestines. Under normal circumstances, most of the portal vein ammonia load is metabolized to urea in hepatocytes in the Krebs-Henseleit (urea) cycle during the first pass through the liver; this process includes intramitochondrial and cytosolic enzyme-catalyzed steps (Figure 50-6).

Ammonia enters tissue of the central nervous system by passive diffusion. The rate of entry increases in proportion to the plasma concentration and is dependent on pH. Ammonia crosses the blood-brain barrier membranes more readily than the ammonium ion. As pH increases, the rate of entry of ammonia into the central nervous system tissue increases as the result of an increase in ammonia relative to ammonium. Given that the pK_a of ammonia is 8.9 at 37 °C, approximately 3% of blood ammonia is NH_3 at the normal physiological pH of 7.4. An increase in pH to 7.6 produces an increase in NH_3 to approximately 5% of total blood ammonia—a 67% increase in concentration.

Clinical Significance

Animal and human studies have shown that an elevated concentration of ammonia (hyperammonemia) exerts toxic effects on the central nervous system. Several causes, both inherited and acquired, of hyperammonemia are known. Inherited deficiencies of urea cycle enzymes are the major cause of hyperammonemia in infants.[55] The two major inherited disorders are those involving the metabolism of the dibasic amino acids lysine and ornithine and those involving the metabolism of organic acids, such as propionic acid, methylmalonic acid, isovaleric acid, and others (see Chapter 58).

Acquired causes of hyperammonemia are advanced liver disease and renal failure. Severe or chronic liver failure (as occurs in fulminant hepatitis or cirrhosis, respectively) leads to significant impairment of normal ammonia metabolism. Reye's syndrome, which is primarily a central nervous system disorder with minor hepatic dysfunction, is also associated with hyperammonemia. Hepatic encephalopathy in the cirrhotic patient is often precipitated by GI bleeding, which enhances ammonia production through bacterial metabolism of protein found in blood. Other precipitating causes of encephalopathy include (1) excess dietary protein,

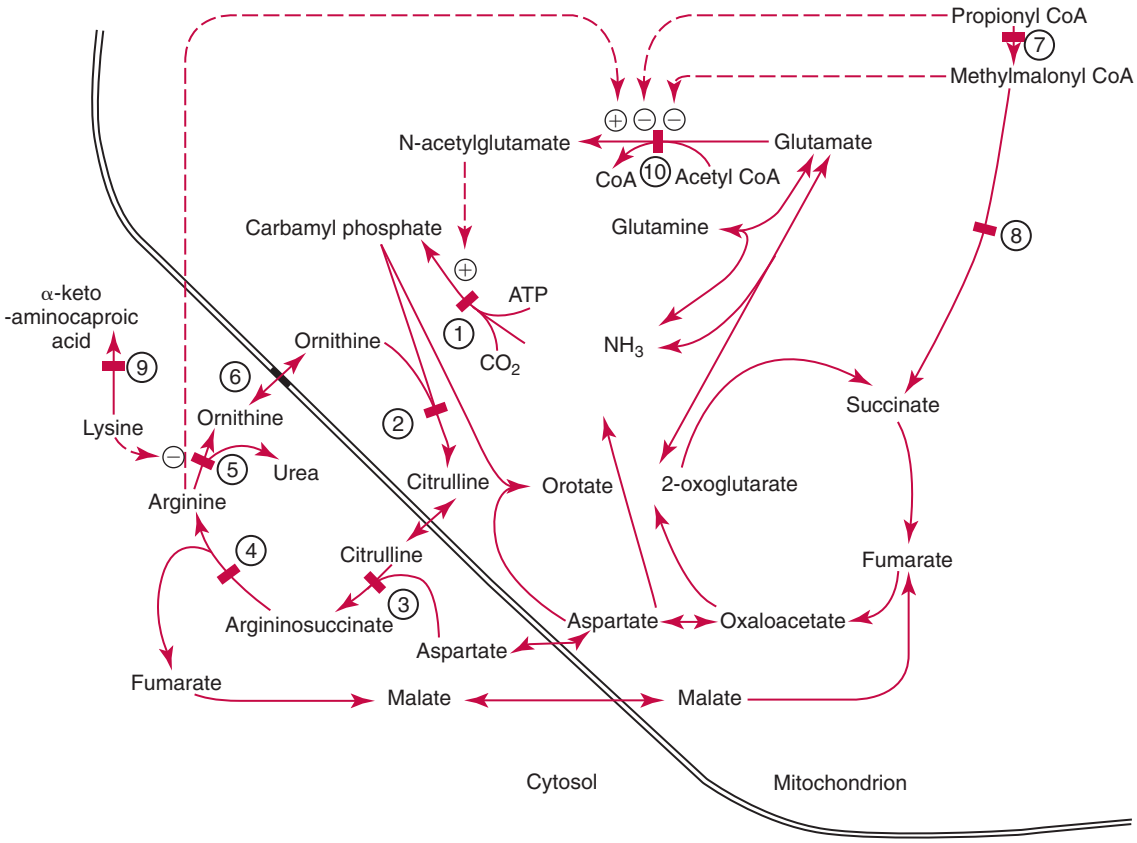

Figure 50-6 Major metabolic pathways for the use of ammonia by the hepatocyte. *Solid bars* indicate the sites of primary enzyme defects in various metabolic disorders associated with hyperammonemia: *(1)* carbamyl phosphate synthetase 1, *(2)* ornithine transcarbamylase, *(3)* argininosuccinate synthetase, *(4)* argininosuccinate lyase, *(5)* arginase, *(6)* mitochondrial ornithine transport, *(7)* propionyl CoA carboxylase, *(8)* methylmalonyl CoA mutase, *(9)* L-lysine dehydrogenase, and *(10)* *N*-acetyl glutamine synthetase. *Dotted lines* indicate the site of pathway activation (+) or inhibition (–). *(From Flannery OB, Hsia YE, Wolf B. Current status of hyperammonemia syndromes. Hepatology 1982;2:495-506.)*

(2) constipation, (3) infection, (4) drugs, and (5) electrolyte and acid-base imbalance. Because cirrhosis is accompanied by portosystemic shunting, ammonia clearance is impaired, leading to increased concentrations of blood ammonia. Impaired renal function also causes hyperammonemia. As blood urea nitrogen (BUN) concentration increases, more diffuses into the GI tract, where is it converted to ammonia.

The fasting venous plasma ammonia concentration is useful in the differential diagnosis of encephalopathy when it is unclear whether encephalopathy is of hepatic origin.[126] It is especially helpful in diagnosing Reye's syndrome and the inherited disorders of urea metabolism, as well as increased ammonia concentrations due to drugs such as salicylates or valproate. In acute liver injury, ammonia concentrations greater than 200 µmol/L are associated with cerebral edema and a poor prognosis,[83] and it has been suggested that ammonia concentrations should be used as part of the evaluation of prognosis in acute liver failure.[37] However, plasma ammonia is not useful in patients with known chronic liver disease.[26] Although ammonia concentrations are higher as the degree of encephalopathy worsens, significant overlap between concentrations is seen in different stages of encephalopathy, and about 70% of those with cirrhosis without encephalopathy have elevated ammonia concentrations.[350] Ammonia concentrations may actually better reflect the presence of shunting blood around the portal veins than the degree of liver dysfunction.[441]

Analytical Methodology

Both enzymatic and chemical methods are used to measure ammonia in body fluids. Enzymatic assay with glutamate dehydrogenase is the most frequently used method. Plasma ammonia measurement is particularly susceptible to contamination, leading to falsely elevated concentrations. Common sampling problems are discussed in the third edition of this textbook.

tahir99-VRG & vip.persianss.ir

Reference Intervals

For the enzymatic method, the reference interval is 15 to 45 µg/dL or 11 to 32 µmol/L.

Carbohydrate Metabolism

Because the liver is a major processor of dietary and endogenous carbohydrates, liver disease affects carbohydrate metabolism in a variety of ways (see Chapter 26). However, none of the conventional modes of evaluating carbohydrate metabolism have value in the diagnosis of liver disease. Because the liver is the major site of both glycogen storage and gluconeogenesis, hypoglycemia is a common complication in certain liver diseases, particularly Reye's syndrome, fulminant hepatic failure, advanced cirrhosis, and hepatocellular carcinoma.

Xenobiotic Metabolism and Excretion

Xenobiotics are chemical substances that are foreign to the biological system. Biochemically, they are cleared and/or metabolized by the liver; some have been used as tests of liver function. Rates of metabolism of these compounds are sometimes referred to as *quantitative liver function tests,* to distinguish them from the more commonly used term, *liver function tests,* often used to refer to measurements of liver-associated enzymes. As liver disease progresses, quantitative liver function test results gradually worsen, and their measurement adds slightly to that obtained by widely used tests such as bilirubin, albumin, and INR measurement.[130] Even when these tests are used, significant overlap of values is noted in persons with cirrhosis and less severe degrees of liver scarring, limiting their utility.

Dye Excretion Tests

Dye excretion tests [such as bromsulphthalein (BSP) and indocyanine green (ICG) clearance] were formerly used as indicators of liver disease. With the development of more sensitive and specific indicators of liver disease, dye excretion tests have become obsolete. Until the 1970s, BSP was the most frequently used dye excretion test. Because of reports of fatalities resulting from hypersensitivity and other adverse effects (nausea, syncope, headache, chills, and thrombophlebitis at the site of injection), BSP use has been discontinued. ICG clearance was used for investigating hepatic blood flow and for predicting clearance rates of drugs that undergo first-pass clearance by the liver, such as lidocaine. Typical ICG clearance values in healthy subjects range from 6.5 to 14 mL/min/kg. ICG clearance is still used occasionally.

Drug Clearance Tests

A variety of drugs that are metabolized by the liver have been used to study the action of various P_{450} enzymes. *Aminopyrine* is demethylated to form carbon dioxide and aminoantipyrine. With the use of ^{13}C- or ^{14}C -labeled aminopyrine, the resulting isotopically labeled CO_2 is measured in breath as a reflection of functioning liver mass. Decreases in metabolism are common in persons with cirrhosis,[162] but metabolism is also affected by other factors such as cigarette smoking and use of drugs such as oral contraceptives; significant intraindividual variation in results has been noted.[63] Overall diagnostic sensitivity is similar to that of other more routine laboratory tests.[340] *Caffeine* is rapidly and nearly completely absorbed from the GI tract and then undergoes *N*-demethylation by the hepatic mixed-function oxidase system. Caffeine clearance is altered during hepatic injury, being prolonged in both chronic hepatitis and cirrhosis.[484] A single dose of caffeine (3.5 mg/kg to a maximum dose of 200 mg, dissolved in water, fruit juice, or milk for oral administration) is administered. This caffeine dose is equivalent to that found in one cup of brewed coffee or in one can of commercial soft drink.

Blood (or salivary samples) obtained before and at timed intervals after caffeine ingestion can be analyzed by reversed-phase HPLC or immunoassay. A close correlation is found between plasma and salivary caffeine concentrations. Caffeine half-life is approximately 5.5 hours in healthy adults and 3 hours in healthy children, with clearance of approximately 2 mL/min/kg in healthy adults and 10 mL/min/kg in healthy children. Caffeine clearance correlates with the aminopyrine breath test and has similar limitations, although it is less subject to effects of variables, such as smoking and oral contraceptive use.[63] *Lidocaine* undergoes *N*-de-ethylation in the liver by cytochrome P450 to form monoethylglycinexylidide (MEGX); the rate of appearance of MEGX in plasma reflects hepatic lidocaine clearance. Because lidocaine is highly extracted, its clearance is flow dependent. Thus alterations in hepatic blood flow also influence lidocaine elimination.[502] Lidocaine (1 mg/kg) is given by intravenous bolus; plasma is obtained at baseline and at 15 minutes for MEGX concentration (time of plateau concentration in healthy individuals). MEGX is most commonly measured using immunoassay. Lidocaine clearance has been used to assess liver transplant function, but its use is limited by the effect of hypoperfusion (as occurs in sepsis or volume depletion).[155]

Hepatic Storage Function

Because individual cells are unable to store a sufficient supply of energy-rich carbohydrate substrates, the liver serves as the major site for their storage. For example, hepatic storage of glycogen allows the release of glucose to other tissue when the need exists (e.g., when plasma concentrations of glucose decrease). Other tissues, such as muscle and adipose tissue, store proteins and triglycerides, respectively, and are capable of adaptation. Depending on the availability of oxidizable fuels, these tissues also switch from the storage mode to the synthesis or release mode during periods of decreased carbohydrate intake.

CLINICAL MANIFESTATIONS OF LIVER DISEASE

Various characteristics indicate the presence of liver disease, including (1) jaundice, (2) portal hypertension, (3) abnormal renal function, (4) altered drug metabolism, (5) nutritional and metabolic abnormalities, (6) disordered hemostasis, and (7) release of enzymes into various body fluids.

tahir99-VRG & vip.persianss.ir

Jaundice

Jaundice (or icterus) is a physical sign characterized by a yellow appearance of the skin, mucous membranes, and sclera caused by bilirubin deposition. It is the most specific clinical manifestation of hepatic dysfunction, but is not present in many individuals with liver disease (especially chronic liver disease) and may occur in states of bilirubin overproduction (such as hemolysis). Jaundice is seen most easily in the sclera of the eyes, where yellow contrasts sharply with the usual bright white color. Jaundice is usually apparent clinically when the plasma bilirubin concentration reaches 2 to 3 mg/dL (34 to 51 µmol/L), although higher concentrations may be required when fluorescent lighting is used. When bilirubin clearance from the liver to the intestinal tract is impaired (as in acute hepatitis and bile duct obstruction), acholic (gray-colored) stools may be noted. Bilirubin is the source of stercobilin, which produces the brown color of normal stool. Increases in plasma conjugated bilirubin lead to tea-colored urine, because conjugated bilirubin is water soluble. Jaundice may also be due to disorders of bilirubin metabolism. Bilirubin metabolism is discussed more fully in Chapter 32. Classification of jaundice, based on the site of altered bilirubin metabolism, is shown in Box 32-1 of that chapter.

Portal Hypertension

The portal circulation handles all venous outflow of the GI tract, the spleen, the pancreas, and the gallbladder (Figure 50-7). The portal vein is formed by the union of the splenic vein and the superior mesenteric vein. Portal flow is normally 1000 to 1200 mL/min with pressure of 5 to 7 mm Hg. Portal hypertension occurs when portal flow is obstructed anywhere along its course. Causes of obstruction leading to portal hypertension are classified by site: (1) presinusoidal, (2) sinusoidal, and (3) postsinusoidal. Presinusoidal portal hypertension is most commonly caused by portal vein thrombosis or schistosomiasis but may also occur with increased portal flow, such as occurs with Felty syndrome (a combination of chronic rheumatoid arthritis, splenomegaly, leukopenia, pigmented spots on the lower extremities, and sometimes other evidence of hypersplenism, such as anemia and thrombocytopenia). Sinusoidal hypertension is most commonly caused by cirrhosis but may occur transiently with acute and chronic hepatitis or acute fatty liver. The most important cause of postsinusoidal hypertension is hepatic vein occlusion or Budd-Chiari syndrome,[149A] in which sudden obstruction or occlusion of the hepatic veins (associated with myeloproliferative disorders in half of cases) causes hepatomegaly, abdominal pain, severe ascites, mild jaundice, and eventually portal hypertension and liver failure.[364] The most common cause of postsinusoidal hypertension is cardiac disease, most commonly congestive heart failure. Chronic congestive heart failure is usually associated with portal hypertension and ascites, and may even lead to increased activities of aminotransferases.[323] Other causes include abscesses, membranous obstruction of the vena cava, and veno-occlusive disease (as may be seen in patients following

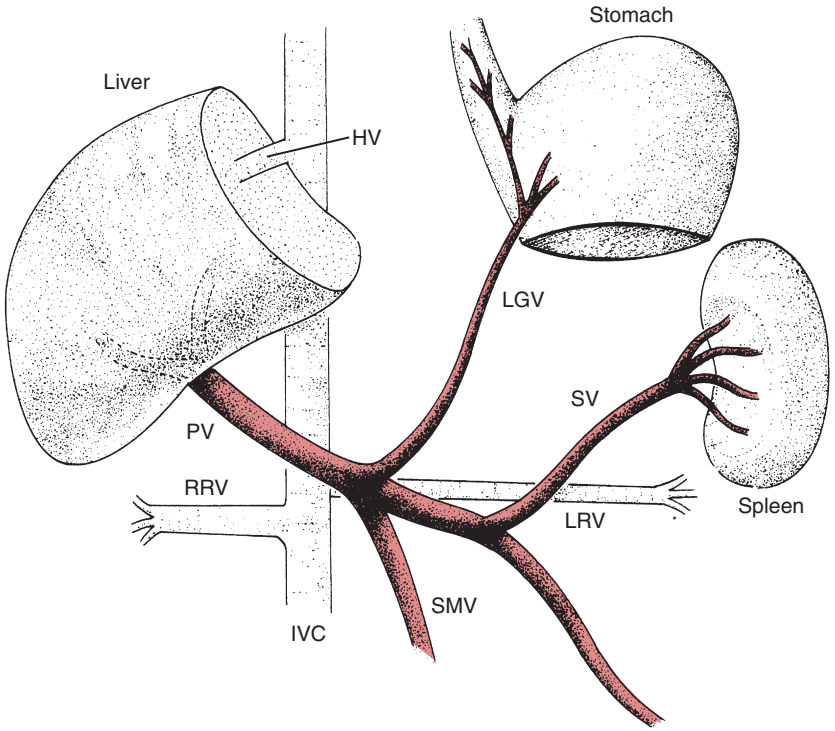

Figure 50-7 The portal-venous system. *HV,* Hepatic vein; *IMV,* inferior mesenteric vein; *IVC,* inferior vena cava; *LGV,* left gastric vein; *LRV,* left renal vein; *PV,* portal vein; *RRV,* right renal vein; *SMV,* superior mesenteric vein; *SV,* splenic vein. *(From Zakim O, Boyer TD. tahir99-VRG & vip.persianss.ir

bone marrow transplantation). Although increased portal resistance is the major factor causing portal hypertension, it is often accompanied by decreased resistance to blood flow through other blood vessels, which enhances blood flow through the portal veins.

When portal pressure increases, the portal venous system becomes dilated and forms collateral connections to the systemic venous flow (Figure 50-8), leading to portosystemic shunting. Initially, this is clinically silent, but as portal hypertension worsens, it compromises many of the metabolic functions of the liver. One such abnormality is altered estrogen metabolism, which increases the ratio of estrogen to testosterone. Clinical consequences include spider telangiectasias and palmar erythema, gynecomastia in men, and abnormal vaginal bleeding and irregular menstrual periods in women. Impaired protein metabolic functions cause the accumulation of ammonia and abnormal neurotransmitters, ultimately leading to hepatic encephalopathy.[60A] Because most nutrients arrive through the portal vein, synthetic functions are also impaired, leading to hypoalbuminemia (contributing to ascites), decreased clotting factors (predisposing to bleeding), and reduced thrombolytic factors, such as antithrombin (predisposing to venous thrombosis).

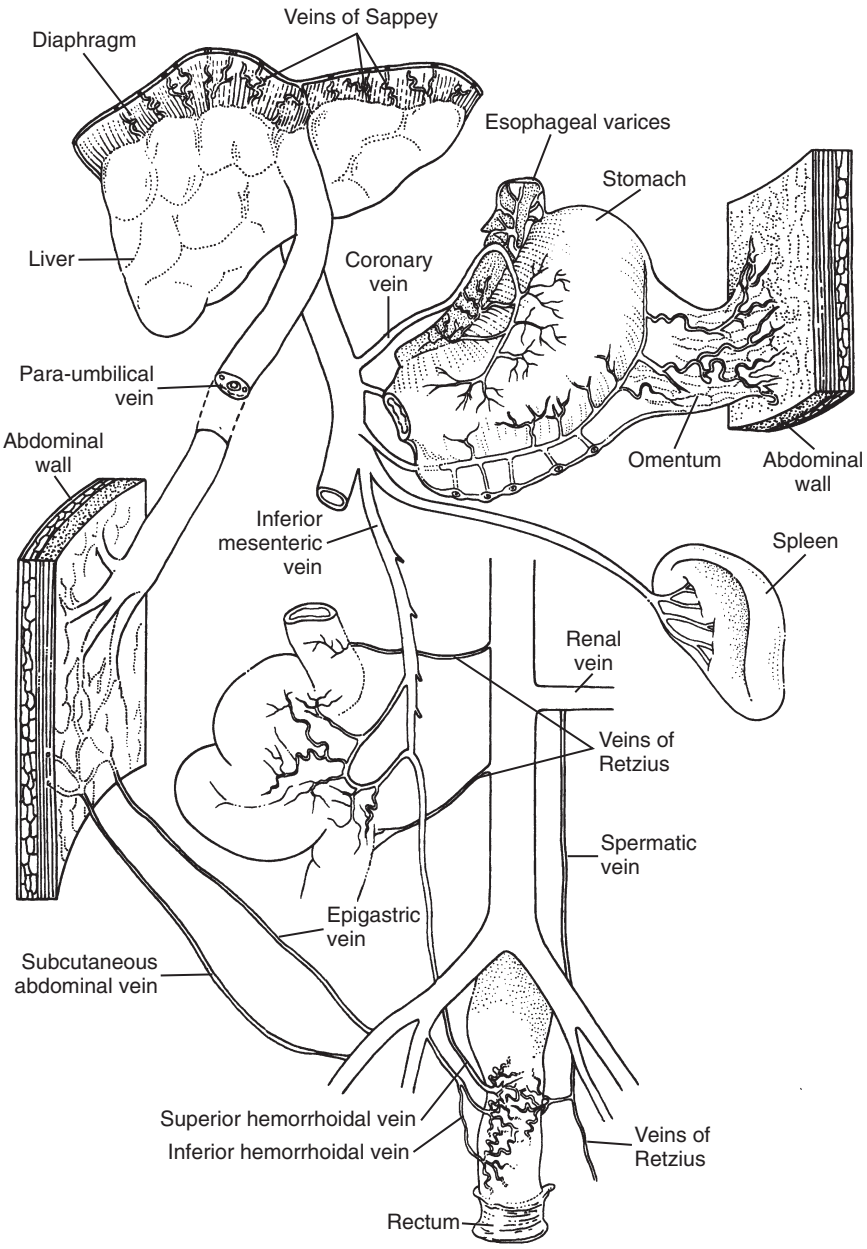

Figure 50-8 Sites of portosystemic collateral circulation in cirrhosis of the liver. *(From Sherlock S, Dooley J, eds. Diseases of the liver and biliary system, 9th edition. London, United Kingdom: Blackwell Scientific Publications, 1993:134.)*

tahir99-VRG & vip.persianss.ir

Bleeding Esophageal Varices

The most life-threatening consequence of portosystemic shunting is the development of varices (enlarged and tortuous veins), which can occur throughout the GI tract but are most common in the esophagus and stomach. Bleeding from varices is one of the leading causes of morbidity and mortality in patients with cirrhosis. Varices are present at the time of diagnosis of cirrhosis in about 40% of patients and occur in an additional 6% per year.[156] In general, the risk of bleeding is low until portal vein pressure exceeds 12 mm Hg. The major consequences of varices are rupture and bleeding, usually presenting as hematemesis. Treatment of portal hypertension and varices is directed at obliterating the dilated blood vessels or reducing portal pressure. Pressure can be reduced by pharmacologic agents, such as nonselective β-adrenergic blockers, but if this is not effective, invasive procedures can be used, most commonly by putting rubber bands around large varices ("banding") or, if not successful, by placing a stent through the jugular and hepatic veins to connect to the portal vein, called transjugular intrahepatic portosystemic shunt (TIPS).[46] Because portal flow is already significantly reduced before shunting, minimal change in liver function is usually seen, but the incidence of hepatic encephalopathy following shunts is markedly increased.

Ascites

Ascites is the effusion and accumulation of fluid in the abdominal cavity. Ascites is the most common clinical finding in patients with portal hypertension. Ascites itself is not life threatening, but it is uncomfortable and may compromise respiration (from upward displacement of the diaphragm and compression of the lungs). It predisposes individuals to spontaneous bacterial peritonitis, which is life threatening.

The pathogenesis of ascites is complex because of a number of simultaneously operating factors. Of these, the most important are (1) increased hydrostatic portal venous pressure, with increased resistance to flow, (2) decreased colloid osmotic (oncotic) pressure due to hypoalbuminemia, and (3) leakage of protein-enriched fluid from the surface of the liver, which increases intraperitoneal colloid pressure. The primary event is probably peripheral vasodilation due to an imbalance of vasoactive factors, including endothelins. The net effect of these forces is shrinkage of the central blood volume, which decreases renal perfusion and leads to sodium retention through activation of the renin-angiotensin system. Sodium retention leads to water retention, but because of increased portal hydrostatic pressure and decreased intravascular colloid pressure, the fluid leaks into the so-called third space, causing ascites and edema.

Ascites has many causes, and it is important to differentiate ascites secondary to portal hypertension from ascites due to other causes. This is done by analyzing ascitic fluid. The feature that best distinguishes portal hypertension is an increase in the serum-ascites albumin gradient (sometimes abbreviated as SAAG). A gradient greater than 1.1 g/dL (11 g/L) is characteristic of ascites caused by portal hypertension,[5] but a high SAAG can also be seen in congestive heart failure or nephrotic syndrome.

Ascites due to portal hypertension is managed by creating a negative sodium balance or by relieving portal hypertension. A negative sodium balance is obtained by reducing sodium intake and enhancing sodium excretion with the use of diuretics. In cirrhosis, activation of the renin-aldosterone axis (caused by a variety of factors) necessitates use of agents that act at the distal nephron as the primary diuretic used, but these can be combined with other diuretics that act more proximally. In patients who require more urgent treatment for relief of symptoms, or who do not respond adequately to diuretics, ascitic fluid may be removed with a catheter placed percutaneously through the abdominal wall. More than 10 L of fluid may be drained to relieve patient discomfort or respiratory compromise. Repeated or large-volume paracentesis also requires plasma volume expansion to prevent renal failure; albumin is effective as an expander.[315]

Spontaneous Bacterial Peritonitis

Ascites predisposes to spontaneous bacterial peritonitis, defined as bacteremia (typically gram negative), in the absence of mechanical disruption of the bowel.[234] The condition usually presents in an individual with known cirrhosis who develops abdominal pain, fever, or leukocytosis. The diagnosis is established by examination of the ascitic fluid; greater than 250 neutrophils per microliter, or more than 500 in the absence of a positive blood culture, is considered diagnostic. In contrast, secondary peritonitis is usually associated with higher neutrophil counts, along with high protein and low glucose in ascitic fluid. Several studies have suggested that dipsticks that detect the presence of leukocyte esterase could be used to identify increased leukocytes and to diagnose spontaneous bacterial peritonitis; however, a recent review found poor sensitivity and frequent false-negative results in asymptomatic patients.[334,387] Unless cell counts are not available (e.g., in an office setting in a remote site), use of dipsticks for leukocyte esterase is not recommended.

Hepatic (Portosystemic) Encephalopathy

Hepatic encephalopathy is a metabolic disorder characterized by a wide spectrum of neuropsychiatric dysfunction.[60A,86] It may occur as an acute syndrome in patients with acute hepatic failure, or as a chronic, relapsing syndrome associated with cirrhosis. As implied by the synonym, chronic hepatic encephalopathy occurs in the setting of portosystemic shunting, usually as a result of cirrhosis.

The clinical syndrome is variable but follows a reasonably predictable course. Disturbed consciousness always occurs. It usually starts as hypersomnia and progresses to sleep reversal, in which the patient tends to sleep through the day and be awake at night. This is followed by decreased spontaneous movement, apathy, and gradually increasing levels of coma. Personality changes may be conspicuous, especially in patients with chronic disease. Irritability and disturbed social behavior may follow. Intellectual deterioration occurs and generally progresses to overt confusion. Neurologic abnormalities

tahir99-VRG & vip.persianss.ir

include slurred speech, a characteristic flapping tremor called *asterixis,* increased muscle tone, and abnormal reflexes. Disturbed gait may ensue. In chronic encephalopathy, these changes typically fluctuate over time and follow a waxing and waning course. Acute encephalopathy progresses rapidly, often within hours, and is characterized by cerebral edema, which may result in brainstem herniation and death.

The pathophysiology of hepatic encephalopathy is not completely understood but includes an increased sensitivity to dietary proteins. Ammonia concentrations are always increased with acute encephalopathy[476] and are usually increased with chronic encephalopathy. A reduction in plasma ammonia is often associated with symptomatic improvement. However, because plasma ammonia concentrations do not correlate with the severity of the encephalopathy, it has been suggested that other factors are involved.[186] It is recognized that a variety of neurotransmitter systems are dysfunctional in hepatic encephalopathy, but the exact cause of the changes is not known. One important contributor is the endogenous benzodiazepine agonist system.

The diagnosis of chronic hepatic encephalopathy is usually made on clinical grounds. Plasma ammonia concentrations are rarely helpful for diagnosis or for monitoring the patient's disorder; normal ammonia concentrations are helpful in excluding hepatic encephalopathy as a cause of cerebral dysfunction when the clinical picture is not clear. As discussed earlier, ammonia is more helpful in acute encephalopathy in proving a hepatic cause, and is of some prognostic importance in acute liver failure.[37] Elevated ammonia concentrations in that situation suggest acute hepatic failure or Reye's syndrome.

Treatment is largely empirical, based on observations that intestinal bacteria and protein loads in the intestinal tract are important in the symptoms of hepatic encephalopathy. Lactulose has long been known to reduce symptoms in chronic hepatic encephalopathy. Antibiotic treatment with a nonabsorbable antibiotic such as rifaxamin reduces the number of bacteria and is especially helpful in patients with GI bleeding. Patients with acute encephalopathy may require measures to reduce intracranial pressure, such as osmotic diuretics.

Hepatorenal Syndrome

Hepatorenal syndrome (HRS) refers to decreased renal function secondary to hepatic disease; portal hypertension is a common factor in all cases of HRS that develop in chronic liver disease, but HRS may also occur in acute liver failure. Although formerly thought to be a rapidly progressing, terminal event in a person with end-stage liver disease, it is now recognized that HRS falls into two major varieties.[322] Type 2 HRS is more common; it represents a slowly progressive or stable decline in renal function that is due to peripheral vasodilation and renal vasoconstriction. Type 1, or classic, HRS represents rapidly declining renal function, which is usually seen in a person with preexisting type 2 HRS. Type 1 HRS usually develops in the setting of an acute decrease in blood pressure, often due to spontaneous bacterial peritonitis or variceal bleeding.

A common feature in both forms of HRS is activation of the renin-angiotensin-aldosterone axis caused by intravascular volume depletion.[26] As with other forms of prerenal azotemia (elevated concentrations of urea, creatinine, and other compounds rich in nitrogen.), HRS in the untreated patient is generally associated with increased antidiuretic hormone and with profound thirst. This leads to the development of (1) hyponatremia, (2) hypokalemia, (3) metabolic alkalosis, (4) low urine sodium, (5) high urine potassium excretion, and (6) high urine osmolality. BUN, creatinine, and creatinine clearance are not reliable indicators of renal function in HRS.[77] Urea is produced by the liver and is often decreased in advanced liver disease; it is also increased after upper GI bleeding—a common cause of worsening renal function in HRS. Creatinine production by muscle is reduced in cirrhosis, causing falsely low serum creatinine and creatinine clearance. Although cystatin-C has better correlation with measured glomerular filtration rate (GFR),[110,462] it has not been widely adopted for monitoring persons with cirrhosis, and one study has suggested that it may be misleading following liver transplantation.[44]

Despite its limitations, the most widely accepted criterion for diagnosis of HRS is an increase in serum creatinine or a reduction in estimated GFR. Because no specific clinical or laboratory features of HRS have been identified, diagnosis depends on (1) the presence of severe liver disease, (2) a rise in creatinine to greater than 1.5 mg/dL (25.6 µmol/L), (3) no evidence of other renal disease by urinalysis and clinical history, and (4) lack of improvement in renal function with treatments that increase intravascular volume (such as stopping diuretics, or administration of fluids and/or albumin).[322] The latter two criteria are important because laboratory findings are similar to those of volume depletion, with low urine output, low urine sodium concentration, and increased urine osmolality.

Treatment of HRS is best accomplished by increasing systemic vascular resistance, as with the vasopressin analog terlipressin, or by reducing portal venous pressure, which is most commonly accomplished with TIPS. Both approaches have shown promise in improving renal function in HRS.[291]

Altered Drug Metabolism

Because of the central role of the liver in drug metabolism and disposition, alterations in drug metabolism may occur in patients with liver disease. In general, this is reflected in delayed metabolism. Only patients with evidence of liver failure, such as encephalopathy, coagulopathy, or ascites, need alterations in dosing. In general, patients with liver disease are not more susceptible to drug-induced hepatotoxicity. However, those with alcoholic liver disease who continue to consume alcohol are susceptible to liver injury from acetaminophen, even at therapeutic doses.[411]

Nutritional and Metabolic Abnormalities

The intake and disposition of nutrients in patients with chronic liver disease are altered, which subjects them to nutritional imbalance. Severe metabolic and nutritional

tahir99-VRG & vip.persianss.ir

derangements have been observed in the cirrhotic patient, including alterations in glucose metabolism caused by insulin resistance, and hypokalemia caused by secondary hyperaldosteronism. In addition, hypoalbuminemia is frequently present because of decreased production and sinusoidal leakage of albumin in patients with portal hypertension. Also, in patients with chronic cholestasis, impaired delivery of bile salts to the duodenum results in malabsorption of lipids and fat-soluble vitamins, leading to deficiencies in vitamins A, D, E, and K (see Chapters 31 and 52). Vitamin A deficiency may cause night blindness, but rarely progresses to serious visual impairment. Vitamin D deficiency causes osteopenia and, in severe cases, osteomalacia. In fact, osteopenic bone disease may be one of the most crippling results of chronic cholestatic liver disease, such as primary biliary cirrhosis.[189] Vitamin E deficiency is of little clinical significance. Vitamin K deficiency leads to hypoprothrombinemia, with easy bruising and bleeding.

Disordered Hemostasis in Liver Disease

As was discussed earlier and in Chapter 59, the liver manufactures most of the soluble clotting factors (the major exceptions being factor VIII and von Willebrand factor), as well as a number of inhibitors of clotting (proteins C and S, antithrombin). The liver also clears activated clotting factors from the circulation. Bile acids are necessary for vitamin K absorption and are needed to produce the active forms of several clotting factors, as well as proteins C and S. Disorders of fibrinogen also occur in liver disease. For example, dysfibrinogenemia may be seen in both acute and chronic liver disease and leads to prolongation of the partial thromboplastin time.[150] Patients with autoimmune hepatitis may have anticardiolipin antibodies and antibodies to platelets. The liver is the major source of thrombopoietin, which is needed to produce platelets. Portal hypertension results in splenomegaly, which often leads to thrombocytopenia. In addition, persons with liver disease often have evidence of platelet-associated antibodies,[218] although their contribution to low platelet counts in liver disease is questionable.[164]

Although these facts suggest that hemostatic problems are common in patients with liver disease, discordance is often noted between degree of abnormality of laboratory tests of coagulation and clinical evidence of bleeding.[260,446,455] Even in patients bleeding from esophageal varices and having prolonged clotting times, administration of blood components (including activated factor VII) was not associated with any clinical difference in degree of bleeding or need for blood transfusions.[455]

Enzymes Released from Diseased Liver Tissue

Because hepatic function is often normal in many patients with liver disease, the plasma activities of several cytosolic, mitochondrial, and membrane-associated enzymes are measured, because they are increased in many forms of liver disease. Because plasma enzyme measurements are discussed in greater detail in Chapter 22, only those factors relevant to an understanding of liver disease will be summarized here.

Reference Limits for Alanine Aminotransferase

One area of significant concern is the reference limits for liver-associated enzymes, particularly for alanine aminotransferase (ALT, EC 2.6.1.2). In most laboratories, reference intervals are based on samples of the "apparently healthy" population. For ALT, that upper reference limit is often around 40 to 45 U/L in males, but many laboratories have upper reference limits of 65 to 70 U/L.[332] These differences are greater than can be explained by analytical differences between methods.[332] Although ALT values are approximately 40% lower in females (a difference found even in children[128]), not all laboratories have different reference limits for the two genders.

Population-based reference intervals may not, however, be adequate for identifying persons with liver disease, or for recognizing persons who may be at risk for metabolic syndrome or cardiovascular disease. Because many chronic liver disorders (e.g., hepatitis C, alcoholic liver disease, nonalcoholic fatty liver disease) are prevalent in the population, such reference intervals may include many persons with liver disease. A widely cited Italian study, which excluded persons with known or likely liver disease, suggested lowering reference limits for ALT to about 30 U/L in males and 19 U/L in females.[370] A similar study in the author's laboratory (data unpublished), excluding persons with positive anti–hepatitis C virus (HCV), hepatitis B surface antigen (HBsAg), or obesity, found upper reference limits of 33 U/L in males and 19 U/L in females. A study among dialysis patients [who had 25% lower aspartate aminotransferase (AST) and ALT compared with healthy controls] in Taiwan found that the optimal cutoff value for detecting viral hepatitis was 17 U/L.[201] In Korea, risk of development of liver steatosis increased with serum ALT activity, even among those within its usual reference limits,[69] as was true with risk of death from cardiovascular disease.[230] A study using the Framingham offspring in the United States found that risk of metabolic syndrome and cardiovascular disease increased significantly, starting at ALT, above the lowest quartile of the normal reference limits.[166] The National Academy of Clinical Biochemistry and American Association for the Study of Liver Diseases guidelines on liver-related tests recommend that health-related reference limits should be developed for alanine aminotransferase.[118] These data provide some preliminary information toward that end.

Factors Affecting Plasma Enzyme Quantities

Because the pattern and degree of elevation of enzyme activity vary with the type of liver disease, their measurement is extremely helpful in the recognition and differential diagnosis of liver damage. Several factors govern the ability of liver enzymes to assist in diagnosis, including their (1) tissue specificity, (2) subcellular distribution, (3) relative activity of enzyme activity in liver and plasma, (4) patterns of release, and (5) clearance from plasma.

tahir99-VRG & vip.persianss.ir

Tissue Specificity

Five enzymes are used in the diagnosis of liver disease: ALT, AST (EC 2.6.1.1), alkaline phosphatase (ALP; 3.1.3.1), and γ-glutamyltransferase (GGT; EC 2.3.2.2) are commonly used to detect liver injury, and lactate dehydrogenase (LD; EC 1.1.1.27) is occasionally used. ALT and GGT are present in several tissues, but increased plasma activities primarily reflect liver injury. AST is found in liver and muscle (cardiac and skeletal), and to a limited extent in red cells. LD has wide tissue distribution and is thus relatively nonspecific. ALP is found in a number of tissues, but in normal individuals primarily reflects bone and liver sources. Thus based on tissue distribution, ALT and GGT would seem to be the most specific markers for liver injury.

Subcellular Distribution

Enzymes are found at different locations within cells. AST, ALT, and LD are cytosolic enzymes. As such, they can be released with cell injury and appear in plasma relatively rapidly. AST and ALT have both mitochondrial and cytosolic isoenzymes in hepatocytes and other cells containing these enzymes. In the case of ALT, the relative amount of mitochondrial isoenzyme is small, and its plasma half-life is extremely short, making it of no diagnostic significance. In the case of AST, the mitochondrial isoenzyme represents a significant fraction of total AST within hepatocytes. In contrast, ALP and GGT are membrane-bound glycoprotein enzymes. The most important location of both enzymes is on the canalicular membrane of hepatocytes.

Relative Activity in Liver and Plasma

For cytoplasmic enzymes, the relative amount of enzyme in the liver relative to plasma is an important determinant of diagnostic sensitivity. The activity of AST within hepatocytes is about twice that of ALT, although plasma activities are similar. In contrast, hepatocyte activities of LD are much lower (relative to plasma) than those of the other two enzymes, and plasma activities of LD are several times higher than those of AST and ALT. This means that a smaller increase in LD is seen with liver injury than occurs with AST and ALT. The relative amount of enzyme in tissue is not necessarily the same in disease; in cirrhosis and malnutrition, and with alcohol abuse, greater decreases are seen in cytoplasmic ALT than in cytoplasmic AST.[272] In addition, other mechanisms may be responsible for this difference in enzyme activity. The development of immunoassays for measuring ALT has led to the observation of discordance between enzymatic activity and mass in several types of liver disease.[227] In chronic hepatitis and in healthy individuals, ALT activity and mass change in parallel. In acute hepatitis, activity is increased to a much greater degree than is mass; the opposite pattern is seen in cirrhosis and hepatocellular carcinoma. Additional studies are necessary to confirm this finding, but these results suggest that as yet, poorly understood factors affect enzyme activity.

Mechanisms of Release

Several mechanisms appear to be involved in release of enzymes from hepatocytes. Cell injury, the simplest mechanism, appears to allow leakage of cytoplasmic enzymes from cells, but minimal release of other types of enzymes. Thus necroinflammatory disease leads to release of AST and ALT, and to a lesser extent LD, but not of mitochondrial isoenzyme of AST nor ALP or GGT. Alcohol appears to induce expression of mitochondrial AST on the surface of hepatocytes.[501]

The mechanism of release of membrane-bound enzymes such as GGT and ALP into the circulation is less well understood. Synthesis of GGT and ALP appears to be increased in diseased human liver.[318] How this enhanced synthesis of tissue-bound enzymes translates into increased activity in plasma is not clear. However, fragments of hepatocyte membrane rich in GGT and ALP activity have been detected in the plasma of patients with cholestasis; this process may be a result of membrane fragmentation by bile acids. Furthermore, bile acids, which are detergents, could solubilize and release GGT and ALP from plasma membranes. In vitro studies of membranes treated with bile acids show that this possibility exists.[398]

Rate of Clearance of Enzyme from Plasma

Clearance of liver enzymes from plasma occurs at variable rates. The half-life of ALT is 47 hours, and of cytosolic AST, 17 hours; thus although more AST is released from the liver, the much longer half-life of ALT leads to higher activities of ALT than AST in most forms of hepatocellular injury. The half-life of the liver isoenzyme of ALP has been variously reported as from 1 to 10 days; the former figure appears to correspond better to changes seen with removal of gallstones. The half-life of GGT has been reported as 4.1 days. The mechanism by which enzymes are removed from the circulation is not completely known, although receptor-mediated endocytosis by liver macrophages is likely involved.

DISEASES OF THE LIVER

The liver has a limited number of ways of responding to injury.[371A] Acute injury to the liver may be asymptomatic, but often presents as jaundice. The major acute liver diseases are (1) acute hepatitis and (2) cholestasis. Chronic liver injury generally takes the clinical form of chronic hepatitis; its long-term complications include cirrhosis and HCC. The discussion of liver disease will focus mainly on these patterns and on a few diseases that differ from this general pattern.

Mechanisms and Patterns of Injury

Cell death occurs by necrosis (death of cell) or apoptosis (programmed cell death) or both. The target cell determines the pattern of injury, with hepatocyte injury leading to hepatocellular disease and biliary cell injury leading to cholestasis. All cellular injury induces fibrosis as an adaptive or healing response, with the duration of injury and genetic factors

tahir99-VRG & vip.persianss.ir

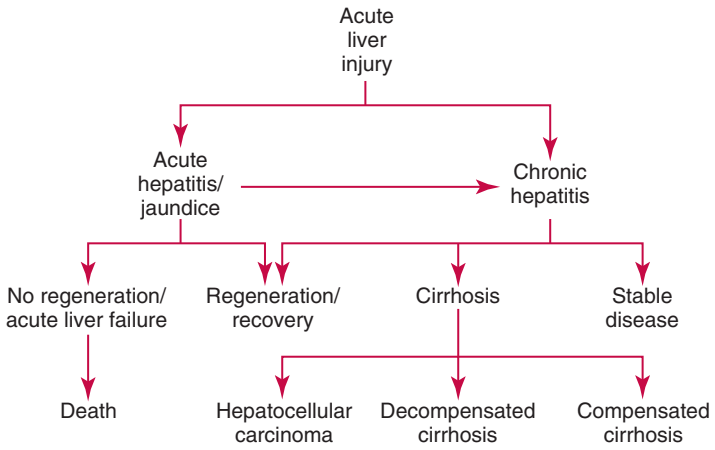

Figure 50-9 Natural history of liver disease. With acute injury to the liver, several outcomes are possible. In many individuals, damage is clinically inapparent and recovery occurs with clearance of the causative agent. In some, clinical acute hepatitis occurs. In the overwhelming majority of these, clearance of the causative agent results in complete recovery; in a very small minority, damage is so severe that acute liver failure (fulminant hepatitis) develops, which is usually fatal without liver transplantation. A variable percentage of persons with acute liver injury (dependent on the cause) progress to chronic hepatitis. In some, recovery eventually occurs naturally or following treatment of the underlying cause. Among those in whom chronic hepatitis persists, many will never progress to cirrhosis. A majority of those who do will remain well for many years, but about 3% per year develop decompensated cirrhosis (bleeding varices, ascites, hepatic encephalopathy) or hepatocellular carcinoma. These are the most common causes of death from liver disease.

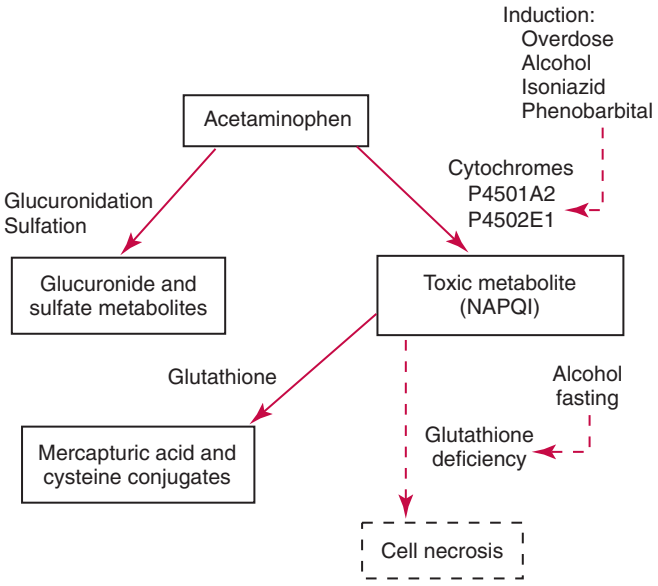

Figure 50-10 Metabolism of acetaminophen by the liver.

determining whether cirrhosis and ultimately carcinoma occur (Figure 50-9).

Cellular necrosis occurs as the result of an injurious environment and has been referred to as "murder." It is characterized by cellular swelling with loss of membrane integrity. Toxic injury from compounds such as carbon tetrachloride, aspirin, and acetaminophen (Figure 50-10) occurs for the most part by necrosis. Apoptosis occurs as the result of accelerated programmed death in which the cell participates in its own demise and thus commits "suicide." It is characterized by cell shrinkage, with nuclear chromatin condensation and fragmentation forming apoptotic bodies. Regardless of the cause, cell death typically leads to leakage of cytoplasmic enzymes. Most forms of hepatitis are associated with apoptosis.

Laboratory tests are helpful in distinguishing (1) the pattern of injury (hepatocellular vs. cholestatic), (2) the chronicity of injury (acute vs. chronic), and (3) the severity of injury (mild vs. severe). In general, the aminotransferase enzymes and ALP are used to distinguish the pattern, the plasma albumin to determine the chronicity, and the PT or factor V concentration to determine the severity. At the present time, the only way to accurately detect fibrosis is by liver biopsy.

Disorders of Bilirubin Metabolism

Defects in bilirubin metabolism resulting in jaundice are known to occur at each step in the metabolic pathway (see Figure 32-22, Chapter 32). Disorders related to these defects are discussed in Chapter 32 (see Box 32-1).

Hepatic Viral Infection

Five viruses have been identified (A, B, C, D, E) as causes of infection that primarily targets the liver. In addition, certain other viruses may infect the liver as part of a more generalized

infection, among them cytomegalovirus (CMV), Epstein-Barr virus (EBV), and herpes simplex virus (HSV). Several other viruses have been proposed as causes of liver injury; these include hepatitis G virus[1](discussed later), transfusion-transmitted virus (TTV),[194] and the closely related SEN-V virus.[486] Although all three are bloodborne chronic viral infections and, in the case of TTV and SEN-V, have been known to replicate in the liver, none of these viruses appear to cause acute or chronic liver injury.[341,461,494] The various hepatitis viruses are outlined in Table 50-2.

Hepatitis A Virus

Hepatitis A virus (HAV) has historically accounted for about one fourth to one third of cases of clinical acute hepatitis in the United States and 20 to 25% worldwide. Since the mid-1980s, a vaccine has been available for HAV, and incidence has declined to its lowest ever in the United States.[21] Current recommendations are that all children should be immunized for HAV, along with adults at high risk for HAV,[18] as well as persons planning international travel and individuals exposed to HAV.[19] Although most commonly an infection of children and adolescents before immunization, the disease has become more common in adults than children, and most common in young adult men, particularly in injection drug users and in males who have sex with other males.[471] It tends to be most virulent in middle-aged and older people. Epidemics have been associated with waterborne and foodborne contamination. Ingestion of raw shellfish from contaminated waters has caused both sporadic and epidemic cases. Although not as common a cause of liver infection as hepatitis B, it is more frequently associated with jaundice when occurring in adults than hepatitis B or C; an estimated 50 to 70% of infected adults develop jaundice, and mortality is almost 2% with infection in those older than 60.[20] In contrast, hepatitis A infection in children is rarely associated with jaundice, and thus is usually not detected clinically. Hepatitis A may cause severe hepatitis and death in those who have chronic hepatitis, particularly hepatitis C.[465]

Hepatitis A is caused by a 27 nm RNA picornavirus. It has four capsid proteins (VP1-4), but only one serotype has been identified. The virus is not cytopathic to hepatoctyes, but causes liver injury by stimulating both cellular and humoral immune responses. Hepatitis A occurs in sporadic and epidemic forms, with an incubation period of 15 to 50 days. The clinical course of acute hepatitis A is usually that of a mild flulike illness that lasts for a few days to a few weeks. There is no chronic form of hepatitis A, but cholestasis (manifested by several weeks of jaundice and pruritus) may occur in some adults. Although a rare occurrence, relapse has been known to happen 1 to 3 months after the acute illness in up to 5% of patients. It resembles the acute illness and is associated with viremia, but recovery always ensues.

Although tests for HAV RNA are available for research purposes, diagnosis of HAV is based primarily on serologic tests for antibody to HAV. Total anti-HAV is believed to be protective and occurs with natural exposure to HAV and to HAV vaccine. With natural exposure, HAV antibodies appear to persist for life.[424] IgM antibodies to HAV are always present

tahir99-VRG & vip.persianss.ir

at the time of diagnosis of acute hepatitis A and generally remain present for 3 to 6 months, although they may persist for longer in about 14% of individuals.[221] With the falling prevalence of HAV, the number of cases of "acute" HAV reported to the Centers for Disease Control and Prevention (CDC) that are due to false-positive results exceeds the frequency of actual cases of HAV.[108] For this reason, IgM anti-HAV should be used only in the clinical setting of acute hepatitis.

Hepatitis B Virus

Hepatitis B virus (HBV) is the most common cause of acute hepatitis, and the most common chronic viral infection worldwide. An estimated 350 million individuals are chronically infected with HBV, and several times as many individuals have been exposed to HBV. The frequency of chronic HBV infection varies worldwide and it is highest in most of central and southeast Asia, central Africa, and southern Europe (prevalence >8% of the population), and intermediate (2 to 8%) in most of the rest of Asia, Africa, and South America. It occurs rarely among those born in North America and Europe[5]; one study found that 86% of U.S. residents with chronic HBV were actually born outside the United States.[228] In endemic areas, the incidence of new infection has decreased markedly in those places where HBV vaccine has been introduced. HBV is transmitted through body fluids, primarily by parenteral or sexual contact; it can be transmitted from mother to child, usually at or after delivery (termed *vertical transmission*). In parts of the world with high rates of chronic infection, much of the transmission is vertical. The residual risk from transfusion is estimated to be 1 in 600,000.[56]

Hepatitis B is caused by a 42 nm DNA virus that is a member of the hepadnavirus family. The DNA is partially double stranded and contains 3200 nucleotides with overlapping coding regions, leading to several major open reading frames. The S gene codes for several different length variants of surface protein; the smallest form, HBsAg, is produced independently of and in excess of the amount needed for viral replication; the largest form (S1) makes up the surface coat of circulating viral particles. The C gene encodes the hepatitis B core antigen (HBcAg), which is part of the infectious core of the virus. The X gene codes for a transactivating factor that may be involved with viral replication and the development of malignancy. The precore and basal core promoter regions code for production of hepatitis B e antigen (HBeAg), a protein found only in those with (but separate from) circulating viral particles. The final major viral protein is a polymerase, which has several different enzymatically active sites. Hepadnaviruses are unusual among DNA viruses in that they produce the first strand of DNA from a form of viral messenger RNA, using the reverse transcriptase activity of HBV polymerase. This error-prone reproductive strategy, along with an extremely high rate of viral replication in chronically infected individuals, leads to a very high rate of mutation in HBV. The significance of several mutants is described later.

Hepatitis B was first described in the 1960s by Blumberg and colleagues following discovery of a protein, termed the *Australia antigen,* which was initially believed to be a tumor marker for leukemia.[38] Subsequent studies confirmed it to be a marker for a form of hepatitis initially termed *serum hepatitis.* Later work established that this was hepatitis B surface antigen (HBsAg). The complete HBV virion (Dane particle) consists of a core containing DNA attached to DNA polymerase and core antigen (HBcAg), surrounded by the S1 form of surface protein. HBsAg and other forms of surface protein contain a common determinant, a, and four subdeterminants designated d, y, w, and r. These determinants are responsible for determining HBV genotypes; the eight major genotypes, termed A through H, have less than 92% homology with other types.[80] Geographic differences in genotype distribution have been noted; genotype A predominates among those infected in North America, whereas genotype C is the dominant form in those infected in Asia. Although not routinely determined at present, evidence indicates that genotype is an important predictor of the natural course of HBV and response to certain forms of treatment.[296] For example, genotypes A1 and F1 are associated with hepatocellular carcinoma in young adults and (in Alaska with genotype F1) children.[263] Genotype C has a higher risk of development of cirrhosis and hepatocellular carcinoma than is the case with most other genotypes. Genotype C has a low likelihood of response to interferon treatment.

Several mutants of HBV may have clinical importance.

HBeAg and HBeAg Mutants

Hepatitis B e antigen (HBeAg) is a protein of uncertain function produced by viral messenger RNA. It is released into the circulation by infected hepatocytes and may be involved as a "decoy," preventing the immune system from attacking HBV viral particles. The most common HBV mutations involve the regions that code for production of HBeAg. The highest frequency is for a mutation at nucleotide 1896 that inserts a stop codon in the mRNA, preventing production of HBeAg. Mutations in the precore promoter region, particularly at nucleotides 1762 and 1764, are associated with reduced production of normal HBeAg. Such mutants are associated with undetectable HBeAg, although they are characterized by production of anti-HBe. Precore and core promoter mutants are found in most individuals chronically infected with HBV in areas with high rates of infection, such as Asia and Southern Europe. In North America, it is estimated that 10 to 20% of individuals with chronic HBV infection have such precore mutants.[202] Such mutants may be present at the time of infection or may develop during the course of disease. Although initially it was thought that individuals infected with such mutants are much more likely to have severe acute infection, the high prevalence of such mutants suggests that this is not the case. Infection with these mutant strains is associated with a higher risk of development of hepatocellular carcinoma, and risk is stronger for the basal core promoter mutations.[449]

Polymerase Mutants

Treatment with antiviral agents that inhibit the reverse transcriptase domain of HBV polymerase is now the most widely used therapy for chronic HBV.[112] As is the case with human immunodeficiency virus (HIV), specific amino acid substitutions have been linked to resistance with several of the commonly used agents, particularly lamivudine and adefovir. The longer these agents are used, the greater is the likelihood that resistant mutants will emerge. Testing to detect resistant mutants is becoming more wide performed, particularly from individuals who have been exposed to more than one reverse transcriptase inhibitor (such as those who also are infected with HIV).

HBsAg Mutants

Mutations in the "a" determinant of HBsAg are the most important HBsAg mutants. Antibody to HBsAg, developed by natural exposure or by the HBV vaccine, is primarily directed against the "a" determinant. Exposure to strains that have mutants in this domain can result in infection despite the presence of protective titers of anti-HBs. In areas where HBV is endemic, up to 25% of cases of HBV in immunized infants are due to infection by such mutants.[31,200] In addition, the reagents used to detect HBsAg are antibodies to anti-HBs; therefore, mutant strains can be missed by HBsAg assays.[85,158] In fact, the ability of reagents to identify these mutant strains differs, mainly because of the specific epitopes recognized by the antibody (or antibodies) used in the assay.[312] Use of assays with antibodies to multiple epitopes improves detection of such mutant strains.[125] At present, the importance of such mutant strains is unknown.[117] Data suggest that most individuals infected with mutant strains have such viral particles at low titerss, usually in the presence of larger amounts of wild-type virus. Thus, most infected persons will be detected by the current assays for HBV. However, some infected individuals (perhaps more commonly those immunized for HBV) will be missed by some current assays.

Immunization

Hepatitis B may be prevented by passive [hepatitis B immune globulin (HBIG)] or active (hepatitis B recombinant vaccine) immunization. In the United States, current data suggest that more than 90% of children have been immunized against HBV infection, leading to a historically low incidence of acute HBV infection. Because infants born to HBsAg mothers have a high risk of developing chronic HBV infection, routine prenatal testing for HBsAg is needed to identify infants at risk. Infection occurs in only about 2% of infants before birth[439]; postexposure prophylaxis (typically used in infants of HBsAg-positive mothers) consisting of passive immunization with 0.06 mL/kg of HBIG and the first dose of hepatitis B vaccine within 24 hours of birth is more than 95% effective in preventing infection.[107] A universal immunization program in Taiwan, where vertical transmission of HBV was endemic, has greatly reduced the death rate from HCC in young individuals.[67]

Diagnostic Tests for Hepatitis B

More diagnostic tests exist to measure Hepatitis B than any of the hepatitis viruses; consequently, interprertation of results is complicated. Testing currently involves primarily enzyme-linked immunosorbent assay (ELISA) or related techniques to measure viral antigens or antibodies, but nucleic acid–based tests are becoming more widely used.

Hepatitis B surface antigen, the most widely used marker for detecting current hepatitis B infection, is detected by kits using antibody to HBsAg. Occasionally, false-positive results occur in testing, particularly during pregnancy; a neutralization assay is available. Low-level reactivity [as evaluated by the ratio of the signal from the sample to that of the cutoff for distinguishing positive and negative, termed the *signal/cutoff (S:C) ratio*] is highly predictive of samples that fail to confirm on neutralization.[346] False-negative results can occur with mutants in the surface antigen (see earlier), and they occur more commonly in early HBV infection. Most assays are qualitative; quantitative HBsAg assays have been available in Europe for over a decade. Some studies have shown a direct relationship (in untreated individuals) between quantitative HBV DNA and viral load[507]; others have not.[238] Declines in quantitative HBsAg during treatment have been found predictive of response to treatment for chronic HBV.[52,320]

Antibody to the hepatitis B core antigen (anti-HBc) is the most commonly detected antibody against HBV. Two assays are usually employed: IgM and total anti-HBc. IgM anti-HBc assays typically employ a large dilution of plasma (1:100) before analysis to reduce the likelihood of positivity in individuals with chronic HBV. The total antibody assay measures both IgM and IgG antibodies. Anti-HBc appears to last longer than anti-HBs in natural infection, and is still present in 97% of previously infected individuals more than 30 years after exposure.[410] Isolated anti-HBc is a relatively common finding, particularly in the setting of hepatitis C virus (HCV) coinfection,[472] but also in immunosuppressed individuals.[450] Although this may represent a false-positive result, particularly as a transient phenomenon following influenza vaccination, current guidelines on hepatitis B recommend consideration of individuals with isolated anti-HBc who have been exposed to HBV.[22]

Antibody to the hepatitis B surface antigen (anti-HBs) is considered evidence of immunity to hepatitis B and is the only marker found in those receiving the hepatitis B vaccine. The World Health Organization has developed a reference material that contains 10 IU/mL of anti-HBs. Current guidelines suggest that immunocompetent individuals who ever achieve an anti-HBs of 10 IU/mL or greater have life-long immunity to hepatitis B.

The hepatitis B e antigen (HBeAg) and antibody to the e antigen (anti-HBe) are typically used only in the setting of chronic HBV infection. Although HBeAg typically appears at about the same time as HBsAg in acute hepatitis, it is rarely used as a marker for acute infection. In chronic infection, HBeAg has historically been used as a marker of persistence of infectious virus; its clearance and the appearance of

anti-HBe have been used as indicators of conversion to the nonreplicating state and as goals of antiviral treatment. With widespread availability of HBV DNA assays with low detection limits, the discordance between HBeAg and the presence of infectious viral particles has become apparent. Although a vast majority of untreated patients with HBV who are HBeAg positive have very high viral loads (usually $>10^6$ IU/mL), detectable HBV DNA is also found (usually with lower viral load) in about 70% of those who are HBeAg negative. When HBeAg-positive individuals are treated with reverse transcriptase inhibitors, loss of HBV DNA occurs in the majority, and HBeAg usually remains detectable. Loss of HBeAg during treatment, with development of anti-HBe, indicates a high likelihood that viral suppression will be maintained after discontinuation of treatment.[112] In contrast, in those who were HBeAg negative (and anti-HBe positive) before treatment, discontinuation of treatment almost always leads to recurrence of viremia. Thus, HBeAg remains an important marker for monitoring therapy, but has largely been replaced by HBV DNA for detection of those who harbor infectious virus.

Hepatitis B viral DNA is now routinely measured using amplification techniques (see Chapter 42). The World Health Organization has established an international reference material for HBV DNA, and results are typically reported in IU/mL[391]; conversion from copies/mL differs on the basis of viral load and is different for various assays. Because much older literature and some currently published papers still report HBV DNA in copies/mL, a rough conversion factor is 5 copies/mL = 1 IU/mL. Currently, assays using amplification, particularly polymerase chain reaction (PCR) methods, have detection limits of 100 IU/mL, although nonamplified assays are still available. It is unclear what amount of HBV DNA represents clinically important viremia; however, data (primarily from Taiwan) have shown that risk of progression to cirrhosis or hepatocellular carcinoma increases at viral loads above 10,000 copies/mL (2000 IU/mL).[70] Current treatment guidelines suggest that this number should be used as one criterion in treatment decision making.[265]

Hepatitis B mutants and genotypes are usually determined by direct sequencing or with the use of line probes.

Hepatitis C Virus

The hepatitis C virus (HCV) is the cause of most cases previously known as non-A, non-B hepatitis. It was recognized in 1989[78] and fully characterized 2 years later.[198] It is the most common cause of chronic hepatitis in North America, Europe, and Japan and is estimated to infect approximately 170 million individuals worldwide. Although HBV infection appears to have been present for a long time, evidence suggests that HCV is a more recently developing viral infection, because rates of HCV-related liver disease have been increasing in many parts of the world. Predictions are that HCV-related end-stage chronic liver disease will increase twofold to threefold over the next 20 to 30 years.[102] HCV infection primarily occurs through plasma; major risk factors are injection drug use and transfusion. For example, before the recognition of and availability of tests for HCV, the frequency of post-transfusion hepatitis (mainly due to HCV) was 3.5%[414]; the risk of HCV transmission by transfusion is currently estimated at 1:2,000,000.[56] Because of its mode of spread, HCV infection is rare in children; the only common causes of pediatric infection are vertical transmission from an infected mother (estimated to occur in about 5% of infected women[381]) and, previously, transfusion of infected blood.

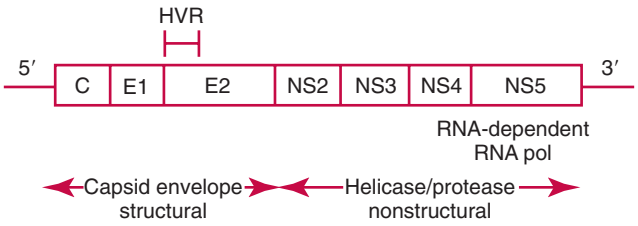

Figure 50-11 Structure of the hepatitis C genome.

HCV is a single-stranded enveloped RNA virus of the flavivirus family, which includes other hepatitis viruses (yellow fever virus) and viruses that cause unrelated disease (such as West Nile virus). HCV RNA contains one reading frame (Figure 50-11). The resulting polypeptide is cleaved to core and envelope antigens and a number of nonstructural (NS) proteins, including a polymerase, a protease, and an interferon-response element. As an RNA virus, HCV is subject to a high rate of spontaneous mutation, giving rise to large numbers of variants. This results in six major genotypes (<70% nucleotide homology), along with a number of subtypes (77 to 80% homology).[53] In a chronically infected individual, numerous quasispecies (>90% homology) develop over time. These quasispecies seem to be important in establishing chronic infection[133] and appear related to the fluctuating nature of chronic inflammation in chronic HCV infection.[134] Quasispecies are unique to the individual infected; those infected from a common source show different patterns of mutation.[258]

Chronic HCV infection is associated with evidence of chronic liver injury in most cases. Elevations in liver-associated enzymes, particularly ALT, are usually mild and fluctuate between normal and abnormal in most infected individuals. In an estimated 15 to 20% of cases, cirrhosis becomes evident an average of 20 to 30 years after exposure. HCC may develop once cirrhosis is present, at an average rate of 1.5 to 3 cases per year. In North America, Europe, and Japan, HCV is the most common risk factor in the development of HCC. Various extrahepatic manifestations of chronic HCV infection may be noted; the most common are cryoglobulinemia and porphyria cutanea tarda. Epidemiologic evidence has linked HCV to increased risk of lymphoma and type 2 diabetes mellitus.

Prevention

Prevention of hepatitis C has proved more difficult than that of HAV and HBV. However, an 80% decrease in the incidence of acute HCV has occurred[6]—similar to what occurred with HAV and HBV; this is thought to be due to testing of blood

donors for HCV and to safe injection practices instituted to reduce the risk of HIV infection. Vaccine development has been difficult because of the many subspecies of virus and the presence of many quasispecies with different antigenic determinants. Significant improvement has been noted in the treatment of HCV infection, however. Treatment of acute hepatitis C with α-interferon monotherapy has been found effective in preventing chronic hepatitis in a large majority of patients in nonrandomized trials. The use of pegylated interferon and ribavirin combination therapy leads to viral eradication in about 75% of those infected with genotypes 2, 3, and 4, and in almost half of those infected with genotype 1.

Diagnostic Tests for Hepatitis C

Measurement of the antibody to HCV (anti-HCV) is the principal screening test for HCV exposure. These tests, using ELISA and related microparticle, chemiluminescence formats, detect the presence of antibodies to one or more HCV antigens (derived by recombinant technology from yeast cultures or through production of synthetic peptides). Although the initial assay detected only antibody to a single antigen, subsequent tests have used antigens from four different regions of the HCV genome. Second-generation assays become positive on average 12 weeks after exposure, and third-generation assays become positive on average 9 weeks after exposure. After comparison with a cutoff value, results are interpreted as positive or negative. As is true for HBsAg, samples with a low S:C ratio are often false positive, whereas false-positive results are rare in samples with a high S:C ratio.[120,121] Current CDC recommendations[22] suggest use of an S:C ratio less than 3.8 for both second- and third-generation ELISA assays, and an S:C ratio less than 8.0 for the chemiluminescence assay, to define low-positive results.[22] Samples with a low S:C ratio are recommended to be confirmed, ideally with the use of recombinant immunoblot assay (RIBA).

RIBA is a technique similar in principle to Western blot. HCV antigens used in anti-HCV assays are typically blotted onto a membrane as dots, and reactivity is detected after incubation with serum. Results are interpreted as negative if there is less than 1+ reactivity with any of the four antigens, indeterminate if there is 1+ or greater reactivity to only a single antigen (or to more than one antigen along with the nonspecific yeast marker superoxide dismutase), and positive with 1+ or greater reactivity to multiple antigens. Third-generation RIBA has considerably fewer indeterminate results than second-generation RIBA.

HCV RNA measurement has become the most widely used test to detect current HCV infection. Typical of RNA in general, HCV RNA is labile in whole blood because of the action of RNAses primarily found in blood cells. Rapid separation of serum from clot is critical for accurate measurement of HCV RNA. If serum is separated from the clot by centrifugation within 1 hour, HCV RNA does not show an appreciable decline until 6 hours after collection. If serum is physically separated from cells within 1 hour, samples are stable at room temperature for 3 days, at refrigerator temperatures for 1 week, and indefinitely if frozen.[103] Samples collected in ethylenediaminetetraacetic acid (EDTA), which inhibits enzyme activity, are stable for 24 hours, even if plasma is not separated from red cells.[174]

Assays for HCV RNA historically were divided into qualitative and quantitative variants. An international reference material for quantification of HCV RNA has been developed,[392] and quantitative HCV RNA assay results are calibrated using this material and are reported in international units per milliliter (IU/mL). The relationship between IU/mL and copies/mL differs significantly for different assays. Results expressed in IU/mL agree within 1 log in about 90% of samples, but discrepant results do occur.[419] Until recently, qualitative assays had significantly lower detection limits than quantitative assays, but quantitative assays using real-time PCR have equivalent or lower detection limits compared with qualitative assays; if assays with detection limits of 10 to 20 IU/mL are used (as is the case in many settings), qualitative assays are no longer needed.[161] One of the currently available real-time PCR assays tends to underreport viral load among 15% of individuals infected with genotype 2[73] and may cause falsely negative results with genotype 4.[74]

Hepatitis C core antigen (HCV Ag) is produced by the most constant part of the HCV genome. HCV Ag is one of the major targets of antibody formation, and most HCV Ag circulates bound to antibody. HCV Ag has a similar time course to that of HCV RNA in both acute and chronic HCV infection[438]; the currently available assay for HCV Ag becomes reliably positive when HCV RNA is 20,000 IU/mL or greater.[45] In our experience with several thousand HCV RNA samples, less than 5% of untreated HCV RNA–positive individuals had a viral load lower than 20,000 IU/mL. In contrast to HCV RNA, HCV Ag is stable on storage. Currently, no commercial HCV core antigen assays are available in North America.

Hepatitis C genotype is an important parameter in determining the length and intensity of antiviral therapy. Several methods are currently used to determine the infecting genotype. Although serologic assays to detect antibody to specific genotypes of HCV are available, their correlation with direct tests is approximately 90%,[361] and a significant minority of infected individuals have antibodies to more than one genotype.[451] However, detection of viral RNA of more than one genotype is exceptionally rare. The most reliable method involves direct sequencing of regions of the genome that show characteristic patterns with specific genotypes and subtypes. Commercial assays using the 5′-untranslated region are most widely used,[384] although assays using the NS5b region are now available. All currently available assays show good agreement on genotype, although they differ in their detection limits.[403] Line probe assays are also widely used and show good agreement with direct sequencing assays.[309]

Hepatitis D Virus (Delta Agent)

Hepatitis D virus (HDV) is an incomplete, 36 nm RNA particle that cannot replicate on its own.[425] It is coated with HBsAg and is dependent on HBV for its activation. It is thus a satellite virus similar to that seen in plants. The D virus is a single-stranded antisense RNA virus. It is very infectious

and strongly associated with intravenous drug abuse; approximately 10 million persons have been infected worldwide, although the incidence is declining with the fall in incidence of HBV infection.[379] It occurs as simultaneous infection with hepatitis B (coinfection) or as superimposed infection in someone with chronic hepatitis B (superinfection). Coinfection usually runs the same time course as acute hepatitis B, and HDV is spontaneously cleared as the hepatitis B resolves, but the risk of fulminant hepatitis is higher than in HBV infection alone, and mortality is higher. Superinfection typically results in chronic HDV infection, suppression of HBV DNA replication, and more rapid progression to cirrhosis (estimated 4% per year) and hepatocellular carcinoma (estimated 3% per year).[383] It should be suspected in a chronically infected HBV patient whose condition worsens.[488] Although it is traditionally diagnosed serologically by detection of anti-HDV (total or IgM) and/or HDV Ag,[329] HDV RNA measurements are often used as evidence of current infection.[311]

Hepatitis E Virus

Hepatitis E virus (HEV) is a 34 nm, single-stranded, unenveloped RNA virus. It accounts for sporadic and epidemic hepatitis in tropical and semitropical countries and in people returning from these areas.[487] Although considered to be rare in Europe and nontropical areas of North America, HEV RNA is frequently isolated from city sewage treatment plants in such nonendemic areas.[82] A number of small outbreaks have occurred in Europe over the past several years[95]; in one institution in England, HEV was responsible for about 10% of otherwise undiagnosed cases of acute hepatitis.[96] It is enterically transmitted, as is HAV, and viral RNA has been detected in plasma and in stool.[459] There is probably only one species, although four genotypes are known. Tests to detect antibody to HEV have been developed; specificity for HEV is high only for assays detecting antibody to the open reading frame 2 (ORF2) antigen.[285] The prevalence of antibodies to HEV is high in the United States, with 21% of randomly selected individuals having anti-HEV during the period from 1988 to 1994.[240] HEV has been isolated from a number of animals, notably rats[217] and pigs[302]; the significance of this is unclear, although it has been speculated that HEV is a zoonotic disease.[301] In fact, in several countries, HEV has been linked to ingestion of pork,[95] and in the United States, to ingestion of liver (from unclassified species).[240]

As with HAV, IgM anti-HEV, detection of antibodies have been considered diagnostic of acute infection by HEV, but false-positive results have been reported with hepatitis due to cytomegalovirus and Epstein-Barr virus.[143] The clinical course is similar to that of HAV infection in that HEV typically infects young people, has a self-limited course, and was not associated with chronicity. Recently, however, chronic infection with HEV has been documented in organ transplant recipients.[179,219] A peculiar feature of this disease is its virulent course in late pregnancy in India, with mortality generally in the range of 20 to 25%, but rates as high as 50% have been reported[226]; it is interesting to note that mortality during pregnancy is not increased in other parts of the world.[328] Mortality is increased among the elderly and in those with chronic liver disease.[96]

Hepatitis G Virus

Hepatitis G virus (HGV), also known as GBV-C, is an RNA virus of the flavivirus family, closely related to HCV.[7] It is most commonly transmitted by plasma[213]; vertical transmission has been reported.[310] Although it has a very high infectivity rate in recipients of contaminated blood (>90%), HGV infection appears to have no adverse consequences.[473] In fact, although it has been called a hepatitis virus, viral RNA cannot be isolated from the liver in chronic infection.[246] Coinfection with HCV and HGV is common, but coinfection has no effect on prognosis in HCV.[351,491] HGV and HIV coinfection is common; individuals coinfected with HGV and HIV have lower HIV viral loads and a better prognosis than those infected with HIV alone.[251,448,452] The pathogenesis of this presumed viral interaction is still unknown,[27] although stimulation of innate immunity may be involved.[242]

Acute Hepatitis

Acute hepatitis refers to an acute injury directed against the hepatocytes. The injury may be mediated directly, as occurs with certain drugs, such as acetaminophen or with ischemia, or indirectly, as occurs with immunologically mediated injury from most of the hepatitis viruses and most drugs, including ethanol. In direct injury, a typical rapid rise in cytosolic enzymes, such as AST, ALT, and LD, is followed by a rapid fall, with rates of decline similar to known half-lives of the enzymes. With immunologic injury, a gradual rise in cytosolic enzymes occurs, followed by a plateau phase and gradual resolution of enzyme elevation. Although jaundice is a key clinical finding in acute hepatitis, it is often absent (as discussed later under the various forms of viral infection). An increase in AST activity to greater than 200 U/L, or in ALT activity to greater than 300 U/L, has sensitivity and specificity greater than 90% for acute hepatitis.[386]

ALP usually is mildly elevated and is less than three times the upper reference limit in 90% of cases of acute hepatitis.[386] Bilirubin elevation, when present, typically is predominant in direct reacting bilirubin; indirect bilirubin is higher than direct bilirubin in about 15% of cases.[42] The distribution of direct bilirubin percentage is identical in acute hepatitis and bile duct obstruction, making the relative amount of direct bilirubin inconsequential in the differential between hepatitis and obstruction.[42] Liver synthetic function usually is well preserved in most forms of acute hepatitis. These and other features that are helpful in the differential diagnosis of acute hepatitis are summarized in Table 50-3.

The outcome of acute hepatitis is variable. In most cases, complete recovery occurs and liver regeneration leads to normal structure and function. With some viruses, failure to clear infection leads to development of chronic hepatitis. In a small percentage of cases, massive destruction of the liver leads to acute (fulminant) hepatic failure, which is associated with high mortality unless liver transplantation is performed.[2A,25A]

TABLE 50-3 Laboratory Features of Different Forms of Acute Hepatitis

Type	AST/ALT	ALP	Bilirubin	PT	Serology	Other
Viral	8-50× URL	<3× URL	5-15 mg/dL	<15 s	Positive	
HAV					IgM anti-HAV	
HBV					HBsAg, IgM anti-HBc	
HCV					HCV RNA ±anti-HCV	
Alcoholic	<8× URL	>3× URL in 25%	5-15 mg/dL	<15 s	Negative	AST > ALT
Toxic	>50× URL	Normal	<5 mg/dL	>15 s	Negative	Toxin usually detectable; acute renal failure common
Ischemic	>50× URL	Normal	<5 mg/dL	>15 s	Negative	Acute renal failure common
Drug induced	8-50× URL	>3× URL in 50%	5-15 mg/dL	<15 s	Negative	Eosinophilia, skin rash common
Autoimmune	8-50× URL	<3× URL	5-15 mg/dL	<15 s	Positive ANA or ASMA	Low albumin, high globulins
Wilson's	8-50× URL	Low normal or decreased	5-15 mg/dL	<15 s	Negative	Hemolytic anemia, renal failure, low ALP common; low ceruloplasmin often absent

Acute Viral Hepatitis

All forms of acute viral hepatitis have similar pathology and a similar clinical course. They are all diagnosed on the basis of marked elevations in aminotransferases, usually between 8 and 50 times the upper reference limits, with only slight elevations in ALP and little or no effect on hepatic synthetic function. ALT is typically higher than AST because of slower clearance. Enzyme elevations typically peak before peak bilirubin occurs, and remain increased for an average of 4 to 5 weeks (longer for ALT than AST because of its longer half-life). Bilirubin elevation is variable, as is discussed later. The incidence of acute viral hepatitis due to HAV, HBV, and HCV had reached historically low levels by 2007, the last year for which complete statistics were available at the time of preparation of this chapter.[21]

Acute Hepatitis A

In adults, about 70% of those with acute HAV infection develop jaundice, much more commonly than with HBV or HCV. In children, acute HAV infection typically goes unrecognized and is often considered to be a viral gastroenteritis or other viral disease, because only 10% of children become jaundiced. The disease is more prolonged and serious in individuals over age 60,[4] and can cause liver failure in persons with chronic HCV[465] or cirrhosis,[376] with high mortality. The specific etiologic diagnosis is made with serologic tests. An IgM antibody (anti-HAV IgM) appears early in the course of illness and persists for an average of 2 to 6 months; rarely, IgM antibodies may remain positive for a year or longer. The presence of IgM anti-HAV has therefore been considered diagnostic of recent HAV infection. No antigen tests are available for detection of hepatitis A in plasma. Incubation of stool samples with labeled antibodies to hepatitis A and examination with an electron microscope have been used in the past to detect infectious viral particles. Amplification techniques [usually with reverse transcriptase PCR (rt-PCR)] have been used to detect virus in epidemiologic studies, but are not routinely used to diagnose infection.

Acute Hepatitis B

In most of the world, HBV is the most common cause of acute viral hepatitis. As with HAV, most infections in children are clinically silent. An estimated one third of adolescents and adults with acute HBV infection develop jaundice. The outcome in acute HBV infection is strongly influenced by age and immune status. In healthy adolescents and adults, an estimated 1 to 3% of cases will progress to chronic infection. In a person with immunosuppression, the likelihood of chronic infection increases to 10%. Neonates infected with HBV have a 90% likelihood of chronic infection, and the risk falls gradually over the first 5 years of life.[255]

The serologic course of acute hepatitis B infection is illustrated in Figure 50-12. HBsAg is the first serologic marker to appear, although HBV DNA may be detectable slightly earlier. HBsAg usually appears 1 to 2 months after infection and before the onset of clinical illness, and is the last protein marker to disappear. HBV DNA replication is slower than that of HCV; doubling time averages 2 to 3 days.[477] Persistence of HBsAg for longer than 6 months beyond the onset of acute hepatitis indicates chronic infection. HBeAg appears at about the same time as HBsAg; however, because it is not usually measured except in the setting of chronic HBV infection, it

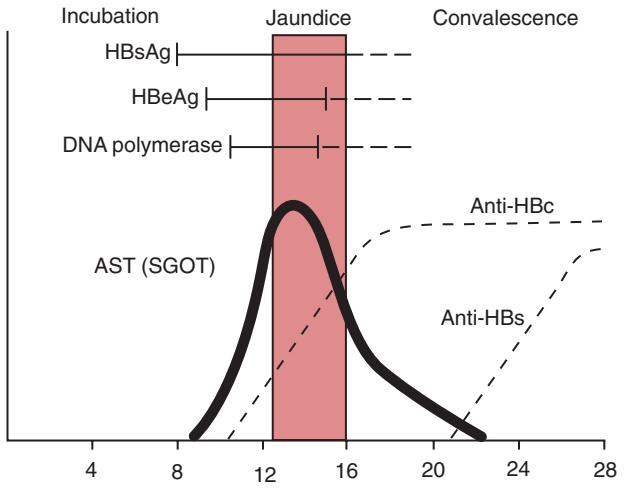

Figure 50-12 Course of acute type B hepatitis with recovery. *1,* Onset of hepatitis with jaundice 3 months after exposure; *2,* detection of hepatitis B surface antigen (HBsAg) 2 to 8 weeks after exposure, followed by appearance of its antibody (anti-HBs) 2 to 4 weeks after HBsAg is no longer detectable; *3,* detection of hepatitis Be antigen (HBeAg) shortly after HBsAg disappears [this is usually followed by the appearance of antibody to HbeAg (anti-HBe), which persists]; *4,* detection of hepatitis B core antibody (anti-HBc) at the time of onset of disease 2 to 3 months after exposure. Anti-HBc immunoglobulin (Ig)M will be detectable in high levels for ≈5 months. *(From Balistreri WF. Viral hepatitis: unique aspects of infection during childhood. Consultant 1984;24:131-53.)*

usually is not helpful as a marker to document acute infection. The first antibody to appear, usually coinciding with the onset of clinical evidence of hepatitis 3 to 6 months after infection, is antibody to the hepatitis B core antigen (anti-HBc). As with hepatitis A, an IgM antibody is the first to appear and usually persists for 3 to 6 months; it is usually considered diagnostic of acute hepatitis B infection. In chronic infection, however, IgM antibody may become detectable with flares of severity of disease and thus is not completely reliable in recognizing a recent infection.[94] The typical pattern at clinical presentation is positive serology for anti-HBc (both total and IgM), HBsAg, HBeAg (when measured), and negative anti-HBs. A small percentage of individuals have negative HBsAg and anti-HBs at the time of initial presentation, leaving IgM anti-HBc as the only commonly measured marker to be positive; this finding has been termed the *core window.* With current, sensitive assays for HBsAg, it is rare to encounter individuals in the core window. Clearance of HBeAg with development of anti-HBe is the first sign of viral clearance and usually predates loss of HBsAg. Clinically, HBsAg clearance from serum is associated with recovery from acute hepatitis and has been thought to confer life-long immunity to HBV.

Accumulating evidence indicates that HBV remains dormant in the body and HBV DNA circulates in many to most individuals who have "recovered" from acute hepatitis. This has been termed *occult* HBV infection.[48] Several studies have demonstrated that HBV DNA is still present in low amounts, in both plasma and liver, in most individuals who had past acute HBV infection and who were HBsAg negative and anti-HBc positive.[450,472,496] Viral loads typically consist of 100 copies/mL or fewer, and it has been estimated that the number of liver cells infected may be as low as 1%. Such individuals have been shown to transmit HBV infection if their organs are used for transplantation (if treatment to prevent this is not given). The significance of circulating HBV DNA for the individual infected or for others (in the absence of transplantation) seems to be minimal, however, in that liver enzymes are usually normal and circulating HBV DNA is found mainly in immune complexes.

In recent years, the problem of reactivation of HBV has been increasingly recognized. *Reactivation* refers to return of viral replication, often accompanied by acute liver injury (and, in a high percentage of cases, liver failure), in a person with occult HBV (sometimes also called *seroreversion*) or, more frequently, in a person with HBsAg but inactive viral replication. Typically, agents that suppress the immune system (chemotherapeutic agents, glucocorticosteroids, antilymphoid treatments) allow return of viral replication that had been kept in check by the immune system.[241,267,492] Withdrawal of immune suppression (including immune restoration in persons with HIV[385]) leads to liver injury. Treatment with lamivudine (or other agents that suppress HBV replication) before immune suppression is highly effective in preventing such reactivation, and guidelines have recommended testing all patients who will be receiving immune suppression for HBV before such agents are used.[20,430]

Acute Hepatitis C

Acute HCV infection is responsible for 10 to 15% of cases of acute hepatitis in the United States; an estimated 10 to 30% of those with acute infection develop jaundice. Increased aminotransferases usually develop about 6 to 8 weeks after infection. In those cases in which clinical acute hepatitis develops, jaundice typically begins about 2 to 3 months after exposure. HCV RNA and HCV core antigen are detectable in plasma 2 to 4 weeks after initial exposure. Viremia increases rapidly (average doubling time, 17 hours) and plateaus at high viral loads (often $>10^7$ IU/mL). In acute hepatitis C infection, anti-HCV is present in a little more than half of cases at the time of presentation.[29,176] IgM anti-HCV assays are not commercially available, but in contrast to HAV and HBV, IgM antibodies are encountered in both acute and chronic HCV infection, making the test useless diagnostically.[338] HCV RNA and HCV core antigen usually are both present at the time of diagnosis, and viral load is often significantly elevated compared with values seen in chronic hepatitis. Diagnosis of acute HCV is likely if anti-HCV is absent but HCV RNA is positive. Diagnosis of acute HCV is also likely if HCV RNA viral load is high and anti-HCV titer is low or increases with time.[338,352] Viral load falls with development of antibody to one or more HCV proteins, and may become transiently negative. HCV antibodies never appear, or disappear, in 30 to

50% of those who recover from acute HCV.[412,481] The importance of recognizing acute hepatitis C is that, if virus does not clear spontaneously, treatment is highly effective when given in the first 6 months after diagnosis.[9]

Other Types of Acute Viral Hepatitis

Numerous other viruses can affect the liver, causing acute hepatitis. The most common are the Epstein-Barr virus and cytomegalovirus. Features are otherwise typical of viral hepatitis, although signs of systemic infection are often seen as well. Herpes simplex virus occasionally may cause severe hepatitis in adults.[223] Infection with each of these agents is more commonly associated with hepatitis in the neonatal period, during which it is part of disseminated infection. Diagnosis of infection with these viruses involves serologic and nucleic acid tests; none are specific to the liver.

Sudden flares of activity in individuals with chronic hepatitis B may mimic acute hepatitis. An acute rise in cytoplasmic enzymes commonly occurs, often in association with jaundice and other clinical features, suggesting an acute liver disease. For example, development of an immune response that leads to clearance of HBeAg or HBsAg is often associated with clinical and enzymatic features of acute hepatitis.[296] Recognition of this cause of the clinical picture of acute hepatitis in a person with chronic hepatitis relies on demonstration of antigen loss and antibody development, along with absence of other causes of acute hepatitis.

Toxic Hepatitis

Toxic hepatitis refers to direct damage of hepatocytes by a toxin or toxic metabolite. Toxic reactions are usually predictable and are directly related to the dose of the agent ingested. In North America and Europe, the most common cause of toxic hepatitis (and the most common cause of acute liver failure) is acetaminophen, a widely used nonprescription pain reliever.[249] The metabolism of acetaminophen is affected by dose, induction of metabolic enzymes, and concentrations of glutathione (see Figure 50-10). When a large dose of acetaminophen is ingested (average lethal dose as a single ingestion = 15 g), the metabolic pathways are overwhelmed, glutathione is depleted, and toxic intermediates accumulate, causing liver damage. When metabolic enzymes are induced (such as by ethanol) or glutathione is depleted (as occurs in alcoholism and with starvation), toxicity can occur with relatively small doses of acetaminophen (total doses of 2 to 4 g).[411] Toxicity can also occur with excessive cumulative doses of acetaminophen; such accidental overdoses appear to be responsible for about half of cases of toxicity.[244] Diagnosis is often based on history and increased acetaminophen concentrations; in patients who present later, and for whom history cannot be obtained, measurement of acetaminophen-protein adducts allows diagnosis.[101] The first laboratory abnormality to appear is an increase in PT, followed by increased activity of cytosolic enzymes. Initially, LD is often increased to higher absolute amounts than AST, and AST tends to be higher than ALT.[61] Peak activities (typically more than 100 times the upper reference limits) usually occur by 24 to 48 hours, followed by rapid clearance at rates approximating the known half-lives of the enzymes.[423] PT elevations are typical and are greater than 4 seconds above the control value in most cases.[347] Prognosis is related most closely to the prolonged increase in PT; persistent elevation of PT 4 days after ingestion is associated with a poor prognosis.[184] Other markers of risk include development of acute renal failure and the presence of lactic acidosis, particularly if pH is less than 7.30.

Ischemic Hepatitis ("Shock Liver")

Hepatic hypoperfusion (ischemic hepatitis) is one of the most common causes of elevated cytosolic enzymes; in hospital patients, it is the cause of most cases of acute hepatitis.[193,478] Ischemic hepatitis may follow any cause of shock; the most common causes are septic and cardiogenic shock (sometimes termed *cardiac hepatopathy*[323]). Not all patients with shock develop ischemic hepatitis; in one recent study, only 13.8% of those with septic shock did, but mortality was significantly higher in such patients.[377] Another study found that cardiac dysfunction, especially right heart failure, appeared necessary to cause the clinical picture of ischemic hepatitis.[415] Bilirubin elevations typically are minimal, and they usually peak several days after enzyme activity reaches its greatest point.[122] Laboratory findings are similar to those seen in toxic hepatitis (including high LD), and acute renal failure is a common complicating factor. Prognosis is primarily related to the underlying cause of hypotension[122]; individuals with prolonged elevation of bilirubin appear to have a poor prognosis.[28]

Reye's Syndrome

Acute encephalopathy in combination with fatty degeneration of the viscera was initially described by Reye and associates in Australia in 1963,[378] with nearly simultaneous case descriptions by Johnson and colleagues in the United States.[214] In most of these early cases, the disease was fatal. It most frequently strikes children aged 6 to 11 years and infants, although it may affect other ages. The syndrome is characterized by a prodromal, febrile viral illness (usually influenza B or varicella), followed in about a week by protracted vomiting associated with lethargy and confusion, which may deteriorate rapidly into stupor and coma.[256] At the same time, the liver enlarges, increased aminotransferases and PT develop, and ammonia increases. A prolonged PT greater than 3 seconds above normal and a plasma ammonia concentration greater than 100 µmol/L usually indicate a poor prognosis. Bilirubin typically is normal or only mildly increased. Other laboratory features include hypoglycemia and hyperuricemia.

Only sporadic case descriptions of Reye's syndrome were published until 1974, when 379 cases in the United States were reported to the CDC. The mortality rate in this series was 41%. The number of cases peaked in 1980 at 555.[32] At about the same time, articles began to appear linking Reye's syndrome with aspirin treatment of viral illness[420]; these were followed by a case control study that strongly implicated

salicylate in the pathogenesis of Reye's syndrome.[182] Although CDC guidelines recommending avoidance of aspirin in children with febrile illness were not published until 1985,[203] a decline in salicylate use began before this time, and Reye's syndrome has again become a rare disease. A 2008 review suggested that children who present with a clinical picture similar to Reye's syndrome are actually much more likely to have inborn metabolic errors, particularly those involving the urea cycle or mitochondrial enzymes, and should be evaluated for those before a diagnosis of Reye's syndrome is considered.[171]

Other Causes of Acute Hepatitis

Alcoholic hepatitis is discussed more fully in the alcoholic liver disease section later in the chapter. Alcoholic hepatitis is often suspected by the combination of mild elevations in enzymes (peak AST typically <300 U/L), AST-to-ALT ratio greater than 2:1, and leukocytosis.[270] Drugs can cause liver injury through a number of mechanisms, but the most common is idiosyncratic, immune-mediated injury to hepatocytes. The most common pattern is similar to that of other types of acute hepatitis; cholestatic hepatitis, with increased aminotransferases and ALP, is more common in drug-induced hepatitis than with other causes of acute hepatitis, but is present only in a minority of cases (40% in a 2008 U.S. study).[65] Criteria used to recognize drug-induced liver injury include a temporal relationship between drug exposure and onset of hepatitis; exclusion of other known causes of hepatitis; the presence of extrahepatic hypersensitivity (especially skin rash, arthralgia, renal injury, and eosinophilia); the development of liver injury on rechallenge; and, ideally, previously published reports of similar reactions.[282] Several standardized approaches to evaluation of possible drug-induced liver disease have been developed.[23,97,147] Hepatic drug reactions represent about 6% of all adverse drug reactions[115] and about 1% of cases of acute hepatitis.[237] Although usually associated with prescription drugs, complementary and alternative products are becoming increasingly recognized as causes of acute hepatitis[99,408] and in a U.S. study were responsible for 9% of all cases.[65] Although drug reactions typically develop soon after that start of treatment, several months may elapse between the time of initial exposure and development of acute hepatitis. Approximately 60% of cases cause severe acute hepatitis with jaundice; fatalities can occur,[145] although often death is not due to liver disease.[65] Serious reactions are more common in individuals who are continued on the medication.[359] In 15 to 30% of cases, liver injury persists and becomes chronic following cessation of the drug.[20,65]

Some of the disorders that usually produce chronic hepatitis (and are discussed more fully later) may occasionally present in an acute fashion. Autoimmune hepatitis has an acute component in up to 40% of cases. Clinically, it differs from other forms of acute hepatitis in having decreased albumin, increased globulins, and a more protracted increase in aminotransferases.[88,185,365] Acute autoimmune hepatitis is diagnosed by the absence of other causes of acute hepatitis and the presence of autoimmune markers (discussed in detail in the section on chronic hepatitis). Wilson's disease is the result of deficiency of an intracellular ATPase[54,362A,440] and typically presents with neuropsychiatric findings, often associated with chronic liver injury. Wilson's disease may also present as acute hepatitis, often associated with fulminant hepatic failure[35]; in one study, 8 of 14 patients who had hepatic injury due to Wilson's disease had an acute presentation.[172] The classic biochemical findings of Wilson's disease are often absent (low ceruloplasmin, low plasma copper, and Kayser-Fleischer rings) or misleading (high urine copper is common to all forms of acute hepatitis) in the setting of acute Wilson's disease.[35,433] Additional features often suggest the diagnosis, including nonimmune hemolytic anemia, acute tubular necrosis, and a low ratio of ALP (in U/L) to bilirubin (in mg/dL); one recent study found that if this ratio was less than 4, sensitivity was 94% and specificity was 96%—far superior to tests such as ceruloplasmin and plasma copper.[233]

Other Disorders With Laboratory Findings Similar to Acute Hepatitis

Several conditions mimic the laboratory picture of acute hepatitis. Hemolytic anemia can cause jaundice, increased LD, and slight increases in AST and ALT. In contrast to hepatitis, the increase in bilirubin is predominantly (often >80%) indirect reacting. LD activity is elevated to several times that of AST, and AST activity usually is several times that of ALT. Acute injury to skeletal or cardiac muscle may cause significant increases in AST and, to a lesser extent, ALT, but the ratio of AST to ALT activity is generally more than 3:1 at presentation (although, as with liver injury, the shorter half-life of AST will cause the ratio to become less than 1 with time, usually after 3 days)[327]; bilirubin usually is not elevated, but mild increases in unconjugated bilirubin from metabolism of myoglobin may be seen in severe skeletal muscle injury. Acute bile duct obstruction, particularly when caused by gallstones, can cause a picture that resembles acute hepatitis. In the early stages of obstruction, transient increases in AST and ALT are common,[431] and rarely their activities may exceed 2000 U/L.[15,149] Increases in ALP develop more slowly than those of the aminotransferases, masking the presence of cholestasis early in the course. Increases in bilirubin are typically predominantly direct reacting, creating a presentation similar to that seen in acute hepatitis. Even if obstruction persists, aminotransferase activity falls rapidly, with AST typically returning to normal within 8 days[360] and ALP activity gradually increasing. ALP activities greater than 300 U/L in this setting strongly suggest the presence of obstructive jaundice.[469] Acute biliary obstruction by gallstones is often accompanied by acute pancreatitis; increased amylase and lipase should suggest biliary tract obstruction as the cause of any liver abnormalities noted.

Approach to the Patient With Acute Hepatitis

Once a diagnosis of acute hepatitis has been established, additional laboratory testing is usually required to determine the cause. Although the incidence of acute viral hepatitis has decreased, serologic studies should be performed to rule out

infectious causes. A typical panel of tests would include IgM anti-HAV, HBsAg, IgM anti-HBc, anti-HCV, and HCV RNA (or HCV core antigen, if available). Marked elevations (>100 times the upper reference limits) in AST or ALT, particularly if AST is higher than ALT, should suggest the possibility of toxic or ischemic liver injury. Minimal increases (<8 times the reference limit) in AST, with AST greater than ALT, in a patient with jaundice and leukocytosis indicate likely alcoholic hepatitis. Imaging studies of the biliary tract are appropriate to rule out obstruction in those who present with sudden onset of symptoms, especially if accompanied by right upper quadrant pain and tenderness, laboratory evidence of pancreatitis, or a history of gallstones. The presence of increased globulins and decreased albumin, or the presence of hemolytic anemia and acute renal failure, should suggest the possibility of autoimmune hepatitis or Wilson's disease, respectively.

Follow-up of Acute Hepatitis

Important uses of laboratory tests in acute hepatitis are to (1) identify individuals with fulminant hepatic failure, (2) document recovery, and (3) determine clearance of any infectious agents. The most important tests in determining extent of injury are not plasma activities of cytosolic enzymes, but evidence of impaired liver function. The most important indicator of prognosis in acute viral hepatitis is impairment in synthetic function, with PT a widely accepted indicator. In acute viral or alcoholic hepatitis, PT more than 3 seconds above normal is associated with a poor prognosis,[347] whereas in toxic hepatitis, persistent elevation more than 4 days after ingestion has prognostic importance.[184] Low concentrations of other markers of synthetic function, such as transthyretin or actin-free Gc globulin,[397] or of markers of hepatocyte regeneration, such as α-fetoprotein,[197] have been found to predict poor prognosis. In alcoholic hepatitis, bilirubin and INR are the most reliable predictors of prognosis; several indices, discussed later in the section on alcoholic liver disease, have been used to predict risk of death and need for treatment.[270] Cytosolic enzyme activities decrease rapidly in ischemic and toxic hepatitis or obstruction, regardless of outcome, and fall more gradually in viral and alcoholic hepatitis, but are not helpful in evaluating outcome. With hepatitis B and C, cytosolic enzyme activities may return to normal even if viral replication persists[105,211]; serologic tests are the only reliable means to evaluate resolution of infection.

Chronic Hepatitis

Chronic hepatitis is defined as chronic inflammation of the liver that persists for at least 6 months, or signs and symptoms of chronic liver disease in the presence of elevated cytosolic enzymes.[119] It is characterized by ongoing inflammatory damage to hepatocytes, often accompanied by hepatocyte regeneration and scarring. Formerly, chronic hepatitis was subdivided into three forms (chronic persistent, chronic lobular, and chronic active) based on histologic characteristics. It was recognized that individuals often had each of these "diseases" at different points in time, and often in different areas of the liver in the same biopsy. Current classifications describe the cause and evaluate the severity of inflammatory injury (termed *grade*) and the extent of fibrosis (termed *stage*). The importance of these findings will be discussed in detail later. Common causes of chronic hepatitis and tests used to make a specific etiologic diagnosis are listed in Table 50-4.

TABLE 50-4 Causes of Chronic Hepatitis and Diagnostic Strategies

Cause	Diagnosis
Hepatitis B	History, HBsAg, anti-HBs, anti-HBc, HBV DNA
Hepatitis C	Anti-HCV, HCV RNA by PCR
Autoimmune type 1	ANA, anti–smooth muscle antibody
Autoimmune type 2	SLA, anti-LKM_1
Wilson's disease	Ceruloplasmin
Drugs	History
α_1-Antitrypsin deficiency	α_1-AT phenotype
Nonalcoholic fatty liver disease (NAFLD)	Metabolic syndrome, liver ultrasound, liver biopsy
Idiopathic	Liver biopsy, absence of markers

ANA, Antinuclear antibody; *AT,* antitrypsin; *HBc,* hepatitis B core antigen; *HBsAg,* hepatitis B surface antigen; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *LKM_1,* liver-kidney microsomal antigen type 1; *PCR,* polymerase chain reaction; *SLA,* soluble liver antigen.

The clinical features of chronic hepatitis are highly variable. Most patients are asymptomatic, but nonspecific features such as fatigue, lack of concentration, and weakness may be present. Most patients are diagnosed because of an unexplained abnormality in aminotransferase activities or detection of positive results on a screening test for a cause of chronic hepatitis. Moderate elevations in aminotransferase activities (an average of about twofold, and in most cases less than fivefold) are characteristic, whereas results of most other tests are normal. Normal aminotransferase activities do not rule out histologic evidence of chronic hepatitis, especially in the presence of chronic viral hepatitis or nonalcoholic steatohepatitis (NASH).[161,180,313] Characteristically, ALT is elevated to a greater degree than AST,[66] although elevations in both are common; reversal of the AST/ALT ratio to greater than 1 suggests coexisting alcohol abuse or development of cirrhosis in patients with a variety of causes of chronic liver disease[16,146,344,345] (as discussed in greater detail later in this chapter). One study found that the AST/ALT ratio was significantly higher in women than in men;[304]however, in most studies in which the AST/ALT ratio is used, separate analyses are not done by gender. Although ALT is relatively specific for the liver, skeletal muscle sources for AST and ALT should always be considered, especially in physically active young individuals.[111,239,327] A finding of persistent elevation of

TABLE 50-5 Patterns of Chronic Hepatitis B Virus Infection

Type	AST/ALT	HBsAg	HBeAg	Anti-HBc	HBV DNA
Occult	Normal	Neg	Neg	Pos	Neg*
Immune control	Normal	Pos	Neg	Pos	Neg*
Immune tolerant	Normal	Pos	Neg/Pos	Pos	Pos
Immune active	Increased	Pos	Pos	Pos	Pos, viral load usually $>10^6$ IU/mL
HBeAg-negative chronic hepatitis	Increased	Pos	Neg	Pos	Pos, viral load usually $<10^6$ IU/mL

*May have very low level (usually $<10^2$ IU/mL) in serum.
ALT, Alanine aminotransferase; *AST,* aspartate aminotransferase; *HBc,* hepatitis B core antigen; *HBeAg,* hepatitis B e antigen; *HBsAg,* hepatitis B surface antigen; *HBV,* hepatitis B virus.

aminotransferase activity should lead to an evaluation for chronic hepatitis using the tests outlined in Table 50-4. A liver biopsy may be helpful in determining the cause, assessing severity, and following treatment. A specific etiologic diagnosis is essential because it dictates the treatment. The most common causes of chronic hepatitis are chronic HBV and HCV and NASH, but a variety of other disease processes may cause chronic hepatitis.

Chronic Hepatitis B

Worldwide, HBV infection is the most important cause of chronic hepatitis.[137] Approximately 350 million individuals worldwide have chronic HBV infection; most cases are found in Asia, Africa, and southern Europe.

In most circumstances, HBV is not cytopathic because the injury results from an immune-mediated inflammatory attack against hepatocytes. Chronic hepatitis results when the immune response is incomplete and the virus is not eliminated from infected cells. This leads to a continuing cycle of viral replication, reinfection of regenerating hepatocytes, and immune damage to newly infected cells that is inadequate to clear infection. The details are not completely understood, but it appears that in the normal circumstance, hepatocytes express surface markers (in this case, HBcAg and HLA class 1 proteins).[316] Primed lymphocytes then attack the infected hepatocytes.[75] Expression of HLA class 1 markers is stimulated by interferon. It appears that many chronic hepatitis B patients are deficient in or have an inadequate response to interferon and, by inference, are unable to express HLA antigens that would attract an appropriate lymphocyte response.[248] The discovery of interferon deficiency led to the successful use of α-interferon (IFN-α) therapy in chronic HBV. The clinical presentation may be complicated by various extrahepatic complications (which occur in 1 to 10% of those with HBV[255]), including (1) polyarteritis, (2) glomerulonephritis, (3) polymyalgia rheumatica, (4) cryoglobulinemia, (5) myocarditis, and (6) Guillain-Barré syndrome. These conditions are associated with circulating immune complexes containing HBsAg.[456] Immunocompromised persons, such as HBV/HIV-coinfected individuals, typically have higher replication markers, less hepatic inflammation, and poorer survival than those with HIV alone.[339,447]

The natural history of chronic hepatitis B (defined by the persistence of HBsAg) varies.[296] Features of the different stages of chronic HBV are given in Table 50-5. It is convenient to divide chronic hepatitis B infection into two basic types—replicative and nonreplicative—although transitions between these stages are common. In the chronic replicative form, viral DNA is found in the cytoplasm of infected hepatocytes, and complete viral particles are produced and released into the circulation. In the replicating form of infection, viral loads in plasma are usually high ($>10^5$ copies/mL, often $>10^8$ copies/mL). In those infected later in life who develop chronic hepatitis, evidence of hepatocyte injury (elevated aminotransferase activity and inflammation in liver biopsy sections) is found in most cases (termed *immune active*[296] or *chronic active phase*). In those infected early in life, however, evidence of hepatocyte injury is often minimal; this has been referred to as the *immunotolerant phase of chronic HBV.* Those in the immune tolerant phase may transition to the immune active phase, but do not always do so. In the nonreplicating form, circulating viral load is low or undetectable, and evidence of hepatocyte injury is usually absent. This variant has been termed *HBV carrier state,* although current terminology describes this phase as the *immune control phase.* Traditionally, HBeAg had been used to differentiate replicative and nonreplicative types of chronic hepatitis, with negative HBeAg and positive anti-HBe thought to indicate the nonreplicating stage of infection. As discussed earlier, however, this distinction is inaccurate, and classification is based on HBV DNA concentrations along with ALT activities and histology.[296] All of these three phases of chronic HBV are associated with the presence of HBsAg in serum. As mentioned earlier, occult HBV infection is present in many individuals previously exposed to HBV, but is not associated with inflammation in the liver or elevated aminotransferases.

In general, chronic HBV passes through stages in untreated persons. For those infected early in life, the immune tolerant phase is usually followed by an immune active phase, then often the immune control phase or occult infection. For those affected as older children or adults, the immune active phase usually is seen first, and the immune tolerant phase is never seen or is present for only a short period. About 8 to 10% of persons per year will transition from the immune active to the immune control phase of chronic HBV.[112] A variable, but low, proportion of those in the immune control phase will revert to the immune active phase (mainly dependent on genotype).[296] About 0.5 to 1% of persons per year will convert

from HBsAg positive to HBsAg negative, entering the occult phase of infection (or, in a minority, resolved HBV). Each of these transitions can be associated with an acute rise in aminotransferase activities in a clinical picture mimicking acute viral hepatitis, as discussed earlier.

For individuals who have chronic replicating infection, the major risk is development of cirrhosis and HCC. An estimated 20 to 30% of individuals with chronic hepatitis B will develop cirrhosis over a 20-year follow-up period; the risk is directly related to amount of HBV DNA, with risk progressively increasing at viral loads greater than 2000 IU/mL (10,000 copies/mL).[209] Once cirrhosis has developed, a 1.5 to 5% annual risk of development of HCC is noted. Although the risk of HCC is lower in individuals with HBV infection who do not have cirrhosis, risk is directly related to viral load and rises at quantities above 2000 IU/mL.[71] Even a person in the nonreplicating stage of infection has a tenfold higher risk of HCC.[70] On a worldwide basis, hepatitis B infection is the most common cause of liver cancer.

Several agents have been approved for the treatment of chronic HBV infection, including interferon (both standard and pegylated) and several nucleoside/nucleotide inhibitors of HBV polymerase (adefovir, entecavir, lamivudine, telbivudine, and tenofovir).[112] Other polymerase inhibitors (largely used for HIV treatment) have been evaluated in research studies but are not yet approved for use in North America. At present, only single-agent therapy is used, although it has been suggested that combinations of polymerase inhibitors should be used in persons with lack of response to single agents, particularly in those with cirrhosis.[405] Combinations of interferon plus lamivudine show higher rates of response to treatment, but no additional long-term benefit, compared with interferon alone.[444] Major criteria for initiating treatment include HBV viral load and activity of ALT; viral load greater than 20,000 IU/mL (100,000 copies/mL) is currently considered a criterion for treatment, as are ALT at least two times the upper reference limit and detectable HBV DNA.[106] For persons who do not meet these criteria, indications for treatment include active liver disease on biopsy and the presence of cirrhosis. Treatment is about equally effective for persons positive or negative for HBeAg; those who are HBeAg negative have slightly higher response rates on treatment but have a low likelihood of maintaining suppression of viral replication if treatment is stopped.[112]

Efficacy of treatment is typically measured by response of alanine and/or aspartate aminotransferase and HBV DNA; goals of treatment include normalization of ALT and suppression of HBV DNA below the limits of detection of assays, ideally with detection limits of about 20 to 50 IU/mL. With polymerase inhibitors, about 70 to 80% of patients will achieve these goals within 1 year of treatment. Duration of treatment is largely dependent on HBeAg status before the start of therapy and, for those HBeAg positive before treatment, response of HBeAg on therapy. For those who are HBeAg negative, treatment typically is continued indefinitely, as long as treatment is effective. For those who are HBeAg positive before treatment, loss of HBeAg and development of anti-HBe indicate a high likelihood of maintenance of HBV DNA control and normalization of ALT once treatment is stopped (after 6 to 12 months of further treatment once anti-HBe appears). With interferon therapy, response rates to 1 year of treatment are somewhat lower than with polymerase inhibitors, but treatment requires only 6 to 12 months. Loss of HBsAg is uncommon; with most agents, the likelihood of loss of HBsAg usually is not higher than in untreated persons, although it may be higher with interferon and tenofovir.[112]

Chronic Hepatitis C

Approximately 170 million individuals worldwide have been diagnosed with chronic HCV infection; most cases are found in North America, Northern Europe, and Japan.[383A] In contrast to HBV, the risk of chronic hepatitis does not appear related to age at exposure (although perinatal infection is uncommon with HCV), and the likelihood of chronic infection is much higher overall. Many references state about an 80 to 85% likelihood of chronic infection by HCV; this interpretation is based on the frequency of finding HCV RNA on a chronic basis among those who are anti-HCV positive. As mentioned earlier, however, many individuals who clear HCV with acute exposure never develop or lose anti-HCV. Among persons followed prospectively after acute HCV infection, chronic HCV infection actually developed in only about 50 to 70%.[224,413,481] Once viremia becomes established beyond 6 months after initial exposure, it essentially never resolves spontaneously; in one study of 320 patients followed serially for longer than 3 years, only 6 patients with end-stage liver disease lost detectable HCV RNA.[493] HCV viral load fluctuates little over time; in most individuals, viral load differs by less than 0.5 log,[132,181] and gradually increases by an average of 0.2 to 0.3 log/y.[132,333] It is estimated that approximately 20 to 30% of patients with hepatitis C will progress to cirrhosis over a period of 20 years.[409] The frequency of progression appears to be increased by age over 40 at the time of infection, male gender, alcohol abuse,[281] and immunosuppression, but it is less than 5% after 20 years of infection in those infected during the first 20 to 30 years of life.[224,382,413,481] In those who develop recurrent HCV after liver transplantation, the response rate is lower and the rate of progression to cirrhosis is faster than in primary infection. As with HBV, the likelihood of progression to HCC is between 1.5 and 5% per year in those with cirrhosis.[254]

The clinical picture of chronic HCV is similar to that of HBV in producing chronic hepatitis. Infection with HCV is characterized by fluctuating ALT activities over time. Only about one third of those with chronic HCV have continually increased ALT, and many of these individuals show variation in ALT activity.[116] It is common for individuals with fluctuating values to have multiple normal ALT activity values separating elevated values.[211,375] Individuals with normal ALT tend to have milder fibrosis and less severe disease on liver biopsy, but a minority have advanced fibrosis.[161] In contrast to HBV, individuals with continually normal ALT activity have a similar rate of response to antiviral treatment.[161]

TABLE 50-6 Tests for Evaluating Chronic Hepatitis C Virus (HCV) Infection and Its Treatment

Time of Testing	Test	Condition	Use/Interpretation
Pretreatment	HCV viral load	Detectable	Baseline (to compare with 12 wk value)
	Genotype	2 or 3 vs. other	Length of treatment (24 wk genotype if 2 or 3, 48 wk if other genotype)
4 wk on treatment	HCV viral load	Undetectable	Rapid virologic response (RVR)—high likelihood of treatment success
12 wk on treatment	HCV viral load	<2 log drop	Stop treatment (nonresponder)*
		>2 log drop	Continue treatment (on treatment responder)
End of treatment†	Sensitive HCV RNA‡	Detectable	Nonresponder or breakthrough (if was previously undetectable)
24 wk after completion	Sensitive HCV RNA§	Not detectable	Treatment responder
		Detectable	Relapser
		Not detectable	Sustained virologic responder

*Less than 3% chance of sustained virologic response; some continue treatment to 24 weeks and re-evaluate.
†Done at 24 weeks if genotype 2 or 3, done at 48 weeks if other genotypes; not all recommend evaluating end of treatment response.
‡Lower detection limit <50 IU/mL.
§Done only if genotype not 2 or 3.

Treatment of chronic HCV is based predominantly on a combination of pegylated (long-acting) interferon plus ribavirin. New agents, including HCV protease inhibitors, have shown promise in increasing treatment response rates when used along with standard treatment[295]; a high rate of spontaneous mutations to the most widely tested protease inhibitor precludes monotherapy.[157] In contrast to HBV, for which treatment is aimed at inhibiting viral replication, treatment of HCV is often successful in eradicating the virus.

Measurement of HCV RNA at several time points after the start of therapy has been found predictive of the likelihood of the ultimate goal—sustained virologic response (SVR, defined as absent HCV RNA at least 3 to 6 months after completion of treatment). Persons who achieve SVR have a less than 1% likelihood of recurrent viremia, and have no detectable HCV RNA in the liver.[474] Several terms have been used to describe treatment response.[161] Rapid virologic response (RVR) refers to undetectable HCV RNA after 4 weeks of treatment; those who achieve RVR have a 90% likelihood of achieving SVR. Early virologic response (EVR) refers to at least a 2 log decrease in viral load after 12 weeks of treatment. Persons who have undetectable HCV RNA after 12 weeks have a 70% likelihood of SVR; those with reduced, but detectable, HCV RNA have a lower but significant likelihood of SVR. Persons who fail to achieve EVR have a less than 3% likelihood of SVR and usually are not continued on treatment. End of treatment (EOT) response refers to undetectable HCV RNA at the end of therapy. Several factors may influence response to treatment. The most important is genotype; individuals with genotypes 2, 3, and 4 have response rates approximately twice those of other genotypes (SVR 70 to 80% vs. 45%), and those infected by genotypes 2 and 3 require only 6 months of treatment rather than the 12 months needed for other genotypes. Response rates are lower in those of African ancestry with high body mass index (BMI) and with higher viral load. Table 50-6 summarizes laboratory tests used to evaluate and monitor treatment for HCV.

Hepatitis B and C Coinfection

Approximately 2 to 10% of individuals infected with HCV are coinfected with HBV; of those with chronic HBV, 15 to 20% are also HCV positive.[90,500] Clinical and laboratory features of coinfected patients are somewhat contradictory and differ from those in individuals infected with a single hepatitis virus. Coinfected patients have lower viral loads than do those with single infection.[89] In patients with chronic HBV who develop acute HCV infection, the likelihood of progressing to chronic HCV infection is low,[81] and acute infection with HBV can lead to clearance of HCV.[389] These features would suggest a beneficial effect of coinfection. In contrast, patients with chronic HBV/HCV coinfection have more rapid progression to cirrhosis.[388] Patients with acute coinfection more frequently have severe acute hepatitis.[10,500] Some studies suggest a high frequency of HBV DNA viral replication in the liver even in the absence of circulating HBsAg; such subclinically coinfected patients have more severe liver injury and a higher frequency of cirrhosis.[58,232] Despite some favorable findings, the outcome of hepatitis in coinfected patients seems to be worse than for those infected with only a single agent.

Nonalcoholic Fatty Liver Disease[103A] and Nonalcoholic Steatohepatitis

Ludwig first described patients who had histologic features identical to those of alcoholic hepatitis, but who had no history of alcohol abuse and did not have AST higher than ALT.[271] He introduced the term *nonalcoholic steatohepatitis (NASH)* to describe this entity, which was more common in women than in men and usually was associated with diabetes and/or obesity. [Because alcohol ingestion is common in the

population, and alcoholic liver disease does not occur with daily ingestion of less than 20 g ethanol, this threshold has been suggested as the maximum alcohol intake compatible with a diagnosis of nonalcoholic fatty liver disease (NAFLD).][84A,331] It is now recognized that NAFLD is associated strongly with the presence of the metabolic syndrome; almost half of individuals who meet the criteria for metabolic syndrome have NAFLD, and as many as 20 to 30% of the population in North America and Europe has NAFLD,[371] making it far and away the most common form of liver disease and an extremely common condition in the population in the developed world. About 10% of those with NAFLD have the more severe form, NASH. The frequency in obese or diabetic individuals is much higher, with NAFLD in 60 to 75% and NASH in 20 to 25%.[331,470] Prospective studies of patients with liver disease have confirmed that NASH is a common cause of elevated liver enzymes in an unselected population of patients referred to gastroenterologists or seen in primary care settings.[57,98,287] The frequency of cirrhosis in NASH is not well established, but it has been suggested that NASH may be a major cause of *cryptogenic* cirrhosis, for which no underlying cause can be determined. As weight loss develops with chronic illness, fat may disappear from the liver, leaving only fibrosis.

Current evidence suggests that accumulation of fat in NAFLD is a consequence of insulin resistance. A variety of mechanisms may lead to insulin resistance, including genetic predisposition, increased concentrations of free fatty acids, and the presence of cytokines such as tumor necrosis factor-alpha (TNF-α). Because TNF-α is produced by fat cells, correlates with body fat, and is critical to development of insulin resistance in obesity, it may be a key factor in the development of NAFLD. The pathogenesis is likely to be more complicated, however, because a variety of other factors lead to increased fat accumulation in the liver, including increased carbohydrate intake, certain drugs, and mutations in lipid synthesis, but they have not been associated with the development of NASH.

Laboratory diagnosis of NASH and NAFLD is currently not possible.[479] Although oxidative stress, inflammation, and abnormal concentrations of adipocyte-produced peptides are believed to be involved in the pathogenesis of NAFLD, laboratory tests evaluating these have not be found to be reliable predictors of histologic changes. A clinical approach typically involves a compatible clinical history and the presence of steatosis on imaging studies, exclusion of other causes of liver injury, and (if indicated) biopsy to confirm the diagnosis and determine the extent of injury. Although increased activities of liver enzymes are often used to distinguish NASH from other forms of NAFLD, the degree of necroinflammatory damage is not related to elevations in AST or ALT activity, and the likelihood of significant liver damage is similar in those with normal or elevated ALT.[313]

To date, major treatments for NAFLD have been aimed at lowering body weight and fat content. Loss of weight is often associated with decreased ALT values; in one study, a 1% decrease in weight was associated with an 8% decrease in ALT activity.[354] The association of NAFLD with insulin resistance has suggested treatment with antidiabetic medications, particularly those that increase insulin responsiveness [such as peroxisome proliferator-activated receptor (PPAR)-γ agonists and metformin]; studies have not been conclusive as to the benefits of such treatment.[426]

Autoimmune Hepatitis

Autoimmune hepatitis (AIH) represents a rapidly progressive form of chronic hepatitis, with up to 40% 6-month mortality in untreated individuals[428] associated with the presence of autoimmune markers. Although typically a chronic disease, it may have an acute presentation in up to 40% of cases, as discussed earlier. It is relatively uncommon, with an annual incidence of 1.9 cases per 100,000 population,[39] but it is responsible for 3 to 6% of all liver transplants[483]; the disease recurs in about 30% of patients after transplantation.[307] As with most autoimmune diseases, there is a strong female predominance. Forms of AIH has been found in individuals of all ages, with no racial or ethnic predilection. It has been associated with specific HLA haplotypes, notably DR3 and DR4, as is true for many other autoimmune diseases. Practice guidelines on autoimmune chronic hepatitis have been developed by the American Association for the Study of Liver Diseases (AASLD).[93]

AIH is associated with the presence of liver and nonliver autoantibodies in plasma. These are helpful in diagnosis, but are not likely to be the cause of liver injury. The most important antibodies for diagnosis include (1) antinuclear antibody (ANA), (2) anti–smooth muscle (or antiactin) antibody (ASMA), (3) anti–liver-kidney microsomal antigen type 1 (LKM_1), and (4) anti–soluble liver antigen (SLA), which is insensitive but highly specific. A variety of other autoantibodies are found frequently in AIH, some of which are found in other disorders. A summary of the most common autoantibodies, their associations, and their molecular targets (when known) is given in Table 50-7. Tests for these autoimmune markers initially used cell or tissue preparations studied by indirect immunofluorescence, but these have largely been replaced by assays that detect antibodies to purified proteins. Individuals who are negative for common autoantibodies, but otherwise meet criteria for diagnosis, have a similar prognosis and response to treatment.[297]

Criteria for the diagnosis of AIH were developed by an international group[215] and subsequently revised[13]; a simplified scoring system has also been developed.[190] The simplified criteria include (1) exclusion of viral hepatitis, (2) increased IgG, (3) positive autoantibodies, and (4) compatible histologic features.

It is controversial whether AIH should be further divided into subtypes; the international group that codified diagnostic criteria does not recommend use of subtypes,[19] but many authorities recognize three different forms (Types 1, 2, and 3). Although differences in epidemiology may be evident among the different forms, there do not seem to be differences in clinical course or response to treatment. Type 1, which is the most common form and the only one seen

TABLE 50-7 Serologic Markers of Autoimmune Liver Disease

Antibody Name	Antigen Target	Associations
Antiactin	Actin	AIH type 1; more specific than ASMA, poor response to corticosteroids, early age of onset
Anti-asialoglycoprotein receptor (ASGPR)	Transmembrane antigen binding protein	AIH, correlate with activity, disappear with successful treatment
Anti–liver-kidney microsome (LKM_1)	Cytochrome P450 2D6	AIH type 2; seen in only 4% of U.S. cases; usually in children
Anti–liver-specific cytosol (LC_1)	Enzyme (possibly formiminotransferase cyclodeaminase or argininosuccinate lyase)	AIH in younger patients, often with anti-LKM_1, primary sclerosing cholangitis; vary with activity of disease
Antimitochondrial antibody (AMA M2 type)	Dihydrolipoamide acyltransferase	Primary biliary cirrhosis
Antineutrophil cytoplasmic antibodies (ANCAs)	Bactericidal/permeability protein, cathepsin G, lactoferrin	Primary sclerosing cholangitis (PSC; 50-70%), ulcerative colitis (50-70%), AIH; nonspecific
Antinuclear antibody (ANA)	Multiple targets (centromere, ribonucleoproteins); may not be detected by ELISA	AIH type 1, some PSC cases
Anti–smooth muscle antigen (ASMA)	Actin, tubulin, vimentin, desmin, skelitin	AIH type 1, seen in other autoimmune diseases in lower titers
Anti–soluble liver antigen/ liver pancreas (SLA)	UGA tRNA suppressor–associated transfer protein	AIH type 3; very specific for AIH, correlate with relapse after corticosteroid withdrawal

AIH, Autoimmune hepatitis; *ELISA,* enzyme-linked immunosorbent assay.

frequently in North America, is predominantly a disease of middle-aged women. It is characterized by ASMA or anti-actin (found in 87% of cases) and/or ANA (found in 67% of cases); one or the other is present in nearly 100% of cases. Because of the nonspecific nature of these antibodies, the strength of the antibody reaction (titer or immunoassay signal) is important in determining the likelihood of AIH. In children, the strength of the reaction is typically lower than in adults. Type 2 AIH, which characteristically occurs in children (although 20% occurs in adults), represents up to 20% of cases in Europe. It is associated with antibodies to liver-kidney microsomal antigen 1 (anti-LKM_1) or cytochrome P450 2D6 (CYP2D6).[499] Some cross-reactivity has been noted between this antibody and certain HCV antigens, leading to positive anti-CYP2D6 in individuals with HCV infection. The epitopes recognized by anti-HCV antibodies are different from those in persons with type 2 AIH.[273] Type 3 often lacks other autoimmune markers but is positive for antibody to soluble liver antigen liver-pancreas. This antibody is directed against UGA tRNA suppressor–associated antigenic protein.[466]

Immunosuppressive treatment using prednisone, alone or in combination with azathioprine, is effective in inducing clinical remission of disease in about 80% of cases; other immunosuppressants are now being used to reduce dependence on corticosteroids.[445] Because inherited differences in the activity of thiopurine methyltransferase affect about 10% of the population,[253] it has been recommended that pretreatment determination of enzyme activity should be used to reduce the likelihood of toxicity. Remission typically begins with improvement in symptoms, followed by normalization in laboratory abnormalities, and finally histologic resolution.[93] Laboratory remission generally does not occur until after at least 12 months of treatment, but it almost always occurs within 24 months in responders. Histologic remission is less common and usually requires at least 3 to 6 months longer than laboratory evidence of remission.[428] Sustained remission can persist off treatment in 80% of those with normal histology following therapy, but relapse occurs in 50% within 6 months if inflammation persists in the liver biopsy.[92]

Inherited Liver Disease Presenting as Chronic Hepatitis

Inherited liver diseases that present as chronic hepatitis include (1) hemochromatosis, (2) Wilson's disease, and (3) α_1-antitrypsin (AAT) deficiency.

Hemochromatosis

Hereditary hemochromatosis (HH) is an autosomal recessive disorder of iron metabolism that results in excessive iron absorption and accumulation in tissue (see Chapter 32). The gene for HH has long been linked to chromosome 6, close to the genes for the HLA system; it has been definitively identified and termed the *HFE* gene, which codes for a transmembrane protein similar to the class I major histocompatibility complex (MHC) molecule.[140] In North America and Europe, more than 90% of individuals with HH are homozygous for a single point mutation that inserts a tyrosine instead of

cysteine at residue 282 (termed the *C282Y* mutation).[442] Although it is a frequent genetic trait (estimated 1 in 8 persons of northern European ancestry are carriers, with about 1 in 250 being homozygous), most individuals who are homozygous for this mutation do not develop evidence of iron overload. A large population-based study showed that only 28% of males and about 1% of females homozygous for the *C282Y* mutation develop HH.[11] Other mutations in the *HFE* gene have been linked to hemochromatosis, and mutations in other proteins that regulate iron absorption have been identified as causes of HH.[363]

Liver disease due to hemochromatosis is rare in younger individuals, but becomes more common after the age of 30. The likelihood of liver disease is related to serum ferritin concentrations. Ferritin greater than 1000 ng/mL is associated with a high likelihood of significant liver disease, and concentrations between 500 and 1000 indicate moderate risk[17]; in those who are not found to have liver disease, serum ferritin less than 300 indicates a low likelihood of progressive rise in ferritin to greater than 1000 during follow-up for an average of 12 years.[178] Treatment consists of phlebotomy to remove iron, or iron chelation therapy for those who cannot tolerate phlebotomy (with the goal of serum ferritin <50 ng/mL).[349]

Wilson's Disease

Wilson's disease is an autosomal recessive disorder of copper metabolism (see Chapters 31 and 40).[362A] It has a gene frequency of 1 in 200 and a disease frequency of 1 in 30,000. It is due to one of more than 200 mutations in a gene on chromosome 13 coding for a copper-transporting ATPase (ATP7B).[54,440] This enzyme, found mainly in the liver, is involved in movement of copper into bile; deficiency leads to accumulation of copper in the liver and, eventually, in other tissues. Guidelines on diagnosis and treatment of Wilson's disease have been updated.[380]

Wilson's disease usually manifests before age 30 and patients in their 70s have rarely been identified.[6] For reasons that are unknown, patients usually have the hepatic or the neuropsychiatric form of the disease. In children, hepatic involvement tends to predominate, whereas in adolescents and adults, the neuropsychiatric form becomes more common. Hepatic manifestations include fulminant hepatitis (as discussed earlier), but more commonly chronic hepatitis, with or without cirrhosis, is the presenting finding.[396,404] Occasionally, the features mimic those of autoimmune hepatitis, with increased globulins and positive ANA.[308]

The classic clinical finding of increased copper deposition in the eye is the Kayser-Fleischer ring, caused by deposition of copper at the edge of the cornea. Although found in about 95% of patients with neurologic or psychiatric manifestations, it is present in only about half of patients with hepatic forms of Wilson's disease[433] and is rarely present in children.[393] As mentioned earlier, hemolytic anemia and renal failure commonly accompany acute forms of Wilson's disease; hemolytic anemia may be episodic even in chronic forms of Wilson's disease.[380]

Several laboratory tests are available for the diagnosis of Wilson's disease; ceruloplasmin measurement is discussed in detail in Chapter 21 and copper measurement in Chapter 31. Test results are often affected by other conditions, sometimes making diagnosis difficult. Classic findings of Wilson's disease include (1) decreased ceruloplasmin, (2) decreased total plasma copper, (3) increased plasma-free (or noncaeruloplasmin) copper, (4) increased urine copper excretion, and (5) increased hepatic copper content. Ceruloplasmin is a ferroxidase that typically is measured by enzymatic activity or by immunoassay. Although controversy is ongoing over which assay format is preferable, guidelines have not specified one type.[119,380] Ceruloplasmin is very low in infants, gradually rises to higher than adult concentrations in early childhood, then gradually declines to adult concentrations. Use of age-appropriate reference intervals is critical for diagnosis in children. Ceruloplasmin is an acute-phase protein, and its synthesis is induced by estrogen; concentrations may be falsely normal with acute illness or with high estrogen states. Low concentrations of ceruloplasmin are seen with malnutrition, in protein-losing states, and in cirrhosis of any cause. These preanalytical variables cause ceruloplasmin to have a low predictive value as a single test for Wilson's disease; in one study of patients with chronic hepatitis, the positive predictive value was only 6%.[64] Ceruloplasmin is also decreased in about 20% of heterozygous carriers of the Wilson's disease gene.[165] Because most plasma copper is bound to ceruloplasmin, total plasma copper is affected by factors that affect ceruloplasmin. Some estimate free (noncaeruloplasmin) copper as the difference between total copper (μg/dL) and ceruloplasmin (3 × mg/dL); values greater than 25 μg/dL suggest Wilson's disease.[154] Urine copper excretion is the most specific noninvasive test for Wilson's disease; 24 hour urine copper excretion is typically more than 100 μg/d in Wilson's disease. Unfortunately, the clinical sensitivity of copper excretion appears to be only 75 to 85%.[393,433]

Treatment of active, symptomatic Wilson's disease is aimed at increasing urine copper excretion to eliminate excess copper from tissue. The primary therapy for Wilson's disease usually involves chelating agents such as D-penicillamine and trientine, which now is more widely used because of its lower rate of side effects. Zinc (particularly zinc acetate) inhibits copper absorption from the intestinal tract; it is usually used for maintenance after copper chelation and can also be used as initial therapy. Monitoring treatment (particularly with zinc) by measuring yearly urine copper excretion can be helpful in ensuring that excess copper is no longer being excreted.[380]

α_1-Antitrypsin Deficiency

Alpha$_1$-antitrypsin (AAT) is the most important of the serine protease inhibitors (collectively termed *serpins*). As its name implies, AAT inhibits trypsin, but it also inhibits other proteolytic enzymes, including neutrophil-derived elastase, cathepsin G, and proteinase 3. The gene for AAT (originally called *PI,* but now called *SERPINA1*) is located on chromosome 14. Several genetic variants of AAT (differing by a single

amino acid) have been classified on the basis of their electrophoretic mobility; the slowest migrating of these was termed the *Z variant*. Some variants, particularly S and Z, form loop sheet polymers,[266] causing impaired release from the endoplasmic reticulum, hepatocytic inclusions of AAT, and reduced plasma concentrations. The most severe forms of disease have been associated with homozygosity for the Z variant, found in 1 in 1000 to 2000 individuals in Europe and North America.[206] However, it is estimated that only about 10% of those with AAT deficiency develop disease manifestations.[422]

The effects of AAT deficiency on the liver are controversial. In neonates, AAT deficiency is often associated with hepatitis; in one study, almost one third of infants with prolonged jaundice were found to be AAT deficient.[497] About 20% of AAT-deficient infants develop hepatitis,[366] with up to 25% 1-year mortality.[205] In those who survive the first year, however, evidence of liver injury diminishes and usually resolves by age 12.[436,468] At age 18, none of 183 individuals with AAT deficiency had clinical evidence of liver disease, none had elevated procollagen III peptide, and less than 20% had increased concentrations of liver-associated enzymes in serum.[437]

Data on association of AAT deficiency with liver disease in adults are somewhat contradictory.[131] In several studies, cirrhosis was present in one third to one half of those with AAT deficiency, and HCC was present in about one third of those with cirrhosis.[129,373] The frequency was similar in those with heterozygous and homozygous presence of the PiZ variant.[373] In two studies of patients with cryptogenic liver disease, the frequency of the PiZ heterozygotes was significantly higher than that found in the general population.[59,175] Two other studies, however, found a similar frequency of liver disease in those with AAT deficiency and controls.[142,317] Some evidence suggests that AAT deficiency may increase risk of liver damage from other factors. In one study, most individuals with AAT deficiency and liver injury were also positive for anti-HCV; only 11% had no other liver risk factors.[372] In those with AAT deficiency and no evidence of liver disease (usually viral related), life expectancy was no different from that in healthy controls. A 2007 research conference found evidence that defects in degradation of AAT underlie differences in protein accumulation, which is necessary for the development of liver disease.[362] It is likely that, as with hemochromatosis, the abnormal form of AAT is necessary, but perhaps not sufficient, to cause liver disease.

AAT is estimated by protein electrophoresis, in which it constitutes most of the α_1-globulin band; this was the original means by which AAT deficiency was recognized.[129] It also is quantified by a variety of other techniques (see Chapter 21). AAT is an acute-phase response protein; falsely normal quantitative concentrations have been reported in about 40% of PiZ heterozygotes,[196] although rarely in PiZZ homozygotes. Determination of phenotype was typically accomplished by isoelectric focusing and had been recommended as the diagnostic test of choice in one guideline,[119] but phenotype cannot distinguish true homozygotes from heterozygotes who have a null phenotype on the other AAT gene. Molecular tests are now available to determine AAT genotype.[41] Because the prognosis may vary between those who are actually homozygous for the Z variant and those with null phenotype, such molecular testing of the *SERPINA1* gene is considered preferable.[422]

Drug-Induced Liver Injury

As discussed earlier, most cases of drug-induced liver injury present as acute hepatitis. Less commonly, drugs have produced chronic liver injury in a pattern mimicking chronic hepatitis or other chronic liver injury (chronic cholestasis and hepatic granulomas).[407] The drugs most commonly linked to chronic hepatitis are nitrofurantoin, methyldopa, and HMG-CoA reductase inhibitors; however, a large number of drugs have been associated with liver injury,[504] and herbal medications have been linked to chronic hepatitis.[76,432] In individuals with increased activities of aminotransferases and no obvious cause, prescription drug use was significantly more likely to be present than in those with a known cause for elevated enzyme activities.[286] As with acute drug reactions, establishing drugs as the cause of chronic hepatitis is difficult; temporal relationships to drug ingestion are not as clear as with acute hepatitis, and reactions can be seen first in those who have been taking the medication for many months.[169,262] Most chronic drug reactions resolve when administration of the drug is discontinued.[4,14]

Significance of Chronic Hepatitis

In many cases, chronic hepatitis is a disease with minimal consequences. As mentioned earlier, an average of 20 to 30% of individuals with chronic HBV or HCV progress to cirrhosis over a 20 year period. However, cirrhosis was the 12th leading cause of death in the United States in 2006 (the most recent year for which full data are available).[191] The frequency of cirrhosis and HCC has been increasing in much of the Western world,[229] mostly caused by the increase in cases related to HCV. The proportions of individuals with HCV with cirrhosis and HCC are expected to double by 2020, and the number of deaths caused by liver disease is expected to almost triple.[102] The ability to predict which patients are at increased risk for such late complications of chronic hepatitis would allow more appropriate treatment.

Fibrosis and necroinflammatory activity are the two major components of chronic hepatitis. The extent of fibrosis (stage) is strongly related to the risk of progression,[208,356,490] whereas necroinflammatory activity (grade) is correlated with progression in some,[160,288,490] but not all,[62,367] studies. Because ALT activity is strongly correlated with necroinflammatory activity,[292] it is also associated with risk of progression to cirrhosis in some, but not all, studies. Clinical variables are associated with risk of progression as well; these include age at infection, male gender, alcohol intake, and the presence of immunosuppression.[62,151,284,369]

The process of scar formation in the liver involves numerous factors and differs in some important ways from that in other sites in the body.[7,402] Increasing evidence suggests that

the process of fibrosis is reversible, even when cirrhosis is histologically present.[153] For example, two studies found that successful treatment of HBV[113] and HCV[368] was associated with reversal of cirrhosis in 50 to 75% of cases. Although the principal component of hepatic scars is type III collagen, other components include type I and type IV collagen, laminin, elastin, and fibronectin. Proteoglycans, especially hyaluronate, are also involved in scar formation. Production of scar in the liver is affected by the rate of enzymatic degradation; a variety of matrix metalloproteinases (MPs) are found in areas of scar formation, along with several tissue inhibitors of metalloproteinases (TIMPs). MPs are involved in degradation of the normal connective tissue of the liver (a necessary prequel to fibrosis), but they are also involved in breakdown and remodeling of collagen. Hepatic stellate cells are critical in this process; they produce both MP and TIMP, as well as collagen and other matrix materials.[34,152] Recruitment and activation of stellate cells involve the action of a number of cytokines, particularly transforming growth factor (TGF)-β, platelet-derived growth factor (PDGF), and interleukin-6.[152] Evidence indicates that a variety of other cells also contribute to development of scar tissue within the liver.[475]

The gold standard for evaluation of the extent of liver damage has been liver biopsy. Because the degree of injury is not uniform throughout the liver, the sample taken may not be representative of the extent of damage.[280] This has led to interest in the use of laboratory tests to predict the extent of fibrosis in the liver. Several approaches have been used to identify markers that correlate with the extent of fibrosis. One approach uses routine laboratory tests; among the markers found to correlate with extent of fibrosis are the ratio of activities of AST to ALT and AST to platelet count (sometimes called APRI). A second approach evaluates multiple markers, either direct markers of proteins and other compounds involved in scar formation or indirect markers of liver injury,[280] using multivariate analysis to determine indices that correlate with extent of fibrosis. Although a variety of indices of this type have been proposed, the most widely studied is the FibroTest.[210] A third approach uses proteomic analysis of serum to discern patterns that correlate with disease.[72] Significant overlap in such markers is evident between individuals with cirrhosis and those with varying stages of fibrosis in chronic hepatitis; in analyses of published studies of markers, indeterminate scores were found, on average, in 35% of patients in reported series.[357] Evidence also suggests that marker concentrations change with alteration in necroinflammatory activity and may actually reflect the activity of disease at the time of sampling, rather than cumulative fibrosis.[458] Because criteria for treatment in the most common causes of chronic hepatitis, HBV and HCV, depend on the severity of liver damage, perhaps the greatest use of such markers at present is in identifying patients who have minimal cumulative damage (in whom risk of treatment outweighs possible benefit). Many marker panels have high negative predictive value for significant fibrosis; their use alone or in combination may significantly reduce the need for liver biopsy.[406]

Alcoholic Liver Disease

Alcoholic liver disease differs clinically and biochemically from other forms of hepatitis and liver disease.[431A] It is a common cause of liver disease in the developed world, but the incidence of acute alcoholic hepatitis and death from alcoholic cirrhosis is declining in North America and Europe.[278,279] Risk factors for developing alcoholic liver disease include the following:

1. *Duration and magnitude of alcohol ingestion.* As discussed later in the chapter, alcoholic liver disease does not occur in all individuals with chronic ethanol intake; although there appears to be a threshold intake of 40 g/d in men and 10 g/d in women,[303] meta-analysis of published studies shows that risk increases even at intakes below 25 g/d.[87] Most individuals with alcoholic liver disease ingest more than 80 g of alcohol per day.[252] Daily drinking appears to be riskier than intermittent drinking.
2. *Gender.* In women there is a greater likelihood of progression to cirrhosis.[467] Although some studies have suggested that this is due to lower activities of gastric mucosal alcohol dehydrogenase in women, 2002 data show that this is true only in younger women, and that older women actually have higher activities than older men.[358]
3. *Hepatitis B or C infection.* Both may increase the severity of liver damage in persons who drink heavily, and both correlate with degree of liver damage. For example, antibodies to HCV are several times more common in individuals with alcoholic hepatitis than in alcoholic individuals without hepatitis or in age- and gender-matched controls, suggesting a synergistic role for HCV.[300]
4. *Genetic factors.* As discussed later, an inherited predisposition to alcoholism has been clearly established. *HFE* gene mutations are more common in alcoholic individuals with liver disease than in those with no evidence of liver disease.[277]
5. *Nutritional status.* Protein-calorie malnutrition is extremely common among alcoholic individuals. Malnutrition may be due not only to poor intake but also to abnormal nutrient metabolism. Whereas poor nutrition may contribute to the evolution of alcoholic liver disease, adequate nutrition does not prevent its development. In fact, studies suggest that obesity may be a risk factor (perhaps because of the presence of coexisting nonalcoholic fatty liver disease).

Alcohol is metabolized to acetaldehyde by cytosolic alcohol dehydrogenase and microsomal enzymes (primarily CYP2E1). Acetaldehyde is subsequently metabolized to acetyl-CoA by aldehyde dehydrogenase. This is further broken down to acetate, which may be converted to carbon dioxide and water or enter the citric acid cycle to be converted to fatty acids. The latter is a major mechanism for induction of fatty liver by alcohol, but acetaldehyde is probably the primary toxin. It causes most of the injury to liver cells, as well as the induction of collagen synthesis leading to fibrosis and, ultimately, cirrhosis.

The mechanism for liver injury in alcohol abuse is still unclear. Only a minority of patients (less than one third) who abuse alcohol develop alcoholic liver disease,[173] and only 5%

of the heaviest drinkers develop cirrhosis.[270] Acetylation of a variety of liver proteins occurs with alcohol abuse, leading to loss of function of affected proteins in many cases.[417] Antibodies to acetylated liver proteins have been detected in patients with alcoholic liver disease.[2,443] Alcohol causes damage to intestinal epithelial cells, leading to release of lipopolysaccharide, which can also damage liver cells.[395] Activation of innate immunity, through either or both of these mechanisms, appears central to damage in alcoholic liver disease.[40] A variety of other metabolic changes have been observed in alcoholic liver disease, including changes in methionine metabolism and oxidative stress.[8]

Genetic factors seem to play a role in both alcohol abuse[289,401] and alcoholic liver disease.[104] As much as 40 to 60% of alcohol abuse is due to inherited factors.[289] Much effort has been expended in finding specific genetic markers; some of the more commonly implicated specific genes are those coding for alcohol dehydrogenase and several brain receptors, including those for γ-aminobutyric acid (GABA) and acetylcholine. Genetic variants in alcohol-metabolizing enzymes (including alcohol dehydrogenase, aldehyde dehydrogenase, and microsomal enzymes such as CYP2E1) are linked to alcohol abuse. However, most believe that multiple genes are involved in alcohol abuse. Genetic factors may also be important in determining which persons with alcohol abuse develop liver disease; as with alcohol abuse itself, as much as half of the risk of cirrhosis is due to genetic factors.[435] Similar genes may be involved; a 2009 study showed that alcoholic individuals with cirrhosis were much more likely to have mutations in *CPP2E1* and GABA receptors than alcoholics without cirrhosis.[225]

Acute alcoholic hepatitis clinically is an acute febrile illness,[270] characteristically associated with leukocytosis[299] and increased concentrations of acute-phase response proteins.[177] It causes mild increases in cytosolic enzymes; AST activity is typically more than two times greater than that of ALT,[84] and it is rare for AST to be more than eight times the upper reference limit.[299] Among the factors involved in causing the higher AST/ALT ratio in alcoholic hepatitis are damage to mitochondria, causing release of mitochondrial AST,[276,325] deficiency of pyridoxal-5′-phosphate,[272] and reduction in ALT content within the liver.[272] A cholestatic form of the disease, with increases in ALP activity to greater than three times the upper reference limit, is seen in up to 20% of cases; it is associated with higher mortality.[342] Increases in bilirubin are common, and reduced liver-synthesized protein concentrations are commonly present. Increased bilirubin, decreased albumin, and prolonged PT are poor prognostic markers in alcoholic hepatitis.[167] The Maddrey discriminant function [4.6 × (PT − Control PT)] + Plasma bilirubin (mg/dL)] value greater than 32 indicates individuals with a high mortality rate,[303] and a Model for End-Stage Liver Disease (MELD) score greater than 11 has been found to have similar sensitivity and better specificity.[418]

A large number of biochemical markers have been proposed for the detection of excessive alcohol consumption.[100,183,336] Among routine laboratory tests, the most widely used are γ-glutamyltransferase (GGT) and mean corpuscular volume (MCV). Serum GGT activity is commonly used as a screening test for alcohol abuse. However, GGT is an inducible enzyme that is elevated by many drugs and a variety of other factors such as cigarette smoking and other forms of liver disease.[118] The threshold for positivity is about 2 drinks/d, and elevation is more common in those who drink regularly than in binge drinkers. Although the clinical sensitivity of GGT for alcohol abuse is in the range of 70%, specificity is poor.[195] GGT remains elevated for an average of 25 days after alcohol abstention.[24] MCV has similar clinical sensitivity, and specificity is low.[195]

Alcohol leads to production of isoforms of transferrin with low sialic acid content, termed *carbohydrate-deficient transferrin* (CDT; also called hyposialyl- and asialyltransferrin). The use of CDT for detecting problem drinkers has been reviewed.[231] CDT returns to a normal concentration in a mean of 10 days with abstention from alcohol.[24] In a pilot study, CDT was found to be the only test to reliably distinguish alcoholic hepatitis from nonalcoholic fatty liver disease.[348] It has been suggested that combining markers such as CDT and GGT will enhance accuracy in identifying problem drinkers.[195] CDT is frequently elevated in persons with end-stage liver disease regardless of cause.[114]

Other markers of alcohol abuse have been studied, but with fewer data than for the markers mentioned earlier. Fatty acid ethyl esters are formed with acute and chronic alcohol intake.[243] Similarly, alcohol metabolites combine with glucuronic acid, forming ethyl glucuronides in patients who abuse alcohol.[355] Acetaldehyde adducts with serum proteins[335] and sialic acid[79] have also been evaluated as markers of alcohol abuse. Proteomic techniques have been used to try to identify additional markers,[343] with the suggestion that these will perform better than currently used markers such as GGT and CDT.

Cirrhosis

Cirrhosis, defined anatomically as diffuse fibrosis with nodular regeneration, represents the end stage of scar formation and regeneration in chronic liver injury. This response to injury occurs independently of the etiology and thus it is not possible, in most circumstances, to determine the cause of cirrhosis based on histology. Classically, cirrhosis has been classified as (1) micronodular, (2) macronodular, or (3) mixed, based on the histology and gross appearance of the liver. However, this is considered inadequate for etiologic or prognostic purposes. Consequently, it is more common to classify cirrhosis on the basis of its presumed or known etiology. Common causes of cirrhosis and their therapies are listed in Table 50-8. Virtually all chronic liver diseases are known to lead to cirrhosis (see Figure 50-9), but most cases of cirrhosis occur as a result of chronic hepatitis.

In the early stages of transition from chronic hepatitis to cirrhosis, termed *compensated cirrhosis,* no signs or symptoms of liver damage may be noted. Laboratory abnormalities usually appear before clinical findings such as ascites, gynecomastia, palmar erythema (reddening of palms), and portal

hypertension begin to develop. The earliest laboratory abnormalities to develop in cirrhosis are (1) fall in platelet count, (2) increase in PT, (3) decrease in the albumin-to-globulin ratio to less than 1, and (4) increase in the AST/ALT activity ratio to greater than 1.[163,274] In those with documented cirrhosis, decompensation occurs slowly, at a rate of about 3% per year; 10-year survival with compensated cirrhosis is 90%.[136] Once decompensation occurs, however, 10-year survival is only about 20%.[136] Jaundice is a late finding in decompensated cirrhosis. A variety of staging systems have been used to predict prognosis in cirrhosis. For many years, the most common classification system was the Child-Pugh class system, summarized in Table 50-9. Currently, the MELD score [calculated as 3.8 + ln bilirubin (mg/dL) + 11.2 ln international normalized ratio + 9.6 ln creatinine (mg/dL) + 6.4 etiology score (0 if alcohol or obstruction, 1 for all other causes)] is used to identify patients with advanced cirrhosis who may be candidates for liver transplantation; it appears superior to the Child-Pugh scoring system in predicting short-term survival.[43,50,148] Risk of death over 3 months is low in those with MELD scores less than 10, intermediate in those with scores of 10 to 20, and high in those with scores greater than 20.[220]

TABLE 50-8 Causes and Treatment of Cirrhosis

Cause	Treatment
Viral	
Hepatitis B	Administration of α-interferon or reverse transcriptase inhibitors
Hepatitis C	Administration of α-interferon
Toxic	
Alcohol	Abstinence, liver transplantation
Metabolic	
Hemochromatosis	Phlebotomy
Wilson's disease	Penicillamine, zinc trientine
α_1-Antitrypsin deficiency	Gene therapy, protein administration
Nonalcoholic fatty liver disease	Diet, exercise, insulin sensitizers
Biliary	
Primary biliary cirrhosis	Ursodeoxycholic acid
Primary sclerosing cholangitis	Liver transplantation
Autoimmune hepatitis	Corticosteroids, azathioprine, other immunosuppressants
Idiopathic	

Laboratory findings in cirrhosis reflect ongoing liver injury and decreased hepatic function. Activities of aminotransferases are variable in cirrhosis and reflect underlying necroinflammatory activity. If the cause of cirrhosis has been eliminated (as by abstinence from ethanol or successful treatment of viral hepatitis), aminotransferase activity is often within the reference interval. If aminotransferases remain increased, risk of development of HCC is increased.[394] As described earlier, the ratio of AST/ALT activity is often greater than 1 in cirrhosis; this is usually associated with a fall in ALT and minimal change in AST activities. The mechanism for the change in ratio is not clear, but there appears to be a decrease in the production of enzymatically active ALT in cirrhotic individuals,[399] along with a high ratio of immunoreactive to enzymatically active ALT.[227] Increases in α-fetoprotein (AFP) are common in cirrhotic patients, even in the absence of HCC.[168]

Hepatic Glycogenoses

The glycogenoses are a group of disorders that are characterized by excessive and/or aberrant glycogen storage in various tissues.[353] Most of these have deficient glucose production by the liver, leading to hypoglycemia. All are inherited by autosomal recessive transmission except for type IV, which is sex linked. The hepatic glycogen storage diseases and their enzyme defects are listed in Table 50-10. Most of these disorders are associated with growth retardation and hepatosplenomegaly. Mental development is usually normal. Hypoglycemia is a prominent feature in types I, III, and VI and needs to be treated with continuous glucose feeding of uncooked cornstarch, which results in slow release of glucose. The diagnosis is based on the demonstration of excess glycogen in the liver biopsy and in vitro identification of the abnormal enzyme or aberrant glycogen. Prognosis and treatment vary with each entity.

TABLE 50-9 Child-Pugh System for Classifying Severity of Cirrhosis

Feature	1 Point	2 Points	3 Points
Encephalopathy	None	Grade 1-2	Grade 3-4
Ascites	None	Slight	Moderate-severe
Albumin, g/dL	>3.5	2.8-3.5	<2.8
Prothrombin time, s prolonged	<4	4-6	>6
Bilirubin, mg/dL	<4	4-10	>10

Scoring: <7 points—class A; 7 to 9 points—class B; >9 points—class C.

TABLE 50-10 Hepatic Glycogen Storage Diseases

Type	Eponym	Enzyme Defect	Involved Tissues
0		Glycogen synthetase	Liver
I	von Gierke's	Ia glucose-6-phosphatase Ib translocase for glucose 6-phosphatase Ic phosphate/pyrophosphate translocase	Liver, kidney, intestines
II	Pompe's	Lysosomal acid α-1,4 glucosidase	Most tissues
III	Cori's	Amylo-1,6 glucosidase debranching enzyme	Liver, muscle, WBCs
IV	Anderson's	Amylo-1,4,1,6 trans-glucosidase (branching enzyme)	Most tissue
VI	Hers'	Liver phosphorylase	Liver, WBCs
VII		Phosphorylase activation	Liver
IXa		Phosphorylase kinase	Liver, WBCs, RBCs

RBCs, Red blood cells; *WBCs,* white blood cells.

Cholestatic Liver Disease

Cholestasis (stoppage or suppression of the flow of bile) is associated with retention of bile within the excretory system. The term *obstruction* is often used inappropriately, because cholestasis has been known to occur occur without mechanical obstruction to the biliary tract. Although intrahepatic cholestasis may be due to functional or mechanical problems, extrahepatic cholestasis is always due to physical obstruction of the bile ducts by processes such as gallstones (choledocholithiasis), biliary strictures, and tumors. The major cholestatic diseases include (1) mechanical obstruction of the bile ducts, (2) primary biliary cirrhosis (PBC), and (3) primary sclerosing cholangitis (PSC). Other cholestatic disorders consist of (1) post–bone marrow transplant cholangiopathy, (2) post–liver transplant cholangiopathy, (3) drug-induced cholestasis, (4) acquired immunodeficiency syndrome (AIDS) cholangiopathy, and (5) bilirubinostasis of acute illness. Cholestatic hepatitis, which was discussed previously, may also cause cholestasis, but generally presents in a fashion closer to hepatitis.

The clinical consequences of prolonged cholestasis are related to impaired biliary drainage. Deficiency of bile acids in the intestinal tract leads to malabsorption of fat and the fat-soluble vitamins A, D, E, and K (see Chapters 31 and 52). Vitamin A malabsorption results in night blindness. Vitamin D malabsorption leads to calcium and phosphate malabsorption, causing rickets in children and osteomalacia in adults. Vitamin K malabsorption results in deficiency of coagulation factors II, VII, IX, and X, leading to prolonged clotting times and, sometimes, bleeding. Lack of excretion of normal bile contents results in their accumulation in plasma. Bile acid retention leads to increased bile acid concentrations in plasma. Bilirubin retention leads to jaundice, dark urine, and pale stools. Increased bilirubin generally occurs only with complete obstruction and thus is more commonly seen with extrahepatic than intrahepatic cholestasis.

Laboratory features of cholestasis vary, depending on whether the process causes complete or partial impairment of biliary drainage. A common feature of all cholestatic disorders is an increase in plasma activities of canalicular enzymes, such as ALP and GGT. Because this process involves both increased synthesis of enzyme and release of enzyme from its membrane-bound forms, a short lag period is generally seen between the onset of cholestasis and the increase in plasma activities. In the early stages of an acute mechanical obstruction (especially from gallstones), transient increases may be noted in plasma activities of liver cytosolic enzymes, such as AST and ALT. Activities of plasma AST and ALT may exceed 400 U/L, and in 1 to 2% of cases are greater than 2000 U/L.[21] Even in the presence of continued obstruction, AST and ALT activity gradually decreases, and AST is typically within the reference interval within 8 to 10 days. Increases in total bilirubin typically occur only with complete extrahepatic obstruction, although they may be seen with extensive intrahepatic cholestasis. Increases in direct bilirubin are more commonly seen, and direct bilirubin has been reported to be the most sensitive functional test for the presence of cholestasis. Prolonged PT is the most commonly detected coagulation abnormality. It usually is corrected by administration of parenteral vitamin K. Accumulation of cholesterol is associated with the development of an abnormal lipoprotein-X,[305,326] containing phospholipids, cholesterol, fragments of cell membrane (along with ALP),[49] and albumin; the lipid may deposit in connective tissue, producing xanthomas. Although it is often measured as low-density lipoprotein (LDL) cholesterol,[144] lipoprotein-X is actually antiatherogenic.[429]

Mechanical Bile Duct Obstruction

The most common cause of cholestasis is biliary tract obstruction by space-occupying lesions.[416] Extrahepatic bile duct obstruction occurs most commonly as the result of gallstones in the common bile duct or because of tumors in the head of the pancreas or duodenum. Other causes of extrahepatic obstruction include (1) bile duct strictures, (2) extrinsic compression of the bile ducts by enlarged lymph nodes, (3) congenital biliary atresia, and (4) PSC. Extrahepatic obstruction is commonly associated with jaundice, especially when obstruction is complete. Elevation in canalicular enzymes is common, but is not present in all cases[269]; marked increases

(>3 × the upper reference limit) are more common with gallstones as a cause of obstruction.[469] Transient increases in aminotransferases are more common with choledocholithiasis than with other causes of extrahepatic obstruction.[212] Transient increases in CA 19-9 occur with bile duct obstruction[30]; this is an important consideration, because CA 19-9 is often used as a diagnostic test for pancreatic and bile duct carcinoma. A key feature of extrahepatic obstruction is dilation of more proximal and intrahepatic bile ducts, which is visualized by imaging studies.

Intrahepatic cholestasis caused by mechanical obstruction is also common, but is rarely associated with jaundice or with visibly dilated ducts on imaging studies, although it may be associated with increased direct bilirubin. Jaundice typically occurs only with lesions that are very large, or are located near the porta hepatis, where they may obstruct both hepatic ducts. Common causes of intrahepatic obstruction include (1) tumors (particularly metastases), (2) granulomatous diseases (such as sarcoidosis and tuberculosis), and (3) infiltrative processes (such as lymphoma, leukemia, and extramedullary hematopoiesis).

Primary Biliary Cirrhosis

PBC, or nonsuppurative destructive cholangitis, is an uncommon autoimmune disorder targeting intrahepatic bile ducts.[330] Its prevalence is approximately 2 to 8 per 100,000 population in the developed world, but it is much lower in developing areas. The median age at onset is 50 years, and the female-to-male ratio is about 6:1. An association with HLA class II antigen DR8 has been noted in some populations. A family history of PBC is seen in 1 to 4% of cases. In up to 80% of cases, the condition is associated with other autoimmune processes, most commonly Sjögren's syndrome and hypothyroidism (which often develops before onset of PBC).[91]

The pathogenesis of PBC is not well understood. However, it is known that destruction of the bile duct is mediated by T cells in the presence of upregulation of HLA class I antigens on hepatocytes and HLA class II antigens on biliary epithelial cells.[159] Although the target antigens of the T cells have not been identified, at least 95% of patients have antimitochondrial antibodies that react against the dihydrolipoamide acyltransferase component of the pyruvate decarboxylase complex.[463] Part of this complex is found on the apical surface of biliary epithelial cells, suggesting a role for this antigen as an immune target.[319] In individuals with coexisting Sjögren's syndrome, the antigen is also expressed on the surface of salivary gland cells.[457]

PBC typically presents as an asymptomatic elevation of ALP, but may present with features of cholestasis or with fatigue.[290] Metabolic bone disease and xanthomas are common complications of PBC.[259] Occasionally, autoantibodies are detected (usually because of the presence of another autoimmune disease or because of a family history of PBC) before elevation of ALP.[306] Aminotransferase activities are increased in 50% of cases, but are more than twice the upper reference limit in only 20% of cases.[264] Increased bilirubin is a late finding and is important in predicting decompensation.[236] Antibodies to mitochondria or to the recombinant pyruvate decarboxylase complex appear similar in sensitivity, although the latter are more specific.[464] A liver biopsy is not required for diagnosis in most cases, but may be helpful in those with low titer antibodies or with a greater than twofold increase in aminotransferase activity.

The natural history of PBC is one of slow progression to portal hypertension, often without development of cirrhosis; average time from diagnosis to death in untreated patients is 22 years.[290] Development of jaundice is the most important indicator of advanced disease and serves as the most important prognostic test.[259] Medical management of PBC consists of ursodeoxycholic acid therapy; most evidence suggests that survival is improved in treated patients.[259] Although a rare complication, the relative risk of developing HCC is significantly increased in individuals with PBC.[337] Liver transplantation is the only definitive treatment, but even when it is performed, PBC may recur in the transplanted organ.[139]

Primary Sclerosing Cholangitis

PSC is a chronic inflammatory disease of the biliary tree, most commonly affecting extrahepatic bile ducts; involvement of intrahepatic ducts, with extrahepatic involvement or as an isolated finding, is also possible.[170,421] In contrast to PBC, PSC has a male predominance (60 to 70%) and a younger median age at onset (30 years). In 70 to 90% of patients, PSC is associated with ulcerative colitis, which usually (but not always) precedes onset of PSC; conversely, only about 2 to 4% of patients with ulcerative colitis develop PSC.[170] This has led to speculation that bacterial antigens in portal blood might be involved in the pathogenesis of PSC.[17] An autoimmune component is likely, as 97% of patients with PSC have one or more autoantibodies present in their plasma.[199] The prevalence of PSC is similar to that of PBC, but geographic differences in prevalence have been observed; it is most common in Northern Europe, where PSC is the most common indication for liver transplantation.[400] A markedly increased prevalence of HLA antigens B8 and DR3 has been noted.[480]

The clinical presentation of PSC, similar to that of PBC, is typically an asymptomatic patient with elevated ALP activities found during routine laboratory screening. Symptoms are ultimately present in most patients with PSC; the most common are pruritus and intermittent abdominal pain, but fever may also be present.[421] Treatment, whether medical or surgical, may improve laboratory tests and symptoms, but does not improve long-term survival.[250,298] Transplantation, the major treatment available for end-stage PSC, has a high rate of long-term survival. Although PSC recurs after transplantation in about 20 to 35% of cases, it does not appear to affect survival.[245] Transplantation also appears to increase the severity of underlying ulcerative colitis, when present.[124] The major cause of death in individuals with PSC is cholangiocarcinoma, which ultimately develops in up to 40% of patients.[170,421] Transplantation in the presence of cholangiocarcinoma is associated with rapid development of metastatic disease and poor survival.[3] PSC also increases the likelihood of colon carcinoma in individuals with coexisting

ulcerative colitis, although the risk is not affected by liver transplantation.[482]

At the time of diagnosis, most patients with PSC have elevated ALP activities and other canalicular enzymes; bilirubin concentration is typically normal, although it may increase with acute exacerbations. The diagnosis of PSC is based on the typical radiographic appearance of beading and irregularity of the bile ducts. Antineutrophil cytoplasmic antibodies (ANCAs) are present in approximately 80% of patients[321] but are not specific for PSC; they are also present in PBC and autoimmune hepatitis. Typically, the antibodies have an atypical perinuclear pattern, being located near the nucleus in formalin- and methanol-fixed preparations. Antigens include lactoferrin, bactericidal/permeability increasing protein, and cathepsin G.[199]

Drug-Induced Cholestasis

Drugs are a common cause of cholestasis, causing about 15% of cases.[505,506] Drug reactions are especially common in older individuals, among whom up to 50% of individuals have increased enzymes because of medications.[505] Nonmedicinal drugs are also increasingly recognized as a cause of cholestasis.[314] Drugs can cause a cholestatic picture by two major mechanisms.[503] In some cases, only conjugated bilirubin is increased, whereas canalicular enzymes are not elevated. This picture, often seen with estrogen and anabolic steroids, appears due to inhibition of production of MRP2,[453] as discussed earlier in other cholestatic disorders. More commonly, drugs induce a cholestatic hepatitis, as discussed earlier.

Gallstones

Gallstones are solid formations in the gallbladder that are composed of cholesterol and bile salts. Although they vary in chemical composition, they generally contain a mixture of cholesterol, bilirubin, calcium, and mucoproteins. In the United States, 70 to 85% of all gallstones are predominantly cholesterol, and more than 10% of the adult population is affected.

Three major types of gallstones are (1) cholesterol gallstones, (2) pigmented gallstones, and, most common, (3) mixed gallstones. These stones form whenever bile is supersaturated with cholesterol or unconjugated bilirubin. Most gallstones are mixed cholesterol and pigment stones. For these stones or cholesterol gallstones to form, bile must be supersaturated with cholesterol. Whenever an increase in cholesterol or a decrease in bile acids or lecithin occurs, bile becomes lithogenic (prone to stone formation), and cholesterol may precipitate. Factors that predispose to cholesterol hypersecretion are (1) obesity, (2) aging, (3) certain drugs such as clofibrate and nicotine, and (4) certain hormones such as estrogen. Factors that decrease bile acid secretion are terminal ileal disease and cholestatic diseases, such as PBC, PSC, and cystic fibrosis. Genetic factors also appear to be involved. Within racial groups, women are more frequently affected than men. Diet may play a role because it appears that people who ingest diets high in polyunsaturated fats have a higher incidence, whereas those with a diet high in fiber have a decreased incidence.

Pigmented gallstones are associated with conditions in which the bilirubin concentration is increased, such as hemolytic anemia, or bilirubin becomes insoluble (i.e., deconjugated), such as occurs in cholestasis or chronic biliary infection.

Rare Causes of Cholestasis

Several other disorders are associated with cholestasis. Because they occur in specific settings, they are often suggested by the clinical picture. Laboratory tests are of little help in establishing the correct diagnosis.

Cholestasis may develop following bone marrow transplantation because of a variety of factors. Acute graft-versus-host disease (GVHD) is a consequence of the infusion of allogeneic immunocompetent T-lymphoid cells into an immunocompromised host that cannot reject these cells.[427] Periductular epithelial cells are the primary targets of injury in both acute and chronic GVHD.[36] Clinical features of GVHD include skin rash, intestinal symptoms (nausea, vomiting, diarrhea, and abdominal pain), and cholestasis. The histologic appearance is characteristic, but a liver biopsy is somewhat hazardous in these patients; thus most cases are diagnosed on clinical grounds.

Although acute liver transplant rejection is associated with necroinflammatory changes and increased aminotransferases, chronic rejection is often associated with cholestasis. The primary targets of immunologic injury are bile ductules and blood vessels.[109] Because of cholestasis, plasma bile acids are often increased early in the process of rejection. Increased numbers of canalicular membranes are often the first evidence of rejection.[109] Although eosinophilia is common in rejection,[324] it is also a common finding in drug-induced cholestasis and thus is not helpful in the differential diagnosis.

AIDS cholangiopathies are caused by organisms not previously known to infect the biliary tree; they have become less common with reduction in the frequency of immunosuppression because of combination antiretroviral treatment. *Cryptosporidium* is the most common organism. *Microsporidium,* cytomegalovirus, *Mycobacterium avium* complex, and *Cyclospora* have also been identified. The clinical presentation usually includes abdominal pain, diarrhea, and cholestasis manifested by threefold to tenfold elevations in plasma ALP, mild elevations in aminotransferases, and rarely jaundice. Papillary stenosis at the ampulla of Vater is present in patients with pain, and the bile ducts have features of PSC. Cholangiography is needed for the diagnosis but is indicated only in patients with pain. Brushings and biopsies at the time of cholangiography will establish the diagnosis. Treatment is primarily endoscopic. Sphincterotomy will give pain relief in approximately 70% of patients.

Hepatic Tumors

The liver is host to a wide variety of benign and malignant primary tumors. It is the second most common site of metastases; metastatic tumors account for 90 to 95% of all hepatic

TABLE 50-11 Classification of Hepatic Tumors

Type	Benign	Malignant
Epithelial	Adenoma Bile duct adenoma Cystadenoma Carcinoid Focal nodular hyperplasia Diffuse nodular hyperplasia	Hepatocellular carcinoma Cholangiocarcinoma Cystadenocarcinoma Squamous carcinoma
Mesenchymal tumors	Cavernous hemangioma Fibroma Leiomyoma Hematoma	Hemangiosarcoma Fibrosarcoma Leiomyosarcoma Hepatoblastoma
Metastatic tumors (most common sources)	Colon Pancreas Stomach Breast Lung Unknown primary	

malignancies. Primary tumors may arise from many cell lines in the liver, but they arise most commonly from parenchymal and biliary epithelial cells and mesenchymal cells (Table 50-11). The two most important primary liver tumors are HCC and cholangiocarcinoma.

Hepatocellular Carcinoma

HCC is the fifth most common cancer worldwide and a leading cause of cancer death; more than 500,000 cases occur annually, with a similar number of deaths.[204] Wide geographic and ethnic variations are noted in the incidence, suggesting that both host and environmental factors are involved in its origin. For example, approximately 75% of HCC cases occur in Asia, with an annual incidence of HCC in China of approximately 30 cases per 100,000 males. Worldwide, the incidence is twofold to threefold higher among men than among women. The incidence of HCC has been increasing in the United States[12,127] and much of Europe because of the increasing frequency of cirrhosis caused by HCV; however, incidence has declined in many parts of the world, owing to success in prevention of infection by HBV.[68,247] Although cirrhosis is present in most patients with HCC, it is absent in about 25 to 30% of cases, often in association with HBV.[47,498] More important, the presence of cirrhosis had been recognized before diagnosis of HCC in only about one third of cases.[495,498] Wide variations in the incidence of HCC are associated with different causes of cirrhosis. For example, HCC occurs commonly in cirrhosis caused by alcohol abuse, hemochromatosis, AAT deficiency, HBV, and HCV, but is rare in that caused by autoimmune hepatitis and Wilson's disease.

In most parts of the world, the major risk factors for development of HCC are infection with HBV or HCV. In Asia, Africa, and Alaska, the major risk factor is HBV infection. The presence of HBsAg and HBeAg is associated with a relative risk of HCC of 60, whereas the presence of HBsAg with negative HBeAg is associated with a relative risk of 10.[489] This is probably due to the lower viral loads in HBeAg-negative chronic HBV; in all forms of chronic HBV, risk of HCC is directly related to viral load.[71] Once cirrhosis has developed, the rate of development of HCC is about 1.5 to 5% per year in both HBV and HCV[137,138]; the relative risk of HCC doubles in those coinfected with these viruses.[135] The risk of HCC is higher in those with cirrhosis who have elevated aminotransferase activities than in those with normal ALT activity.[187,394] The mechanism of increased risk in HBV is thought to be related to integration of HBV DNA into the host genome, possibly caused by the action of the HBV X gene, which may block the activity of p53.[141,460] The mechanism of increased risk of HCC in HCV has not been identified, but may be related to ongoing injury.

Aflatoxin, a product of *Aspergillus flavus* contamination of grain, has been linked to risk of HCC; although it is harmless, it is metabolized to aflatoxin 8,9-epoxide. This reactive intermediate binds to guanosine bases in DNA, leading to mutagenesis. If the formed adduct is not repaired, G-to-T transversion occurs in codon 249 of the *TP53* gene *(p53),* causing an inactivating mutation.[374] Under normal circumstances, the mutagenic aflatoxin 8,9-epoxide is rendered harmless by glutathione-S-transferase, which converts it to a glutathione conjugate, which in turn is metabolized to 1,2-dihydrodiol by epoxide hydrolase.[261] However, both detoxifying enzymes are polymorphic in humans, and the mutant forms are less active. Patients with HCC are more likely to have the mutant forms of epoxide hydrolase and glutathione-S-transferase; this allows accumulation of the epoxide.[294]

The clinical presentation of HCC is variable and usually does not occur until late in the course of disease, when the tumor is large and resection is impossible. In some cases, acute decompensation occurs in a patient with cirrhosis, but clinical presentation may include detection of a right upper quadrant mass, shock due to hemorrhage into the peritoneal cavity, or right upper quadrant pain. Nonspecific signs and symptoms, such as fever, malaise, anorexia, and anemia, are common, and jaundice may occur with central tumors that obstruct biliary drainage. In a small number of cases, paraneoplastic features, such as hypoglycemia, hypercalcemia [due to parathyroid hormone–related peptide (PTHrP) production], or erythrocytosis (due to erythropoietin production), may be the initial presenting findings; such paraneoplastic findings occur in up to 20% of cases, usually in association with poor prognosis.[222,275] Laboratory findings include those of cirrhosis and cholestasis and (except for tumor markers discussed later) are nonspecific.

Because treatment usually is not possible in individuals with clinically diagnosed HCC, much interest has focused on screening high-risk individuals. Most professional societies have not advocated screening for HCC in Europe or North America, although the American Association for the Study of Liver Diseases (AASLD) has endorsed screening of high-risk patients every 6 to 12 months.[51] Although some data have suggested that screening is effective in detecting small, treatable tumors, other data have not been as supportive.

The most common screening programs have used plasma tumor marker concentrations or tumor markers plus imaging studies; the AASLD recommends imaging as the primary screening modality and recommends against using only tumor markers (although tumor markers were noted to be useful as an addition to imaging).[51] Ultrasound is typically used as the imaging modality for screening because of its low cost. The tumor marker most widely used for screening purposes is AFP; it is typically quantified using assays that measure its total concentration. Although it appears to be relatively sensitive,[283] elevation of AFP is common in individuals with chronic hepatitis and cirrhosis—the group at highest risk for HCC. In our experience, AFP above the upper reference limit has a positive predictive value of only 16% for HCC. Use of higher cutoff values than the upper reference limit improves clinical specificity of total AFP, at the expense of clinical sensitivity; for example, at a cutoff of 20 ng/mL, about three times the upper reference limit, sensitivity is only 60%.[51] As discussed in Chapter 24, modified forms of AFP are more specific for tumors, particularly the L3 isoform recognized by lens culinaris (lentil) lectin. The L3 isoform by itself has low sensitivity for HCC,[434] and in only a small number of cases, it is the only positive tumor marker. On the other hand, specificity and positive predictive value are significantly improved when the L3 isoform is combined with the AFP total.[434] An L3 isoform more than 15% of total AFP may be associated with more aggressive and less well-differentiated tumors.[60]

Des-γ-carboxy prothrombin (DCP)—also called PIVKA-2 (factor II protein induced by vitamin K antagonists)—is the inactive form of prothrombin found in individuals taking warfarin or other vitamin K antagonists. It was first found to be increased in HCC in 1984,[257] but was not widely used until the early 1990s. Initial studies found that DCP was increased in some patients who did not have elevated AFP, but was insensitive to small HCC that might be curable. DCP immunoassays with lowered detection limits have been developed and have shown increased sensitivity for small HCC, and DCP seems directly related to tumor size[123] and prognosis.[434] Pretreatment with vitamin K, to eliminate other causes of increased DCP, further improves specificity.[390] DCP is best used as an adjunct to AFP, because tumors often produce one or the other tumor marker.[25]

Treatment of HCC is dependent on the extent of the tumor. Small tumors are often treated by transplantation, which has a low rate of recurrent tumor. Local techniques, such as ethanol injection, chemoembolization, and use of radiofrequency ablation, are increasingly used before transplant or instead of transplantation. Larger tumors generally are not resectable, but may be treated by chemoembolization if a single feeding vessel is identified. A novel approach to identifying micrometastases has been described using rt-PCR to amplify mRNA for AFP to detect recurrence or metastasis.[485]

Tumors of the Gallbladder and Bile Ducts

Benign lesions such as papillomas or adenomas may be seen as an incidental finding at cholecystectomy; malignant disease of the gallbladder is uncommon. Cholelithiasis may be an etiologic factor, because 85% of gallbladder carcinomas occur in patients with gallstones. However, less than 1% of patients with gallstones develop carcinoma. It has been suggested that a calcified gallbladder is especially prone to malignant transformation. Various pathologic forms exist, including papillary adenocarcinoma, squamous cell carcinoma, and anaplastic tumors. These tumors usually arise in the neck of the gallbladder and spread rapidly, causing obstruction and cholestasis. Physical examination reveals a hard, tender mass in the gallbladder fossa. These lesions are particularly difficult to treat, and most cases are inoperable at the time of diagnosis.

Cholangiocarcinoma, or primary carcinoma of the bile ducts, can arise at any point in the biliary tree, including the small intrahepatic bile duct radicals. This lesion is typically associated with underlying liver disease, such as (1) PSC, (2) congenital cystic lesions, or (3) chronic infestation with *Clonorchis sinensis*. The clinical presentation is that of cholestasis, including jaundice, dark urine, tan-colored stool, and pruritus. This condition is differentiated from other cholestatic diseases by visualizing the biliary tree.

DIAGNOSTIC STRATEGY

Liver function tests are useful in detecting and diagnosing liver disease and dysfunction, as well as in evaluating severity, monitoring therapy, and assessing prognosis. They are also useful in directing further diagnostic work-up. The array of tests useful for these purposes (Table 50-12) includes measurement in plasma of total and direct bilirubin, protein, and albumin concentrations and the activity of enzymes such as the aminotransferases (AST and ALT), ALP, LD, and GGT. By using a combination of these tests, it is possible to categorize broad types of liver disease, which can then be more accurately diagnosed through disease-specific tests. An algorithm for this process is presented in Figure 50-13.

Plasma Enzymes

In practice, plasma aminotransferases and ALP are the most useful tests, because they allow differentiation of hepatocellular disease from cholestatic disease in most cases. The importance of this distinction cannot be overstated: failure to recognize cholestatic disease caused by extrahepatic biliary obstruction will result in liver failure if the obstruction is not quickly corrected. It is also important to recognize that there may be a gray zone of mixed hepatocellular and cholestatic

TABLE 50-12 Tests of Hepatic Function and Injury

Test	Utility
Bilirubin	Diagnosing jaundice, modest correlation with severity
Alkaline phosphatase (ALP)	Diagnosing disorders of metabolism and disorders of the newborn
Bilirubin fractionation	Diagnosing cholestasis and space-occupying lesions
Aspartate aminotransferase (AST)	Sensitive test of hepatocellular disease; AST > ALT in alcoholic disease
Alanine aminotransferase (ALT)	Sensitive and more specific test of hepatocellular disease
Albumin	Indicator of chronicity and severity
Prothrombin time (PT)	Indicator of severity of cholestasis

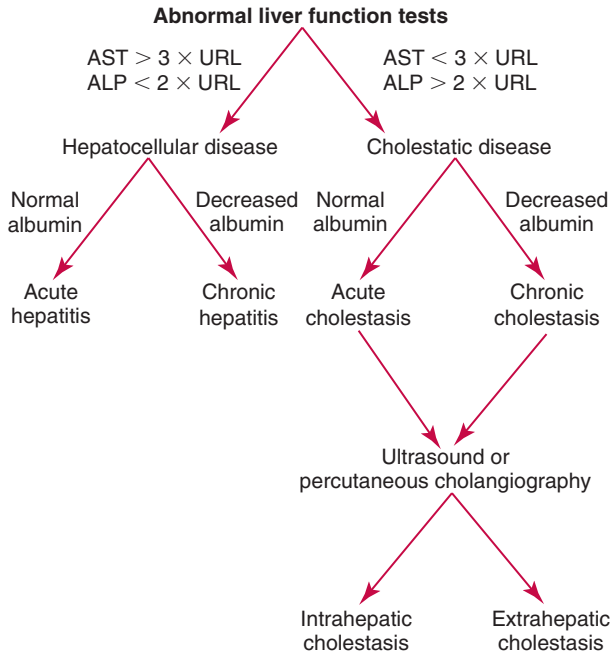

Figure 50-13 Algorithm for using abnormal liver function tests to classify and diagnose various types of liver disease. *ALP,* Alkaline phosphatase; *AST,* aspartate aminotransferase; *URL,* upper reference limit. Initial evaluation is best accomplished by examining the pattern of liver-associated enzymes. If elevation primarily affects one of the aminotransferases, then hepatocellular disease is likely; an increase primarily in ALP suggests a cholestatic disorder. If only ALP is elevated, then it is appropriate to consider nonhepatic sources before further investigation [using measurement of other canalicular enzymes such as γ-glutamyltransferase (GGT) or alkaline phosphatase isoenzymes]. If liver is the source of elevated ALP, then an imaging study to evaluate the ducts is the next test performed; dilated ducts establish a mechanical cause of obstruction, and normal ducts indicate intrahepatic cholestasis requiring further evaluation, as discussed in the text. Predominant increases in aminotransferases suggest hepatocellular injury; values greater than 10× URL usually indicate acute hepatitis, and lower values are typical of chronic hepatitis. If AST > ALT, common causes include very early hepatic injury, nonhepatic injury (such as muscle injury), and, with mildly increased values, cirrhosis.

disease wherein the tests do not distinguish one disease from the other. In this case, it is wise to assume that the problem is cholestatic and rule out biliary obstruction.

Patients are occasionally seen with isolated elevations in ALP or aminotransferase enzyme activities. In practice, an isolated increase in ALP activity is difficult to interpret. In children, *benign transient hyperphosphatasemia* should always be considered. In adults, it is necessary to first confirm that the ALP is of hepatobiliary origin. This can be done by isoenzyme fractionation (see Chapter 22) or by measurement of activity of another canalicular enzyme such as 5′ nucleotidase or GGT, which tends to parallel the activity of ALP in cholestasis. The most important aspect of the work-up is to rule out space-occupying lesions by visualizing the liver with computed tomography (CT), and biliary tract disease by visualizing the biliary tree with ultrasound or cholangiography.

Elevated plasma activities of AST and ALT are common in many disorders (see Chapter 21). To determine whether this elevation is liver related, administration of all drugs and alcohol intake (especially if AST is higher than ALT) should be discontinued. If the elevation persists, ultrasound (looking for nonalcoholic fatty liver) and hepatitis B and C serology should be performed. More than 50% of isolated enzyme elevations of liver origin will be caused by these disorders. A liver biopsy is often needed to allow a more specific diagnosis. No reliable test other than liver biopsy can be used to detect fibrosis.

Plasma Albumin

Plasma albumin measurements are useful in assessing the chronicity and severity of liver disease. For example, the plasma albumin concentration is decreased in advanced chronic liver disease. However, its utility for this purpose is somewhat limited, as the plasma albumin concentration is also decreased in severe acute liver disease and is lowered by many other disorders, and nonspecifically in acute illness. Serial measurements of plasma albumin can be used to assess the severity of liver disease.

Prothrombin Time

Serial PT measurements can be used to differentiate between cholestasis and severe hepatocellular disease. In practice, PT should be measured again after vitamin K injection, because cholestasis will cause a decrease in PT as the result

of malabsorption of vitamin K. The patient has cholestasis if the PT corrects after vitamin K replacement (10 mg subcutaneously or intramuscularly, followed by PT measurement 4 hours later). Over time, if the PT does not return to normal, the patient has severe hepatocellular disease.

Serum Bilirubin

Serial measurement of bilirubin is helpful in assessing the severity of liver damage in several types of liver disease (e.g., alcoholic hepatitis, cirrhosis). In acute hepatitis, bilirubin peaks later than enzymes do, and serum bilirubin remains elevated for longer than urine bilirubin because of the presence of biliprotein (δ-bilirubin). Increases in bilirubin in most liver diseases are primarily due to an increase in conjugated bilirubin, usually detected as direct reacting bilirubin. An increase in unconjugated bilirubin usually is not due to liver disease, although severe acute hepatitis and cirrhosis are often associated with elevations primarily of unconjugated bilirubin.

Patients are occasionally seen with isolated elevations in bilirubin concentration and normal quantitess of liver-associated enzymes. Increased unconjugated (indirect reacting) bilirubin in such situations is usually due to increased production of bilirubin (hemolysis, rhabdomyolysis, large hematomas) or to impaired conjugation (inherited decrease in activity of conjugation in Gilbert's syndrome or Crigler-Najjar syndrome, drug-induced inhibition of enzyme activity by atazanavir, immaturity of liver in physiologic jaundice of the newborn). Increases in conjugated (direct reacting) bilirubin are common in seriously ill individuals (bilirubinostasis of sepsis) and are less common with inherited defects in excretion of conjugated bilirubin (Dubin-Johnson syndrome, Rotor syndrome). An algorithm for differentiating the familial causes of hyperbilirubinemia is presented in Figure 50-14.

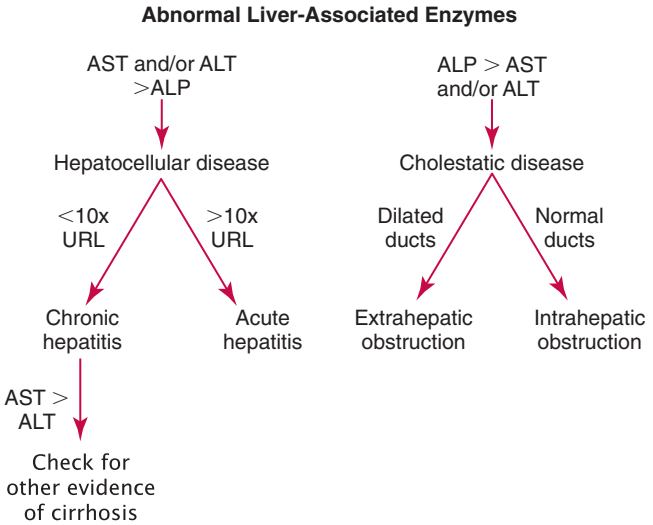

Figure 50-14 Algorithm for differentiating familial causes of hyperbilirubinemia.

CHAPTER 51

Gastric, Pancreatic, and Intestinal Function

*Peter G. Hill, B.Sc., Ph.D., F.R.C.Path., Dip.Hlth.Mgt.**

The stomach, intestinal tract, and pancreas are closely related, both anatomically and functionally, and symptoms, such as diarrhea or malabsorption, may be associated with diseases or disorders of any of these organs. It is therefore appropriate to discuss them together. Advances in imaging techniques and improvements in endoscopic procedures have led to enormous changes in the investigation of gastrointestinal (GI) and pancreatic function so that many laboratory tests, once considered important, have now been superseded.

In this chapter, the anatomy and physiology of the GI tract, and the normal processes of digestion and absorption, are briefly reviewed. Disorders of the stomach, pancreas, and intestine associated with malabsorption or diarrhea, in which the laboratory can play a role in diagnosis and monitoring, are discussed. The chapter concludes with an overview of GI regulatory peptides and neuroendocrine tumors in which GI symptoms are prominent, and with two sections that present more integrated approaches to the problems of investigating malabsorption and diarrhea.

INTRODUCTION TO ANATOMY AND PHYSIOLOGY OF THE GASTROINTESTINAL TRACT[176]

The major organs of the GI tract include the stomach, the small and large intestines, the pancreas, and the gallbladder, all of which are involved in the digestive processes that commence with the ingestion of food and water and culminate in the excretion of feces.

Anatomy

The GI tract is a tube, 8 meters in length, beginning with the mouth and ending with the anus. The esophagus, which is about 25 cm in length, is a muscular tube connecting the pharynx to the stomach. For this chapter, the key organs are the stomach, intestines, and pancreas.

Stomach[152]

The stomach consists of three major zones: the cardiac zone, the body, and the pyloric zone (Figure 51-1). The upper cardiac zone, which includes the fundus, contains mucus-secreting surface epithelial cells, which also secrete group II pepsinogens and several types of endocrine secreting cells. The body of the stomach contains cells or cell groups of many different types: (1) surface epithelial cells, which secrete mucus; (2) parietal (oxyntic) cells, which secrete hydrochloric acid and intrinsic factor; (3) the chief, zymogen, or peptic cells, which secrete group I and II pepsinogens; (4) enterochromaffin cells, which secrete serotonin; and (5) several types of endocrine secreting cells. The pyloric zone is subdivided into the antrum (which is approximately the distal third of the stomach), the pyloric canal, and the sphincter. The cells of the pyloric zone secrete mucus, group II pepsinogens, serotonin, gastrin, and several other hormones but no hydrochloric acid.

Small Intestine

In the stomach, food is converted into a semifluid, homogeneous, gruel-like material (chyme) that passes through the pyloric sphincter into the small intestine. The small intestine consists of three parts: the duodenum, jejunum, and ileum. In the adult human, the small intestine is approximately 6 m long and decreases in cross-section as it proceeds distally. The duodenum is about 25 cm long and is the shortest and widest part of the small intestine. The jejunum and ileum make up the remainder of the small intestine. There is no clear demarcation, but the ileum is the distal 3.5 m.

The wall of the small intestine consists of four layers: mucous, submucous, muscular, and serous. The internal surface of the upper small intestine contains valvelike circular folds (valvulae conniventes or plicae circulares) that project 3 to 10 mm into the lumen of the intestine. Covering the entire mucous surface of the small intestine are very small (1 mm) finger-like projections (villi), giving it a "velvety"

*The author gratefully acknowledges the original contributions of Drs. A. Ralph Henderson and Alan D. Rinker, upon which a portion of this chapter is based.

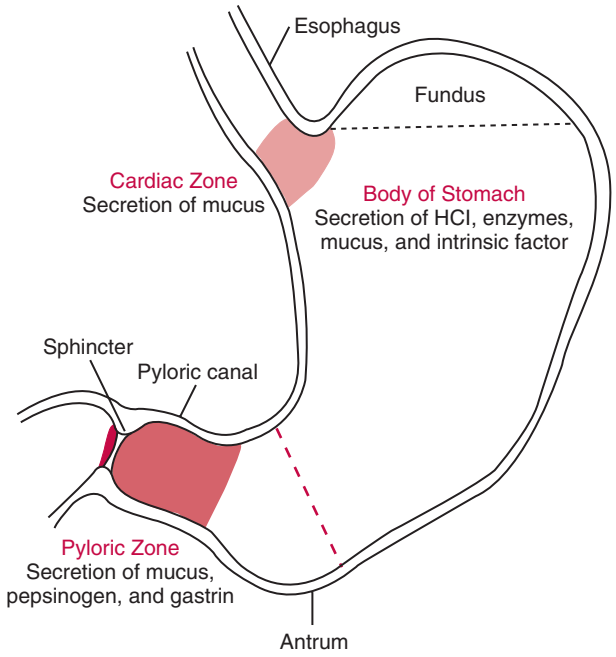

Figure 51-1 Schematic drawing of the stomach, with major zones.

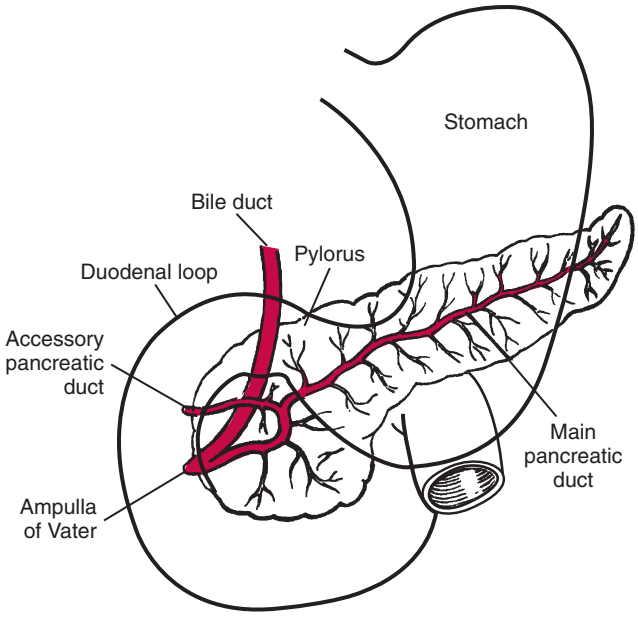

Figure 51-2 Cross-section through the pancreas.

appearance. The luminal surface (brush border) of each epithelial cell consists of some 1700 microvilli projecting about 1 μm from the cell. The folds, villi, and microvilli together present an absorptive surface some 600 times greater than would be inferred from the length and diameter of this portion of the gut. The absorptive surface area of the small intestine is estimated to be about 250 m^2,[73] which is comparable with the area of a doubles tennis court.

Large Intestine

The large intestine is about 1.5 m in length, extending from the ileum to the anus, and includes the cecum, appendix, colon, rectum, and anal canal. The cecum is a blind pouch that begins the large intestine; it is connected to the terminal ileum via the ileocecal sphincter. The appendix is a "worm-shaped" tube connected to the blind end of the cecum. The colon is about 1 m long and is divided into the ascending, transverse, descending, and sigmoid sections. The sigmoid colon connects to the rectum, which is approximately 15 cm long. The rectum in turn connects to the anal canal—the terminal end of the large intestine.

Pancreas

The pancreas is 12 to 15 cm in length and lies across the posterior wall of the abdominal cavity. The head is located in the duodenal curve; the body and tail are directed toward the left, extending to the spleen (Figure 51-2). Pancreatic digestive enzymes, in bicarbonate-rich juice, enter the duodenum through the ampulla of Vater and the sphincter of Oddi and mix with the food bolus as it passes through the small bowel.

Phases of Digestion

The process of digestion can be conveniently subdivided into neurogenic, gastric, and intestinal phases.

Neurogenic Phase

The neurogenic or cephalic phase is initiated by the intake of food into the mouth; the sight, smell, and taste of food stimulate the cerebral cortex and subsequently the vagal nuclei. The process is chemically mediated by acetylcholine from postganglionic parasympathetic nerve endings, which acts on gastric parietal cells. The vagus also stimulates gastric chief and parietal (oxyntic) cells to secrete pepsinogen and hydrochloric acid. [Cutting of the vagus nerve (vagotomy) decreases the volume and acidity of gastric secretion.]

The mechanism of acid secretion is still widely debated; there is, however, significant agreement that acetylcholine, histamine, and gastrin act through their respective neurocrine, paracrine, and endocrine pathways to stimulate the parietal cells, and that specific parietal cell receptors to these transmitters exist. Also, potentiating interactions between the mentioned secretagogues probably occur at the parietal cell itself. Histamine has a role as a mediator or a potentiator of the actions of other secretagogues. Administration of histamine markedly increases the secretion provoked by pentagastrin or by cholinergic agonists. Histamine H_2-receptor antagonists inhibit acid secretion provoked by most types of stimulation, confirming the important role of histamine in acid secretion.

The parietal cell undergoes marked changes when acid secretion is stimulated. The tubulovesicular membranes, prominent in the resting cell, diminish, whereas a marked increase in the apical plasma membrane (the secretory surface

of the cell) is noted, together with the appearance of long apical microvilli.

Cimetidine (Tagamet) and other H_2-receptor antagonists [such as ranitidine (Zantac) and famotidine (Pepcid)] block both the morphologic changes of the parietal cell and H^+ secretion. Proton pump inhibitors (PPIs) have a different mechanism of action. Omeprazole (a PPI) is taken up by the parietal cell and is converted to an active metabolite that inactivates the parietal H^+,K^+-ATPase. H^+ secretion is inhibited until new ATPase is synthesized, which takes at least 24 hours.

The secretion of H^+ against a million-fold concentration gradient requires energy from the cell, and this process is coupled to H^+,K^+-ATPase. Histamine-stimulated acid secretion involves cyclic adenosine monophosphate (cAMP); cholinergic stimulation is not associated with increases in intracellular cAMP in isolated parietal cells, and this process may be mediated by changes in permeability of the cell's plasma membrane to Ca^{2+}. The latter activates a chain of events that alter cell function in various ways. In addition to the previously mentioned mechanisms, vagal fibers to the pyloric glandular mucosa cause the release of gastrin, which also stimulates hydrochloric acid and pepsinogen secretion.

Agents that inhibit acid secretion include somatostatin, prostaglandins, gastric inhibitory polypeptide (GIP), secretin, glucagon, vasoactive intestinal polypeptide (VIP), neurotensin, calcitonin gene-related peptide, corticotropin-releasing factor, thyrotropin-releasing hormone, peptide YY, dopamine, and serotonin. Acid secretion is decreased in the presence of decreased quantities of circulating pituitary, adrenal, thyroid, and parathyroid hormones. Pituitary hormones are apparently essential for maintenance of the structural integrity of the gastric mucosa and are necessary for secretory function; human growth hormone may be necessary for growth of the gastric mucosa.

Gastric Phase

When food enters the stomach, the resulting distention initiates the gastric phase of digestion, mediated by local and vagal reflexes. Hydrochloric acid release is caused by (1) direct vagal stimulation of the parietal cells; (2) local distention of the antrum and vagal stimulation of antral cells to secrete gastrin, which causes hydrochloric acid release from parietal cells; and (3) release of gastrin, stimulated by the near neutralization (pH 5 to 7) of gastric hydrochloric acid by ingested food entering the pyloric zone. Gastrin also stimulates antral motility, secretion of pepsinogens and of pancreatic fluid rich in enzymes, and release of a number of GI hormones (secretin, insulin, acetylcholine, somatostatin, and pancreatic polypeptide; for further information on GI hormones, see the later section of this chapter, "GI Regulatory Peptides"). As a result of the acid environment, pepsinogen is rapidly converted to the active proteolytic enzyme, pepsin. Food is mixed by contractions of the stomach and is partially degraded into chyme by the chemical secretions of the stomach. The pylorus plays a role in emptying chyme into the duodenum by virtue of its strong musculature.

Intestinal Phase

The intestinal phase of digestion begins when the weakly acidic digestive products of proteins and lipids enter the duodenum. Many GI hormones and other regulatory peptides are released by both neural and local stimulation and act within the GI tract to regulate digestion and absorption. These are described in greater detail in the section, "GI Regulatory Peptides." Digestion, absorption, and storage functions are stimulated or inhibited by different hormones, creating an intricate hormonal control system that regulates the action of intestinal hormones and provides for secretion of bile acids, bicarbonate, and numerous enzymes involved in the digestion of food. In this system, the intestinal hormones secretin and VIP, for example, inhibit gastrin release and decrease the secretion of hydrochloric acid and pepsinogen; cholecystokinin (CCK; see discussion later in this chapter) binds to gastrin receptors and thus also decreases hydrochloric acid secretion. Somatostatin inhibits gastrin, secretin, CCK, and other hormones.

During the intestinal phase, carbohydrates, proteins, and fats are broken down and absorbed as described in the next section. Most nutrients, including vitamins and minerals, have been absorbed by the time the food passes from the jejunum and ileum into the large bowel. In the large intestine, water is actively absorbed, electrolyte balance is regulated, and bacterial actions take place. These processes result in the formation of feces.

PROCESSES OF DIGESTION AND ABSORPTION[52]

The total quantity of fluid absorbed each day by the gut is estimated to be about 9 L, which is composed of 2 L oral intake, 1.5 L saliva, 2.5 L gastric juice, 0.5 L bile, 1.5 L pancreatic juice, and 1 L intestinal secretions. More than 90% of this fluid is absorbed in the small intestine. The maximal absorptive capacity for fluid is probably at least 20 L. Several hundred grams of carbohydrates, about 100 g of fat, and 50 to 100 g of amino acids are absorbed daily in the small gut, but maximal absorptive capacity is believed to be at least 10 times greater. This considerable reserve capacity may compensate for mild to moderate degrees of dysfunction induced by disease processes, at least in the early phases. The efficiency of absorption is due to the unique features of the absorptive surface of the bowel and the relationship of the epithelial cells to the underlying rich vascular plexus and the lymphatic vessels.

Digestion of ingested food takes place both within the lumen of the small intestine and at the mucosal (brush border) surface. Defects of digestion may occur at one or more stages in the process. The terms *maldigestion* and *malabsorption* refer to different functional abnormalities. *Maldigestion* is a dysfunction of the digestive process that may occur at various sites in the GI tract. For example, hypoacidity in the stomach will reduce peptic digestion of protein; hyperacidity of the duodenum (e.g., due to overproduction of gastrin by tumor in the Zollinger-Ellison syndrome) can

inactivate pancreatic enzymes; loss of brush border enzymes in the small intestine, because of any of a variety of processes, can prevent oligosaccharides and disaccharides from being further hydrolyzed; pancreatic insufficiency will reduce intraluminal enzyme activity in the small gut, causing maldigestion of fats and proteins. By contrast, *malabsorption* is strictly a dysfunction of the absorptive process in the small gut due to loss of absorptive epithelial cells caused, for example, by gluten, inflammation, infection, surgical resection, and infiltration. Various transport defects also lead to malabsorption of specific substances (e.g., glucose-galactose malabsorption or zinc deficiency in the congenital disorder acrodermatitis enteropathica). In clinical practice, however, the term *malabsorption* is often used to encompass all aspects of impaired digestion and absorption. As Figure 51-3 shows, absorption of the different nutrients proceeds at different rates and at different sites within the small bowel.

In the following three sections, the digestion and absorption of fats, carbohydrates, and proteins will be discussed separately. It must be remembered, however, that a complex interplay takes place among nutrients, regulatory peptides, enzymes, gallbladder and pancreatic function, and bowel motility, leading to an integrated absorptive process that commences with the ingestion of food and culminates in the excretion of feces.

Digestion and Absorption of Carbohydrates

After the action of salivary and pancreatic α-amylases on dietary starch and glycogen, the carbohydrate content of the small intestine consists of newly formed maltose; ingested monosaccharides; dietary disaccharides, such as lactose, sucrose, maltose, and trehalose; oligosaccharides, such as dextrins and maltotriose; and indigestible oligosaccharides and polysaccharides, such as cellulose, agar, and other oligosaccharide dietary fibers.

The brush border enzymes with disaccharidase and oligosaccharidase activity are listed in Table 51-1. The sucrase-isomaltase complex comprises most of the sucrase, isomaltase, and maltase (80%) activity of the small intestine. It hydrolyzes sucrose to its constituent monosaccharides, cleaves glucose

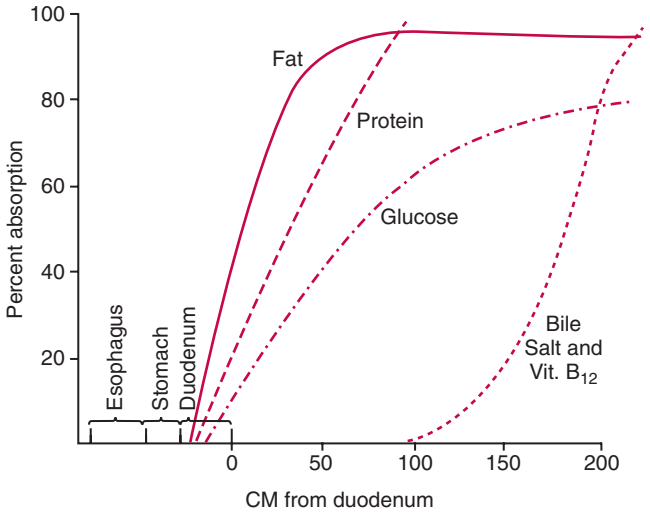

Figure 51-3 The location of small intestinal absorption. *(Modified from Morris JA, Selivanov V, Sheldon GF. Nutritional management of patients with malabsorption syndrome. Clin Gastroenterol 1983;12;463-74, based on Borgstrom B, et al. Studies of intestinal digestion and absorption in the human. J Clin Invest 1957;36:1521-36.)*

TABLE 51-1 Brush Border Oligosaccharidases

Enzyme or Complex	Principal Substrate(s)	Products
β-Glycosidase Complex		
Lactase (EC 3.2.1.23)	Lactose	Glucose + galactose
Glycosylceramidase (EC 3.2.1.45-46) [also called phlorizin hydrolase (EC 3.2.1.62)]	Galactosyl and glucosyl-β-ceramides	Galactose/glucose + ceramides
Sucrase-Isomaltase Complex		
Sucrase-(maltase) (EC 3.2.1.48)	Maltose/sucrose	Glucose/fructose + glucose
Isomaltase-(maltase) (EC 3.2.1.10)	1,6-α-linkages in isomaltose and α-dextrins	Glucose
	Maltose	Glucose
Trehalase (EC 3.2.1.28)	Trehalose	Glucose
Glucoamylase Complex (EC 3.2.1.20)		
Glucoamylase-(maltase)-1 and glucoamylase-(maltase)-2 (have similar substrate specificities)	1,4-α-linkages at nonreducing ends of amylose, amylopectin, glycogen, and straight chain 1,4-α-glucopyranosyl oligomers, including maltose	Glucose

From Semenza G, Auricchio S, Mantei N. Small-intestinal disaccharidases. In: Scriver CR, Beaudet AL, Sly WS, Valle D, eds. The metabolic and molecular bases of inherited disease, 8th edition. New York, NY: McGraw-Hill, 2001:1623-50.

from α-limit dextrins with 1,6 bonds, and hydrolyzes maltose. The activity of the complex is fourfold to fivefold greater in the jejunum than in the ileum. Changes in diet have a marked effect on the expression of the complex; starvation leads to a rapid decline in activity, which is rapidly restored on refeeding. All small intestinal saccharidases may decrease with infection or inflammation of the small bowel to the extent that carbohydrate malabsorption occurs, leading to diarrhea, flatulence, and weight loss. Paradoxically, diabetes mellitus causes a striking increase in sucrase-isomaltase activity; an increase is also observed in monosaccharide and amino acid transport. The lactase–phlorizin hydrolase complex is the only brush border enzyme able to hydrolyze lactose and therefore is essential for the survival of mammals early in life.

This complex also has glycosylceramidase, β-glycosidase, and phlorizin hydrolase activities. Infectious and inflammatory diseases greatly reduce lactase–phlorizin hydrolase activity, leading to symptomatic intolerance to milk. Recovery of enzyme activity following intestinal disease may be slow. The activity of the complex is resistant to starvation. The developmental regulation of lactase is discussed later in the section on disaccharidase deficiencies. Also present in the brush border is the α-glucosidase maltase-glucoamylase, which removes individual glucose molecules from the nonreducing end of α(1,4) oligosaccharides and disaccharides. This enzyme accounts for about 20% of the total maltase activity of the small intestine. Trehalase is also found in the brush border of the small intestine and hydrolyzes trehalose, an α(1,1) disaccharide of glucose found in yeast and mushrooms. The developmental pattern of trehalase appears to follow that of sucrase-isomaltase.

In addition to their actions on disaccharides, the brush border enzymes further hydrolyze the products of amylase action, including maltose, maltotriose, and α-limit dextrins. The brush border enzymes appear to act in an integrated manner in that a flow of substrate occurs from glucoamylase and isomaltase to sucrase producing the monosaccharides glucose, galactose, and fructose. These monosaccharides are transported into the enterocyte by facilitative transport systems, such as the Na^+-dependent glucose (and galactose) transporter (SGLT1) and GLUT5 (one of the GLUT family of monosaccharide transporters), which transports fructose across the apical membrane of the enterocyte. Subsequently, absorbed glucose and fructose are transported across the basolateral membrane and out of the enterocyte and into the portal system by the GLUT2 transporter.

It is increasingly being realized that the limiting factor in carbohydrate digestion and absorption may be diffusion from the intestinal lumen to the membrane surface where the enzymes are localized. Normally, little disaccharidase activity is seen in the luminal contents. For most oligosaccharides (with the exception of lactose), hydrolysis is rapid, and transport is the rate-limiting step in reducing the concentration of monosaccharides and the osmotic load in the gut. When the transport system is operating at its maximum rate but monosaccharide concentration is still high, inhibition of hydrolases by their monosaccharide products (i.e., product inhibition) slows hydrolytic activity, keeping monosaccharide concentrations relatively constant, thereby controlling osmotic load and water concentration in the gut. The importance of this control is evident from the consequences of intestinal disorders in which ingested disaccharide is not split and absorbed, leading to increased fluid secretion into the gut and increased intestinal motility. Enteric bacteria ferment the unabsorbed sugars, producing hydrogen, carbon dioxide, and organic acids causing abdominal discomfort such as bloating, distention and cramping. Absorption of fermentation products may lead to metabolic acidosis. In the large bowel, the presence of CO_2 and organic acids decreases pH and keeps the osmolality high, so that water reabsorption is decreased. The result is an acidic, liquid stool. Normally, however, accumulation of monosaccharide products does not occur, because the transport system is sufficiently fast to remove them. Mucosal lactase activity is the lowest of all the disaccharidases; for lactose, the rate-limiting step in absorption is thought to be hydrolysis. Lactase activity is not increased by feeding large amounts of lactose, as is the case for maltase and sucrase. Lactase, maltase, and sucrase all show circadian rhythms in their activities; minimum and maximum activities may vary by a factor of 2.

Carbohydrate digestion is not always complete in the small intestine. Indeed, it is likely that some starch and sucrose normally pass undigested and unabsorbed into the colon. It has been estimated that colonic bacteria require 70 g of carbohydrate/d. Much of this is derived from endogenous sources, such as from glycoproteins in GI secretions, with the remainder coming from unabsorbed dietary carbohydrate and dietary fiber. Up to 15% of the carbohydrate from white bread reaches the colon, and the effects of indigestible oligosaccharides upon reaching the large bowel are well known. As was pointed out earlier, bacterial action creates short chain fatty acids, which are rapidly absorbed by the colonic mucosa and are thought to provide fuel for the colonocyte. Starch and oligosaccharides are osmotically active and draw water into the gut. The colon, however, can absorb up to four times the normal colonic water load; for this reason, diarrhea is not always present in oligosaccharide malabsorption.

Digestion and Absorption of Lipids

The recommended daily dietary fat intake in Europe and North America is 70 to 95 g. Less than 5 g/24 h is recovered in the feces, indicating the overall efficiency of the normal processes of fat digestion and absorption. Most dietary fat is in the form of long chain triacylglycerols (triglycerides). Pancreatic lipase is quantitatively the most important hydrolytic enzyme, but the contribution of gastric lipase to overall hydrolysis should not be underestimated. Gastric lipase is secreted by the gastric mucosa and normally accounts for up to 17.5% of fatty acids released from triglycerides following a meal.[18] The enzyme has a wide pH optimum and is active in both the stomach and the duodenum. This nonpancreatic lipase may have a significant role in lipid digestion when pancreatic function is impaired and in the neonatal period before pancreatic lipase activity is fully developed. A lingual

lipase is also present, secreted by the tongue, but is thought not to be of much significance normally in humans. Fats first are emulsified in the stomach by its churning action and are stabilized by interaction with luminal lecithin and protein fragments. The lingual and gastric lipases do not require bile salts or cofactors to function; they have a pH optimum of 3 to 6, and their action produces 1,2-diacylglycerols and fatty acids. These products further stabilize the surface of the triglyceride emulsion and in the duodenum promote the binding of pancreatic colipase. In addition, the liberated fatty acids stimulate release of CCK from the duodenal mucosa.

Pancreatic lipase, in the presence of bile salts and colipase, acts at the oil-water interface of the triglyceride emulsion to produce fatty acids and 2-monoacylglycerols. Colipase is secreted in pancreatic juice as an inactive proenzyme, which is converted to the active form by trypsin. Other significant enzymes involved in the breakdown of fats within the intestinal lumen are cholesterol ester hydrolase, phospholipase A2, and a nonspecific bile salt–activated lipase.

Only a small proportion of ingested triacylglycerol is completely hydrolyzed to glycerol and fatty acids. These products form micelles with bile salts and lysophosphoglycerides; the micelles convey the nonpolar lipid molecules from the lumen to the epithelial cell surface and dissociate there to produce a high concentration of monoacylglycerols, lysophosphoglycerides, and fatty acids, which are absorbed into the mucosal cell. Absorption involves both passive and active transport processes and is facilitated by a fatty acid–binding protein in the cytosol of the cell that has a high affinity for fatty acids. Within the cell, triacylglycerols are resynthesized from the absorbed 2-monoacylglycerols and fatty acids. The triacylglycerols, together with phospholipids, cholesterol and its esters, fat-soluble vitamins, and a specific apolipoprotein, are formed into chylomicrons, which are then released by exocytosis into the lymphatic system of the small bowel. The absorption of long chain fatty acids is facilitated by transmembrane fatty acid transport proteins.

From the lymphatics, chylomicrons enter the bloodstream via the thoracic duct and are distributed to the liver, adipose tissue, and other organs. Medium and short chain fatty acids (chain length <12 carbon atoms) in mixed triglycerides are preferentially split by lipases and pass into the aqueous phase, from which they are rapidly absorbed. Medium chain triglycerides can be absorbed without complete lipolysis and in the absence of bile. They do not require micellar solubilization and are transported from the intestinal epithelial cells predominantly via the hepatic portal vein. Figure 51-4 summarizes the processes involved in fat absorption and conditions that compromise the efficiency of one or more stages in the process of fat digestion and absorption leading to fat malabsorption.[24]

Digestion and Absorption of Proteins

Average daily dietary intake of protein in North America is about 100 g compared with an estimated requirement for adults of 50 to 70 g. Another 50 to 60 g of protein enters the intestinal tract daily in GI secretions and from desquamated mucosal cells. Normal daily fecal loss of protein is about 10 g.

Protein digestion is initiated in the stomach by the action of pepsin in a highly acid medium. The acidity also denatures the protein, unfolding the polypeptide chains for better access by the gastric, pancreatic, and intestinal proteolytic enzymes. The polypeptides and amino acids produced in the stomach

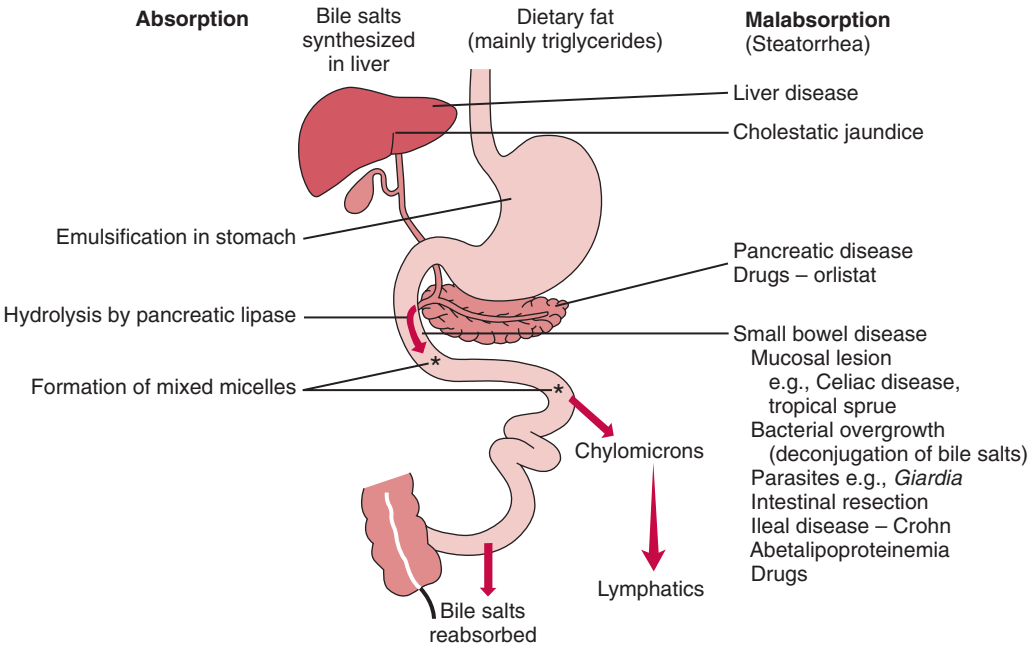

Figure 51-4 Summary of the processes involved in fat absorption and malabsorption.
(From Clark ML, Silk DB. Gastrointestinal disease. In: Kumar P, Clark M, eds. Clinical medicine, 6th edition. Edinburgh: WB Saunders, 2005:265-345.)

by the action of pepsin are potent secretagogues for hormones that stimulate the pancreas and intestine. Stimulated pancreatic secretion contains proenzyme forms of the proteolytic enzymes trypsin, chymotrypsin, elastase, exopeptidases, and carboxypeptidases. Proteolytic enzymes may be endopeptidases (e.g., pepsin, trypsin, chymotrypsin, elastase), which hydrolyze peptide bonds within the polypeptide chain, or exopeptidases, which hydrolyze peptide bonds of the terminal amino acids (enzymes such as carboxypeptidase and aminopeptidase). Stimulation of the intestine by GI hormones liberates several proteolytic enzymes from the brush border. One of them, enterokinase, selectively cleaves a hexapeptide from the *N*-terminus of trypsinogen to form trypsin. Trypsin then activates more trypsin (autocatalysis) and also converts other pancreatic proenzymes into their active forms. The action of the pancreatic enzymes on partially digested proteins within the lumen produces peptides that are 2 to 6 amino acid residues in length, as well as single amino acids. The peptides are largely hydrolyzed to single amino acids by the aminopeptidases and dipeptidases of the brush border before absorption, although some dipeptides and tripeptides are absorbed and are hydrolyzed to amino acids by cytosolic peptidases within the enterocytes. Multiple carrier systems with overlapping specificities for the 20 amino acids are involved in the transport of amino acids into the cells. Absorption of amino acids by these transport systems is faster in the jejunum than in the ileum. The amino acids pass across the enterocyte basolateral membrane by passive diffusion and by active transport systems, which are distinct from those at the brush border membrane. The underlying rich vascular plexus is drained by the portal circulation, and it is by this route that absorbed amino acids reach the liver and then the systemic circulation.

Individuals with achlorhydria or total gastrectomy have normal protein digestion and absorption because small intestinal function compensates for the lack of pepsin activity. Pancreatic and small intestinal diseases are the major causes of protein maldigestion and malabsorption. However, fecal loss of protein rarely becomes significant in pancreatic insufficiency until trypsin levels fall to about 10% of normal. Two rare disorders, trypsin deficiency and enterokinase deficiency, have far-reaching effects on the efficiency of protein digestion, as would be expected from their roles in the activation of proteolytic proenzymes. Mucosal diseases may affect protein assimilation through a number of mechanisms. Reduction in the number of mucosal cells decreases peptidase activity in the intestine and intestinal absorptive capacity for amino acids. Disease may increase the turnover of intestinal cells and the rate of desquamation. This cell loss, together with increased losses of plasma proteins from the damaged intestinal surface, can cause a negative nitrogen balance. Surgical resection of the intestine not only reduces the total intestinal absorptive surface but also may remove a segment of the gut that is specialized for absorption of certain nutrients (e.g., resection of the distal ileum removes the active transport system for the vitamin B_{12}–intrinsic factor complex). Resection may also alter intestinal motility, leading to stasis and bacterial overgrowth that can intensify a negative nitrogen balance. Also, rare hereditary defects in amino acid transporters (e.g., Hartnup's disease) may produce distinct syndromes.

STOMACH: DISEASES AND LABORATORY INVESTIGATIONS

Growth in endoscopic procedures, with direct visualization of the interior of the stomach, has largely removed the need for the clinical laboratory to carry out analysis of gastric contents. Situations remain, however, in which the laboratory continues to play a significant role in diagnosing gastric diseases and in monitoring the effectiveness of treatment. This section describes peptic ulcer disease, tests for *Helicobacter pylori (H. pylori),* and measurement of basal acid output from the stomach.

Peptic Ulcer Disease and *Helicobacter pylori*[64,123,158,180]

Although the presence of spiral-shaped organisms in the stomach has been acknowledged for many years, it was only in 1985 that the association was described between *H. pylori* (known then as *Campylobacter pylori*) and peptic ulcer disease.[125] Most estimates suggest that the bacterium is present in the mucous layer of the stomach in half the population of the world. In Europe, 30 to 50% of adults, and in the United States, at least 20% of the adult population, are infected with the organism. In all cases, colonization with *H. pylori* causes a chronic inflammatory reaction in the gastric mucosa even when direct endoscopic observation of the mucosa appears normal. Carriers of the organism are at increased risk for gastric cancer (twofold to tenfold) and peptic ulcer (threefold to tenfold).[12] Some of this increased risk is due to infection with strains of the organism that produce the cytotoxic CagA protein. About 90% of gastric cancer patients are infected with *H. pylori,* compared with 40 to 60% of age-matched controls.[141,142] In a European study comparing the prevalence of *H. pylori* versus gastric cancer rates in 13 countries, a significant correlation was observed between infection rate and gastric cancer incidence and mortality.[175] It is, however, important to remember that although a large proportion of gastric cancer can be attributed to infection with *H. pylori,* only in a minority of infected subjects will the inflammatory reaction progress to gastric cancer. Gastric cancer rates in Western countries have declined in recent decades, but the incidence remains high in less developed countries.

At least 95% of patients with duodenal ulcer disease are infected with *H. pylori,* and eradication of the organism leads to healing of the ulcer and a reduction in relapse rates.[147] Eradication of *H. pylori* is now the recommended treatment for patients with duodenal or gastric ulcer who are *H. pylori*–positive. Effective combined antibiotic and acid suppression regimens (using PPIs) are available with eradication rates of up to 90% after first-line treatment.[64] However, increases in the prevalence of antibiotic resistance have led to the

development of alternative treatment regimes to maintain high eradication rates.[122A]

H. pylori infection predominantly affects the gastric mucosa, with the antrum usually the most densely colonized area. The reasons why a gastric mucosal infection predisposes to duodenal ulceration are complex and involve several pathways leading to increased acid production. Before there was an awareness of the role of *H. pylori* in the pathogenesis of peptic ulcer disease, vagotomy (surgical sectioning, or cutting, of the vagus nerve) was the mainstay of treatment as a means of reducing gastric acid output, thereby leading to an environment more conducive to healing of the ulcer.

Infection with the organism, with or without duodenal ulceration, leads to increases in both basal and meal-stimulated serum gastrin concentrations, principally due to an increase in gastrin-17.[134] Basal acid output is increased in *H. pylori*–positive subjects (Figure 51-5) and resolves completely after successful eradication of the organism. Hypergastrinemia is believed to be only one of the mechanisms leading to increased acid output. Studies using the neuropeptide gastrin-releasing peptide (GRP) suggest that impairment of inhibitory control mechanisms that regulate acid production may be responsible for the increased acid output associated with *H. pylori* infection.[49] In addition to stimulating G cells of the antrum to release gastrin, which leads to acid secretion by parietal cells, GRP activates neuroendocrine pathways that inhibit gastric acid secretion—an effect that is mediated via peptides (including cholecystokinin and secretin) that stimulate release of the inhibitory peptide somatostatin from the gastric mucosa.

H. pylori produces urease, and hydrolysis of endogenous urea to bicarbonate and ammonia may create a more hospitable microenvironment for survival of the organism in the stomach. Mammalian cells do not hydrolyze urea, and it was only in 1984 that "gastric urease" was associated with the presence of *H. pylori*.[110] The ability of the organism to rapidly hydrolyze urea is the basis of urea breath tests and of direct urease tests on gastric biopsy samples.

Diagnostic Tests for *H. pylori*

Numerous invasive and noninvasive diagnostic tests for *H. pylori* have been described (Box 51-1), and many have been reviewed.[68]

All tests in the "invasive" group necessitate oral gastroduodenoscopy with biopsy of the gastric mucosa; false-negative results may occur as the result of sampling errors, as colonization may be patchy. The antrum is the preferred biopsy site, but multiple biopsies from the anterior and posterior walls of the antrum and the body of the stomach are recommended for maximum diagnostic accuracy of this group of tests. False negatives may also occur when biopsy specimens are taken during treatment with PPIs or within 2 weeks of stopping PPI therapy. These drugs alter the intragastric distribution of *H. pylori* and suppress its activity.[118] During PPI therapy, biopsies

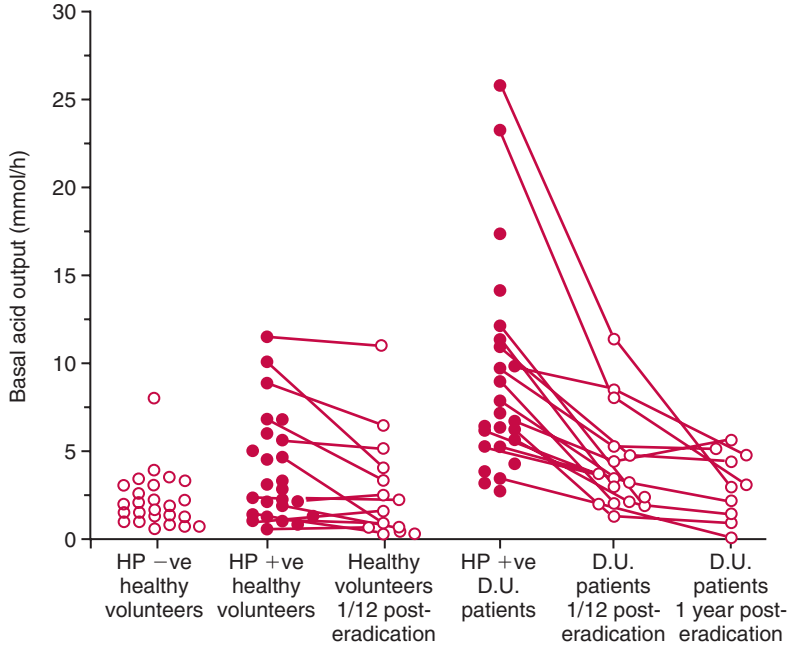

Figure 51-5 Basal acid output in healthy volunteers and patients with duodenal ulcers (DUs) of varying *Helicobacter pylori* status (•, *H. pylori* positive). Compared with *H. pylori*–negative healthy volunteers, basal acid output is increased in *H. pylori*–positive healthy volunteers ($P < 0.05$), *H. pylori*–positive patients with DU ($P < 0.0001$), and patients with DU 1 month after eradication ($P < 0.01$). *(From El-Omar EM, Penman ID, Ardill JES, Chittajallu RS, Howie C, McColl KE.* **H. pylori** *infection and abnormalities of acid secretion in patients with duodenal ulcer disease. Gastroenterology 1995;109:681-91, with permission from the American Gastroenterological Association.)*

BOX 51-1 Diagnostic Tests for *Helicobacter pylori*

Invasive Tests—Using Gastric Mucosal Biopsy Samples
Histology: microscopy after Giemsa or silver staining
Histology: microscopy after immunohistochemical staining
Direct urease test: biopsy incubated in urea/indicator solution; visual end point
Culture: incubation on suitable media for 4 to 10 days
Polymerase chain reaction: amplification of specific DNA sequences

Noninvasive Tests—Using Breath, Blood, Saliva, or Feces
Breath tests: rise in breath $^{14}CO_2$ or $^{13}CO_2$ after ingestion of ^{14}C- or ^{13}C-labeled urea
Serum tests: laboratory measurement of specific immunoglobulin (Ig)G antibody
Whole blood tests: point-of-care tests for specific IgG antibody
Saliva tests: detection of specific IgG antibody
Fecal tests: detection of specific antigen

should be taken from the body and fundus to prevent false negatives. PPIs can also lead to falsely negative urea breath test results. If PPIs cannot be withheld for at least 2 weeks before a breath test, a negative result must be interpreted with caution. Histamine H_2-receptor antagonists should be stopped at least 24 hours before a breath test. Antacids do not affect the test results.

Tests for *H. pylori* are required for the diagnosis of infection and to ascertain, in some situations, whether eradication therapy has been successful. High sensitivity is required to ensure that positives are not missed; similarly, high specificity is essential to prevent inappropriate use of eradication therapy. The Maastricht III Consensus Guidelines[123] recommend a "test and treat" strategy in adults with appropriate dyspeptic symptoms younger than 45 years using a breath test or a stool antigen test. The age limit may vary depending on local prevalence and the age distribution of gastric cancer (e.g., in the United Kingdom, testing and treatment are now an option in any patients with uncomplicated dyspepsia, although for those aged 55 years and older with unexplained and persistent recent-onset dyspepsia alone, referral should be made for urgent endoscopy).[139] Successful eradication of *H. pylori* should be confirmed with the urea breath test or by a monoclonal antibody-based stool antigen test if urea breath tests are not available. Other national guidelines confirm the urea breath test as the preferred procedure, both for initial diagnosis and for confirmation of eradication.[22A,86,139] Testing to confirm eradication should be done at least 4 weeks after completion of the course of treatment.

Urea breath tests are simple to perform, and both sensitivity and specificity are greater than 95%. Urea labeled with ^{14}C or ^{13}C is given orally as a drink or a capsule to be swallowed with water; urease from gastric *H. pylori* rapidly hydrolyzes the ingested urea to produce labeled bicarbonate, which is absorbed into the blood and exhaled as $^{14}CO_2$ or $^{13}CO_2$. The principal advantages of the ^{13}C-urea breath test over the ^{14}C-urea breath test are the simplicity of breath collection and the avoidance of regulations and environmental issues related to the use and disposal of radioisotopes. In the ^{14}C-urea breath test, CO_2 in expired air is trapped in methanolic hyamine hydroxide as the patient exhales through a straw, which should be fitted with a one-way valve to ensure that the patient does not suck the trapping solution into the mouth. A color change of an indicator (thymol blue) in the solution shows that the required quantity of CO_2 has been trapped. Scintillant is then added and $^{14}CO_2$ measured. In the ^{13}C-urea breath test, the patient blows through a straw into an empty 15 mL tube, which is then capped. $^{13}CO_2/^{12}CO_2$ ratios are compared for basal and postdose samples using isotope ratio mass spectrometry or alternative infrared measurement methods.[106,117]

In the stool test, specific *H. pylori* antigens are detected in microtiter plates coated with polyclonal or monoclonal antibodies. Sensitivity and specificity are lower than for the ^{13}C-urea breath test. Monoclonal antibody tests are recommended for posteradication testing if the urea breath test is not available.[123]

Although still widely available, serologic tests are recommended only in specific situations (e.g., when PPI therapy cannot be withheld, when a patient with a bleeding ulcer is investigated).[123] The systemic antibody response is variable, leading to equivocal results in some subjects; in subjects older than 50 years, diagnostic accuracy is unsatisfactory. Serology cannot be used to confirm eradication because of the slow decline in antibody levels after treatment. Laboratory-based enzyme-linked immunosorbent assays (ELISAs) and point-of-care tests are available to measure specific immunoglobulin (Ig)G antibodies in serum or whole blood samples. In younger subjects, laboratory-based tests generally perform well, although some have sensitivity and/or specificity less than 95%. Office-based serology testing has inadequate sensitivity and specificity and currently is not recommended.[123] Calculations based on reported diagnostic accuracy data show that when these tests are used for diagnosis, as many as 28% of those receiving eradication therapy are being treated as a result of false-positive test results.[23]

Determination of Basal Acid Output[35,91]

Documentation of increased basal acid output (BAO) in gastric juice provides strong evidence that a high serum gastrin concentration is caused by Zollinger-Ellison syndrome. Therefore, this test is used in patients with duodenal ulceration and a raised serum gastrin concentration. The test is not appropriate in patients with atrophic gastritis. Pernicious anemia, which also causes hypergastrinemia, should be excluded before BAO is assessed. PPIs must be stopped for at least 14 days, and H_2-receptor antagonists for at least 3 days, before the test. *H. pylori* as a cause of increased serum gastrin should be excluded before BAO is estimated.

A basal condition, in the context of gastric analysis, is one in which the patient is at complete rest and is not exposed to any visual, auditory, or olfactory stimuli. Such a condition is maintained during sleep. It is for this reason that a 12 hour

overnight collection of gastric juice has been used traditionally for the determination of BAO. Such an approach has the disadvantage that the patient is exposed to significant discomfort because of the need to retain the tube overnight, while sitting upright and slightly turned to the left to prevent loss of gastric contents into the duodenum. Close supervision throughout the entire night is necessary. A satisfactory alternative is the collection of gastric juice for 60 minutes after the patient has had a restful night's sleep in a quiet separate room. After waking, the patient must remain fasting; smoking and exercise must be avoided before and during the test.

Collection of Gastric Juice

A gastric tube is inserted orally, or nasal intubation may be used if the patient has a hyperactive gag reflex. X-ray or fluoroscopic confirmation that the tip of the radiopaque tube is in the lowest portion of the stomach is necessary. Ten or 15 minutes after the patient has become calm and adjusted to the presence of the tube, the patient is positioned with the trunk upright and inclined slightly to the left. Gastric juice is then aspirated and discarded. After checking that no further juice can be aspirated, note the time, and collect and transfer to plastic bottles all gastric juice that can be aspirated over the next 60 minutes. The patient must be asked to expectorate all saliva during the collection period. The total volume of collected juice is recorded and free acid determined by titration as described in the following section.

Determination of Free Hydrochloric Acid in Gastric Juice

1. Measure and transfer a convenient volume of gastric juice (e.g., 5.0 to 10.0 mL) into a clean titration vessel. If the gastric juice contains food particles or mucus, centrifuge the sample or filter it through gauze.
2. Determine the pH of the gastric specimen with a pH meter. If the pH is above 3.5, no free acid is present. Such a specimen need not be titrated.
3. Titrate the sample with NaOH, 0.10 mol/L, to a pH of 3.5, using a pH meter.

Calculation:

$$\text{Free HCl (mmol/L)} = \frac{\text{mL of NaOH} \times 100}{\text{mL of gastric juice titrated}}$$

If 5 mL of gastric specimen is titrated, the calculation becomes as follows:

$$\text{Free HCl (mmol/L)} = \text{mL of NaOH} \times 20$$

$$\text{Free HCl (mmol/hr)} = \frac{\text{mL of NaOH} \times 20 \times \text{60 min volume of gastric juice in mL}}{1000}$$

Comments and Sources of Error

Titration to a pH of 3 to 3.5 detects essentially all free hydrochloric acid. (Because HCl is the only strongly ionized acid in gastric contents, this test is essentially a test for free HCl.) Titration beyond a pH of 3.5, as recommended by some, will overestimate the HCl concentration to varying degrees, depending on the composition of the gastric residue. On the other hand, titration to pH 3.5 may underestimate the amount of free H^+ secreted if some of these H^+ ions are bound to or have reacted with other constituents of gastric contents. Thus no fully satisfactory procedure is available to measure accurately the true total amount of free acid secreted by the gastric mucosa.

The effectiveness of gastric aspiration may be compromised by both the position of the patient and the position of the tube in the stomach (likened to the position of a straw above or below the fluid level in a glass), by the loss of gastric fluid into the pylorus, and by regurgitation of pyloric contents into the stomach. Some evidence suggests that the exact position of the tube in the stomach does not appear to alter the recovery of gastric juice, because the stomach is not rigid and its walls contract, thus shifting the stomach contents toward the tip of the tube.

Interpretation

Gastric juice pH: if the pH is greater than 2.5, then it is unlikely that the raised gastrin is caused by Zollinger-Ellison syndrome.

BAO: Normal: male 0 to 10.5 mmol/h; female: 0 to 5.6 mmol/h

Zollinger-Ellison syndrome: 15 to 100 mmol/h, or greater than 5 mmol/h if acid-reducing surgery was performed previously.

A level of free acid greater than 15 mmol/h should prompt suspicion of gastrinoma but is not diagnostic; a level greater than 25 mmol/h with high serum gastrin is virtually diagnostic of Zollinger-Ellison syndrome.

Further discussion of the Zollinger-Ellison syndrome can be found in the section of this chapter on neuroendocrine tumors.

INTESTINAL DISORDERS AND THEIR LABORATORY INVESTIGATION

This section includes discussions of celiac disease, disaccharidase deficiency, bacterial overgrowth, bile salt malabsorption, inflammatory bowel disease, and protein-losing enteropathy, and the main laboratory investigations associated with diagnosing or monitoring these disorders.

Celiac Disease (Celiac Sprue, Gluten-Sensitive Enteropathy)[53,54,124,162,181A]

Celiac disease is sometimes called nontropical sprue, celiac sprue, or gluten-sensitive enteropathy.

Pathophysiology of Celiac Disease

Celiac disease occurs in genetically predisposed subjects as a consequence of an inappropriate T cell–mediated immune response to ingestion of gluten from wheat and to similar proteins in barley and rye.

The role of genetic factors in celiac disease has been recognized for many years; a 70% concordance for celiac disease has been reported in identical twins, and typically 10% of

first-degree relatives of an affected individual will be found to have the disease. Only recently has the major genetic component been localized to the human leukocyte antigen (HLA) region of chromosome 6. Approximately 95% of subjects with celiac disease express a specific HLA heterodimer (HLA DQ2 α/β heterodimer). Most Caucasian populations have a high frequency (20 to 30%) of DQ2, but only a small minority will develop celiac disease.

The external trigger to the development of celiac disease in genetically susceptible individuals is found in gluten, which is the complex group of proteins present in wheat that form a sticky mass when dough is washed with water and the starch is removed. All proteins (and peptides) that are toxic to the small bowel mucosa in subjects with celiac disease contain large amounts of glutamine. The major toxic proteins of wheat are the gliadins, with homologous proteins (the hordeins and secalins) occurring in barley and rye, respectively. The gliadins are a large family of proteins accounting for about 50% of the wheat protein.

Recent evidence indicates that oats do not lead to an immune-mediated response nor to mucosal damage in subjects with celiac disease.[90] Addition of oats to the list of permitted cereals increases choices and would be welcomed by most subjects with celiac disease. However, if oats are to be introduced into the diet, they must be obtained from a reliable source to ensure no contamination from wheat, barley, or rye proteins at any stage in the process from harvesting to packaging.

The identification in 1997 of small bowel tissue transglutaminase (tTG)-2 as the autoantigen of celiac disease[36] was a major step forward in understanding the pathogenesis of this disorder. The tissue transglutaminases are a family of calcium-dependent cytoplasmic enzymes that are released from cells during wounding. Although their physiologic role is incompletely understood, they are able to catalyze the cross-linking of proteins, leading to stabilization of the wound area. Expression of the enzyme is increased during apoptosis and in active celiac disease. It selectively cross-links or deamidates protein-bound glutamine residues. Deamidation of gliadin peptides by the enzyme enhances their binding to HLA DQ2/DQ8 and increases recognition of these peptides by gut-derived T cells from subjects with celiac disease.[163] The pathogenesis of the disease is therefore believed to involve an interaction between tissue transglutaminase and gliadin peptides in genetically susceptible individuals.

The toxic cereal proteins lead to intestinal epithelial damage, releasing tissue transglutaminase. Cross-linking by the enzyme produces gliadin-gliadin or gliadin-enzyme complexes, unmasking new antigenic epitopes that bind to HLA DQ2 molecules on the antigen-presenting cells, producing an immune response by gut-derived T cells. The characteristic enteropathy is then induced by the release of interferon-γ and other proinflammatory cytokines, as outlined in Figure 51-6.

A 33-mer peptide of gluten appears to be the primary initiator of the inflammatory response.[156] It is resistant to breakdown by all gastric, pancreatic, and intestinal brush border membrane proteases, thus allowing it to reach the small intestine intact. After deamidation by tissue transglutaminase, it is a potent inducer of gut-derived human T-cell lines from patients with celiac disease. Homologs of the peptide are found in food grains that are toxic to patients with celiac disease, but are absent from nontoxic food grains. The peptide could be detoxified by exposure to a bacterial prolyl endopeptidase, suggesting a therapeutic strategy for celiac disease.[156]

Increased intestinal permeability in untreated celiac disease that is reversible on withdrawal of gluten from the diet has been recognized since the early 1980s.[74] Evidence suggests that this may be mediated by increased expression of zonulin,[56] a protein that opens small intestinal tight junctions, or by decreased expression of intercellular epithelial cell adhesion molecules, such as Z0-1, catenin, and cadherin.[144] The zonulin pathway is now thought to play a significant role in the entry of allergens into the cell and hence in the autoimmune response.[54A]

Clinical Considerations

Celiac disease is a common chronic disorder in Caucasian populations, with a prevalence of about 1%.[122,186] It also occurs in northern Indian and North African populations. It is rare among Chinese, Japanese, and African-Caribbean people. It was previously considered to be a rare disorder in North America, but recent serologic and histologic evidence shows that the disease has been underdiagnosed, and that its prevalence is comparable, as might be expected, with that found in Europe.[55,77]

A wide spectrum has been noted in the clinical presentation of celiac disease, with most diagnoses made in adult life. Classical celiac disease, presenting in infancy up to the age of 2 years, with failure to thrive, abdominal distention, and diarrhea, is now an uncommon presentation. The spectrum of presenting symptoms in adults has changed over the past 20 years, and frank malabsorption is now uncommon.[87,185] Most adults present now with nonspecific symptoms; mild iron deficiency is common. A strong association with other autoimmune disease, especially with type 1 diabetes mellitus and autoimmune thyroid disease, has been reported. In type 1 diabetes, the prevalence of celiac disease is about 5%, and serologic screening to detect these cases has been advocated.[84] The initial presentation may be seen by a wide range of clinical specialties, as shown in Table 51-2. To make the diagnosis, there must be a high index of suspicion, along with awareness of the wide range of nonspecific symptoms and easy availability of serologic tests to select those patients in whom endoscopy is indicated to confirm the diagnosis.

Tests for Celiac Disease

Serologic tests have played a significant role in raising awareness of the high prevalence of this disorder, and appropriately standardized tests have high clinical sensitivity and specificity for diagnosis and for monitoring compliance with a gluten-free diet during treatment after diagnosis.

Table 51-3 compares the sensitivity and specificity of the four IgA class antibodies commonly used. Both antireticulin

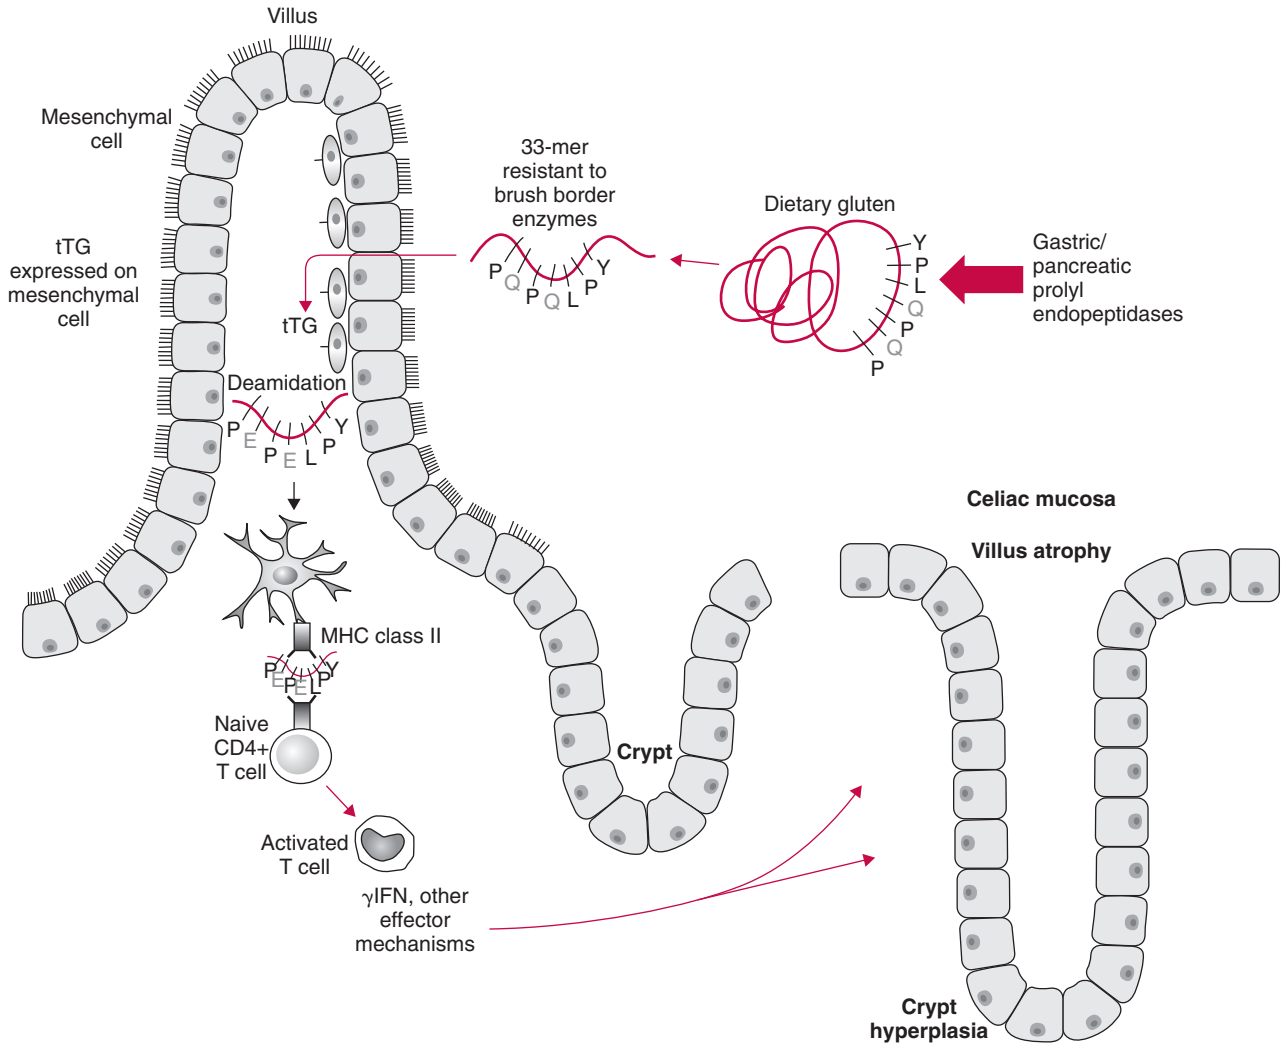

Figure 51-6 Hypothetical scheme for interaction between intestinal protein processing and the specific immune system in celiac disease. Dietary gluten is exposed to intraluminal digestive enzymes (including prolyl endopeptidases), producing stable 33-mer peptide-containing overlapping proline-rich epitopes with the PQPQLPY central motif. 33-mer peptide is absorbed intact by transcellular or paracellular routes into the lamina propria, and exposure to tTG results in deamidation of glutamine residues to glutamic acid. Modified peptide is presented to specific $CD4^+$ T cells in association with HLA DQ2 or DQ8. Activated IFN-γ–producing T-effector cells return to the mucosa and produce characteristic villous atrophy and crypt hyperplasia. *E,* Glutamate; *F,* phenylalanine; *IFN,* interferon; *L,* leucine; *P,* proline; *Q,* glutamine; *tTG,* tissue transglutaminase; and *Y,* tyrosine. *(From Mowat AM. Coeliac disease—a meeting point for genetics, immunology, and protein chemistry. Lancet 2003;361:1290-2.)*

(ARA) and endomysial (EMA) antibodies are measured by indirect immunofluorescence, ARA on rat kidney sections and EMA on monkey esophagus or human umbilical cord sections. The presence of ARA indicates the need to measure antibodies with higher specificity before small bowel histology is recommended for confirmation of the diagnosis. ARA and EMA are tissue type–dependent methods that detect autoantibodies to tissue transglutaminase-2.[107]

Lack of standardization of assays for IgA-antigliadin antibodies (AGA) contributes to the variable diagnostic accuracy of this marker,[81] but the sensitivity and specificity of AGA are poor, and use of this test should be abandoned. The sensitivity and specificity of current deamidated gliadin peptide antibody tests offer no advantages over tissue transglutaminase antibody (TGA) and may give significantly more false positives in subjects with liver disease.[80,136] The sensitivity of EMA in some reports is compromised by selection bias,[115] but most larger series in which patients have not been selected for a biopsy on the basis of positive serology indicate that the true sensitivity for EMA is between 90% and 95% (i.e., 5 to

10% of subjects with celiac disease have a negative EMA at diagnosis). When carried out correctly, the assay has very high specificity (>99%); laboratories should monitor their performance, as small reductions in specificity will lead to a significant increase in the numbers of patients subjected unnecessarily to a small bowel biopsy. Table 51-4 shows the effects of test specificity on the numbers of true and false positives per 1000 subjects tested, and on the positive predictive value at disease prevalence (in the population tested) of 3%, assuming a sensitivity of 95%.

Many commercial kits are now available to measure IgA antibodies against tissue transglutaminase ["transglutaminase antibody" (TGA)] using human recombinant tissue transglutaminase or purified human enzyme as antigen. Their role in the investigation of celiac disease has been reviewed.[80] Lack of standardization and differences in recombinant technology (e.g., the use of eukaryotic or prokaryotic organisms to produce tTG) can lead to variable performance.[11,126] Specificity should be evaluated using a large series of samples representative of those routinely tested, and procedures should be selected on the basis of high specificity (minimum 99%) and high sensitivity (>90%). The use of TGA has advantages over EMA. Unlike EMA, which may be subject to observer bias, TGA is a quantitative procedure that does not require the use of primate tissue. It can be automated and therefore is appropriate for larger numbers of samples. This test has replaced EMA as the antibody of choice for performing serologic testing and for assessing dietary compliance of subjects on a gluten-free diet.[14,79] As with all tests, not all kits perform to the same high standards, and laboratories should ensure that they participate in external quality assessment programs and select a well-validated method.[45,80] In view of the growing public interest in celiac disorder, further standardization of these kits is urgently needed.

For diagnosis, current guidelines require a jejunal biopsy with the characteristic villous atrophy, increased intraepithelial lymphocytes, and hyperplasia of the crypts.[124] Wider use of serology has led to the recognition of more cases with minimal histologic changes and to use of the terms *potential* and *latent* celiac disease.[83] Patients with positive EMA or TGA are described as having *potential celiac disease* when the jejunal biopsy has normal villi but shows subtle changes, such as increased numbers of intraepithelial lymphocytes. It is thought that in time these patients will develop a flat mucosa. The term *latent celiac disease* is used to describe patients who have at some time had positive antibodies and a flat mucosa that recovers on a gluten-free diet, but have also been found to have a normal mucosa while on a normal diet.

Subjects with selective IgA deficiency (IgA <0.05 g/L, incidence about 1:600) are at greater risk of celiac disease. It is therefore important to identify these individuals rather than risk excluding the diagnosis on the basis of a negative test for IgA class antibodies.[22] When EMA is used, total serum IgA should be measured on all samples submitted for celiac serology to identify those patients with IgA deficiency. A TGA method should be used that can distinguish those with a "normal" concentration from the small proportion of subjects with *very* low concentrations, in whom total IgA measurement is indicated to confirm or exclude IgA deficiency.[57] When IgA deficiency is identified, IgG antibodies (IgG-EMA, IgG-TGA, and IgG anti-deamidated gliadin peptide) should be used as serologic screening tests.[21] In view of the increased risk of the disorder in IgA deficiency, a small bowel biopsy should be considered in all IgA-deficient subjects with symptoms of celiac disease.[22]

Strict adherence to a gluten-free diet leads to mucosal recovery in celiac disease and reduces the risk of bowel

TABLE 51-2 An Indication of the Wide Range of Clinical Specialties to Which a Child or Adult With Celiac Disease May Present

Clinical Specialty	Symptoms/Manifestations
General medicine	Tired all the time
Gastroenterology	Diarrhea, flatulence, weight loss
Hematology	Anemia
Obstetrics/gynecology	Infertility
Orthopedics	Fracture, osteopenia
Dermatology	Dermatitis herpetiformis, hyperkeratosis
Neurology	Peripheral neuropathy
Rheumatology	Arthropathy
Endocrinology	Short stature, thyroid disease
Diabetes	Diarrhea, anemia

TABLE 51-3 Comparison of Serologic Tests for Celiac Disease

Antibody	Method	Sensitivity	Specificity
Antireticulin antibody (R1-ARA)	Immunofluorescence on rat or mouse kidney	25-30%	>90%
IgA-endomysial antibody	Immunofluorescence on monkey esophagus or human umbilical cord	80-100%	>99%
IgA-antigliadin antibody	Quantitative ELISA	75-95%	95%
IgA-antitissue transglutaminase antibody (human antigen)	Quantitative ELISA	>90%	>99%
IgA-deamidated gliadin peptide antibody	Quantitative ELISA	90%	90%

ELISA, Enzyme-linked immunosorbent assay; *Ig,* immunoglobulin.

TABLE 51-4 Comparison of True and False Positives and Positive Predictive Values at Different Specificities, Assuming a Prevalence of Celiac Disease of 3% in the Population (n = 1000) Tested (Test Sensitivity of 95%)

Specificity	True Positives	False Positives	Positive Predictive Value
90%	29	97	0.23
95%	29	49	0.38
98%	29	19	0.60
99%	29	10	0.74
99.5%	29	5	0.85

malignancy. TGA can be used as a marker for monitoring dietary compliance, in addition to its diagnostic role.[14] Failure of symptoms to respond to a prescribed gluten-free diet may indicate (1) nonadherence to the diet, (2) other coexisting conditions (such as small bowel bacterial overgrowth, lactose intolerance, and microscopic colitis), or (3) the presence of *refractory celiac disease*. Refractory celiac disease is characterized by persistent villous atrophy with an increase in intraepithelial lymphocytes in the small bowel while the patient is on a long-term gluten-free diet. In both responsive and refractory celiac disease, celiac antibodies typically are decreased with dietary therapy and remain within reference intervals unless individuals are re-exposed to gluten.

Two types of refractory celiac disease may occur and are differentiated by the types of T-cell populations found in the intestinal mucosa—polyclonal in type I disease and clonal in type II disease. Differentiation of the two types is accomplished by immunohistochemical, flow cytometric, or T-cell receptor γ gene rearrangement analysis of intestinal mucosal T cells.[129A] Type II celiac disease has an unfavorable prognosis and typically is viewed as a precursor to enteropathy-associated T-cell lymphoma (EATL).

With the availability now of serologic tests with high diagnostic accuracy, older tests used to investigate celiac disease should be abandoned. For example, there is no place now in routine use for the xylose absorption test. Dual sugar tests (e.g., cellobiose and mannitol) to assess small bowel permeability have a role in research studies but as yet have not established a place in the routine diagnosis or monitoring of celiac disease. Tests of fat malabsorption are also inappropriate in the diagnosis of celiac disease, although appropriate tests of pancreatic function (e.g., fecal elastase) may be indicated in patients diagnosed with celiac disease who fail to respond to a gluten-free diet.

Disaccharidase Deficiencies[155,171]

The presence of the brush border disaccharidases is essential for carbohydrate absorption, and a reduction in their activity leads to carbohydrate malabsorption and intolerance. Carbohydrate malabsorption does not always lead to clinical symptoms, but when symptoms do occur (e.g., abdominal pain, flatulence, diarrhea) as a consequence of malabsorption, the patient is described as having carbohydrate intolerance.

TABLE 51-5 Prevalence of Hypolactasia in Adults

Racial Group	Prevalence, %
Chinese	>90
American blacks	54-81
Asians	60-90
Greeks	60-78
Northern Europeans	5-30

Adult-type hypolactasia is the single most common absorptive defect in adults, with an incidence of 5 to 90% depending on the racial group, as shown in Table 51-5.

Congenital Lactase Deficiency

Intestinal lactase is essential in infancy, and congenital lactase deficiency is a very rare disorder in which lactase activities in the mucosa are low or undetectable at birth. Severe diarrhea occurs as soon as milk is taken; stools have a low pH and contain large amounts of lactose and glucose produced by bacterial action on undigested lactose. A definitive diagnosis must be deferred until after maturation of the lactase synthesis system has occurred. In the interim, relief is dependent on adjustments to dietary composition that appear to reduce the severity of symptoms. An abnormal oral lactose tolerance test obtained a few months after birth could also be caused by congenital glucose-galactose intolerance (see discussion later in this chapter); the differential diagnosis requires performance of an oral glucose tolerance test in conjunction with the lactose tolerance test.

Adult-type Hypolactasia ("Acquired Lactase Deficiency")

In most humans (and in all other mammals), expression of the enzyme decreases during childhood, and by adulthood lactase levels are 10% or less of those seen in infancy. If symptoms of flatulence, abdominal discomfort, bloating, or diarrhea occur after consumption of one or two glasses of milk or of a large portion of ice cream or yogurt, lactose intolerance should be suspected. Suspicion would be increased in a subject from an ethnic group with a high incidence of lactose intolerance (see Table 51-5).

Lactose intolerance may also occur as a result of reduced enzyme activity following diffuse intestinal damage from infection (giardiasis, bacterial overgrowth, or viral gastroenteritis), ulcerative colitis, celiac disease, and tropical sprue. This deficiency is usually reversible following recovery from the disorder.

Diagnostic Tests for Lactase Deficiency

Many methods have been proposed for detecting lactase deficiency (Box 51-2). Disaccharidase activities can be measured in homogenates of an intestinal biopsy.[32] These assays are rarely required for routine diagnostic purposes, but when

BOX 51-2 Methods for Detecting Lactase Deficiency

Lactase in mucosal biopsy
Oral lactose tolerance
  Measure increase in plasma glucose
  Measure increase in plasma galactose
  Measure increase in breath H_2
  Measure increase in breath $^{13}CO_2$

BOX 51-3 Protocol for Lactose Tolerance Test With Measurement of Breath Hydrogen

Meal before 0700 (restriction on wheat and fiber), then fasting until test completed
Brush teeth (night and morning) or use mouthwash
Measure end-expiratory fasting breath H_2
Give lactose solution (50 g in 180 mL water for adults)
Rinse mouth with further 20 mL water and swallow
Measure breath H_2 at 15, 30, 60, 90, and 120 minutes
Test can be stopped if earlier rise of greater than 20 ppm above fasting level

necessary (e.g., in investigations in infancy), they must be carried out by laboratories with expertise in these tests. Breath hydrogen is now the preferred test for diagnosing lactase deficiency. The use of hydrogen breath tests in disorders of carbohydrate absorption and in bacterial overgrowth has been reviewed.[159]

Oral Lactose Tolerance Tests

Oral tolerance tests, measuring the increase in plasma glucose or galactose following ingestion of lactose, have been used to diagnose lactase deficiency. The usual dose of lactose is 50 g in 200 mL water; lower doses should be used in children (2 g/kg, up to a maximum of 50 g). Multiple blood samples are collected over a 2 hour period and the peak increment in glucose (or galactose) noted. To exclude lactase deficiency, the increase above baseline for capillary plasma glucose should be greater than 1.1 mmol/L[138] (20 mg/dL) or greater than 1.4 mmol/L (25 mg/dL) when venous plasma is used.[20] In a survey of laboratory practice in the United Kingdom, widely varying cutoffs were found to be in use (1.0 to 2.7 mmol/L) even with the same lactose dose.[44] The requirement for multiple blood samples and lack of procedural standardization suggest that these tests should be abandoned in favor of noninvasive breath hydrogen testing.

Hydrogen Breath Tests

Hydrogen is not an end product of mammalian metabolism, and breath hydrogen is derived from bacterial metabolism in the intestinal tract.[114] Following lactose ingestion, the disaccharide normally will be split into its constituent monosaccharides and absorbed. With lactase deficiency, unabsorbed disaccharide will pass into the large bowel, and bacterial metabolism will produce hydrogen that is absorbed into the systemic circulation and exhaled in the breath. Breath hydrogen can be measured in end-expiratory breath with the use of laboratory or hand-held direct-reading electrochemical hydrogen monitors.

Patient Preparation. Appropriate patient preparation is essential to ensure stable baseline breath hydrogen levels (Box 51-3). Avoidance of wheat-based foods and fiber for 12 hours before the test minimizes the availability of substrates for bacterial metabolism in the large bowel. Fasting breath hydrogen is typically less than 5 ppm (5 µL/L), and concentrations greater than 20 ppm (20 µL/L) may be an indication of malabsorption or bacterial overgrowth.[143] Oral hygiene before ingestion of the substrate in hydrogen breath tests minimizes the production of hydrogen by oral bacteria. Brushing of teeth or use of an antibacterial mouthwash (e.g., 1% chlorhexidine) is recommended.[128] Mouthwash containing alcohol should not be used, because this may interfere with the measurement of hydrogen. Cigarette smoke contains high hydrogen levels; smoking therefore is not permitted immediately before or during the test.

After an overnight fast, a baseline breath hydrogen level is recorded and 50 g of lactose in 180 mL water is drunk, followed by a further 20 mL of water to rinse the mouth and further reduce the possibility of an early rise in breath hydrogen from the action of oral bacteria. The dose in children should be 2 g/kg up to a maximum of 50 g. Breath hydrogen is then measured at 15, 30, 60, 90, and 120 minutes.

Interpretation. Most publications indicate that an increase in breath hydrogen greater than 20 ppm (20 µL/L) above the baseline fasting concentration within 2 hours of ingestion of lactose is indicative of lactose malabsorption.[129,138] However, 1999 data suggest that a cutoff of 10 ppm (10 µL/L) improves diagnostic sensitivity without increasing the number of false-positive test results.[98] In most patients with normal lactose absorption, breath hydrogen levels will remain at 2 to 5 ppm throughout the test. Occasionally, high levels may occur within the first 30 minutes after lactose ingestion. This may indicate very rapid transit of lactose to the cecum or bacterial metabolism in the small bowel due to bacterial overgrowth. Repeating the breath test with lactulose or glucose as the substrate or using imaging techniques to confirm transit time will normally clarify the cause of such results.

In lactose malabsorption, breath hydrogen is typically elevated (30 to 100 ppm, 30 to 100 µL/L) at 60 to 120 minutes after lactose ingestion. In a few subjects, the large bowel bacteria do not produce hydrogen; in such patients a normal result does not exclude lactase deficiency. Very low hydrogen when fasting and throughout the test may therefore indicate a false-negative result. Some estimates suggest that up to 10 to 13% of the population have large bowel bacteria that do not produce hydrogen,[105] although others have found the prevalence of hydrogen nonproducers to be less than 2%.[129,168] Such false negatives can be confirmed by failure to produce hydrogen at 45 to 180 minutes after ingestion of lactulose

(10 g), which is a nonabsorbable disaccharide and therefore is available for bacterial metabolism in the large bowel.

A positive breath hydrogen result following ingestion of lactose may also occur in glucose-galactose malabsorption, which may cause intestinal symptoms. When necessary, glucose-galactose malabsorption can be confirmed or excluded by a breath test in which 25 g each of glucose and galactose is substituted for 50 g lactose. An increase in breath hydrogen confirms the diagnosis.

Sucrase-Isomaltase and Trehalase Deficiencies and Monosaccharide Malabsorption

Sucrase-isomaltase deficiency usually presents clinically in infancy when sucrose and fruit are introduced into the diet,[102] but sometimes first presents in adulthood.[133,179] The deficiency is rare in Caucasians and is more common among Eskimo groups. Deficiencies of both lactase and sucrase-isomaltase may occur secondary to other small bowel diseases (e.g., celiac disease, Crohn's disease,[178] acute gastroenteritis). Trehalase deficiency is a rare disorder,[132,135] except in Greenland, where it occurs in 8% of the population.[70] It is manifested by diarrhea following the ingestion of mushrooms.

Malabsorption of monosaccharides can also cause intestinal symptoms more commonly attributed to maldigestion of disaccharides. Glucose-galactose malabsorption is also inherited as an autosomal recessive trait. Symptoms occur in the affected neonate as soon as milk (lactose) is taken, but they also may follow ingestion of glucose- or galactose-containing foods. Symptoms caused by fructose malabsorption occur upon ingestion of fruit. This dietary intolerance is quite a different disorder from hereditary fructose intolerance, in which the hepatic enzyme aldolase is defective.

The breath hydrogen test described previously can be used to diagnose sucrase-isomaltase deficiency. A total of 50 g sucrose is used instead of lactose. An increase in breath hydrogen greater than 20 ppm (20 µL/L) within 2 hours is diagnostic. It is rarely necessary to test for trehalase deficiency, although a breath test using 25 g trehalose has been described.[4]

Bacterial Overgrowth

The proximal small intestine (duodenum and jejunum) normally contains few bacteria. Most ingested bacteria do not survive the acidic environment of the stomach; therefore few live organisms normally enter the small bowel. The motility of the jejunum prevents fecal-type organisms from progressing up into the jejunum from the cecum. The ileum normally contains some fecal-type bacteria. Colonization of the upper small bowel is described as bacterial overgrowth and usually occurs as a consequence of other abnormalities (structural or motility disorders) of the small intestine (Box 51-4). Use of PPIs is associated with an increased risk of bacterial colonization.

Bacteria colonizing the small bowel (such as *Escherichia coli* and *Bacteroides* species) deconjugate and dehydroxylate bile salts, leading to conjugated bile salt deficiency, which causes fat malabsorption. Bacterial metabolism of vitamin B_{12} may also occur, leading to vitamin B_{12} deficiency. The clinical symptoms of bacterial overgrowth include abdominal pain, diarrhea, and steatorrhea.[108]

BOX 51-4 Abnormalities of the Small Intestine Associated With Bacterial Overgrowth

Jejunal diverticuli
Crohn's disease
Autonomic neuropathy
Scleroderma (systemic sclerosis)
Pseudo-obstruction
Post gastrectomy

The diagnostic gold standard requires intubation with aspiration of jejunal contents and demonstration of a bacterial count of more than 10^5 colonic-type organisms/mL.[159] In practice, hydrogen breath tests using lactulose or preferably glucose as the substrate are used more frequently. An alternative diagnostic approach is to use a therapeutic trial of antibiotics.

For hydrogen breath tests, patient preparation is the same as that described in the previous section for the lactose breath hydrogen test. Lactulose (usually given in a dose of 10 g in 200 mL water) is a nonabsorbable disaccharide. In a normal subject, breath hydrogen does not increase until lactulose enters the large intestine; the time from ingestion to a rise in breath hydrogen therefore is normally an indication of small bowel transit time. In bacterial overgrowth, an early rise in breath hydrogen of at least 20 ppm (20 µL/L) is noted within 30 minutes of ingestion of lactulose. The early increase is diagnostic when it can be distinguished clearly from the later colonic rise. Frequent measurements (e.g., at 5-minute intervals) are essential in the first 30 minutes, followed by measurements every 15 minutes thereafter for up to 3 hours.[150]

Glucose is an alternative substrate; the usual adult dose is 50 g (as monohydrate) in 250 mL water.[101,184] An increase in breath hydrogen greater than 12 ppm (12 µL/L) above the fasting concentration indicates bacterial overgrowth. In bacterial overgrowth, breath hydrogen usually increases within 75 minutes of ingestion of glucose and sometimes within 30 minutes. The finding of an increased fasting breath hydrogen has high specificity for bacterial overgrowth but poor sensitivity; however, a fasting breath hydrogen greater than 15 ppm and an increment of at least 12 ppm within 2 hours of a 50 g glucose challenge are diagnostic of bacterial overgrowth.[101,143] The high fasting breath hydrogen levels, even after adequate dietary preparation, are thought to be caused by stasis of gut contents or by intestinal bacteria producing hydrogen from endogenous glycoproteins.[143] Table 51-6 compares some of the published data for diagnostic accuracy of tests using lactulose or glucose.

Variations in gastric emptying rate and in small bowel transit times are problems that limit the diagnostic accuracy

TABLE 51-6 Reported Sensitivity and Specificity of Lactulose and Glucose Hydrogen Breath Tests for the Diagnosis of Bacterial Overgrowth

Substrate	Increment Over Baseline*	Sensitivity	Specificity	Reference
Glucose 50 g	≥12 ppm	93	78	Kerlin and Wong, 1988[101]
Glucose 50 g	>10 ppm	78	89	Flourie et al, 1989[60A]
Glucose 50 g	≥15 ppm	90	—	Stotzer and Kilander, 2000[167]
Glucose 75 g	≥10 ppm	62	83	Corazza et al, 1990[26]
Lactulose 12 g	>10 ppm	68	44	Corazza et al, 1990[26]

*1 ppm = 1 μL/L.

of breath hydrogen tests. In the face of an appropriate clinical picture and a negative breath hydrogen test, an alternative diagnostic approach is a therapeutic trial of appropriate antibiotics.[5]

Other tests for bacterial overgrowth have used ^{14}C-xylose or ^{14}C-glycocholic acid.[105] When bacterial overgrowth occurs, bacteria deconjugate the glycocholic acid to produce ^{14}C-glycine that is absorbed and metabolized with an increase in breath $^{14}CO_2$. As in other tests, an early rise in the marker indicates bacterial overgrowth or rapid transit to the large bowel, where the normal colonic flora releases ^{14}C-glycine. These tests using radioactive isotopes have been superseded by hydrogen breath tests that offer comparable diagnostic performance and methodologic advantages.[167]

Bile Salt Malabsorption[33]

Bile acids are synthesized in the liver and pass into the lumen of the small bowel via the gallbladder. Bile acids are present in bile as taurine or glycine conjugates; because the pH of bile is slightly alkaline and contains significant amounts of sodium and potassium, most of the bile acids and their conjugates exist as salts (i.e., bile salts). In practice, the terms *bile acids* and *bile salts* are frequently used as synonyms. Their major function is to act as surface-active agents, forming micelles and facilitating the digestion of triglycerides and the absorption of cholesterol and fat-soluble vitamins. Little reabsorption of bile acid occurs in the proximal small bowel, but normally more than 90% is reabsorbed in the terminal ileum. It returns to the liver in the portal circulation and is resecreted into the bile. This is known as the *enterohepatic circulation.* Less than 10% of secreted bile acid is lost in the feces, or about 0.2 to 0.6 g/d.

Bile acid malabsorption leading to chronic diarrhea occurs when ileal disease (e.g., Crohn's disease) is present, or after resection of the terminal ileum; it may also occur following cholecystectomy and in some patients with irritable bowel syndrome.[165] Malabsorption of bile salts produces diarrhea by two different mechanisms. When significant bile salt depletion occurs, the deficiency of intraluminal bile salts leads to fat malabsorption and steatorrhea. More commonly, malabsorption of bile salts in the ileum leads to increased concentrations of bile salts in the colon, where they alter water and electrolyte absorption. This leads to net secretion of water into the lumen and diarrhea. Bile salt malabsorption is probably an underdiagnosed condition and should be suspected in patients with unexplained chronic diarrhea.[161,177,188]

Three different procedures have been used to make a diagnosis of bile salt malabsorption: the ^{75}selenohomocholyltaurine test, measurement of serum 7α-hydroxy-4-cholesten-3-one in serum, and a therapeutic trial of bile acid sequestrants such as cholestyramine. The most widely used test involves the oral administration of the synthetic radioactive bile acid ^{75}selenohomocholyltaurine (^{75}SeHCAT). Following the dose, whole body gamma counting is carried out to estimate the basal level at 1 hour (100%). The gamma count is measured again after 7 days, when normally more than 15% of the administered dose is retained. Retention of less than 10% indicates bile salt malabsorption. Patients with less than 5% retention of ^{75}SeHCAT often have a good response to treatment with bile acid sequestrants.

Measurement of 7α-hydroxy-4-cholesten-3-one has been proposed as a simpler alternative to ^{75}SeHCAT. Evidence indicates that the fasting serum level of this intermediary between cholesterol and taurocholic acid reflects the activity of hepatic cholesterol 7α-hydroxylase and therefore the rate of bile acid synthesis. Bile acid malabsorption is associated with increased serum concentrations of 7α-hydroxy-4-cholesten-3-one as hepatic synthesis increases to maintain the pool of circulating bile acids.[6] Good correlation has been demonstrated between serum 7α-hydroxy-4-cholesten-3-one and results of the ^{75}SeHCAT test.[51] Two subsequent publications on patients with chronic diarrhea have documented the high sensitivity of this measurement for identifying those with bile acid–induced diarrhea.[13,153] The test has been compared with ^{75}SeHCAT and with the response to cholestyramine. The latter avoids the problems of assuming 100% sensitivity and specificity for the ^{75}SeHCAT test. With use of the therapeutic response to cholestyramine as the "gold standard," the positive predictive value of serum 7α-hydroxy-4-cholesten-3-one increased to 74% (from 71%), and the negative predictive value increased to 98% (from 94%).

With growing awareness of the likely role of bile salt malabsorption in the chronic diarrhea of a proportion of patients with irritable bowel syndrome and the therapeutic effectiveness of cholestyramine,[161,165] measurement of serum

7α-hydroxy-4-cholesten-3-one, with its high negative predictive value, could be used to exclude bile salt malabsorption. High concentrations would be confirmed at follow-up ^{75}SeHCAT testing or by a therapeutic trial with cholestyramine.

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) includes Crohn's disease, ulcerative colitis, and a number of microscopic inflammatory bowel disorders. IBD has a high prevalence in the United States and Europe and a much lower, although increasing, prevalence in most Asian countries. Significant overlap in the clinical presentation has been noted, as well as in radiologic and histologic findings in Crohn's disease (which may affect any part of the GI tract) and ulcerative colitis (which is confined to the large bowel). Both conditions present with diarrhea and abdominal pain or discomfort, often associated with fatigue and anemia, and less commonly with inflammation of the joints, skin, and eyes.

Causes of these disorders are unknown; environmental, genetic, and immune factors are believed to be involved in the inflammatory response, which occurs in the mucosa and submucosa as a consequence of activation of innate immune mechanisms. Tissue damage is a consequence of neutrophil activation and the production of proinflammatory mediators. Immunosuppressive drugs and tumor necrosis factor alpha inhibitors are the main medical treatment options, although for many patients, surgery will be required to remove diseased areas of the bowel.

Intestinal symptoms are common to both IBD and irritable bowel syndrome (IBS), although the latter is not an inflammatory disorder and is not associated with organic disease of the bowel. Interest is increasing in the use of markers to differentiate between IBD and IBS when required, and to monitor disease activity or response to anti-inflammatory treatment in patients with IBD.[61,65,113A,170] Interest initially focused on the use of fecal lactoferrin and calprotectin to distinguish organic from functional bowel disorders, but it is now clear that both are markers of the infiltration of neutrophils into the mucosa and are sensitive markers of intestinal inflammation. Negative tests for these proteins therefore exclude significant neutrophilic intestinal inflammation but may not exclude other organic bowel diseases such as celiac disease. Lactoferrin and calprotectin can be used as predictors of relapse in IBD and as markers of mucosal healing following treatment.[160]

Although they have similar diagnostic accuracy, these two markers reflect different aspects of neutrophil function and innate immunity. Lactoferrin (80 kDa) is stored in the granules within neutrophils and is a marker of neutrophil degranulation. Calprotectin is a major cytosolic component of neutrophils and is a complex of two proteins of the S100 family: S100A8 and S100A9. Unlike lactoferrin, which has antibacterial properties and is involved in host defense, the S100 proteins are proinflammatory and are believed to cause tissue damage in IBD. Advances in understanding of the molecular mechanisms surrounding the inflammatory process and of the role of damage-associated molecular pattern proteins suggest that a third member of the S100 family, S100A12, is a strong candidate as a more specific marker of neutrophil activation than calprotectin or lactoferrin.[61,95]

Protein-Losing Enteropathy

Loss of significant quantities of serum proteins into the bowel lumen and their passage into the feces are consequences of a wide range of GI disorders. These may be associated with inflammation or ulceration of a segment of the small or large bowel (as in Crohn's disease and ulcerative colitis) or stomach, with diseases in which the intestinal lymphatics are obstructed or where lymphatic pressure is elevated (e.g., lymphoma, Whipple's disease), or with disorders associated with altered immune status, such as systemic lupus erythematosus and some food allergies.

In the healthy bowel, fecal protein is largely derived from enterocytes shed from the mucosal surface and from intestinal secretions. The normal GI loss of albumin is less than 10% of albumin catabolism, representing a daily loss of less than 1 to 2% of the serum protein pool.[69] Protein loss may be greatly increased in disease. In studies using ^{51}Cr-labeled proteins, 0.1 to 0.7% of an injected dose was excreted in feces over 4 days in healthy subjects; in protein-losing enteropathies this may increase to 40%, leading to hypoalbuminemia and edema.

The diagnosis of protein-losing enteropathy should be considered in the investigation of patients with hypoalbuminemia in whom renal loss, liver disease, and malnutrition have been excluded. The classical test for the diagnosis of protein-losing enteropathy is the measurement of fecal ^{51}Cr-albumin following an intravenous injection, although this test is now rarely available. Imaging techniques that seek to detect the specific site of protein loss by using ^{99m}Tc-human serum albumin or ^{99m}Tc-dextran have been described.

Fecal clearance of alpha-1-antitrypsin (AT) can also be used as a marker of GI protein loss. AT is a glycoprotein (Mw 54,000 Da) that is synthesized in the liver and is normally present in the serum at a concentration of about 1.5 to 2 g/L. It is a protease inhibitor and therefore is resistant to degradation by proteolytic enzymes in the GI tract. The fecal clearance of AT correlates with protein loss measured by ^{51}Cr techniques ($r = 0.96$).[60] The correlation is not influenced by serum AT concentrations or by fecal weight. AT clearance can be used for both small and large bowel disease and is applicable to the evaluation of enteric protein loss in children and adults.[60,82] Work reported in 1990 has confirmed these findings but shown that fecal AT concentration alone does not reliably predict AT clearance (i.e., a timed fecal sample and measurement of serum AT are required).[169] An important observation is that experimentally induced diarrhea in normal subjects leads to increased AT clearance. The mechanism is unclear but may be related to decreased time for degradation of AT if intestinal transit time is shorter. The upper limits of the reference interval [estimated as means ±2 standard deviations (SD)] were found to be 56 mL/d and

24 mL/d in normal subjects with and without diarrhea, respectively. In inflammatory bowel disease, AT clearance may be as high as 200 mL/d; this represents a loss of about 6 g albumin/d.[169] AT clearance must be interpreted with caution in patients with positive fecal occult blood tests, as blood loss might be sufficient to falsely increase AT clearance. Measurement of fecal AT has been suggested as an alternative to fecal occult blood for the detection of colorectal cancer.[131] AT is rapidly destroyed in gastric juice (and in vitro) when the pH is below 3.0; this has meant that the test can be used only to assess protein loss distal to the pylorus.[60] However, administration of PPIs can be used to inhibit gastric acid secretion before collection of the fecal sample, thereby enabling assessment of protein loss from the stomach.[173]

A study evaluating the use of AT clearance as a marker of clinical relapse in patients with Crohn's disease showed a negative predictive value of 94% for predicting relapse in the subsequent 6 months (at a cutoff of 120 mL/d). Sensitivity was only 50% and comparable results were noted when the Bristol Simple Index score was used to predict relapse, so that at present the test appears to have little clinical value in this context.[10]

AT in feces and serum can be measured most conveniently by radial immunodiffusion. Feces should be collected quantitatively, preferably for 3 days, in preweighed containers and kept refrigerated. The AT is extracted into saline before analysis. AT clearance is calculated as follows:

$$\text{AT clearance (mL/day)} = \frac{(\text{fecal weight} \times \text{fecal AT concentration})}{\text{Serum AT}}$$

where fecal weight is expressed in g/d, fecal AT in mg/kg feces, and serum AT in mg/L.

THE PANCREAS: DISEASES AND ASSESSMENT OF EXOCRINE PANCREATIC FUNCTION

It will be evident from the section on digestion and absorption that the pancreas plays a central role in the absorptive process for carbohydrates, fats, and proteins. Disorders of the exocrine pancreas therefore are frequently associated with GI symptoms of malabsorption or diarrhea. In this section, pediatric and adult exocrine pancreatic disorders are briefly discussed, and tests that can be used to assess exocrine pancreatic function are described. Information on exocrine pancreatic tumors can be found in the later section on GI regulatory peptides. Recent textbooks on gastroenterology or medicine provide greater detail on the clinical aspects of exocrine pancreatic disorders.[15,62]

Pediatric Disorders of the Exocrine Pancreas

Pancreatic disorders in childhood have been reviewed[27]; and are summarized in Box 51-5.

Cystic fibrosis (CF) is the most common severe autosomal recessive disease, with an estimated gene frequency in Western Europe and the United States of between 1:25 and 1:35 and a disease incidence of about 1 in 2500 to 1 in 3200. The pathogenesis and diagnosis of CF are described in Chapter 40. Pancreatic insufficiency is present at birth in 65% of infants with CF, and a further 15% develop it during infancy and early childhood. The 20% who do not develop pancreatic insufficiency have a better prognosis and develop fewer complications.

Measurement of pancreatic elastase-1 in feces (see section on noninvasive tests of exocrine pancreatic function) is considered to be a reliable test for pancreatic insufficiency in infants over the age of 2 weeks with CF and in older children at the time of diagnosis of the disorder.[17,113,145] This test can also be used to detect the onset of pancreatic insufficiency in those previously pancreatic sufficient.

BOX 51-5 Spectrum of Pancreatic Disease in Childhood

Disorders of Morphogenesis
Annular pancreas, pancreas divisum, pancreatic hypoplasia and agenesis, heterotopic pancreas

Inherited Syndromes Affecting the Pancreas
Cystic fibrosis
Shwachman-Diamond syndrome, Johnson-Blizzard syndrome, Pearson bone marrow pancreas syndrome

Gene Mutations Leading to Pancreatic Disease
Hereditary pancreatitis; cationic trypsinogen gene mutations, trypsin inhibitor gene mutations

Pancreatic Insufficiency Syndrome
Isolated enzyme deficiencies, lipase, colipase, enterokinase

Pancreatic Insufficiency Secondary to Other Disorders
Celiac disease

Acquired Pancreatitis in Childhood
Idiopathic, traumatic, drugs, viral, metabolic, collagen vascular disease, autoimmune, fibrosing, nutritional (tropical)

Adult Disorders of the Exocrine Pancreas[62]

The major exocrine pancreatic disorders presenting in adult life are acute pancreatitis, chronic pancreatitis,[12A] and carcinoma of the pancreas. The use of enzyme tests in the diagnosis of acute pancreatitis is discussed in Chapter 22. The causes of pancreatitis are given in Box 51-6.

Chronic pancreatitis is defined by irreversible pancreatic damage with histologic evidence of inflammation and fibrosis leading to destruction of endocrine and exocrine function. The major histologic features are similar regardless of the cause. In Western countries, the most common cause is alcohol (60 to 90% of all cases of chronic pancreatitis), although because only 5 to 15% of heavy drinkers develop the disease, clearly other predisposing factors are present (e.g., smoking, diet high in fat and protein).

The role of invasive and noninvasive pancreatic exocrine tests in chronic pancreatitis has been reviewed.[66]

BOX 51-6 Causes of Pancreatitis in Adults

Acute
Gallstones
Alcohol
Infection (e.g., mumps, Coxsackie B)
Pancreatic tumors
Drugs (e.g., azathioprine, estrogens, corticosteroids, didanosine)
Iatrogenic [e.g., postsurgical, endoscopic retrograde cholangiopancreatography (ERCP)]
Hyperlipidemias
Miscellaneous—trauma, scorpion bite, cardiac surgery
Idiopathic

Chronic
Alcohol
Tropical (nutritional)
Hereditary [trypsinogen and inhibitory protein defects, cystic fibrosis]
Idiopathic
Trauma
Hypercalcemia

Tests of Exocrine Function of the Pancreas

The predominant exocrine functions of the pancreas are the production and secretion of pancreatic juice, which is rich in enzymes and bicarbonate. Normal pancreatic juice is colorless and odorless; it has a pH of 8.0 to 8.3 and a specific gravity of 1.007 to 1.042. The total 24 hour secretion volume may be as high as 3000 mL.[151]

Laboratory tests used to measure exocrine function in the investigation of pancreatic insufficiency (most commonly caused by CF in children and chronic pancreatitis in adults) fall into one of two categories: invasive and noninvasive. Invasive tests require GI intubation to collect pancreatic samples; noninvasive ("tubeless") tests were developed to avoid intubation, which is uncomfortable for the patient, time-consuming, and therefore expensive. Noninvasive tests are simpler and cheaper to perform but in general lack the sensitivity and specificity of invasive tests, particularly for the diagnosis of mild pancreatic insufficiency. It is important to recognize that biochemical tests have a limited clinical application in the diagnosis of pancreatic disease because of the complexity of the invasive tests or the inadequate sensitivity and specificity for mild and moderate pancreatic disease of the noninvasive tests. Of greater importance are the imaging procedures (Box 51-7). These techniques continue to be developed. One study shows that administration of secretin, causing stimulation of fluid and bicarbonate secretion, leads to anatomic changes that can be quantified by magnetic resonance cholangiopancreatography, with significant differences between normal volunteers and patients with pancreatic insufficiency.[31] In the future, it may therefore be possible to confidently diagnose pancreatic insufficiency with the use of imaging techniques alone.

BOX 51-7 Pancreatic Imaging Procedures

Plain abdominal radiograph
- May show pancreatic calcification, particularly when alcohol is the cause

Ultrasound
- Useful screening investigation for inflammation and neoplasia. Views may be limited by overlying bowel gas.

Spiral computed tomography (CT)
- With contrast enhancement and following a specific pancreatic protocol remains the gold standard imaging technique for the investigation of pancreatic disease.

Magnetic resonance imaging (MRI) scanning
- An alternative to CT. Magnetic resonance cholangiopancreatography (MRCP) gives clear definition of the pancreatic duct and the biliary tree. Gallstones (including microcalculi) may also be identified in the biliary tree using MRI/MRCP.

Endoscopic ultrasound
- Very useful for identifying distal common bile duct stones which may be the cause of an episode of acute pancreatitis.
- Can identify early changes of chronic pancreatic before these are evident on other imaging methods.
- Has an increasing role for staging the operability of pancreatic adenocarcinoma, particularly with respect to vascular invasion.
- Considered to be the imaging technique of choice for investigating cystic lesions of the pancreas.
- Is a sensitive means of detecting small pancreatic tumors, particularly those of neuroendocrine origin.

Endoscopic retrograde cholangiopancreatography (ERCP)
- This has been considered the gold standard for diagnosing pancreatic disease. However, with MRCP and endoscopic ultrasound, ERCP is restricted to therapeutic intervention.

Invasive Tests of Exocrine Pancreatic Function

The main types of invasive tests are summarized in Table 51-7.

Total volume of pancreatic juice, the amount or concentration of bicarbonate, and activities of pancreatic enzymes are measured in duodenal contents. The enzyme most commonly measured is trypsin, but amylase, lipase, chymotrypsin, and elastase may also be evaluated. The *Lundh test* consists of administering a standardized meal consisting of 5% protein, 6% fat, 15% carbohydrate, and 74% non-nutrient fiber, which provides a physiologic stimulus to the pancreas and is simple to administer. However, administration of the meal prevents determination of the total enzyme and bicarbonate or secretory volume, and in the presence of mucosal disease (e.g., celiac disease), in which hormone release from the duodenal mucosa is impaired, it provides inadequate or no stimulation. In view of these limitations, the Lundh test is largely of historical interest.

The *secretin test* is based on the principle that secretion of pancreatic juice and bicarbonate output are related to the functional mass of pancreatic tissue. After an overnight fast, basal samples of fluid are collected from the stomach and duodenum. One clinical unit (CU) of secretin/kg body weight is administered intravenously, and duodenal fluid is collected at 15 minute intervals for at least 1 hour. Purified porcine secretin has traditionally been used for the test, but synthetic porcine secretin (0.2 μg/kg) can also be used.[164]

Secretin stimulates the secretion of pancreatic juice and bicarbonate, but stimulation of the secretion of pancreatic enzymes is inconsistent. Addition of CCK (or a synthetic equivalent) to the secretin test provides a stimulus to the secretion of pancreatic enzymes, allowing a more complete assessment of pancreatic reserve than can be obtained with secretin alone. The functional activity of CCK resides in the C-terminal octapeptide sequence (CCK-8); this octapeptide or ceruletide (a synthetic decapeptide identical to the natural decapeptide cerulein) can be used to stimulate pancreatic enzyme secretion (Figure 51-7).

The procedure for the *secretin-ceruletide test* is similar to that described for the secretin test. Patients are required to fast overnight; a gastroduodenal tube is then placed into the duodenum under x-ray control. After basal fluid is collected for 15 minutes, 1 U secretin/kg body weight/h is given continuously intravenously for 2 hours; 30 mg ceruletide/kg body weight/h is given simultaneously for the second hour. Pancreatic juice is collected during 15 minute intervals, and volume, pH, bicarbonate, and enzymes are measured.[120]

TABLE 51-7 Summary of Invasive Tests of Pancreatic Exocrine Function

Procedure	Pancreatic Stimulant	Analysis of Duodenal Contents
Lundh test	Standardized meal	Enzyme output
Secretin stimulation test	Purified or synthetic porcine secretin	Bicarbonate output
Secretin-cholecystokinin (CCK) test	Secretin as above plus CCK analog (CCK-8 or ceruletide)	Bicarbonate and enzymes

Procedures and reference values are not standardized among laboratories. It is recommended that doses of secretagogues should be high enough to provide maximal pancreatic stimulation and should be given for at least 60 to 90 minutes to ensure better diagnostic accuracy, especially in mild pancreatic insufficiency.[66]

Noninvasive Tests of Exocrine Pancreatic Function

"For many years, gastroenterologists have searched for the holy grail of pancreatic function tests—the tubeless test."[38] It is not surprising that a range of tests have been proposed, but none has adequate sensitivity for reliably detecting early pancreatic disease. When malabsorption is present, such tests are of value in confirming or excluding pancreatic disease. Considerable overlap often occurs between results observed in normal individuals and those found in patients with pancreatic disorders; this is due mainly to the large functional reserve of the pancreas. It has been estimated that pancreatic insufficiency cannot clearly be demonstrated until at least 50% of the acinar cells have been destroyed. Clinical signs of pancreatic insufficiency often do not appear until 90% of acinar tissue has been destroyed. In general, the noninvasive tests may therefore be used when causes of malabsorption are investigated, but they have inadequate sensitivity for the diagnosis of chronic pancreatitis. Comparison between studies and of different markers is difficult because the "gold standard" may be functional tests, which may differ in procedure and reference values,[111,120,166] or morphologic assessment. In some cases, one noninvasive test has been compared with another. Table 51-8 compares the diagnostic performance of noninvasive tests.

The noninvasive tests are based on the reduction in secretion of pancreatic enzymes with measurement of enzymes in feces (chymotrypsin or elastase) or detection of products of their catalytic reactions, after oral administration of synthetic substrates, in urine [*N*-benzoyl-L-tyrosyl-*p*-aminobenzoic acid (NBT-PABA) or pancreolauryl test] or in breath (^{13}C-mixed chain triglyceride breath test).[183] Fecal elastase (measured by the monoclonal antibody method) is currently the noninvasive test of choice for assessing pancreatic insufficiency.

Pancreatic chymotrypsin is almost completely digested during its passage through the gut in adults, but the residual activity of the enzyme in feces is stable for several days at 20 °C. Its output in stool correlates poorly with chymotrypsin

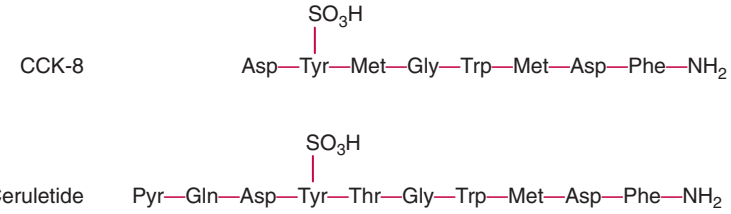

Figure 51-7 Comparison of amino acid sequences of cholecystokinin (CCK)-8 and ceruletide.

TABLE 51-8 Diagnostic Accuracy of Noninvasive Tests for Mild, Moderate, and Severe Pancreatic Insufficiency, as Assessed by Anatomic or Functional Criteria

Sensitivity for Pancreatic Insufficiency				
Test	**Mild**	**Moderate**	**Severe**	**Specificity**
Fecal chymotrypsin[71]	11%	54%	77%	85%
Fecal elastase-1[71]	22%	77%	100%	96%
NBT-PABA[63,140]	—	50%	70%	72%
Pancreolauryl[38,140]	<50%	50%	85%	50%
^{13}C-MCT absorption[119]	62%	—	100%	85%

MCT, Medium chain triglyceride; *NBT-PABA, N*-benzoyl-L-tyrosyl-*p*-aminobenzoic acid.

secretion in duodenal contents when both are measured after stimulation with secretin-CCK. In patients without pancreatic disease, the incidence of falsely low results is about 10 to 15% and may be due to (a) voluminous stools (>300 g/d) and thus less enzyme per gram of feces; (b) inadequate food intake; (c) partial gastrectomy or mucosal disease (e.g., celiac disease), which causes inadequate stimulation of pancreatic secretion; or (d) obstruction of the bile duct. Falsely normal results in patients with mild pancreatic insufficiency may be as high as 50%.[72] In a collaborative study in children, both fecal chymotrypsin and elastase showed 100% sensitivity for detecting pancreatic insufficiency in CF, but the specificity of chymotrypsin was lower than that of elastase in a control group of children with small intestinal disease.[19] Most recent papers conclude that although chymotrypsin measurement is easier than elastase measurement, the latter test has significant advantages in terms of diagnostic accuracy. The recommended procedure[99] uses a stool pretreatment stage that dissociates particle-bound chymotrypsin.

Pancreatic elastase-1 is a pancreas-specific protease present in pancreatic juice. It is not degraded during passage through the gut, and concentrations in feces are fivefold to sixfold greater than those in pancreatic juice.[172] The enzyme can be identified in feces with a commercial ELISA assay that uses two monoclonal antibodies specific to the human enzyme (Schebo Biotech, Giessen, Germany). Treatment of patients with pancreatic enzyme supplements therefore does not interfere with the test (Figure 51-8). Table 51-9 compares chymotrypsin and elastase, indicating some of the advantages of fecal elastase measurement.

Fecal elastase-1 has been evaluated extensively both in CF and in adult pancreatic insufficiency, and its use is recommended in both children and adults.[30,177] In children with CF, the test discriminates between those with and without pancreatic insufficiency.[71] Very low elastase-1 is seen in a wide range of *CFTR* genotypes with undetectable enzyme (<15 μg/g of stool) in most ΔF508 homozygotes.[145,183] Low fecal elastase (<200 μg/g) after 4 weeks of age is indicative of pancreatic insufficiency and provides supporting evidence for a diagnosis of CF.[17]

The test has been evaluated in adults against the secretin-cerulein test[111,120,166] and in patients whose diagnosis of chronic pancreatitis has been made on the basis of anatomic

TABLE 51-9 Comparison of Fecal Chymotrypsin and Elastase

	Fecal Enzyme	
	Chymotrypsin	**Elastase**
10 day intraindividual variation, mean CV	30%	15%
Loss of activity, 7 days at 4 °C	17%	2.5%
Overall diagnostic sensitivity	64%	93%
Overall diagnostic specificity	89%	93%

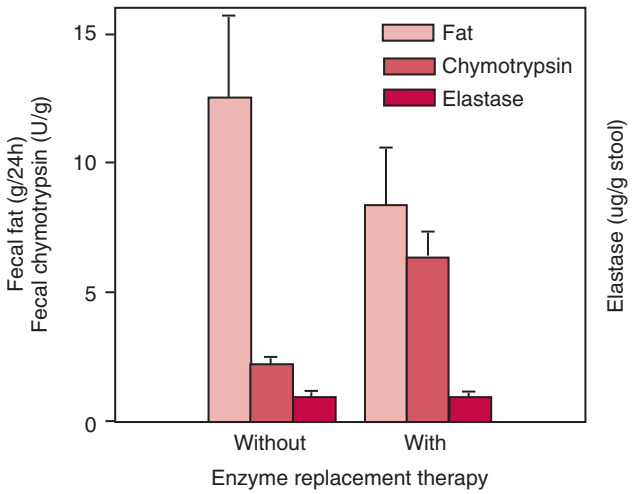

Figure 51-8 Fecal excretion [mean and standard deviation (SD)] of chymotrypsin, fat, and immunoreactive elastase during a 24 hour collection period in 12 patients with cystic fibrosis and steatorrhea, with and without enzyme replacement therapy. *(From Stein J, Jung M, Sziegoleit A, Zeuzem S, Caspary WF, Lembcke B. Immunoreactive elastase 1: clinical evaluation of a new non-invasive test of pancreatic function. Clin Chem 1996;42:222-6.)*

and morphologic changes detected by ultrasound and endoscopic retrograde pancreatography or computed tomography.[39,72,127] The test is routinely carried out on a small random fecal sample, thus it might be expected to give inferior diagnostic accuracy compared with those evaluations carried out on portions of 24 hour or 72 hour fecal collections. However, with random fecal samples, specificities of 98% and 100% have been reported in healthy controls, and specificities of 90 to 97% in patients with nonpancreatic GI disease. Positive results (i.e., <200 μg/g) have been reported in patients with clinical or laboratory evidence of malnutrition who also have inflammatory bowel disease or chronic diarrhea (nonpancreatic). These observations may actually be due to impaired pancreatic secretion as a consequence of malnutrition.[127] The authors also suggest that increased bacterial degradation of the enzyme might be the cause of false positives in some patients with bacterial overgrowth. Similar results have been reported in children with nonpancreatic disease; the finding of low fecal elastase in a child with steatorrhea probably indicates coexisting pancreatic insufficiency.[19]

Measurement of pancreatic elastase-1 in feces has high sensitivity for the detection of severe and moderate chronic pancreatitis in adults. It has better sensitivity than other tests for detecting mild chronic pancreatitis, and high sensitivity and high negative predictive value for discriminating between diarrhea of pancreatic and nonpancreatic origin. The test is not specific for pancreatitis and detects moderate to severe impairment of pancreatic exocrine secretion from any cause. It is considered to be the most suitable test to confirm pancreatic insufficiency in screened cystic fibrosis infants older than 2 weeks,[17] and as previously noted, the test result is not influenced by the administration of pancreatic enzyme supplements. A negative test does not exclude mild disease, and false positives in some nonpancreatic diseases and in very watery samples limit its diagnostic accuracy. Measurement of the enzyme in dried feces avoids the problem associated with watery stool samples.[97] An ELISA based on polyclonal antibodies (and also called a test for "elastase 1") appears to have binding characteristics different from those of the monoclonal antibody assay.[75] Quantitative results differ between the polyclonal and monoclonal assays but a comparative study of 68 patient samples showed that both procedures were comparable in categorizing subjects as normal or as having moderately or severe pancreatic insufficiency.[49A]

The *NBT-PABA test* of pancreatic function is not now available but was based on the intestinal hydrolysis, by chymotrypsin, of a synthetic tripeptide—*N*-benzoyl-L-tyrosyl-*p*-aminobenzoic acid. The tripeptide, variously called NBT-PABA, BTP, and bentiromide, was administered orally together with a test meal to stimulate pancreatic secretion. BTP is specifically hydrolyzed by chymotrypsin in the duodenum to release *p*-aminobenzoic acid (PABA). The amount of PABA detected in serum or urine by high-performance liquid chromatography is an indirect measure of chymotrypsin activity in duodenal content. The test had a lower diagnostic sensitivity and specificity for pancreatic insufficiency than fecal elastase (see Table 51-8).

The *pancreolauryl test* (fluorescein dilaurate test) is also obsolete but was similar in its principle to the NBT-PABA test. Fluorescein dilaurate (FDL), which is specifically hydrolyzed to fluorescein by pancreatic cholesterol esterase, was given orally in the middle of a standard "breakfast" (50 g white bread, 20 g butter, and 1 cup of tea) and is specifically hydrolyzed by pancreatic cholesterol esterase, which requires bile salts for its activity. Fluorescein is water-soluble, readily absorbed by the small intestine, conjugated in the liver, and excreted in the urine. Urine was collected for 10 hours; the test was repeated on a second day using free fluorescein to correct for individual variability in intestinal absorption, hepatic conjugation, and urinary excretion. Urinary recovery of fluorescein was measured on a spectrophotometer each day at 492 nm after hydrolysis with 0.1 mol/L sodium hydroxide under standard conditions. The FDL test produces results very similar to those obtained with the PABA test, although sensitivity was higher (see Table 51-8). Analytically, measurement of fluorescein is simple, and good agreement between laboratories was found from external quality assessment (EQA) results for measurements of fluorescein in urine.[44] The test results could also be expressed as peak serum fluorescein concentration; high sensitivity (100%) was reported in moderate and severe chronic pancreatitis; specificity was poor in small bowel disease because of the influence of factors other than pancreatic enzyme hydrolysis on the absorption of fluorescein.[39] Liver diseases are associated with false-positive results because bile salts are necessary for the digestion and absorption of FDL.

Several different ^{13}C breath tests have been proposed for the evaluation of fat absorption[112]; most of them assess the overall ("global") process of fat absorption and are not able to differentiate fat malabsorption from pancreatic and nonpancreatic causes.

The *^{13}C-mixed chain triglyceride test* is designed as a test of intraluminal pancreatic lipase activity.[182] The substrate for the test is 1,3-distearyl,2(carboxyl-^{13}C) octanoyl glycerol, which contains long chain fatty acids in positions 1 and 3 and the ^{13}C-labeled medium chain fatty acid (octanoic acid) in position 2 (Figure 51-9). The labeled substrate is administered orally to fasting patients with a standard meal of toast and butter. Breath samples are collected over a 5 hour period, and exhaled $^{13}CO_2$ is expressed as a percentage of the

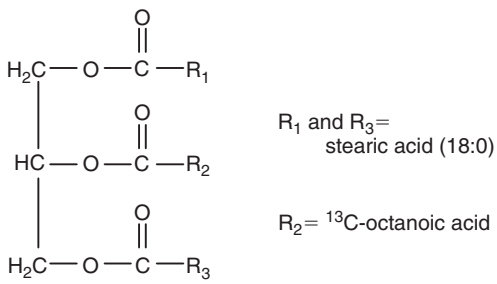

Figure 51-9 The substrate for the ^{13}C-mixed chain triglyceride breath test: 1,3 distearyl,2(carboxyl-^{13}C) octanoyl glycerol.

administered dose. The rationale of the procedure is that before absorption or metabolism of the ^{13}C-octanoate, or ^{13}C-octanoyl monoglyceride, the stearyl groups must be hydrolyzed by the activity of pancreatic lipase. Decreased pancreatic lipase secretion will therefore lead to a reduction in the amount of ^{13}C label absorbed and subsequently metabolized to $^{13}CO_2$.

In an initial assessment, a group of 25 normal control subjects were compared with 29 patients with pancreatic disease. $^{13}CO_2$ in breath (cumulative over 6 hours) was highly correlated with pancreatic lipase output (Figure 51-10).

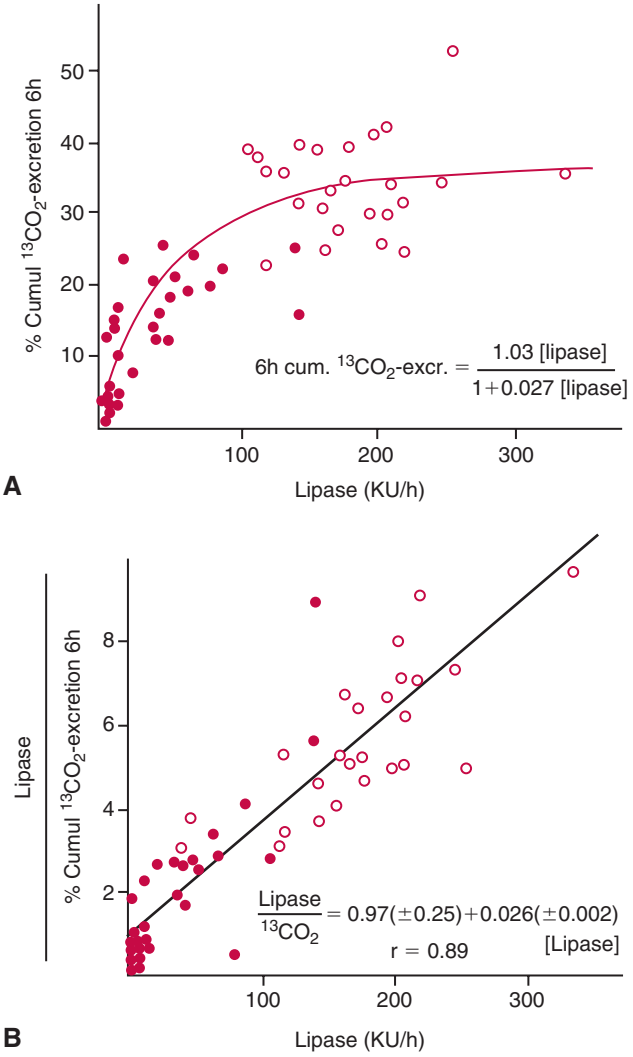

Figure 51-10 A, Cumulative $^{13}CO_2$ excretion (in percentage of ingested dose) 6 hours after intake of the ^{13}C-labeled mixed triglyceride as a function of lipase activity (in kilounits per hour) in normal subjects ○ and patients with pancreatic disease ●. B, Linearly modified saturation curve following the relation given by the following equation: Lipase/$^{13}CO_2$ = (1/A + B/A)(lipase), normal subjects ○, patients with pancreatic disease ●. *(From Vantrappen GR, Rutgeerts PJ, Ghoos YF, Hiele MI. Mixed triglyceride breath test: a noninvasive test of pancreatic lipase activity in the duodenum. Gastroenterology 1989;96:1126-34, with permission from the American Gastroenterological Association.)*

The test was superior to the estimation of fecal fat for detecting impaired pancreatic function. Sensitivity and specificity were 89% and 81%, respectively. In a later evaluation, the test was compared with results from the secretin-cerulein test, with patients categorized as having mild (n = 13) or severe (n = 13) pancreatic insufficiency.[119] Fecal elastase and chymotrypsin were also measured. Fecal elastase and the ^{13}C-mixed chain triglyceride test detected all cases of severe pancreatic insufficiency, but sensitivity was higher for fecal elastase in those with mild disease (see Table 51-8). Similar results were obtained when cholesteryl ^{13}C-octanoate was used as a substrate for a noninvasive test of pancreatic function.[25]

The sensitivity and specificity of these tests are limited by the complexity of the processes of absorption and metabolism. The substrates are specific for pancreatic lipases and the product is absorbed independently of micelle formation, but results of the test are affected by other factors, such as gastric emptying, mucosal absorption, hepatic metabolism, endogenous $^{13}CO_2$, and total CO_2 production.[1,42] These factors may explain the limited diagnostic sensitivity of the test in mild and moderate pancreatic insufficiency and its lack of specificity in nonpancreatic GI disease.

GI REGULATORY PEPTIDES

The gut is the largest endocrine organ in the body[149]; it is also a major target for many hormones, released locally and from other sites. GI regulatory peptides are released from the pancreatic islets (e.g., somatostatin) or from endocrine cells spread throughout the gut mucosa and collectively are referred to as the *diffuse endocrine system.* Many of these peptides (such as VIP and somatostatin) are present in the enteric nerves. They are also found in the central nervous system, and have important roles in the neuroendocrine control of the gut. Although many of them (such as secretin and gastrin) fulfill the classic criteria for a hormone by acting on distant cells (see Chapter 29), others function as neurotransmitters or have local (paracrine) effects on adjacent cells. Collectively, they influence motility, secretion, digestion, and absorption in the gut. They regulate bile flow and secretion of pancreatic hormones and affect the tonicity of vascular walls, blood pressure, and cardiac output.

Understanding of the role of the neuroendocrine system and gut peptides, and of the importance of the gut-hypothalamic pathway, in the normal control of food intake is growing, as is knowledge of the possibility of disorders of these mechanisms as causes of obesity.[154] The gastric peptide ghrelin and cholecystokinin act as short-term regulators of appetite and satiety. The neuropeptide PYY_{3-36}, a member of the neuropeptide Y family, is secreted by endocrine cells in the distal small intestine and colon in response to ingestion of food. Recent evidence shows that infusion of PYY_{3-36} to physiologic plasma concentrations in humans significantly decreases appetite with a 33% reduction in food intake over 24 hours. In mice, the relevant pathway is via the arcuate nucleus of the hypothalamus.[8] PYY_{3-36} therefore is a further

TABLE 51-10 Characteristics of Prominent Forms of Principal Gut Regulatory Peptides

Hormone/ Peptide	Molecular Wt (Da)	No. of Amino Acids	Main Gut Localization	Principal Physiologic Actions
Gastrin Family				
Cholecystokinin	3918	33 (also 385, 59)	Duodenum and jejunum Enteric nerves	Stimulates gallbladder contraction and intestinal motility; stimulates secretion of pancreatic enzymes, insulin, glucagon, and pancreatic polypeptides; has a role in indicating satiety; the C-terminal 8 amino acid peptide cholecystokinin (CCK)-8 retains full activity
Little gastrin Big gastrin	2098 3839	17 34	Both forms of gastrin are found in the gastric antrum and duodenum	Gastrins stimulate the secretion of gastric acid, pepsinogen, intrinsic factor, and secretin; stimulate intestinal mucosal growth; increase gastric and intestinal motility
Secretin-Glucagon Family				
Secretin	3056	27	Duodenum and jejunum	Stimulates pancreatic secretion of HCO_3, enzymes, and insulin; reduces gastric and duodenal motility, inhibits gastrin release and gastric acid secretion
Vasoactive intestinal polypeptide (VIP)	3326	28	Enteric nerves	Relaxes smooth muscle of gut, blood, and genitourinary system; increases water and electrolyte secretion from pancreas and gut; releases hormones from pancreas, gut, and hypothalamus
Glucose-dependent insulinotropic	4976	42	Duodenum and jejunum	Stimulates insulin release; reduces gastric and intestinal motility; increases fluid and electrolyte secretion from small intestine

addition to a growing list of hormones with a role in the regulation of energy balance.

Table 51-10 summarizes basic chemical characteristics of five of the major GI regulatory peptides and indicates their site of origin and major functions. More detailed descriptions of these five peptides are given in the following paragraphs, followed by a listing of other regulatory peptides of the GI tract in Table 51-11.

Cholecystokinin[130,149]

CCK is a linear polypeptide that exists in multiple molecular forms. The first form to be isolated was the 33 amino acid peptide CCK-33. Other major forms are CCK-8, CCK-39, and CCK-58. In all forms, the five C-terminal amino acids are identical to those of gastrin and are necessary, together with a sulfated tyrosyl residue, for physiologic activity. All forms of CCK are produced by enzymatic cleavage of a single 115 amino acid precursor, preprocholecystokinin.

CCK is found in the I cells of the upper small intestinal mucosa. Mixtures of polypeptides and amino acids (especially tryptophan and phenylalanine) stimulate CCK secretion, whereas pure undigested protein does not elicit a response. Secretion is also stimulated by gastric acid entering the duodenum and by fatty acids with chains of nine or more carbons, especially in the form of micelles. Circulating concentrations of CCK therefore are increased following ingestion of a mixed meal. CCK is rapidly cleared from plasma ($t_{1/2}$ = <3 min), predominantly by the kidneys. Secretion of CCK is completely inhibited after somatostatin infusion.

CCK regulates gallbladder contraction and increases small intestinal motility. It possesses the same terminal pentapeptide as gastrin, and therefore also has a mild stimulatory effect on gastric HCl and pepsinogen secretion, antral motility, and pancreatic bicarbonate secretion. Secretion of the less potent CCK results in decreased output of HCl because CCK competes with gastrin for receptor sites on the HCl-secreting cells. Conversely, gastrin and CCK are additive in their stimulation of the pancreas, and both increase the effects of secretin on pancreatic function. CCK also stimulates pancreatic growth, relaxes the sphincter of Oddi, and stimulates secretions from Brunner's (duodenal) glands.

CCK is also present in the brain, with highest concentrations in the cerebral cortex; its function in the CNS is unclear. It is released from the GI tract and acts as a short-term, meal-related satiety signal, thus regulating appetite. CCK is widely

TABLE 51-11 Brief Description of Other GI Regulatory Peptides

Hormone/Peptide	Major Tissue Locations in Gut	Principal Known Actions
Bombesin	Throughout the gut and pancreas	Stimulates release of cholecystokinin (CCK) and gastrin
Calcitonin gene-related peptide	Enteric nerves	Unclear
Chromogranin A	Neuroendocrine cells	Secretory protein
Enkephalins	Stomach, duodenum	Opiate-like actions
Enteroglucagon	Small intestine, pancreas	Inhibits insulin secretion
Galanin	Enteric nerves	
Ghrelin	Stomach	Stimulates appetite, increases gastric emptying
Glucagon-like peptide 1	Pancreas, ileum	Increases insulin secretion
Glucagon-like peptide 2	Ileum, colon	Enterocyte-specific growth hormone
Growth factors	Throughout the gut	Cell proliferation and differentiation
Growth hormone–releasing factor	Small intestine	Unclear
Leptin	Stomach	Appetite control
Motilin	Throughout the gut	Increases gastric emptying and small bowel motility
Neuropeptide Y	Enteric nerves	Regulation of intestinal blood flow
Neurotensin	Ileum	Affects gut motility; increases jejunal and ileal fluid secretion
Pancreastatin	Pancreas	Inhibits pancreatic endocrine and exocrine secretion
Pancreatic polypeptide	Pancreas	Inhibits pancreatic and biliary secretion
PYY_{3-36}	Colon	Inhibits food intake
Somatostatin	Stomach, pancreas	Inhibits secretion and action of many hormones
Substance P	Enteric nerves	Unclear
Trefoil peptides	Stomach, intestine	Mucosal protection and repair

distributed throughout the central and peripheral nervous systems.

Gastrin[130,149]

Three major molecular forms of gastrin occur in blood and tissues: big gastrin (G-34), a linear polypeptide of 34 amino acids; little gastrin (G-17); and mini gastrin (G-14). In addition to these, G-71, G-52, and G-6 are present in small amounts. Gastrins originate from the cleavage of a single precursor, preprogastrin, a peptide consisting of 101 amino acids. The smallest peptide sequence of gastrin possessing biological activity is the carboxy-terminal tetrapeptide (G-4, tetrin); on a molar basis, it is only one sixth to one tenth as potent as G-17. A synthetic pentapeptide (pentagastrin) may be used for stimulation of HCl secretion in gastric function testing.

Gastrin is produced and stored mainly by endocrine cells (G cells) of the antral mucosa and to a lesser extent by G cells of the proximal duodenum and delta cells of the pancreatic islets. After secretion, gastrin is transported by the blood through the liver to the parietal cells of the fundus of the stomach, where it stimulates the secretion of gastric acid. Gastrin also stimulates secretion of gastric pepsinogens and intrinsic factor by the gastric mucosa, release of secretin by the small intestinal mucosa, and secretion of pancreatic bicarbonate and enzymes and hepatic bile; it increases gastric and intestinal motility, mucosal growth, and blood flow to the stomach. It is secreted in response to antral distention meals and by amino acids, peptides, and polypeptides from partially digested proteins in the stomach. Of the free amino acids, glycine, tryptophan, and phenylalanine are the most potent stimulators. Other stimuli of gastrin include alcohol, caffeine, insulin-induced hypoglycemia, and ingestion or intravenous infusion of calcium; vagal stimulation may be initiated by smelling, tasting, chewing, and swallowing food.

Maximal secretion of gastrin occurs at an antral pH of 5 to 7. At pH 2.5, secretion is reduced by about 80%; maximal suppression occurs at pH 1.0. Secretion is inhibited by the direct action of acid on the G cells. This negative feedback safeguards against overacidification by any and all stimulants.

The principal circulating form of gastrin is G-34 in healthy individuals and in patients with hypergastrinemia. Trypsin cleaves G-34 into two fragments, one of which is identical to G-17. On a molar basis, G-17 is six to eight times more potent than G-34 as a stimulant for gastric acid secretion. In the fasting state, the ratio of G-34 to G-17 is about 2:1. After meals, the concentration of G-34 doubles but that of G-17 increases four times, so that the ratio of these two forms in the circulation becomes 1:1. The half-lives of endogenous human G-17 and G-34 in the circulation are about 6 and 36 minutes, respectively; this difference probably accounts for the higher concentration of G-34 in the peripheral blood of individuals in the fasting state.

Secretin[130]

Secretin, a linear polypeptide containing 27 amino acids, has structural similarities to glucagon, VIP, GIP, peptide histidine-isoleucine (PHI), and growth hormone–releasing hormone. The amino acid residues at 14 positions within the molecule are identical to those found in glucagon; 8 are the same as in GIP, and 9 are the same as in VIP. The intact secretin molecule is required for biological activity.

Secretin is secreted by mucosal granular S cells located in greatest concentration in the duodenum but present throughout the small intestine. It is released primarily on contact of the S cells with gastric HCl; however, as pancreatic juice flows into the duodenum, it neutralizes gastric acid, thereby removing one stimulus for its own secretion. Secretin is not released until the pH is lowered to at least 4.5. Below this pH, secretin release is proportional to the amount of acid entering the duodenum. A pH less than 4.5 normally occurs only in the first few centimeters of the duodenum, causing little increase in plasma secretin after a normal meal. Thus secretin release after exposure of S cells to HCl may not be an important physiologic stimulus. However, plasma secretin concentrations that are too low to be measured by current methods may stimulate the pancreas in the presence of physiologic concentrations of CCK, which is known to strongly potentiate the action of secretin. Undigested fat does not stimulate secretin release, but fatty acids with chains of 10 or more carbons are weak stimulants. Alcohol increases secretin release through stimulation of gastric acid secretion with subsequent lowering of duodenal pH rather than by a direct stimulatory effect. The half-life of secretin is about 4 minutes. The kidney is the major site of its degradation. The only known physiologic inhibitor of secretin release is somatostatin.

The primary physiologic role of secretin is stimulation of the pancreas to secrete an increased volume of juice with high bicarbonate content. Other actions include stimulation of bicarbonate and water secretion from the liver and from Brunner's glands; augmentation of gallbladder contraction and increased hepatic bile flow; weak stimulation of insulin secretion (a pharmacologic effect); stimulation of parathyroid hormone (PTH) secretion; release of pancreatic enzymes and of pepsinogen by the chief cells of the stomach; reduction of gastric and duodenal motility; reduction of lower esophageal sphincter pressure; and promotion of pancreatic growth. Secretin inhibits normal gastrin secretion (but does not decrease serum gastrin in the Zollinger-Ellison syndrome) and therefore gastric acid secretion.

Vasoactive Intestinal Polypeptide[130]

VIP is a linear polypeptide consisting of 28 amino acids; it has structural similarities to secretin, GIP, and glucagon. VIP is present throughout the body and is found in highest concentrations in the nervous system and gut. Unlike secretin and other GI hormones, VIP is not found in the mucosal endocrine cells of the GI tract. VIP is believed to be a neurotransmitter limited to peripheral and central nervous tissue. VIP-containing nerve fibers are found throughout the GI tract from the esophagus to the colon and in all tissue layers of the gut.

Little is known about the conditions that cause VIP to be released into the circulation. No evidence suggests that VIP is released during digestion, but its secretion is increased by vagal stimulation. It has a plasma half-life of about 1 minute, and most of the hormone is inactivated by a single passage through the liver.

VIP has a large number of ill-defined physiologic actions, some of which are shared with other similar polypeptide hormones (secretin and GIP). It acts as a neurotransmitter in the central and autonomic nervous systems and causes vasodilation and relaxation of the smooth muscles of the circulatory and genitourinary systems and the gut. Other actions of VIP include an increase of water and electrolyte secretion from the pancreas and gut; release of hormones from the pancreas, gut, and hypothalamus; stimulation of lipolysis, glycolysis, and bile flow; and inhibition of gastrin and gastric acid secretion. Most of the actions of VIP tend to be of short duration because of its rapid degradation.

Glucose-Dependent Insulinotropic Peptide (GIP, Gastric Inhibitory Polypeptide)[130]

GIP is a linear peptide consisting of 42 amino acids. Its N-terminal end has a close resemblance to glucagon and secretin, but the C-terminal amino acid sequence of 17 residues is not common to any other known intestinal hormone.

GIP is synthesized and released by K cells located in the duodenal and jejunal mucosa. Plasma GIP is increased by oral administration of glucose or triacylglycerols, or intraduodenal infusion of solutions containing a mixture of amino acids; none of these, however, increases GIP concentrations when given intravenously. Protein ingestion does not significantly increase GIP. For food components to stimulate GIP release, they must be absorbed by the intestinal mucosa.

The biological actions of GIP include (1) stimulation of insulin secretion in the presence of hyperglycemia; (2) reduction of intestinal motility with stimulation of small intestinal fluid and electrolyte secretion; and (3) in supraphysiologic concentrations, inhibition of gastric acid, pepsin, and gastrin secretion. The insulinotropic action of GIP appears to be the most important of its biological actions; as a result, this hormone has been called *glucose-dependent insulinotropic peptide* as a more accurate description of its physiologic action.

Other Regulatory Peptides

Table 51-11 provides a brief description of tissue locations and the actions of other gut regulatory peptides, although the function of some of these is unclear. The growth factors belong to several families of peptides and have important roles in the control of a wide range of cell functions in the intestine.[37] The current clinical use of GI hormone/regulatory peptide measurements is in the diagnosis of neuroendocrine tumors of the pancreas and GI tract. It is likely that they will have wider applications as understanding of their

functions grows (e.g., in the fields of obesity and appetite modulation).[28,29,137]

GASTROINTESTINAL NEUROENDOCRINE TUMORS AND TUMOR MARKERS

GI neuroendocrine tumors may be endocrine pancreatic tumors or carcinoid tumors arising from enterochromaffin cells that occur throughout the GI tract. Carcinoid tumors are discussed in Chapter 30.

Approximately two thirds of patients with tumors arising from pancreatic islet cells present with clinical syndromes associated with excessive hormone production.[109] This group of tumors includes insulomas, gastrinomas, VIPomas, glucagonomas, and somatostatinomas. Insulinomas and glucagonomas are not usually associated with GI symptoms. Gastrinomas and VIPomas are discussed later. The somatostatinoma syndrome is associated with steatorrhea, gallstones, and diabetes. The remaining one third of patients with endocrine pancreatic tumors have no specific clinical symptoms associated with the tumors, which are described as nonfunctional. Clinical features of these uncommon tumors and measurement of their secretory products have been reviewed.[3]

The pattern of hormone and precursor production by neuroendocrine tumors is complex. Most secrete several tumor markers. Chromogranin A, a member of a family of secretory proteins, has the highest diagnostic sensitivity (94%) for endocrine pancreatic tumors, followed by pancreatic polypeptide (74%).[50] Chromogranin A is elevated in most patients and is an alternative to more specific markers in monitoring the effectiveness of surgery or drug therapy. However, as with other protein and peptide tumor markers, the epitope specificity of antiserum used in the assay has a profound effect on the diagnostic sensitivity of the assay.[109] Although chromogranin A has high sensitivity, false positives have been observed in several nonendocrine tumors, including prostatic cancer.

Gastrinoma and the Zollinger-Ellison Syndrome[7,34,93]

In 1955, Zollinger and Ellison described a syndrome (Zollinger-Ellison, or Z-E, syndrome) consisting of fulminant peptic ulcers, massive gastric hypersecretion, and non-β–islet cell tumors of the pancreas. Hypergastrinemia, diarrhea, steatorrhea, and other endocrinopathies are frequent characteristics of this syndrome. Most cases occur between the ages of 30 and 50 years, although the condition has been described in patients from 7 to 90 years. It is more common in men (60% of cases) than in women. In about 25% of cases, ulcers are found beyond the first portion of the duodenum; such ulcers should always raise suspicion of Z-E syndrome. About 25% of all gastrinomas are part of the multiple endocrine neoplasia 1 syndrome (MEN1), which is characterized by tumors or hyperplasia in the duodenum or pancreatic islets and the parathyroid and pituitary glands. Fasting plasma gastrin usually is greatly increased, ranging from 2 to 2000 times normal. Concentrations more than 10 times the upper limit of normal, in the presence of gastric acid hypersecretion, are virtually diagnostic of gastrinoma. No correlation has been noted between the severity of symptoms and the degree of elevation of the circulating gastrin concentration. However, the fasting plasma gastrin concentration at presentation in sporadic Z-E syndrome is associated with the size and site of the tumor and the presence of hepatic metastases, and therefore has prognostic value.[9] Because management of the patient with Z-E syndrome usually requires surgical intervention, it is important to distinguish hypergastrinemia caused by gastrinoma from other conditions that may lead to similar increases in plasma gastrin.

Increased plasma gastrin occurs in hypochlorhydria or achlorhydria as a consequence of atrophic gastritis or the use of acid-suppressing drugs [e.g., histamine H_2-receptor antagonists, proton pump inhibitors (PPIs)]. Z-E syndrome cannot be diagnosed (or excluded) in patients taking PPIs. These drugs cause a profound reduction in gastric acid secretion and hence a large increase in plasma gastrin. *H. pylori* infection can also lead to increased plasma gastrin and to increased basal acid output, and in some cases to atrophic gastritis and high plasma gastrin.[88] Pernicious anemia and chronic atrophic gastritis associated with parietal cell antibodies are commonly associated with gastrin concentrations that overlap with those found in Z-E syndrome. Increases in plasma gastrin in chronic renal failure appear to be related to the severity of renal failure. A direct correlation has been found between G-cell density and parathyroid function in patients with chronic renal failure, suggesting that secondary hyperparathyroidism may play a role in increasing plasma gastrin. Surgical resection or disease of the kidneys or small intestine can cause hypergastrinemia, possibly because these are important sites of gastrin degradation or excretion.

Increased basal gastrin concentrations may be classified as "appropriate" or "inappropriate" according to their association with decreased or increased gastric acid secretion. In patients with very low or absent acid secretion and a functionally intact gastric antrum, an increase in plasma gastrin is physiologically appropriate and is expected. This increase is caused by hyperplasia of antral G cells as observed in atrophic gastritis, pernicious anemia, previous vagotomy, and renal failure. Inappropriate hypergastrinemia may be caused by gastrinoma, isolated retained antrum after gastric surgery, or primary G-cell hyperfunction.

A secretin stimulation test may assist in the differential diagnosis of Z-E syndrome.[3] The secretin test proved the more useful but is little used now with improved computed tomography scanning and the use of somatostatin-receptor imaging using the somatostatin analog octreotide.[109]

Measurement of Plasma Gastrin

In serum from healthy subjects, the predominant forms of gastrin are amidated G-34 and G-17. In subjects with gastrinomas, the circulating gastrins display unpredictable heterogeneity with a shift toward larger peptides. For the detection of gastrinomas, the assay therefore should be able to detect all secreted forms of gastrin to prevent false negatives.[67]

Gastrin is unstable in serum or plasma, and samples may lose up to 50% of their immunoreactivity during 48 hours at 2 to 8 °C, largely because of the action of proteolytic enzymes. Blood samples should be collected into a tube containing heparin as anticoagulant and aprotinin (e.g., Trasylol, 0.2 mL, 2000 KIU, in a 10 mL tube) to prevent proteolytic degradation. Samples should be mixed by inversion and transported rapidly on ice to the laboratory; the plasma should be separated in a refrigerated centrifuge. The plasma should be frozen at –20 °C within 15 minutes of venipuncture. Samples collected in this way are suitable for analysis of gastrin, VIP, pancreatic polypeptide, somatostatin, neurotensin, and chromogranins A and B.

The Watery Diarrhea Hypokalemia Achlorhydria Syndrome (Werner-Morrison Syndrome, WDHA Syndrome, VIPoma)[92]

The WDHA syndrome may be suspected in a patient who produces large volumes (>1 L/24 h) of secretory diarrhea (see the section on fecal osmolal gap) with dehydration and hypokalemia. The diagnosis is confirmed by the finding of a high plasma VIP concentration and demonstration of the tumor by somatostatin-receptor imaging.

INVESTIGATION OF MALDIGESTION/MALABSORPTION

This section summarizes causes of malabsorption and suggests the general laboratory approach to these disorders.

Box 51-8 summarizes the main causes of malabsorption under the three categories of (1) intraluminal disorders and malabsorption due to disorders of (2) transport into the mucosal cells, and (3) transport out of the mucosal cells.

BOX 51-8 Summary of Disorders Leading to Malabsorption

Disorders of Intraluminal Digestion	
a. Altered gastric function	Postgastrectomy syndrome Zollinger-Ellison syndrome
b. Pancreatic insufficiency	Chronic pancreatitis Cystic fibrosis Pancreatic cancer
c. Bile acid deficiency	Disease/resection of terminal ileum Small bowel bacterial overgrowth
Disorders of Transport Into the Mucosal Cell	
a. Generalized disorders due to reduction in absorptive surface area	Celiac disease, tropical sprue
b. Specific disorders	Hypolactasia Vitamin B_{12} in pernicious anemia Zn in acrodermatitis enteropathica
Disorders of Transport out of the Mucosal Cell	
a. Blockage of the lymphatics	Abdominal lymphoma Primary lymphangiectasia
b. Inherited disorders	α-β-lipoproteinemia

Clinical presentation of the patient suffering from malabsorption or maldigestion classically includes the following features:

- *Evidence of general ill health.* Anorexia, weight loss, fatigue following minor effort, and dyspnea may be seen. Edema (due to hypoalbuminemia or weakness), tetany, and dehydration due to electrolyte imbalance and water loss may be present. In pancreatic exocrine insufficiency, however, hyperphagia is the rule; patients often report a very high (5000 kcal/d) food intake.
- *Isolated nutritional deficiencies.* Iron, folate, or vitamin B_{12} deficiency may manifest as anemia, which may be mild; vitamin K deficiency as a bleeding tendency; and vitamin D deficiency as bone disease. They are reflected by a variety of signs and symptoms (glossitis, pallor, dermatitis, petechiae, bruising, hematuria, muscle or bone pain, or neurologic abnormalities).
- *Abdominal symptoms,* such as discomfort, distention, flatulence, and borborygmi (rumbling and gurgling sounds due to movement of gas in the intestine).
- *Watery diarrhea and possible steatorrhe*a. In severe cases of steatorrhea (excess fat in feces), the stool is typically loose, bulky, offensive, greasy, light-colored, and difficult to flush away. Alternatively, the stools may appear normal but may be more bulky or may be passed with greater frequency.

Early presentation of malabsorption will, however, be more subtle than this list would indicate. The alteration in volume or consistency of the stool may be slight, and only mild symptoms may be attributable to the GI tract. The patient may complain only of anorexia, fatigue, and lack of interest in daily activities. It is in these cases that the physician who suspects malabsorption on clinical grounds will rely on the laboratory to assist in the diagnosis. Initial laboratory investigations consist of routine tests, abnormalities of which may point to the possibility of malabsorption [e.g., blood hemoglobin concentration; mean red cell volume; serum concentrations of folate, ferritin, calcium, albumin, and alkaline phosphatase; tests for antibodies in celiac disease (celiac serology)].

Evaluation of Fat Absorption[78]

The evaluation of fat absorption or malabsorption is required in a small minority of patients undergoing investigation for GI disorders. The guidelines of the British Society of Gastroenterology (BSG)[174] state that gastroenterologists should have access to such tests to "…assess patients with malabsorption who are proving difficult to diagnose."

In a survey in 1997 of 231 hospitals in the United Kingdom,[44] fecal fat was the most widely available of all tests, with an estimated number of fecal fat measurements of 6100 performed annually in the United Kingdom. Fecal fat measurement has many limitations,[85] some of which were highlighted in the 1997 survey, that must be brought to the attention of clinicians to dissuade them from relying on an inherently unreliable test. In addition, dialogue with local

gastroenterologists is necessary to reach consensus that the quantitative demonstration of fat malabsorption is of little value for most patients.

Limitations of Fecal Fat Measurement

The case for abandoning fecal fat measurement can be made on the grounds of physiology and of analytical performance. The physiologic problems of sample collection were convincingly demonstrated in a study in which radiopaque pellets were administered orally (8, three times a day) for 5 days (120 total), and feces were collected for days 3 to 5.[187] Radiographic detection of 72 pellets was taken to indicate 100% recovery. In 52 patients studied, recovery ranged from 14 to 125%, and recovery was within the range of 85 to 115% in only 32 of them. In seven patients, fecal fat was normal but became abnormal after adjustment for marker recovery. Despite this evidence, few laboratories attempt to assess the completeness of collection using markers.

Absorption of dietary fat is a remarkably efficient process, so that in normal health, fecal fat is largely (if not entirely) derived from endogenous rather than dietary sources.[40,76,104] Adequate dietary fat intake therefore is essential to minimize false-negative results. The BSG guidelines recommend a diet containing at least 70 g fat for 6 days.[174] In the United Kingdom, only a minority of laboratories try to control (20%) or retrospectively assess (8%) fat intake.[44] Patients with steatorrhea may reduce their fat intake to control their diarrhea and despite laboratory instructions may not increase their dietary fat before and during the 72 hours of fecal collection; this will result in misleadingly low results.[40]

Also, it is often forgotten that diarrhea increases fecal fat excretion. In 58% of subjects with normal fat excretion, experimental induction of severe diarrhea (fecal weight >800 g/d) led to increased fecal fat (values of up to 49 mmol/d).[58] A borderline increase in fecal fat (i.e., two to three times the upper limit of normal, which is 18 mmol/d) therefore is not specific for a primary defect in fat digestion or absorption.

Available analytical performance data for fecal fat measurements in the United Kingdom indicate that the test should now be consigned to history. Eighty-two percent of laboratories use no internal quality control, and EQA is impractical. When the titration step was assessed in an EQA exercise, between-laboratory coefficients of variation for three samples ranged from 31 to 42%.[44] Infrared spectroscopy offers the possibility of improved within- and between-laboratory precision for fecal fat measurements,[89] but does not address the problems of dietary input and sample collection, and is unlikely to be available to most laboratories.

At the end of an extensive survey of hospital laboratories in the United Kingdom, Duncan (unpublished report of the Clinical Resource and Audit Group, Scottish Office, Edinburgh, 1997) concluded that "the current utilization of the test, with no control of dietary fat intake, no correction for incomplete fecal collections and misgivings over analytical reliability, makes it a highly unsatisfactory investigation and probably of little clinical value."

Quantitative Demonstration of Fat Malabsorption Is Rarely Necessary

Many requests for fecal fat can be avoided or rejected by asking the requesting physician how the demonstration of fat malabsorption will help in diagnosis of the disorder or management of the patient (Table 51-12). In most cases, it will become evident that neither fecal fat nor an alternative test for assessing fat absorption is necessary. There is no justification for assessing fat absorption for the diagnosis or management of celiac disease, and fecal elastase is a more appropriate test for the investigation of suspected pancreatic disease. Measuring fecal fat in patients with offensive, floating, putty-colored stools will not provide a diagnosis.

It is essential to encourage clinicians to use appropriate newer tests of GI function directed toward specific clinical situations (Table 51-13). The availability and use of these tests will discourage the inappropriate use of fecal fat measurement.

The question remains: "Which test should be used when the assessment of fat malabsorption really is indicated?" Box 51-9 indicates the range of possible tests. In the 1997 survey, performance of fecal microscopy was very poor (sensitivity 26%, specificity 64%); however, several studies have reported

TABLE 51-12 Common Situations in Which Fecal Fat May Be Requested but Is Unhelpful in Diagnosis and Management

Clinical Picture or Question	Appropriate Laboratory Response
Abdominal pain, weight loss, and diarrhea; possible small bowel problem	Celiac serology: consider small bowel radiology
Offensive, floating, light-colored stools	None (demonstrating fat malabsorption will not provide a diagnosis)
Elderly patient, weight loss, possible malabsorption	Fat intake probably too low for fecal fat measurement; encourage use of appropriate investigations (see Table 51-13)
Pancreatic insufficiency, patient on enzyme supplements	Monitor stool consistency and clinical response (weight gain); may occasionally need to assess fat absorption
Abdominal pain, weight loss, and possible pancreatic insufficiency	Use a specific pancreatic function test
Child, foul stool, possible malabsorption	May sometimes need to confirm presence of fat globules in stool

From Hill PG. Faecal fat: time to give it up. Ann Clin Biochem 2001;38:164-7.

TABLE 51-13 Laboratory Tests to Assess GI Function

Clinical Application	Appropriate Laboratory Investigations
Investigating diarrhea	Possible lactase deficiency: breath hydrogen after oral lactose Possible bacterial overgrowth: breath hydrogen after oral glucose or lactulose Possible laxative abuse: urine laxative screen Possibly induced by bile acid: ^{75}selenohomocholyltaurine whole body retention or serum 7α-hydroxy-4-cholesten-3-one Fecal osmotic gap: fecal Na, K
Assessing pancreatic function	Pancreolauryl test, fecal elastase
Screening for celiac disease	Tissue transglutaminase antibodies
Assessing fat absorption	^{14}C-triolein absorption (breath $^{14}CO_2$) or fecal microscopy
Other tests	Fecal α-1-antitrypsin for protein-losing enteropathy; gut hormones (gastrin)

From Hill PG. Faecal fat: time to give it up. Ann Clin Biochem 2001;38:164-7.

BOX 51-9 Tests for Assessing Fat Absorption and Malabsorption

Measurement of fecal fat
- Problems of poor recovery during sample collection (requires use of markers), inadequate dietary fat (minimum of 70 g/d), inaccurate analysis, and uncertain interpretation

Butter fat test
- Unreliable, poor discrimination

^{14}C-glyceryl trioleate
- Sensitivity 85%, specificity 93%
- Important factors to consider
  - Fat load (20 g) and form of "meal"
  - Effect of fat load on timing of peak of breath CO_2
  - Effect of assuming a constant CO_2 output of 9 mmol/kg/h

Inappropriate in
- Liver, thyroid, and severe respiratory disease, diabetes, obesity, pregnancy

Mixed chain triglyceride breath test
- Valid test for pancreatic steatorrhea

Fat globules (fecal microscopy)
- Need for standardized procedure

high sensitivity and specificity figures when compared with those derived from fecal fat measurement.[116,121] Some have argued that fecal microscopy after staining with Sudan III has advantages over fecal fat measurement, because it detects fecal triglycerides and fatty acids, which are principally of dietary origin; fecal fats include phospholipids and cholesteryl esters, which largely originate from the turnover of intestinal epithelial cells and gut bacteria.[103] There is still a need to evaluate a well-defined standardized technique for fat globules by fecal microscopy in a multilaboratory study. Meanwhile, Duncan has made several recommendations (unpublished report as previously noted) to improve current performance related to method, interpretation, quality control, and adequate dietary fat before fecal samples are collected.

In a prospective evaluation of the ^{14}C-triolein test in 57 patients, reported sensitivity was 85%, with specificity of 93% for the detection of fat malabsorption.[181] The procedure used a fat load of 19.3 g prepared as a palatable lemon mousse, containing protein (1.4 g) and carbohydrate (10 g). Peak $^{14}CO_2$ occurred within 6 hours in all subjects studied who had normal fat absorption. The "gold standard" for fat malabsorption was the final diagnosis made on clinical, histologic, and radiologic or laboratory grounds. Various fat loads and procedures have been used,[44] and it is clear that larger fat loads (e.g., 60 g) result in significant delays in peak $^{14}CO_2$ in exhaled breath.[42] When a similar fat load was used without the inclusion of protein and carbohydrates, peak $^{14}CO_2$ occurred later in some patients. In 53 patients in whom $^{14}CO_2$ excretion peaked within 6 hours, the sensitivity and specificity of the tests were 100% and 96%, respectively.[42] An additional source of error is that the usually presumed CO_2 output of 9 mmol/kg/h may lead to significant errors in results because actual output varies from 5 to 12.4 mmol/kg/h.[42]

Breath samples for $^{14}CO_2$ measurement are not easily transportable, and the requirement for a scintillation counter and administrative regulations surrounding the use of radioisotopes deter many laboratories from using the test.

With growing interest in the application of stable isotopes, ^{13}C-substrates may replace the use of ^{14}C-triolein. A breath test using ^{13}C-mixed chain triglycerides [1,3-distearyl, 2(carboxyl-^{13}C) octanoyl glycerol] has been used in children[2] and adults.[182] With a medium chain fatty acid in the 2-position, the test is designed to assess intraluminal pancreatic lipase activity and therefore is not a substitute for fecal fat measurement. The ^{13}C-triolein test, using a uniformly labeled long chain triglyceride, is an alternative to fecal fat measurement.[112]

The van de Kamer method[96] for measuring fecal fat has survived for 5 decades but should now be abandoned as a routine diagnostic test; the wider use of more specific tests for investigating disorders of GI function should be encouraged.[177]

INVESTIGATION OF CHRONIC DIARRHEA

Although diarrhea is a common problem, no clear definition has existed to distinguish it from the range of stool weight, frequency, consistency, or volume that occurs in the normal

population. A 2003 proposal, which seeks to encompass these different elements, suggests that for a Western diet, diarrhea may be defined as "the abnormal passage of loose or liquid stools more than three times daily and/or a volume of stool [with a weight] greater than 200 g/day."[177] Guidelines suggest that diarrhea may be defined as chronic when it has continued for 4 weeks; such persistence indicates the likelihood of a noninfectious cause requiring further investigation.

Several quite different mechanisms can lead to diarrhea. In carbohydrate malabsorption, the presence of unabsorbed solutes in the bowel causes an osmotic diarrhea as water enters the bowel from the tissue. By contrast, the diarrhea of most laxative abuse and VIPomas is due to active secretion of water and electrolytes into the bowel, which is described as secretory diarrhea. Inflammatory bowel disease (ulcerative colitis and Crohn's disease) causes diarrhea as a consequence of the inflammatory process with loss of fluid into the bowel.

Many diseases commonly thought to cause "diarrhea" in fact lead to more frequent passage of stools but not usually to an increased stool weight (or volume). Such disorders (e.g., irritable bowel syndrome) generally fall outside the scope of the definition of *chronic diarrhea.* Guidelines for the management of irritable bowel syndrome are available.[40A,94,164A]

Box 51-10 describes the many causes of chronic diarrhea; most chronic diarrhea is due to disease of the colon in which laboratory diagnostic tests are currently of little value. A helpful algorithm for the investigation of chronic diarrhea is given in Figure 51-11.

Investigation of laxative abuse and measurement of fecal osmotic gap are described in the following sections. The other laboratory tests required for the investigation of chronic diarrhea are described in the previous sections on intestinal disease, pancreatic disease, and neuroendocrine tumors.

BOX 51-10 Causes of Chronic Diarrhea

Colonic
- Colonic neoplasia
- Ulcerative and Crohn's colitis
- Microscopic colitis

Small bowel
- Celiac disease
- Crohn's disease
- Other small bowel enteropathies (e.g., Whipple's disease, tropical sprue, amyloid, intestinal lymphangiectasia)
- Bile salt malabsorption
- Disaccharidase deficiency
- Small bowel bacterial overgrowth
- Mesenteric ischemia
- Radiation enteritis
- Lymphoma
- Giardiasis (and other chronic infection)

Pancreatic
- Chronic pancreatitis
- Pancreatic carcinoma
- Cystic fibrosis

Endocrine
- Hyperthyroidism
- Diabetes
- Hypoparathyroidism
- Addison's disease
- Hormone-secreting tumors (VIPoma, gastrinoma, carcinoid)

Other
- Factitious diarrhea
- "Surgical" causes (e.g., small bowel resection, internal fistulas)
- Drugs
- Alcohol
- Autonomic neuropathy

From Thomas PD, Forbes A, Green J, Howdle P, Long R, Playford R, et al. Guidelines for the investigation of chronic diarrhoea, 2nd edition. Gut 2003;52(suppl V):vol 1-15; reproduced with permission from the BMJ Publishing Group.

Laxative Abuse[42,151A]

Surreptitious laxative abuse is an important cause of chronic diarrhea that is often overlooked. It is the final diagnosis for chronic diarrhea in 15 to 26% of patients investigated in secondary or tertiary referral centers[16,46,146,148] and in 4% of a consecutive series of new primary care referrals to a gastroenterology clinic for evaluation of diarrhea.[46] The financial benefits of screening for laxative abuse have been established, and when the diagnosis is not considered early in the investigative pathway, extensive and unnecessary investigations may occur.[16] In Munchausen syndrome by proxy, adults have administered laxatives surreptitiously to young children. A clinical diagnosis can rarely be made; no single clinical feature reliably predicts a positive test, making laboratory support essential.[59,177] The main initial prerequisite for making a diagnosis of surreptitious laxative abuse is a high index of clinical suspicion,[41] followed by a request for appropriate analyses in urine and fecal samples at a time when the patient has diarrhea.

The pattern of laxative abuse has changed following legislation in several countries banning over-the-counter sales of laxatives containing phenolphthalein, traditionally the most widely abused laxative. Abuse of phenolphthalein has therefore decreased, and the laxatives most frequently encountered by clinical laboratories are colonic stimulants containing bisacodyl or anthraquinones (e.g., senna, aloin, cascara). Their absorption, metabolism, and excretion have been reviewed.[41] They can be detected in urine for at least 32 hours after a single dose.[189] Magnesium salts are the active ingredient in some over-the-counter laxatives; these may also be abused. The only reliable diagnostic procedure is the measurement of magnesium in fecal water. Concentrations greater than 30 mmol/L are suggestive of magnesium-induced diarrhea.[43]

A pilot National External Quality Assurance Scheme was set up in the United Kingdom in 1996. In the light of poor overall performance highlighted by the scheme, recommendations were made for a laxative screening service. Subsequently, thin layer chromatography (TLC) methods were extensively evaluated to optimize the detection of

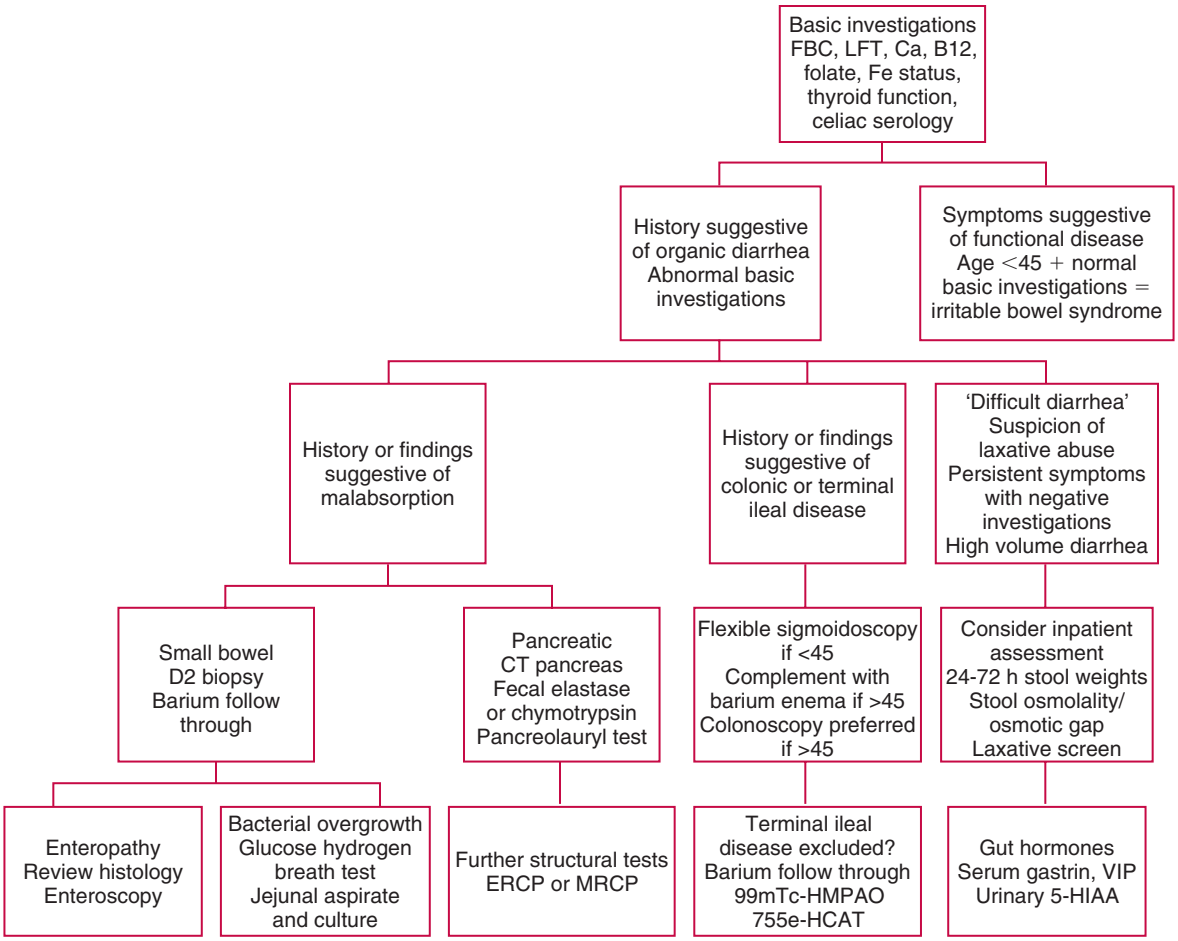

Figure 51-11 An algorithm for the investigation of chronic diarrhea. *CT,* Computed tomography; *ERCP,* endoscopic retrograde cholangiopancreatography; *FBC,* full blood count; *5-HIAA,* 5-hydroxyindoleacetic acid; *LFT,* liver function tests; *MRCP,* magnetic resonance cholangiopancreatography; *75Se-HCAT,* 75Se homotaurocholate; *Tc-HMPAO,* technetium hexa-methyl-propyleneamine oxime. *(From Thomas PD, Forbes A, Green J, Howdle P, Long R, Playford R, et al. Guidelines for the investigation of chronic diarrhoea, 2nd edition. Gut 2003;52(suppl V):v1-15. Used with permission of the BMJ Publishing Group.)*

laxatives.[47] The most important findings for the successful detection of laxatives by TLC were (1) the skill and experience of the operator, (2) the choice of the mobile phase [ethyl acetate:toluene:glacial acetic acid (4:16:1) and hexane:toluene:glacial acetic acid (3:1:1) gave the best results], and (3) use of high-performance TLC plates with a concentrating zone. Increased centralization of laxative analysis led to some improvement in analytical performance, but an assessment of the performance of a reference laboratory in the United States has again highlighted the unreliability of TLC with problems identified for both bisacodyl and senna detection.[157]

For such tests, false positives or false negatives have particularly important implications for the management of the condition, and poor sensitivity and specificity for laxative analysis are unacceptable. The analysis of laxatives should be regarded as part of the toxicology service; the problems identified with TLC suggest that these techniques should be replaced by gas chromatography–mass spectrometry (GC-MS) for all samples requiring laxative analysis.[41] Analyses should be undertaken only by laboratories with appropriate expertise and ability to demonstrate good performance for these tests, so as to ensure that chronic diarrhea is correctly diagnosed and managed.

Fecal Osmotic (Osmolal) Gap

The osmolality of stool "water" normally will be that of serum (i.e., 290 mosm/kg), but the contribution of electrolytes and of nonelectrolytes to the total osmolality will vary, depending on the cause of the diarrhea. Fecal osmotic (osmolal) gap (FOG) expresses the difference between the theoretical normal osmolality (290 mosm/kg) and the contribution of Na^+ and K^+, as follows:

$$\text{Fecal osmotic gap} = 290 - [2(\text{fecal } Na^+ + K^+)]$$

Fecal sodium and potassium are measured in the fluid obtained by rapid centrifugation of a fecal sample. Total fecal osmolality increases significantly in unrefrigerated samples,

and use of the serum osmolality of 290 mosm/kg has been recommended in the above formula, rather than measurement of total fecal osmolality.[48]

Measurement of FOG enables an estimate to be made of the contribution of electrolytes or nonelectrolytes to retention of water in the bowel and therefore can assist in distinguishing between secretory and osmotic diarrhea. In osmotic diarrhea, unabsorbed solutes lead to water retention and thus will make a larger contribution than normal to fecal osmolality; fecal sodium and potassium therefore will be present at lower concentrations than normal, leading to a larger *osmotic gap*. Conversely, in secretory diarrhea, it is electrolytes that lead to water retention, and the FOG therefore will be small. FOG greater than 50 mosm/kg is consistent with an osmotic diarrhea from carbohydrate malabsorption or magnesium-induced diarrhea[43]; by contrast, FOG less than 50 mosm/kg suggests a secretory diarrhea, and further investigation might include a laxative screen for colonic stimulants or, rarely, testing for neuroendocrine tumor.[59] A low FOG will be found in factitious diarrhea because of the addition of water to the stool; if this is suspected and if other causes are excluded, then measurement of total stool osmolality may be helpful.[100]

Measurement of creatinine can be used as an indication of contamination of the fecal sample with urine.

The skeletal system is one of the largest organs in the body and the storehouse for 98 to 99% of the body's calcium. Bones are mineralized connective tissue in which type I collagen forms a network of flexible fibers. Mineralization of this network, or matrix, with calcium salts is required to produce the rigid skeleton. Bones are a living tissue that is constantly being remodeled by degradation of old tissue and its replacement with new bone matrix. Two bone cell types, osteoclasts and osteoblasts, are mainly responsible for remodeling. It is now possible to analyze both bone formation and resorption by clinical laboratory methods.

Calcium is required for mineralization of bone and is a key regulator of body processes. Calcium ions play critical roles in intracellular signaling, in regulation of events at the plasma membrane, and in the function of extracellular proteins such as those involved in blood coagulation. The circulating concentration of calcium ions normally is kept constant under the control of parathyroid hormone and metabolites of vitamin D. Deviations of the concentration of free (unbound) calcium outside its very narrow reference interval can be life threatening. The importance of the tight regulation of free calcium is underscored by the recognition that skeletal health is allowed to suffer markedly to allow physiologic processes in other organs to be maintained.

In this chapter, after providing an overview of skeletal metabolism, we discuss (1) the clinical chemistry of several components of free calcium and review other ions, particularly phosphate and magnesium; (2) key hormones regulating these minerals; (3) markers of bone formation and degradation; and (4) major disorders of bone.

OVERVIEW OF SKELETAL METABOLISM

Bone is composed primarily of an extracellular mineralized matrix with a smaller cellular fraction. Bone is a dynamic tissue that is under continuous turnover or *remodeling,* which enables bone to repair damage and adjust strength. *Osteoclasts* and *osteoblasts,* the two main types of bone cells, are located on bone surfaces and are responsible for bone resorption and formation, respectively. Osteoclasts resorb bone, osteoblasts lay down new bone at a site of previous bone resorption, and osteocytes nourish the skeleton (Figure 52-1). Bone remodeling does not occur at random, but occurs instead in discrete packets known as *bone remodeling units*. Bone resorption and bone formation normally are coupled, with synthesis of new bone following the resorption of old. During menopause, the remodeling rate is often increased, but with excess resorption (a negative bone balance). The remodeling cycle can be divided into activation, resorption, reversal, formation, and termination phases.

Circulating mononuclear osteoclast precursors are recruited, proliferate, and fuse to form osteoclasts. These giant multinucleated cells resorb bone by producing hydrogen ions to mobilize minerals and lysosomal enzymes to digest the organic matrix. Deep foldings of their plasma membrane (ruffled border) are in contact with the bone surface, forming the osteoclastic bone-resorbing compartment (Figure 52-2). The resorption lacuna contains degradative enzymes such as cathepsin K and several matrix metalloproteinases (MMPs). After resorption ceases, a cement line is deposited in the resorption cavity, probably by mononucleated cells. Stromal lining cells differentiate to osteoblasts. Osteoblasts form bone by synthesizing the organic matrix, including type I collagen, and participating in the mineralization of newly synthesized matrix. The development of the osteoblast phenotype has been divided into three consecutive phases, each with its typical gene expression patterns (Figure 52-3).[181] Remodeling is followed by a quiescent or termination phase.

The organic matrix of bone is primarily type I collagen (90%) combined with lesser amounts of a large number of

**The authors gratefully acknowledge the contributions to previous editions by Drs. David B. Endres and Robert K. Rude, upon which portions of this chapter are based.*

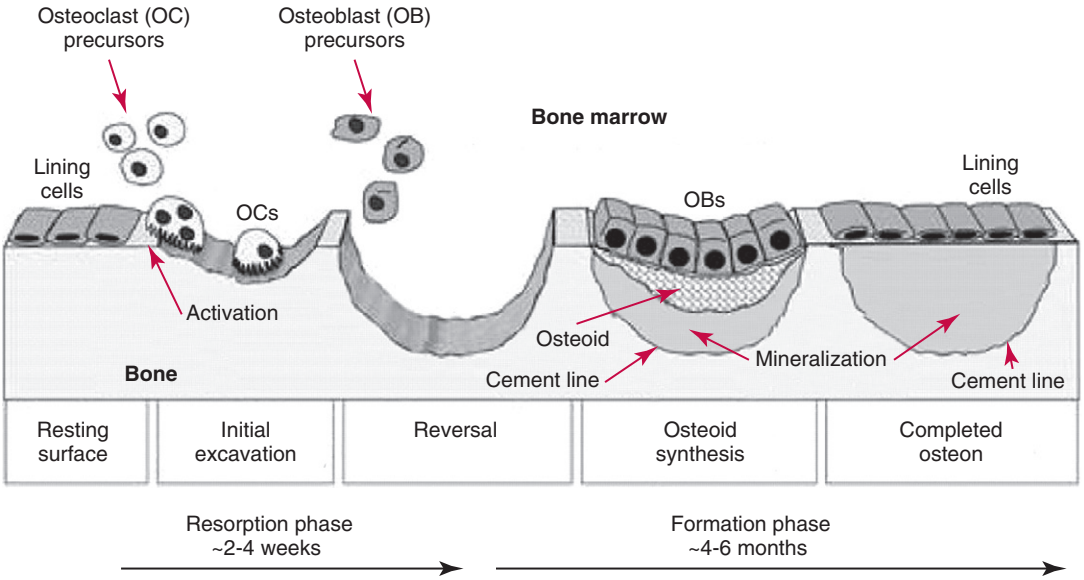

Figure 52-1 Bone remodeling sequence. A cartoon depiction of the sequential action of osteoclasts and osteoblasts in removing old bone and replacing it with new bone. For simplicity of illustration, the cartoon shows remodeling in only two dimensions, whereas in vivo, it occurs in three dimensions, with osteoclasts continuing to enlarge the cavity at one end and osteoblasts beginning to fill it in at the other end. *(From Riggs BL, Parfitt AM. Drugs used to treat osteoporosis: the critical need for a uniform nomenclature based on their action on bone remodeling. J Bone Miner Res 2005;20:177-84.)*

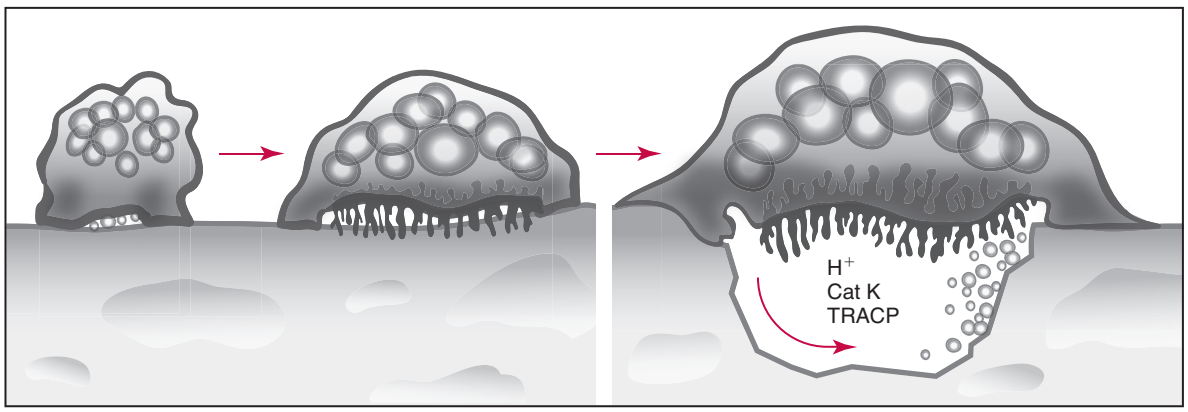

Figure 52-2 Activation of bone resorption. Multinucleated cells are recruited by the action of colony-stimulating factor 1 (CSF-1) and receptor activator for nuclear factor κ B ligand (RANKL) and adhere to bone, undergoing differentiation into mature osteoclasts. RANKL stimulates osteoclast activation by inducing secretion of protons and lytic enzymes into a sealed resorption vacuole formed between the basal surface of the osteoclast and the bone surface. Acidification of the vacuole leads to activation of tartrate-resistant acid phosphatase (TRACP) and cathepsin K (Cat K). *(Modified from Boyle WJ, Simonet WS, Lacey DL. Osteoclast differentiation and activation. Nature 2003;423:337-42.)*

noncollagenous proteins, some of which are found only in bone. Type I collagen is a product of two genes—*COL1A1* on chromosome 17 and *COL1A2* on chromosome 7—that encode two chains of the collagen molecule, called α1(I) and α2(I) chains. The organic matrix is mineralized by the deposition of inorganic calcium and phosphate in small crystals with lesser amounts of carbonate, magnesium, sodium, potassium, and various other ions.

The skeleton is not just a storehouse for ions but is essential for locomotion, protection of vital organs, and production and maturation of major components of the hematopoietic system. Bone contains nearly all of the calcium (≈99%), most of the phosphate (85%), and much of the magnesium (55%) of the body. The structural component of bone required for locomotion and protection of organs is the outer cortical shell, which accounts for 80% of skeletal mass. The less robust

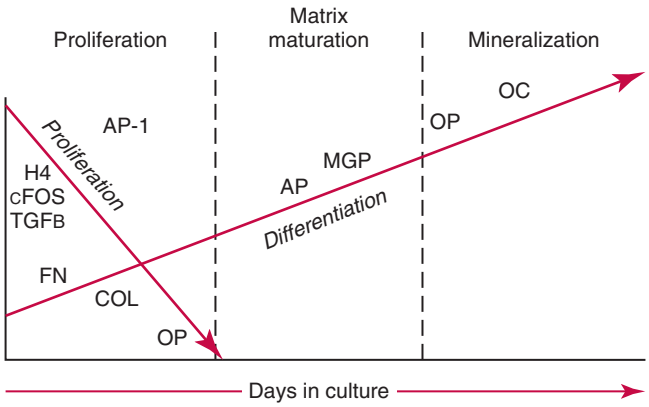

Figure 52-3 Schematic representation of the development of the osteoblast phenotype. Development of the osteoblast phenotype: molecular mechanisms mediating osteoblast growth and differentiation. Iowa Orthop J 1995;15;118-40.)*

inner cancellous (trabecular) bone also has a role in the mechanical stability of the skeleton, in that disruption of its microarchitecture is the dominant contributor to minimal-trauma fractures.

Cell Signaling in Bone

Over the past few years, much new information about control of the bone remodeling cycle has become available. Understanding of signaling pathways has led to the development of potential new therapies.[157] Two key signaling pathways are known as RANK/RANKL/OPG and Wnt.

RANK (receptor activator of nuclear factor κ B) is a membrane protein expressed on the surface of osteoclasts. Its ligand (RANK ligand, or RANKL) is found on the surface of osteoblasts (also on stromal and T cells). Binding of RANK to RANKL activates osteoclasts (see Figure 52-2). Osteoprotegerin (OPG) is a cytokine [a member of the tumor necrosis factor (TNF) receptor superfamily] and a RANK homolog that can inhibit the production and maturation of osteoclasts by blocking the interaction of RANK with its ligand RANKL. OPG production is stimulated by estrogen, and the marked decrease in estrogen at menopause diminishes OPG production, leaving the way open for increased activation of osteoclasts and the resultant accelerated bone loss that accompanies menopause.

The Wnt signaling pathway is far more complex and is involved in many physiologic systems beyond the skeleton. Key components that have been best studied thus far with respect to skeletal physiology include (1) the Frizzled family of G protein–coupled receptor proteins, (2) low-density lipoprotein receptor–related protein 5 encoded by the *LRP5* gene and associated with high bone mass in affected families, (3) cathepsin K, (4) Dickkopf-related protein 1 (DKK1), and (5) sclerostin.[238]

Bone Remodeling

An estimated 10 to 30% of the skeleton is remodeled each year, with wide variation among individuals. Bone growth and turnover are influenced by the metabolism of calcium, phosphate, and magnesium and several hormones, the primary ones being parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D [1,25$(OH)_2$D]. Bone formation and resorption are affected, however, by a large number of other hormones and factors, including thyroid hormones, estrogens, androgens, cortisol, insulin, growth hormone, insulin-like growth factors (IGF-I and IGF-II), transforming growth factor-β (TGF-β), fibroblast growth factor (FGF), and platelet-derived growth factor (PDGF). Numerous cytokines alter bone remodeling primarily by stimulating resorption; these factors include interleukins (IL)-1, -4, -6 and -11; macrophage and granulocyte/macrophage colony-stimulating factors; and tumor necrosis factor-α (TNF-α). Findings suggest that leptin, which is secreted by adipocytes, can negatively regulate bone formation by osteoblasts.[304,305]

Exercise is a major factor in maintaining bone mass, and immobilization leads to rapid bone loss. Lack of gravity, as occurs during space flight, results in dramatic bone loss.

During childhood and adolescence, bone formation markedly exceeds bone resorption (bone modeling)—a situation that ends with epiphyseal closure at the end of puberty and is followed by a period of consolidation for the next 5 to 10 years, during which time the bone becomes fully mineralized. In healthy individuals, resorption and formation remain in balance for the next several decades. At menopause, the decline in estrogen triggers an increase in bone resorption that exceeds the capacity of the formation process and results in a rapid decrease in bone mass. This imbalance continues at an accelerated rate for approximately 5 years before slowing down to a slower rate of loss of bone, termed *age-related bone loss.* Men do not experience the phase of rapid bone loss unless they develop male hypogonadism, but they do experience age-related loss at a rate similar to that seen in women. The disease resulting from remodeling imbalance is osteoporosis.

Several diseases and medications have adverse effects on bone remodeling and bone balance, in which case the term *secondary osteoporosis* is used. Systemic skeletal disease is also seen in primary and secondary abnormalities in parathyroid hormone regulation. This latter group includes osteomalacia caused by deficiency of active metabolites of the vitamin D endocrine system or metabolic disruption of the vitamin D system, as is seen in patients with chronic renal failure. Nonsystemic skeletal disease also occurs as in skeletal metastases or Paget disease of bone. These diseases will be discussed in a later section of this chapter.

CALCIUM

Calcium is the fifth most common element in the body and the most prevalent cation. An average human body contains about 1 kg, or ≈25 mol, of calcium (Table 52-1). The skeleton contains ≈99% of the body's calcium, predominantly as extracellular crystals of unknown structure and a composition approaching that of hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$]. Soft tissues and extracellular fluid contain about 1% of the body's calcium.

Biochemistry and Physiology

In blood, virtually all of the calcium is found in the plasma, which has a mean calcium concentration of ≈9.5 mg/dL (2.38 mmol/L). Calcium exists in three physicochemical states in plasma (Table 52-2): ≈50% is free (ionized), 40% is bound to plasma proteins, and 10% is complexed with small diffusible inorganic and organic anions, including bicarbonate, lactate, phosphate, and citrate.[249]

The free calcium fraction is the biologically active form. Its concentration in plasma is tightly regulated by the calcium-regulating hormones PTH and $1,25(OH)_2D$.

About 80% of protein-bound calcium is associated with albumin,[88,168] with the remaining 20% associated with globulins. Because calcium binds to negatively charged sites on proteins, its binding is pH dependent. Alkalosis leads to an increase in negative charge and binding and a decrease in free calcium; conversely, acidosis leads to a decrease in negative charge and binding and an increase in free calcium. In vitro, for each 0.1 unit change in pH, approximately 0.2 mg/dL (0.05 mmol/L) of inverse change occurs in the serum free calcium concentration.

Calcium can be redistributed among the three plasma pools, acutely or chronically, by alterations in the concentrations of protein and small anions, changes in pH, or changes in the quantities of free calcium and total calcium in the serum (Figure 52-4).

Physiologically, calcium may be classified as intracellular or extracellular. Intracellular calcium has key roles in many important physiologic functions, including muscle contraction, hormone secretion, glycogen metabolism, and cell division.[239] The intracellular concentration of calcium in the cytosol of unstimulated cells is around 0.1 µmol/L, which is less than $\frac{1}{10,000}$ of that in extracellular fluid.

Extracellular calcium provides calcium ion for the maintenance of intracellular calcium, bone mineralization, blood coagulation, and plasma membrane potential. Calcium stabilizes the plasma membranes and influences permeability and excitability. A decrease in the serum free calcium concentration causes increased neuromuscular excitability and tetany; an increased concentration reduces neuromuscular excitability.

TABLE 52-1 Distribution of Calcium, Phosphate, and Magnesium in the Body

Tissue	Calcium	Phosphate	Magnesium
Skeleton	99%	85%	55%
Soft tissues	1%	15%	45%
Extracellular fluid	<0.2%	<0.1%	1%
Total	1000 g (25 mol)	600 g (19.4 mol)	25 g (1.0 mol)

Modified from Aurbach GD, Marx SJ, Speigel AM. Parathyroid hormone, calcitonin, and the calciferols. In: Wilson JD, Foster DW, eds. Williams textbook of endocrinology, 8th edition. Philadelphia, Pa: WB Saunders, 1992:1397-476.

TABLE 52-2 Physicochemical States of Calcium, Phosphate, and Magnesium in Human Plasma

	Approximate Percent of Total		
State	Calcium	Phosphate	Magnesium
Free (ionized)	50	55	55
Protein-bound	40	10	30
Complexed	10	35	15
Total, mg/dL	8.6-10.3	2.5-4.5	1.7-2.4
Total mmol/L	2.15-2.57	0.81-1.45	0.70-0.99

Modified from Marshall RW. Plasma fractions. In: Nordin BEC, ed. Calcium, phosphate and magnesium metabolism. London: Churchill Livingstone, 1976:162-85.

Clinical Significance

Hypocalcemia

Low total serum calcium (hypocalcemia) may be due to a reduction in albumin-bound calcium, the free fraction of calcium, or both (Box 52-1).[272] Hypoalbuminemia is the most common cause of apparent hypocalcemia on a standard biochemical profile, particularly in hospitalized patients, because 1 g/dL of albumin binds approximately 0.8 mg/dL of calcium. Common clinical conditions associated with low serum albumin include chronic liver disease, nephrotic syndrome, congestive heart failure, malnutrition, and postsurgical volume replacement with saline or colloidal solutions. In

BOX 52-1 Differential Diagnosis of Hypocalcemia

Hypoalbuminemia
Chronic renal failure
Magnesium deficiency
Hypoparathyroidism
Pseudohypoparathyroidism
Osteomalacia and rickets due to vitamin D deficiency or resistance
Acute hemorrhagic and edematous pancreatitis, septic shock
Malignancy, osteoblastic metastases
Rhabdomyolysis
Healing phase of bone disease of treated hyperparathyroidism, hyperthyroidism, and hematologic malignancies (hungry bone syndrome)

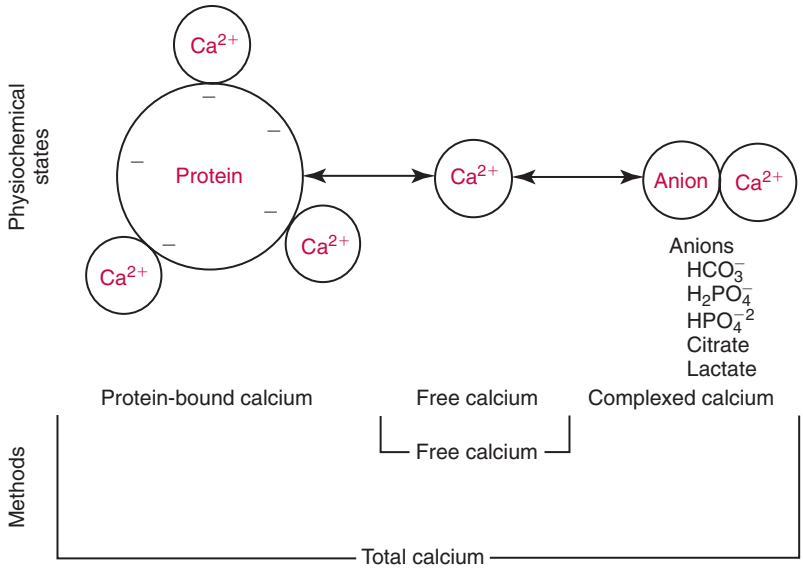

Figure 52-4 Equilibria and determinations of calcium in serum. Calcium can move between three physiochemical pools: (1) free calcium, (2) protein-bound calcium, and (3) calcium complexed with inorganic and organic anions. Methods for determining total calcium measure all three pools, whereas methods for determining free calcium measure only that pool.

these conditions, the concentration of free calcium typically is maintained in its physiologic reference interval. Common causes of true hypocalcemia are chronic renal failure and hypomagnesemia. In chronic renal failure, hypoproteinemia, hyperphosphatemia, low serum $1,25(OH)_2D$ (caused by reduced renal synthesis), and/or skeletal resistance to PTH contribute to hypocalcemia. Magnesium deficiency also can lead to hypocalcemia through several mechanisms, including impairment of PTH secretion and decreased responsiveness of target organs to PTH action (end-organ resistance). Less common causes of hypocalcemia include hypoparathyroidism, pseudohypoparathyroidism, and activating mutations of the calcium-sensing receptor (CaSR). Hypoparathyroidism is due most commonly to parathyroid gland destruction during neck surgery (90%), and less commonly is associated with autoimmune endocrine disorders. Pseudohypoparathyroidism is biochemically similar to hypoparathyroidism, but these patients have (1) an inherited resistance to PTH, and (2) increased concentrations of PTH.[190] The molecular basis for the most common form, pseudohypoparathyroidism type I [Albright's hereditary osteodystrophy (AHO)], is an inactivating mutation in the gene coding for the stimulatory guanine nucleotide-binding protein in the adenylate cyclase complex.

Clinically, hypocalcemia most commonly presents with neuromuscular hyperexcitability, such as tetany, paresthesia, and seizures. A rapid fall in serum calcium may be associated with hypotension and electrocardiographic abnormalities. The severity of symptoms is related to the rate of fall in serum calcium concentration. When symptomatic hypocalcemia is considered, the initial laboratory evaluation must include measurement of ionized calcium and is directed toward assessment of renal function and measurement of serum albumin and magnesium concentrations. Serum intact PTH concentrations are low or inappropriately normal in hypoparathyroidism and elevated in pseudohypoparathyroidism. Vitamin D deficiency is an uncommon cause of symptomatic hypocalcemia and is characterized by low serum 25(OH)D, high PTH (secondary hyperparathyroidism), and high serum alkaline phosphatase (ALP). For symptomatic hypocalcemia, calcium may be administered intravenously, and biochemical response to therapy can be monitored by measurement of total serum calcium. If hypocalcemia is secondary to hypoparathyroidism or pseudohypoparathyroidism, vitamin D and oral calcium supplements are administered.

Activating mutations of the CaSR as a cause of hypocalcemia have been described. Intervention to correct the hypocalcemia may not be needed long term, but in affected neonates, calcium replacement must be provided until genetic confirmation of CaSR status is obtained. Autoimmune destruction of the parathyroid glands may occur in isolation or in combination with other endocrine abnormalities. Postsurgical hypoparathyroidism is uncommon in patients undergoing surgery for primary hyperparathyroidism (PHPT) or secondary hyperparathyroidism (SHPT), but not in patients undergoing extensive neck surgery for treatment of head and neck malignancies. Hypocalcemia in the presence of functional parathyroid glands is a very late manifestation of disease because the interaction of PTH and $1,25(OH)_2D$ will maintain normocalcemia until body stores of 25(OH)D are severely depleted or, in the later stages of chronic renal failure (CRF), $1,25(OH)_2D$ production is inadequate.

Symptoms of hypocalcemia include tingling around the mouth and in the fingers and toes. When more severe, intense,

painful spasm of the fingers and toes develops and may be sustained for several minutes. In the most severe cases, life-threatening laryngospasm may occur. These symptoms reflect decreases in the plasma free calcium and may occur despite a normal total calcium concentration when the complexed or protein-bound fraction is increased. This occurs, for example, during massive transfusion (or pheresis) when large quantities of citrated blood are infused rapidly; citrate complexes calcium, leading to lower free calcium concentration without decreasing the total calcium concentration. An important exception to symptomatic hypocalcemia occurs in CRF when marked acidosis is present. Hypocalcemia triggers muscle contraction, but acidosis hampers muscle contraction. Rapid correction of low serum bicarbonate in patients with CRF without assurance that serum calcium is maintained may trigger muscle spasm.

Hypercalcemia

Hypercalcemia is commonly encountered in clinical practice and results when the influx of calcium into the extracellular fluid compartment from the skeleton, intestine, or kidney is greater than the efflux. For example, when excessive resorption of bone mineral occurs in malignancy, hypercalciuria develops. When the capacity of the kidney to excrete filtered calcium is exceeded, hypercalcemia develops. Hypercalcemia can be caused by increased intestinal absorption (as with rare vitamin D intoxication), increased renal retention (e.g., thiazide diuretics), increased skeletal resorption (e.g., immobilization), or a combination of mechanisms (as in primary hyperparathyroidism).

The causes of hypercalcemia are listed in Box 52-2. Primary hyperparathyroidism is the most common pathologic cause in outpatients, whereas malignancy is more common in hospitalized patients. Together, these two disorders account for 90 to 95% of all cases of hypercalcemia.

PHPT is characterized by excessive secretion of PTH that results in hypercalcemia.[282] It is most often due to a solitary adenoma (80 to 85% of cases), less frequently (about 15%) to hyperplasia involving all glands, and infrequently to parathyroid carcinoma (<1%).[207]

More than 80% of hyperparathyroid patients in developed countries are free of overt symptoms on presentation because of early detection of this disorder through the widespread use of chemistry panels that include calcium.[282] The most common signs and symptoms of hypercalcemia are nonspecific and are related to the neuromuscular system. They include fatigue, malaise, and weakness with mild hypercalcemia (calcium <12 mg/dL or <3 mmol/L); depression, apathy, and inability to concentrate may be present at higher calcium concentrations. Hypercalcemia may induce mild nephrogenic diabetes insipidus with thirst, polydipsia, and polyuria. Renal colic caused by kidney stones can result from chronic hypercalcemia and hypercalciuria. Nephrocalcinosis can lead to slowly developing renal failure. Most patients with primary hyperparathyroidism (>60%) are postmenopausal women.

BOX 52-2 Differential Diagnosis of Hypercalcemia

Primary hyperparathyroidism
- Adenoma, hyperplasia, carcinoma
- Familial
  - Multiple endocrine neoplasia type 1 with pituitary and pancreatic tumors
  - Multiple endocrine neoplasia type 2 with medullary thyroid carcinoma and pheochromocytoma

Malignancy
- With skeletal involvement
  - Direct tumor erosion of the bone
  - Local tumor production of bone-resorbing agents
- No skeletal involvement (humoral hypercalcemia of malignancy)
  - Parathyroid hormone–related protein
  - Growth factor(s) (tumor growth factor, epidermal growth factor, platelet-derived growth factor)
- Hematologic malignancy
  - Cytokines (interleukin-1, tumor necrosis factor, lymphotoxin)
  - 1,25-Dihydroxyvitamin D (lymphoma)
- Coexistent primary hyperparathyroidism

Other endocrine disorders
- Hyperthyroidism
- Hypothyroidism
- Acromegaly
- Acute adrenal insufficiency
- Pheochromocytoma

PHPT is diagnosed by laboratory studies. Hypercalcemia should be documented by measuring total calcium and serum albumin, or by measuring free calcium, on more than one occasion. Measurement of intact PTH (with concomitant measurement of calcium) is the most sensitive and specific test for parathyroid function and is central to the differential diagnosis of hypercalcemia. Serum PTH may not be elevated in some patients, but this should not detract from the diagnosis because, with rare exceptions, nonparathyroid causes of hypercalcemia are associated with suppressed PTH concentrations. Serum $1,25(OH)_2D$ is often in the upper half of the reference interval or is increased in primary hyperparathyroidism, as PTH stimulates its production. By contrast, $1,25(OH)_2D$ (similar to PTH) is low-normal or suppressed in nonparathyroid hypercalcemia, except in sarcoidosis, other granulomatous diseases, and certain lymphomas, in which pathologic tissues contain the 25-hydroxyvitamin D-1α-hydroxylase required to produce $1,25(OH)_2D$.

PTH increases the renal clearance of bicarbonate and phosphate such that in PHPT a mild hyperchloremic metabolic acidosis may be observed, whereas in nonparathyroid hypercalcemia, a mild hypochloremic metabolic alkalosis may be observed. Although hypophosphatemia is often seen in PHPT, measurement of serum phosphate is of limited value because hypophosphatemia is also found in hypercalcemic cancer patients.

Symptomatic patients with PHPT should undergo parathyroid surgery. If the patient is asymptomatic, guidelines have been established recommending surgery over monitoring depending on serum calcium concentration, creatinine clearance, urine calcium, bone mineral density, and age.[282] In the "Guidelines for Management of Asymptomatic Primary Hyperparathyroidism" from the Third International Workshop on the topic,[20A] a serum calcium concentration greater than 1 mg/dL (0.25 mmol/L) above the reference interval was considered an indication for surgical intervention, as was a calculated creatinine clearance less than 60 mL/min. For patients who were to be managed without surgery, annual measurements of serum calcium and creatinine were recommended.

Hypercalcemia occurs in 5 to 30% of individuals with cancer.[188] Solid tissue malignancies commonly produce parathyroid hormone–related peptide (PTHrP), which is secreted into the circulation and stimulates bone resorption. PTHrP binds to the PTH receptor and is the principal mediator of humoral hypercalcemia of malignancy (HHM).[294] Skeletal metastases from cancer also can produce hypercalcemia, but this is a late manifestation, reflecting a large metastatic burden, and less often presents a diagnostic problem. Cytokines such as lymphotoxin, interleukin-1, tumor necrosis factor, and PTHrP appear to be important mediators of hypercalcemia in multiple myeloma and other hematologic malignancies. Some lymphomas associated with acquired immunodeficiency syndrome or human T-lymphotropic virus type 1 (HTLV-1) infection cause hypercalcemia by producing $1,25(OH)_2D$. It is estimated that less than 5% of patients with hypercalcemic cancer have coexisting primary hyperparathyroidism.[188]

Signs and symptoms of hypercalcemia are more evident in patients with hypercalcemia due to malignancy because the serum calcium increases rapidly and often reaches concentrations higher than those usually seen in PHPT. Lethargy, obtundation, nausea, and vomiting are additional symptoms.

Laboratory test selection is similar to that in suspected hyperparathyroidism, with the addition of PTHrP in some individuals with HHM. However, PTHrP is rarely informative if the PTH is not suppressed.[92] In specific instances (e.g., lymphoma, sarcoidosis), measurement of $1,25(OH)_2D$ may be useful.

Therapies are directed toward treating the malignancy, decreasing the serum calcium concentration by saline diuresis, and decreasing osteoclastic resorption (bisphosphonates, calcitonin, etc.). Corticosteroids are useful in reducing intestinal absorption of calcium in $1,25(OH)_2D$-mediated hypercalcemia, particularly in granulomatous disease.

Familial hypocalciuric hypercalcemia (also called *benign familial hypercalcemia*) is characterized, as its name implies, by the presence of hypercalcemia and hypocalciuria. It is due to a mutation in the CaSR found in the parathyroids and the kidney tubules.

Very recent studies of four families with idiopathic hypercalcemia of infancy (see Box 52-2) have identified a genetic basis for this condition.[270A] Sequence analysis of *CYP24A1,* which encodes 25-hydroxyvitamin D 24-hydroxylase, the key enzyme for degrading the active metabolite of vitamin D3, revealed recessive mutations in the affected children. In addition, *CYP24A1* mutations were identified in a group of infants in whom severe hypercalcemia developed after bolus prophylaxis with vitamin D. Functional characterization revealed a complete loss of function in all *CYP24A1* mutations.[270a] The decreased ability to prevent vitamin D actions (see below) appears to explain the hypercalcemia seen in the patients.

Measurement of Calcium

The methods used for quantifying calcium in blood can measure the free Ca^{2+} ion or the total concentration of calcium. The term *ionized calcium,* although widely used, is a misnomer because all calcium in plasma or serum is ionized, irrespective of whether or not it is free or is associated with protein or small anions by ionic binding.

Free calcium is the biologically active fraction of blood calcium; it is tightly regulated by PTH and $1,25(OH)_2D$, and thus is the best indicator of calcium status. Methods for both total and free calcium are currently in use and have their own sources of error. Free calcium measurements have been recommended because of the consequences of delayed treatment and the cost of working-up patients with misleading total calcium results.[30]

Measurement of Total Calcium

Various methods have been described for total calcium measurement. At present, only photometric, ion selective electrode (ISE), and occasionally atomic absorption

spectrophotometry methods are used in clinical laboratories for measuring serum and urine total calcium.[272]

ISEs for the measurement of total calcium were introduced more recently than photometric methods. The specimen is acidified to convert protein-bound and complexed calcium to free calcium before calcium is measured by ISE. Calcium ISEs are discussed later in this chapter.

Photometric Methods

Total calcium is most frequently measured by spectrophotometry using metallochromic indicators or dyes. Of the metallochromic indicators that change color on selectively binding calcium (Figure 52-5), *o*-cresolphthalein complexone (CPC) [3′,3″-bis({bis-[carboxymethyl]amino}-methyl)-5′,5″-dimethylphenolphthalein] and arsenazo III are most widely used. These methods, although less accurate and reproducible than atomic absorption spectrometry, have been readily automated on chemistry analyzers.

***o*-Cresolphthalein Complexone Method.** In alkaline solution, the metal-complexing dye CPC forms a red chromophore with calcium; the color is usually measured at a wavelength between 570 and 580 nm. The sample is diluted with acid to release protein-bound and complexed calcium. Organic base, most often diethylamine, 2-amino-2-methyl-1-propanol, or 2-ethylaminoethanol, is added to buffer the reaction and to produce an alkaline pH. Interference by magnesium is reduced: (1) by adding 8-hydroxyquinoline (see Figure 52-5); (2) by buffering the reaction mixture to near pH 12; and (3) by measuring the absorbance near 580 nm. Urea may be added to reduce the turbidity of lipemic specimens and to enhance complex formation. Blank absorbance may be reduced by adding ethanol or other organic solvents. Calcium forms both 1:1 and 2:1 complexes with CPC, with the former predominating at lower concentrations.[60] Because the 1:1 complex has lower molar absorptivity, the calibration curves are nonlinear at low calcium concentrations. Multipoint calibration of CPC methods has been recommended. Linearity may be improved by adding sodium acetate.[61] The temperature must be carefully controlled because the reaction is temperature sensitive.

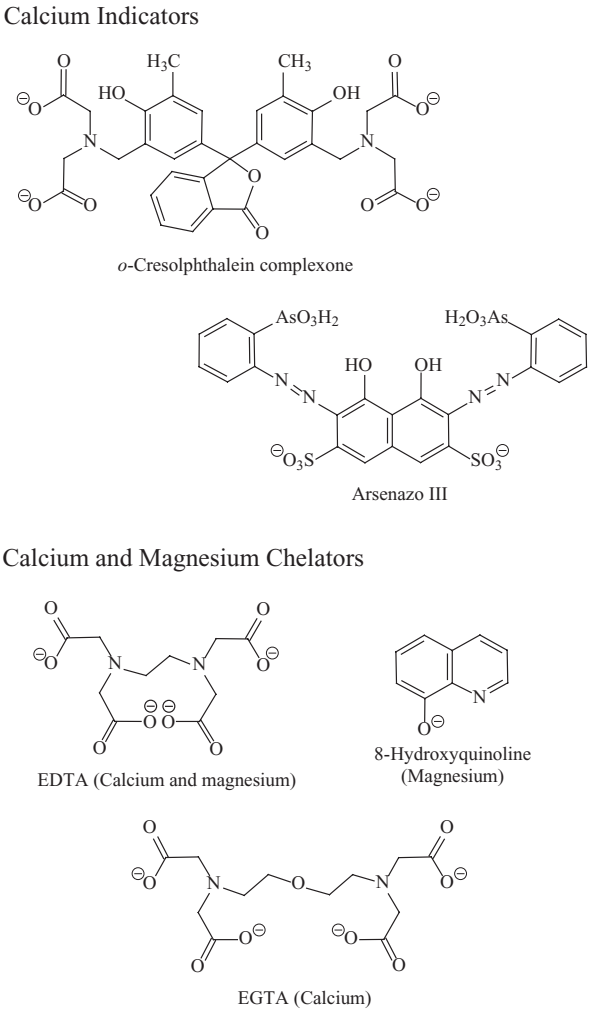

Figure 52-5 Metallochromic indicators for calcium and chelators for calcium and magnesium.

Arsenazo III Method. Arsenazo III [1,8-dihydroxynaphthalene-3,6-disulfonic acid-2,7-bis(azo-2)-phenylarsonic acid] (see Figure 52-5), at mildly acidic pH, has much higher affinity for calcium than magnesium and binds it to produce an intense, purple complex. A reaction pH of about 6 is commonly used; imidazole has been used to buffer the reaction. The solution must be thoroughly buffered because the spectral properties of arsenazo III are dependent on pH. Binding of calcium to arsenazo III can be influenced by buffer and sodium concentration. Interference from most biological pigments is reduced by measuring the calcium-dye complex near 650 nm. Citrate has been reported to cause negative interference, particularly with dry-slide techniques; in these, the only source of fluid is the sample, and the effective concentration of citrate is much higher than in wet-chemistry methods.[16,106] Clinically significant interference may be noted in patients receiving citrated blood or blood products. Unlike CPC, which has limited stability when used as a single reagent, the arsenazo III reagent is stable.[174]

Many photometric methods should not be used within 24 hours after a magnetic resonance imaging (MRI) examination of the patient in which gadolinium has been used as contrast medium, particularly if the patient has impaired renal function.[220] A predictive model has been described to calculate, in patients who have received gadodiamide, the minimum length of time to wait before blood collection to avoid pseudohypocalcemia when the Roche *o*-cresolphthalein method is used.[156]

Atomic Absorption Spectrometry Methods

The Clinical Laboratory and Standards Institute (CLSI) has approved a method by which atomic absorption spectrophotometry (AAS) is used as a reference method in measuring total serum calcium.[44,333] This method has been compared with isotope dilution-mass spectrometry (ID-MS), the definitive method for total serum calcium developed by the National Institute of Standards and Technology. The

reference method is reported to have an accuracy of 100 ± 2%, compared with 100 ± 0.2% for ID-MS.[44] Although AAS provides better accuracy and precision for total serum calcium than the widely used photometric methods, it is used by only a few laboratories. It should continue to be used for validating new total calcium methods. For further information, see the previous edition of this book and the references.[30,44,47,236,272,333]

Adjusted or Corrected Total Calcium

Wide variation in the concentrations of compounds that bind calcium in blood may be noted; this variation will affect the measured total calcium concentration without changing the free calcium fraction. Several types of calculation have been suggested to "adjust" the measured calcium concentration. The goal is to produce a corrected result that would have been found if the concentrations of all compounds that bind calcium had been within their respective reference intervals. In practice, only adjustments based on albumin are used. The term *adjusted calcium* is preferable to *corrected calcium,* because "corrected" may suggest that the result has been corrected because of an error.[105,150,152]

Adjusted calcium is calculated from total calcium and albumin by first calculating a correction factor by multiplying the deviation of plasma albumin from the mean of its reference interval by the slope of the regression of total calcium against albumin. The following two equations can be found in textbooks for results expressed as mg/dL and mmol/L, respectively:

$$\text{Adjusted total calcium (mg/dL)} = \text{Total calcium (mg/dL)} + 0.8\,[4 - \text{Albumin (g/dL)}]$$

$$\text{Adjusted total calcium (mmol/L)} = \text{Total calcium (mmol/L)} + 0.02\,[40 - \text{Albumin (g/L)}]$$

However, it has proved practically impossible to establish calculation methods that would be suitable for all pathologies and all laboratories. This is consistent with the fact that many factors affect the distribution of calcium among free, complexed, and protein-bound fractions (Box 52-3). The reliability of adjustment for serum albumin deteriorates in patients with very low serum albumin concentrations.[105] Equations that are derived for a specific patient group, such as hemodialysis patients[150] or patients with liver disease, may be better than no adjustment in that group of patients. Direct determination of free calcium by ISE is preferable to adjustments.

Specimen Requirements

Serum and heparinized plasma are the preferred specimens. Citrate, oxalate, and ethylenediaminetetraacetic acid (EDTA) anticoagulants should not be used for the spectrophotometric methods, because they interfere by forming complexes with calcium. Total calcium measurements are little affected by storage, provided that loss of water associated with prolonged refrigerator or freezer storage is prevented (by the use of tightly capped containers designed for such storage), although coprecipitation of calcium with fibrin (e.g., in heparinized plasma) or lipids has been reported with storage or freezing. Plastic and glass may also adsorb calcium from dilute solutions during storage.

BOX 52-3 Factors Altering the Distribution Between Protein-Bound, Complexed, and Free Calcium and Compounding the Interpretation of Total Calcium

Factors Altering Protein Binding of Calcium
Altered concentration of albumin or globulins
Abnormal proteins
Heparin
pH
Free fatty acids
Bilirubin
Drugs
Temperature

Factors Altering Complex Formation
Citrate
Bicarbonate
Lactate
Phosphate
Pyruvate and β-hydroxybutyrate
Sulfate
Anion gap

Interferences

Hemolysis, icterus, lipemia, paraproteins, and magnesium have been reported to interfere positively or negatively with photometric methods. Many methods use bichromatic analysis, multiwavelength corrections, or blanking to reduce interference. Lipemic specimens should be ultracentrifuged before analysis.

Although hemolysis can cause a negative error because red blood cells contain lower concentrations of calcium than does serum, more significant errors may be caused by the spectral interference of hemoglobin. Depending on the method used, hemoglobin has been reported to produce negative or positive interference. In photometric methods, if hemolyzed specimens must be analyzed, blanking with ethylene glycol-*O,O′*-bis(2-aminoethyl)-*N,N,N′,N′*-tetraacetic acid (EGTA)-treated serum is suggested.

Individual instruments and methods should be evaluated for their susceptibility to interference from magnesium, hemoglobin, bilirubin, turbidity, and other interferents. Care should be taken in handling specimens, calibrators, and solutions to prevent contamination with calcium. Any glassware or plastic ware that is reused should be washed with dilute hydrochloric acid (HCl), followed by distilled water, to eliminate calcium contamination. Corks should not be used because they can contaminate specimens with calcium. How the patient is prepared and how the specimen is obtained can have a significant effect on both free and total calcium measurements. For information on these preanalytical effects,

BOX 52-4 Preanalytical Factors Affecting Measurement of Serum Total or Free Calcium

In Vivo
Tourniquet use and venous occlusion
Changes in posture: 10 to 12% increase in total calcium and 5 to 6% increase in free calcium on standing
Exercise
Hyperventilation
Fist clenching
Alimentary status
Alterations in protein binding (see Box 52-3)
Alterations in complex formation (see Box 52-3)

In Vitro
Inappropriate anticoagulants
Dilution with liquid heparin
Interfering levels of heparin
Contamination with calcium
Corks, glassware, tubes
Specimen handling
Alterations in pH (free calcium)
Adsorption or precipitation of calcium
Spectrophotometric interference
Hemolysis, icterus, lipemia

see a later section in this chapter on the subject as well as Box 52-4.

Measurement of Free (Ionized) Calcium

(See also Chapters 11 and 28.)

Many blood gas analyzers, using ISEs, provide rapid whole blood determinations of plasma free calcium and electrolytes, as well as determinations of blood gases.[30,40,71,272,277] The free calcium analyzer consists of a system of pumps under microprocessor control that transport calibration solutions, samples, and wash solutions through a measuring cell containing calcium ion-selective, reference, and pH electrodes. Sensitive potentiometers measure the voltage difference between the calcium or pH and reference electrodes for calibrating solutions or samples. A microprocessor calibrates the system and calculates calcium concentration and pH. Most instruments simultaneously measure the actual free calcium and pH at 37 °C.

Calcium ISEs contain a calcium-selective membrane, which encloses an inner reference solution of calcium chloride often containing saturated silver chloride (AgCl) and physiologic concentrations of sodium chloride and potassium chloride (KCl) and an internal reference electrode.[30,40,180,222,272] The reference electrode, usually of Ag/AgCl, is immersed in this inner reference solution. Modern calcium ISEs use liquid membranes containing the ion-selective calcium sensor dissolved in an organic liquid trapped in a polymeric matrix. The Ca^{2+} ionophores may be based on a polyvinyl chloride matrix and contain ETH1001 or ETH129

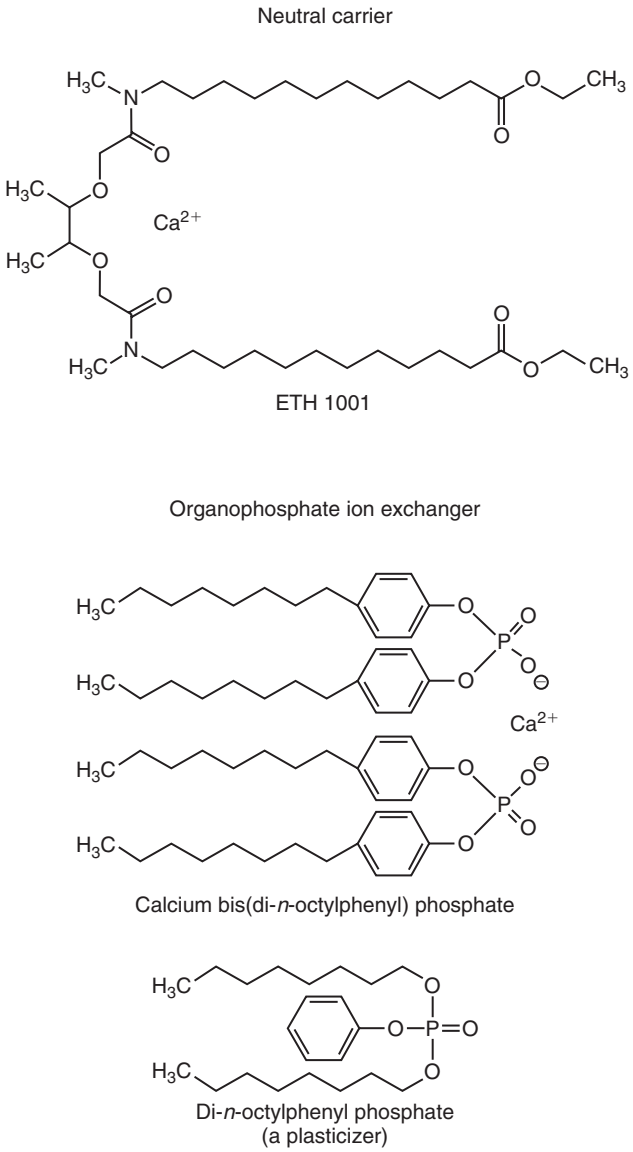

Figure 52-6 Free calcium sensors.

as a carrier. Instead of these two neutral carriers, ion exchangers, such as organophosphate sensors (Figure 52-6), have been used.[30] Neutral carrier membranes contain an uncharged calcium-selective organic molecule, such as ETH1001, dissolved in a plasticizer and trapped in a polyvinyl chloride membrane. These molecules have a favorable steric and electrostatic pocket or site for selectively binding calcium. Ion exchangers or negatively charged carrier membranes are calcium salts, such as calcium bis(di-*n*-octylphenyl) phosphate, dissolved in di-*n*-octylphenyl phosphonate and trapped in a polyvinyl chloride membrane.

The electrochemical cell is completed by the external reference electrode, an Ag/AgCl or calomel electrode, which is in contact with the specimen by a liquid/liquid junction or a salt bridge of KCl or sodium formate. The potential difference across the cell is logarithmically related to the activity of free calcium ions in the sample by the Nernst equation. By

convention, free calcium is converted from activity to concentration with its activity coefficient, which is itself dependent on ionic strength.

Temperature affects electrode response and the extent of calcium binding by protein and small anions. Most free calcium analyzers adjust and maintain samples at 37 °C, thereby ensuring that results are physiologically relevant for most patients.

Carryover has been minimized by various techniques, including (1) using flush solutions containing 5.0 mg/dL (1.25 mmol/L) of free calcium, (2) using the leading edge of the specimen to clean the fluid path, or (3) purging with air.[40] Significant carryover is noted only at extremely low or high concentrations of free calcium.

The International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) has recommended a reference method for free calcium.[41]

Interferences

Because ISEs measure ion activity, they are affected by the ionic strength of a specimen.[71,272] Free calcium analyzers (and the associated calibrators) are optimized for specimens of serum, plasma, or whole blood. Because the ionic strength of these fluids is primarily a result of Na^+ and Cl^-, calibrators usually are prepared in buffer and NaCl with a final ionic strength of 160 mmol/kg.[40,71,277] Although the range of Na^+ and Cl^+ concentrations usually observed in serum or plasma does not cause a clinically significant error in the measurement of free calcium, significant errors can occur with other specimens unless the matrices and the ionic strength of the calibrators and samples are matched closely.

Modern electrodes have high selectivity for calcium over Na^+, K^+, Mg^{2+}, H^+, and Li^+.[40,71] At normal concentrations, these cations have little effect on the accuracy of free calcium measurements. Wide variations in the concentration of Na^+ and high concentrations of Mg^{2+} and Li^+ may influence the apparent concentration of free calcium. Electrodes are quite insensitive to H^+, with insignificant interference noted between pH 5 and 9.

Many physiologic anions, including protein, phosphate, citrate, lactate, sulfate, and oxalate, form complexes with calcium ions. Although these anions reduce the concentration of free calcium by complex formation, they do not directly interfere with measurement of the calcium that is free. Protein deposits on the electrode may act as a divalent cation exchanger, resulting in positive interference with high concentrations of Mg^{2+}. Older electrodes were sensitive to the concentration of protein in the sample. Newer electrodes use a dialysis membrane or a neutral carrier to reduce or eliminate this protein effect,[40,196,222,229] which typically is less than +0.02 mmol/L for 1 g/dL (10 g/L) of protein. Regular instrument maintenance and protein removal are reported to minimize this interference.

Chemicals may interfere with the measurement of free calcium. Anionic surfactants and ethanol have been reported to affect the calcium-selective membrane.

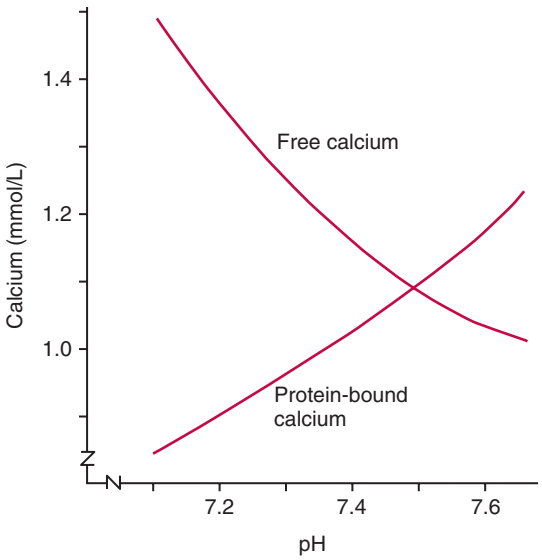

Figure 52-7 Effect of pH on free and protein-bound calcium.

Effect of pH

The binding of calcium by protein and small anions is influenced by pH in vitro and in vivo.[40,71] Albumin, with up to 30 binding sites for calcium,[88,168] accounts for approximately 80% of the protein-bound calcium. Increasing the pH of a specimen in vitro increases the ionization and negative charge on albumin and other proteins, leading to an increase in protein-bound calcium and a decrease in free calcium. Decreasing pH in vitro decreases ionization and negative charge, thereby decreasing protein-bound calcium and increasing free calcium. Free calcium changes by about 5% for each 0.1 unit change in pH (Figure 52-7).

Because of this inverse relationship between free calcium and pH, specimens must be analyzed at the patient's in vivo pH. Usually, this requires that specimens should be handled to prevent alterations in pH.

Specimen Requirements

Preanalytical considerations, including specimen collection and handling, are particularly important for free calcium. Specimens for free calcium must be collected and handled to minimize alterations in pH and free calcium caused by (1) loss of CO_2, and (2) metabolism by blood cells. Free calcium may be measured in heparinized whole blood, heparinized plasma, or serum. For most laboratories in which specimens are analyzed rapidly (within minutes of sampling) by the use of blood gas analyzers, heparinized whole blood is preferable because it reduces processing time and the required specimen volume and avoids the alteration in pH associated with centrifugation. All syringes and evacuated tubes should be filled completely, kept tightly sealed, and handled anaerobically to prevent the loss of CO_2 and the increase in pH that may occur when specimens are exposed to air. If other tests are ordered that are not available on the blood gas analyzer,

it is best that the sample for free calcium is collected in a separate container to minimize the likelihood that the specimen may be analyzed aerobically. Specimens should also be handled to prevent the decrease in pH caused by the production of lactic acid by glycolysis, by erythrocytes, and by white blood cells. The IFCC has published recommendations on sampling, transport, and storage of the samples,[25] and the Clinical and Laboratory Standards Institute (CLSI) has published guidelines (C-31A2) for free calcium specimen collection and handling.[214]

Ideally, whole blood specimens should be analyzed within 15 to 30 minutes of sampling,[25] although free calcium is reported to be stable in whole blood specimens for at least 1 hour at room temperature and for 4 hours at 4 °C.[25,40,307,313] A 2009 study reported that free calcium was stable for at least 7 hours at room temperature in an evacuated blood collection tube.[129] If specimens cannot be analyzed promptly, they can be collected in an ice-water slurry to minimize metabolism. If measurements of plasma K^+ are needed on the sample, cooling will not be appropriate; K^+ concentrations will be increased because of the inhibition of ATPase activity at low temperature.[87]

For delayed analysis, serum may be the optimal sample type because of elimination of the anticoagulant and reduction in the occurrence of microclots. Serum specimens can be collected in evacuated gel tubes.[173,313] These tubes should be filled completely and centrifuged to form an effective barrier between the serum and the clot with its cellular elements. Once centrifuged, specimens are stable for hours at 25 °C and for days at 4 °C, provided the tube remains sealed. Free calcium has been reported to be less stable in specimens from both acidotic and nonacidotic patients with uremia.[217]

The practice of using aerobic specimens for the measurement of free calcium with correction of the free calcium to pH 7.4[40,308] has been criticized[40,263,306,330] and is not recommended. The free calcium value at pH 7.4 may be misleading in patients with respiratory and metabolic alkalosis or acidosis.[217] Furthermore, aerobic handling of specimens may lead to irreversible precipitation of calcium-phosphate complexes and a decrease in free calcium in some specimens that have a high total calcium and phosphate content or a high pH (pH > 7.9).

Effects of Anticoagulants

Because citrate, oxalate, and EDTA bind calcium and significantly reduce free calcium, heparin is the only acceptable anticoagulant for free calcium determinations. However, heparin, a polyanion, significantly lowers free calcium at the concentrations (≥30 to 100 U/mL) found in many conventional blood gas syringes (Table 52-3).[42,71] In addition, the use of liquid heparin should be avoided; it can result in errors in free calcium caused by dilution, as well as high and variable concentrations of heparin.

Several commercially available syringes containing lyophilized heparin are suitable for free calcium determinations: (1) electrolyte-balanced or calcium-titrated heparin syringes (final concentration of 40 to 50 U/mL); (2) very low heparin syringes with heparin in an inert filler, providing a final heparin concentration of 2 to 3 U/mL; and (3) lithium-zinc heparin syringes.[314] With electrolyte-balanced or calcium-titrated heparin syringes, the heparin is titrated with calcium so that the free calcium is not significantly altered over most observed concentrations (3.6 to 6.4 mg/dL or 0.9 to 1.6 mmol/L); however, some bias may be apparent at very low and high free calcium concentrations. Electrolyte-balanced heparin may also produce a bias in specimens with pathologically low protein concentrations.[189] In very low heparin syringes that contain 2 to 3 U/mL of heparin dispersed in a puff of inert proprietary material, the puff allows the heparin to be accurately dispensed during manufacturing and to rapidly dissolve with proper mixing, providing effective anticoagulation. A blend of lithium and zinc heparins has been reported to eliminate the heparin interference in free calcium measurements.[171,300,316] In addition, lithium-zinc heparin did not alter total calcium, unlike electrolyte-balanced or calcium-titrated heparin. Three-milliliter syringes containing a total of 50 U of a 1:1 blend of lithium and zinc heparins did not alter results of any general chemistry tests except total magnesium, which was increased by 0.19 mg/dL or 0.08 mmol/L. In practice individuals obtaining the blood specimen should not place additional liquid heparin in heparinized syringes.

Most evacuated collection tubes, when filled completely, contain concentrations of heparin (15 U/mL) that only slightly decrease free calcium.[311] Specific brands of syringes, evacuated tubes, and heparin should be carefully evaluated. It is important that all syringes and tubes be filled completely to minimize dilution and/or heparin effects.

TABLE 52-3 Effects of Heparin on Free Calcium

Specimen	Heparin, U/mL	Free Calcium mg/dL	Free Calcium mmol/L
Serum	0	5.00	1.25
Plasma	44 (Ca-heparin)	4.96	1.24
Plasma	29 (Na-heparin)	4.84	1.21
Plasma	100 (Na-heparin)	3.76	0.94
Whole blood	44 (Ca-heparin)	5.08	1.27
Whole blood	19 (Na-heparin)	5.04	1.26
Whole blood	100 (Na-heparin)	3.88	0.97

Modified from Toffaletti J. Ionized calcium. In: Pesce AJ, Kaplan LA, eds. Methods in clinical chemistry. St Louis: CV Mosby, 1987:1010-20.

Calibrators and Quality Controls

Various calibration solutions are used by manufacturers for free calcium analyzers. The buffers in which these calibrators are prepared may have an effect on the liquid junction potential and on calcium binding; however, this is usually corrected for by the instrument software.[40] Until reference solutions

are available, it is best to use the calibrators provided by the instrument manufacturer.

Aqueous quality control materials are commercially available for free calcium. Because simple aqueous controls may not reliably detect changes in performance with patient specimens, use of serum-based quality control materials has been recommended.[315] Serum-based controls may be prepared by acidifying serum with 10 µL of 1 mol/L HCl and leaving it exposed in the refrigerator for 1 week to remove carbon dioxide. The pH is then adjusted to 7.4, and the serum is aliquoted and frozen. Alternatively, serum-based controls can be equilibrated with carbon dioxide before undergoing analysis.

Patient Preparation and Sources of Preanalytical Error for Total and Free Calcium Measurements

Patient preparation and the manner of specimen collection can significantly affect the results of total and free calcium determinations (see Box 52-4).[40,115]

A common and important source of preanalytical error in the measurement of calcium is the increase in total, but not free, calcium concentration associated with tourniquet use and venous occlusion during sampling.[245] Errors of 0.5 to 1.0 mg/dL or 0.12 to 0.25 mmol/L in total calcium may result from the increase in protein-bound calcium caused by the efflux of water from the vascular compartment during stasis. Only small and clinically insignificant increases in free calcium have been reported with venous stasis. If a tourniquet is required, it should be applied just before sampling and released as soon as possible.

Fist clenching or other forearm exercise should be avoided before phlebotomy[245] because forearm exercise causes a decrease in pH (lactic acid production) and an increase in free calcium. The NCCLS and the IFCC have published recommendations on blood collection.[42,214]

Changes in posture cause fluid shifts within 10 minutes and thus alter the concentrations of cells and large molecules, including albumin and total calcium (as part of it is protein bound), in the vascular compartment. Standing decreases intravascular water and increases the total calcium concentration by 0.2 to 0.8 mg/dL or 0.05 to 0.20 mmol/L, whereas a much smaller effect has been reported for free calcium.[40,115,245] One partial explanation (along with hypoalbuminemia) for the mild hypocalcemia observed in many hospital patients may be the hemodilution associated with recumbency.

Prolonged immobilization and bed rest[131,295] increase bone resorption, which increases total and free calcium. Hyperventilation and exercise decrease and increase the concentration of free calcium, respectively, because of changes in serum pH.[40,245] Both serum free calcium concentration and calcium excretion are decreased during the night.[45] Food ingestion has been reported to have various effects but usually causes a mild increase in serum calcium. Ingestion of calcium salts may increase serum calcium. Hemolysis can alter free calcium because of dilution and alterations in pH and binding (see previous discussion under "Interferences").

Reference Intervals for Total and Free Calcium in Serum and Plasma

Total Calcium

The reference interval for serum and plasma is usually defined by an upper limit of 10.1 to 10.5 mg/dL (2.52 to 2.62 mmol/L) and a lower limit between 8.5 and 8.8 mg/dL (2.12 to 2.20 mmol/L). The reference interval depends on the method and the reference population chosen.

An analytical goal, or quality specification, for between-day imprecision, expressed as the coefficient of variation (CV), is 0.9% or less based on within-person biological variation.[90] Current methods achieve between-day CVs of 1.5% or less within laboratories.

Free Calcium

For adults, the reference interval of free calcium has been reported as follows:

Adults: 4.6 to 5.3 mg/dL or 1.15 to1.33 mmol/L

Because of the dependence of free calcium on pH, it is recommended that pH be measured and reported with all free calcium determinations. This will assist the laboratory and the physician in identifying specimens in which inappropriate preanalytical handling has led to an in vitro change in pH. Some laboratories report the free calcium corrected to pH 7.4.

Whole blood specimens develop a liquid junction potential different from that of serum or plasma because of the presence of erythrocytes.[40,71,222] A positive bias that is directly proportional to the hematocrit has been reported. In addition, free calcium values have been reported to differ among capillary blood, venous blood, and serum samples because of differences in pH. Therefore, reference intervals should be determined by each laboratory using the local instrument, specimen type, and collection protocol, and reference subjects representative of the patient population served.

Physiologic Variation in Calcium

Calcium has been reported to vary with age, gender, and season and during pregnancy.[166,167,272] Total and free calcium have been reported to decline modestly and to remain unchanged in the elderly.[281] In a healthy ambulatory group of men and women residing in the Southwest of the United States, no age-related decline or gender-related difference could be found in total or free calcium values.[78] During pregnancy, total calcium declines in parallel with serum albumin, whereas free calcium is unchanged.[166,167] The fetal circulation is relatively hypercalcemic,[165,329] as evidenced by higher total and free calcium in cord blood than in maternal serum. Calcium concentrations decline after birth in healthy term neonates during the first few days, but soon rise to concentrations slightly greater than those observed in adults.[166,329]

Interpretation of Total and Free Calcium Results

Calcium status is more accurately determined by measuring free calcium, the tightly regulated, biologically active species.[30,84] Interpretation of total serum calcium value is

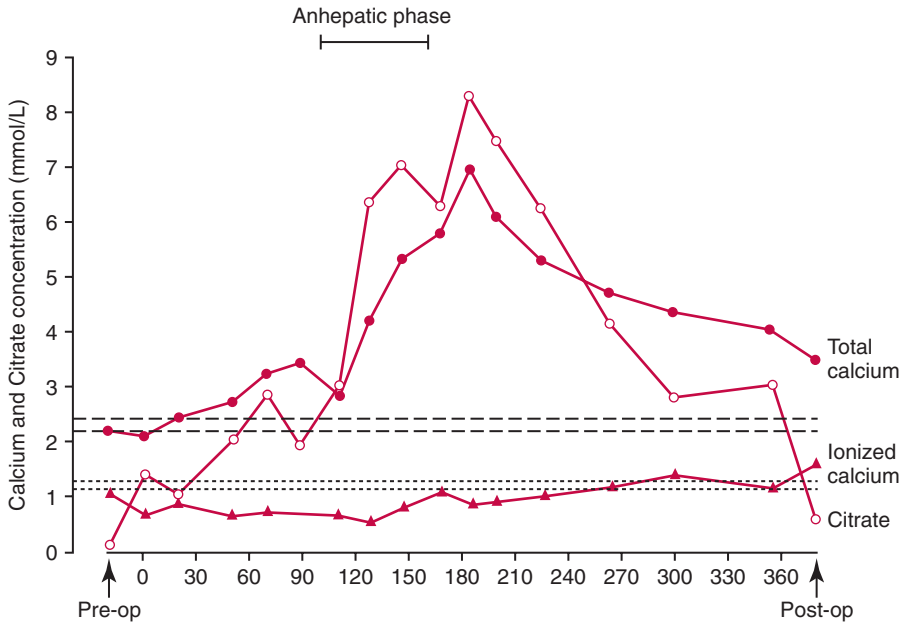

Figure 52-8 Free calcium (▲), total calcium (●), and citrate (○) concentrations in a patient undergoing liver transplantation. Reference intervals are indicated by the *upper* (total calcium) and *lower* (free calcium) sets of *dashed horizontal lines*. The reference interval for citrate is 0.03 to 0.15 mmol/L. *(From Gray TA, Paterson CR. The clinical value of ionized calcium assays. Ann Clin Biochem 1988;25:210-9.)*

complicated by its association with protein and inorganic and organic ions. Interpretation of free calcium concentration is less complicated, provided the specimen has been properly obtained, handled, and analyzed. Disagreement between free and total calcium (abnormal total calcium and normal free calcium, or vice versa) values occurs in a high percentage of specimens. One study of 1213 patients suspected of having calcium disorders found disagreement between free calcium and total calcium or corrected calcium values in 18% and 31% of patients, respectively.[309]

Free calcium is reportedly more useful than total calcium determination in hospital patients, especially those undergoing major surgery (Figure 52-8) who have received citrated blood or platelets, heparin, bicarbonate, intravenous solutions, or calcium.[40] Alterations in blood pH and temperature further reduce the usefulness of total calcium assay in these patients. Rapid measurement of free calcium, blood gases, and potassium permits maintenance of good cardiac function during liver transplant operations and other major operations such as those in which cardiopulmonary bypass is used. Free calcium is more useful than total calcium determination in patients in intensive care because of abnormal protein concentrations and putative circulating factors that alter calcium binding to albumin. Abnormally low free calcium is frequently found in critically ill patients.[12,48,341] A study at one hospital where free calcium has replaced total calcium determinations found that 41% of free calcium concentrations were abnormal among inpatients.[30] Of these cases, 31% were below and 10% were above the reference interval. The recovery room, surgical intensive care unit, renal transplantation ward, medical intensive care unit, and medical oncology unit had the highest percentages of abnormal values.

Another study has questioned the value of frequent measurements of free calcium in hospital patients.[11] In a large academic hospital setting, serial and daily testing was responsible for a large fraction of free calcium analyses. Half of all patients tested had free calcium concentrations below the reference interval. Free calcium was increased by intravenous (IV) administration of calcium, but the increase attributable to administered calcium was small compared with the increase that occurred in patients given no calcium. Retrospective analysis suggested that a total calcium below 8 mg/dL (2 mmol/L) identified most patients with low free calcium (<4 mg/dL, <1.0 mmol/L). Introduction of a reflexive strategy in which free calcium was measured only when total calcium was below that limit reduced free calcium testing by 72 to 76% and reduced IV calcium gluconate therapy by 45 to 81%. An outcomes study showed no evidence of an increase in adverse events.

Bone and mineral disorders are common in patients with renal disease. Therapy and calcium metabolism of these patients is best evaluated by the determination of free calcium because of alterations in protein, pH, protein binding of calcium, and calcium complexes with organic and inorganic anions.

Free calcium may be useful in the diagnosis of hypercalcemia. Patients with subsequently surgically proven primary hyperparathyroidism more often have increases in free calcium than in total calcium (Figure 52-9). Free calcium is more sensitive than total calcium in detecting hypercalcemia

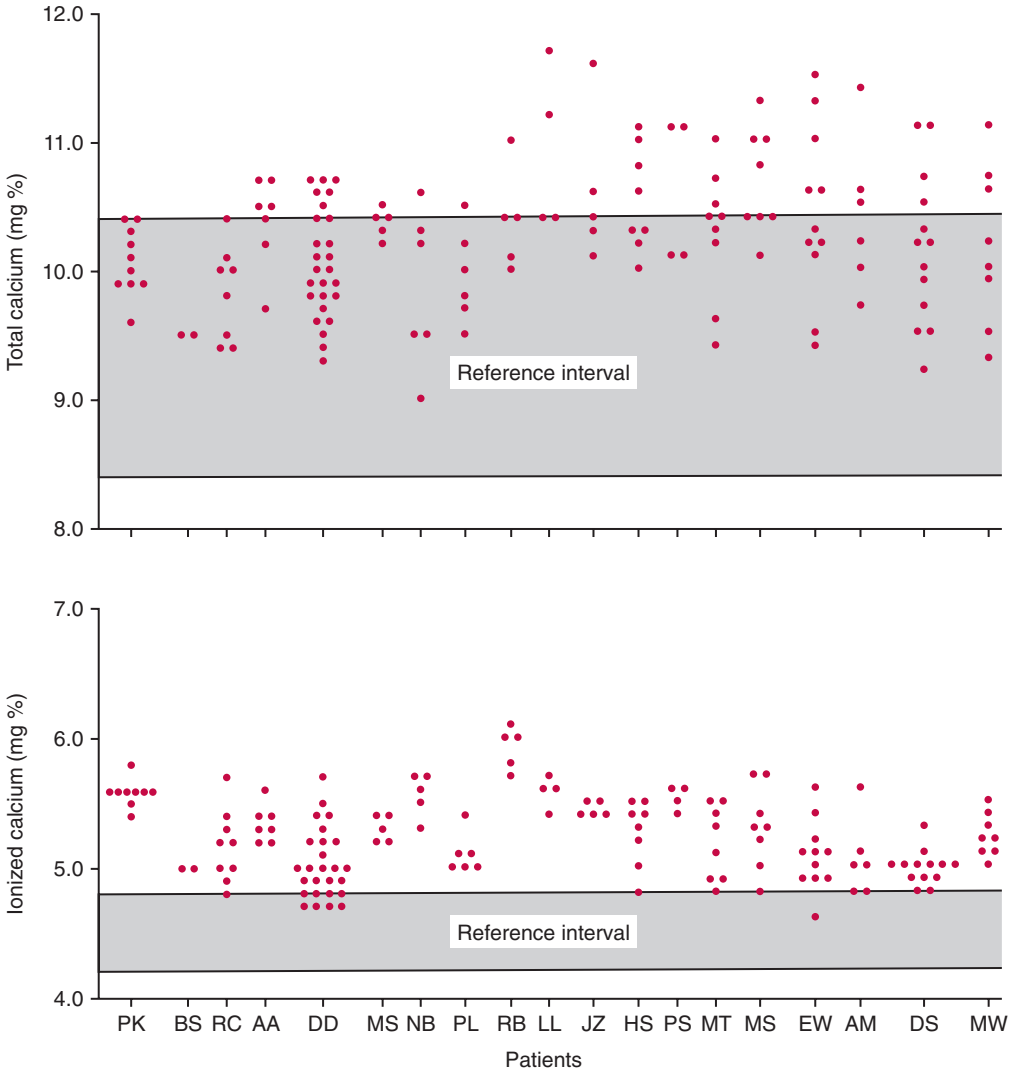

Figure 52-9 Concurrent total and free calcium in patients with primary hyperparathyroidism and intermittent total hypercalcemia. *Shaded areas* represent the reference intervals. *(From McLeod MK, Monchik JM, Martin HF. The role of ionized calcium in the diagnosis of subtle hypercalcemia in symptomatic primary hyperparathyroidism. Surgery 1984;95:667-73.)*

associated with malignancy, as may be expected in patients who frequently have decreased serum albumin. Less commonly, paraproteins produced in myeloma may bind calcium, complicating the interpretation of total or adjusted calcium measurements.

In neonates, assay of free calcium rather than total calcium is recommended because of its speed and the ability to use small skin-puncture specimens, and because of its greater validity in the presence of hyperphosphatemia, with alterations in pH, and with the persistence of α-fetoprotein after birth.[329]

Urinary Calcium

The rate of urinary calcium excretion reflects calcium intake, intestinal absorption, skeletal resorption, and renal tubular filtration and reabsorption.[249] Healthy men and women excrete up to 300 mg or ≈7.5 mmol of calcium per day on a diet with unrestricted calcium content, and up to 200 mg/d or ≈5 mmol/d on a calcium-restricted diet (500 mg or 12.5 mmol dietary calcium per day or less for several days). The reference data for urine calcium are not well established, and it may be preferable to use a value of 4 mg/kg body weight (or 0.1 mmol/kg body weight) as the upper reference limit in an individual patient.

The reference interval for urinary calcium (UCa) for spot fasting or timed specimens collected after an overnight fast is less than 0.16 mg/100 mL or less than 0.04 mmol/L of glomerular filtrate (GF), as calculated by the following equation:

$$\text{UCa (mg/100 mL GF)} = \frac{[\text{UCa (mg/dL)}] \times [\text{Serum creatinine (mg/dL)}]}{\text{Urinary creatinine (mg/dL)}}$$

Alternatively, the ratio of urine calcium to urine creatinine can be calculated; reference intervals for the ratio depend on age and sex.

An important but under-recognized contributor to urine calcium excretion is urine sodium excretion. Patients with hypercalciuria and normal sodium excretion have so-called renal leak hypercalciuria, which can result in increased secretion of PTH and can be corrected with the use of a thiazide diuretic. This condition should not be confused with normocalcemic hyperparathyroidism but should be regarded as a form of secondary hyperparathyroidism. Hypercalciuria with increased urine sodium excretion responds rapidly to reduce dietary sodium intake.

Under fasting conditions, the intestinal and renal components are relatively fixed, and calcium excretion (milligrams per 100 mL of GF) in the fasting state is used to assess the skeletal component. A value exceeding 0.16 mg/100 mL or greater than 0.04 mmol/L of GF usually implies an increase in osteoclastic bone resorption. This test is used in assessing renal stone disease and high-turnover osteoporosis.

Calcium salts, such as calcium oxalate, precipitate in urine specimens during and after collection. Specimens may be collected in a container containing acid to prevent calcium salt precipitation. A commonly used acid is HCl, 6 mol/L, with 20 to 30 mL added to the container for a 24 hour collection (1 to 2 mL for a random specimen). The safety of the patient and the patient's family in handling such a container may be a concern. The measured urinary calcium concentration must be corrected for dilution by the acid solution when the urinary volume is low. The specimen should be kept well mixed during collection. Specimens collected without acid should be acidified and allowed to stand for 1 hour before thorough remixing and aliquoting. Some have questioned the ability of postcollection acidification to redissolve all of the calcium salts with or without heating.[115]

PHOSPHATE

An adult has about 600 g or approximately 20 mol of phosphorus in inorganic and organic phosphates, of which about 85% is in the skeleton, and the rest is principally in soft tissue (see Table 52-1).[249,332]

Biochemistry and Physiology

Plasma contains both inorganic and organic phosphate, but only inorganic phosphate is measured. Inorganic phosphate exists as both monovalent ($H_2PO_4^-$) and divalent (HPO_4^{2-}) phosphate anions. The ratio of $H_2PO_4^-$ to HPO_4^{2-} is pH dependent and varies from approximately 1:1 in acidosis to 1:4 at pH 7.4 and 1:9 in alkalosis. Approximately 10% of the phosphate in serum is protein-bound; 35% is complexed with sodium, calcium, and magnesium; and the remainder, or 55%, is free (see Table 52-1). The organic phosphate esters are located primarily within the cellular elements of blood.

Inorganic phosphate is a major component of hydroxyapatite in bone; thus it plays an important role in the structural support of the body and provides phosphate for the extracellular and intracellular pool.

In the soft tissue, most phosphate is cellular. Although both inorganic and organic phosphate is present in cells, most is organic and is incorporated into nucleic acids, phospholipids, phosphoproteins, and high-energy compounds involved in metabolism. ATP and other phosphates, such as creatine phosphate, are involved in many energy-intensive physiologic functions, such as muscle contractility, neurologic function, and electrolyte transport. Phosphate is also an essential element of cyclic nucleotides (such as cyclic AMP) and cofactors such as nicotinamide-adenine dinucleotide phosphate (NADP). It is important for the activity of several enzymes, including adenylate cyclase, 25-hydroxyvitamin-D-1α-hydroxylase, and those involved in the production of 2,3-diphosphoglycerate, the key compound regulating the oxygen affinity of hemoglobin. Intracellular phosphate therefore is involved in the regulation of intermediary metabolism of proteins, fats, and carbohydrates, and in gene transcription and cell growth.

Fibroblast growth factor (FGF)-23 is a key modulator of phosphate homeostasis.[154A] FGF-23 increases fractional excretion of phosphate by the kidneys. It also decreases production of the active form of vitamin D, 1,25-dihydoxyvitamin D, by decreasing the activity of the enzyme responsible for its formation (25-hydroxyvitamin D, 1-hydroxylase). Both of these key activities lead to decreased serum phosphate. FGF-23 is secreted by bone cells (both osteoblasts and osteoclasts) in response to increased serum phosphate or increased serum 1,25-dihydoxyvitamin D. In chronic kidney disease, FGF-23 increases in a compensatory mechanism to counter increasing serum phosphate. As kidney failure deteriorates further, responsiveness to FGF-23 declines (in association with loss of Klotho, the coreceptor for FGF-23) and thus FGF-23 cannot lower serum phosphate.

Clinical Significance

Disorders of phosphate metabolism are separated into those causing hypophosphatemia and those causing hyperphosphatemia.

Hypophosphatemia

Hypophosphatemia, defined as the concentration of inorganic phosphate in the serum below the reference interval (usually <2.5 mg/dL or <0.81 mmol/L), is relatively common in hospitalized patients (≈2%). Hypophosphatemia is not necessarily associated with intracellular phosphate depletion. Hypophosphatemia may be present when cellular concentrations are normal, and cellular phosphate depletion may exist when serum concentrations are normal or even high.

Hypophosphatemia or phosphate depletion in blood may be caused by (1) a shift of phosphate from extracellular to intracellular spaces, (2) renal phosphate wasting, (3) decreased intestinal absorption, and (4) loss from intracellular phosphate.[249,260,332] Box 52-5 lists the commonly encountered causes of hypophosphatemia and phosphate depletion.

BOX 52-5 Common Causes of Hypophosphatemia and Phosphate Depletion

- Intracellular shift
  - Glucose
    - Oral or intravenous
    - Hyperalimentation
  - Insulin
  - Respiratory alkalosis
- Lowered renal phosphate threshold
  - Primary or secondary hyperparathyroidism
  - Renal tubular defects
    - Familial hypophosphatemia
    - Fanconi syndrome
- Decreased net intestinal phosphate absorption
  - Increased loss
    - Vomiting
    - Diarrhea
    - Phosphate-binding antacids
  - Decreased absorption
    - Malabsorption syndrome
    - Vitamin D deficiency
- Intracellular phosphate loss
  - Acidosis
    - Ketoacidosis
    - Lactic acidosis

A shift of phosphate from extracellular to intracellular fluid is a common cause of hypophosphatemia. A major cause of low serum phosphate is carbohydrate-induced stimulation of insulin secretion, which promotes the transport of glucose and phosphate into insulin-sensitive cells, where phosphate is incorporated into sugar phosphates and ATP. Oral or intravenous carbohydrate and injected insulin decrease serum phosphate. Refeeding of malnourished individuals creates an anabolic state, causing an intracellular shift of phosphate. Respiratory alkalosis leads to an increase in intracellular pH, which activates phosphofructokinase and accelerates glycolysis, causing a shift of phosphate into the cell. Low serum phosphate in these conditions does not indicate a deficiency of phosphate, and hypophosphatemia is self-correcting with stabilization of the patient's condition.

Renal phosphate wasting may also cause hypophosphatemia. Any cause of excessive PTH secretion (primary and secondary hyperparathyroidism) lowers the renal phosphate threshold and may result in hypophosphatemia and phosphate depletion. However, this may not occur if renal failure is the cause of secondary hyperparathyroidism when hyperphosphatemia is more common. The renal phosphate threshold is also lowered in Fanconi syndrome, X-linked hypophosphatemic rickets, and tumor-induced osteomalacia.

Hypophosphatemia and phosphate depletion may result from inadequate intestinal phosphate absorption. Patients taking aluminum- or magnesium-containing antacids may develop hypophosphatemia because these antacids bind phosphate in the intestine, rendering it nonabsorbable. The hypophosphatemia observed in patients with malabsorption may be more closely related to their secondary hyperparathyroidism than to malabsorption of phosphate. Because phosphate is abundant in most foods, dietary deprivation is not usually a cause of phosphate depletion in patients with normal intestinal function and an adequate diet.

Intracellular phosphate may be lost in acidosis as a result of catabolism of organic compounds within the cell. Diabetic ketoacidosis is associated initially with high-normal to increased serum phosphate. Treatment of ketosis and acidosis with insulin and intravenous fluids, however, results in a rapid reduction in the serum phosphate concentration. Consequently, patients being treated for diabetic ketoacidosis may have both intracellular phosphate depletion and hypophosphatemia.

The clinical manifestations of serum phosphate depletion depend on the length and the degree of deficiency. Moderate hypophosphatemia of 1.5 to 2.4 mg/dL, or 0.48 to 0.77 mmol/L, usually is not associated with clinical signs and symptoms (unless chronic, when osteomalacia or rickets develops). Plasma concentrations less than 1.5 mg/dL or 0.48 mmol/L may produce clinical manifestations. Because phosphate is necessary for the formation of ATP, glycolysis and cellular function are impaired by low intracellular phosphate concentrations. Muscle weakness, acute respiratory failure, and decreased cardiac output may occur in phosphate depletion. At very low serum phosphate (<1 mg/dL or <0.32 mmol/L), rhabdomyolysis may be seen. Phosphate depletion in erythrocytes decreases erythrocyte 2,3-diphosphoglycerate, which causes tissue hypoxia as the result of increased affinity of hemoglobin for oxygen. Severe hypophosphatemia (serum phosphate concentration <0.5 mg/dL or <0.16 mmol/L) may result in hemolysis of the red blood cells. Mental confusion and frank coma may be secondary to low ATP and tissue hypoxia. If hypophosphatemia is chronic, impaired mineralization of bone produces rickets in children and osteomalacia in adults.

Treatment of hypophosphatemia depends on the degree of hypophosphatemia and on the presence of symptoms. Patients with moderate hypophosphatemia often require only treatment of the underlying disorder and, possibly, oral phosphate supplementation. In patients with marked symptoms of hypophosphatemia, particularly if respiratory muscle weakness is present, parenteral administration of phosphate may be indicated.

Hyperphosphatemia

Common causes of hyperphosphatemia are listed in Box 52-6.

The most common cause of hyperphosphatemia is inability of the kidneys to excrete phosphate.[260,332] Hyperphosphatemia is a major clinical problem in chronic kidney disease (see Chapter 48). In acute or chronic renal failure, a decrease in glomerular filtration rate (GFR) reduces the renal excretion of phosphate, resulting in hyperphosphatemia. Moderate increases in serum phosphate occur in individuals with low PTH (hypoparathyroidism), PTH resistance (pseudohypoparathyroidism), or acromegaly (increased growth hormone) caused by an increased renal phosphate threshold. Growth

BOX 52-6 Common Causes of Hyperphosphatemia

Decreased renal phosphate excretion
- Decreased glomerular filtration rate
  - Renal failure, chronic and acute
- Increased tubular reabsorption
  - Hypoparathyroidism
  - Pseudohypoparathyroidism
  - Acromegaly
  - Disodium etidronate

Increased phosphate intake
- Oral or intravenous administration
- Phosphate-containing laxatives or enemas

Increased extracellular phosphate load
- Transcellular shift
  - Lactic acidosis
  - Respiratory acidosis
  - Untreated diabetic ketoacidosis
- Cell lysis
  - Rhabdomyolysis
  - Intravascular hemolysis
  - Cytotoxic therapy
  - Leukemia
  - Lymphoma

hormone is responsible for the increased renal phosphate threshold and the higher phosphate concentrations observed in children. EDTA therapy has also been associated with hyperphosphatemia.

Increased intake and a shift of phosphate from the tissues into the extracellular fluid are also causes of hyperphosphatemia. Excessive oral, rectal, or intravenous phosphate administration for the treatment of phosphate depletion is a common cause of hyperphosphatemia. Release of phosphate as the result of cell breakdown in cases of rhabdomyolysis, intravascular hemolysis, or chemotherapy of certain malignancies may cause hyperphosphatemia. Hyperphosphatemia may also be associated with acidosis, a consequence of the hydrolysis of intracellular organic phosphate-containing compounds, with the release of phosphate into the plasma.

The clinical manifestations of hyperphosphatemia depend on its rate of onset. A rapid increase in serum phosphate may be associated with hypocalcemia. Therefore, symptoms may include tetany, seizures, and hypotension. Long-term hyperphosphatemia may be associated with secondary hyperparathyroidism, osteitis fibrosa, and soft tissue calcification of the kidneys, blood vessels, cornea, skin, and periarticular tissue.

Therapy for hyperphosphatemia is directed toward correcting the cause of the increased serum phosphate. In renal failure and in hypoparathyroidism, dietary restriction of phosphate and agents that bind phosphate in the intestine (calcium carbonate and others) are useful in lowering the serum phosphate concentration.[260,332]

Measurement of Phosphate

Most methods used to measure serum inorganic phosphate are based on the reaction of phosphate ions with ammonium molybdate to form a phosphomolybdate complex that is then measured by a spectrophotometer[272]:

$$7H_3PO_4 + 12(NH_4)_6Mo_7O_{24} \bullet 4H_2O \rightarrow 7(NH_4)_3[PO_4(MoO_3)_{12}] + 51NH^{+4} + 51OH^- + 33H_2O$$

The colorless phosphomolybdate complex may be measured directly by ultraviolet absorption (340 nm) or reduced to molybdenum blue and measured at 600 to 700 nm. An acidic pH is necessary for the formation of complexes, but it must be controlled because both complex formation and reduction of molybdate are dependent on pH. A less acidic pH can result in spontaneous reduction of molybdate. The rate of complex formation is also influenced by protein concentration. Solubilizing agents such as Tween 80 are used to prevent protein precipitation.

Measurement of unreduced complexes has several advantages, including simplicity, speed, and reagent stability, and it is the assay that is used in most laboratory analyzers. Disadvantages of the method include greater interference by hemolysis, icterus, and lipemia at 340 nm.

Many reducing agents have been used in producing the blue phosphomolybdate complex, including aminonaphtholsulfonic acid, stannous chloride, methyl-*p*-aminophenol sulfate, ferrous ammonium sulfate, ascorbic acid, and *N*-phenyl-*p*-phenyldiamine (semidine) HCl. Each of these reagents appears to have some individual advantage, such as increased stability, increased color stability, lower detection limit, or reduced hydrolysis of organic esters. Ferrous sulfate and especially ascorbic acid have often been used for biological specimens containing organic esters, because they cause fewer breakdowns of labile phosphate esters. Aminonaphtholsulfonic acid has been used widely but is unstable, tends to precipitate, and requires careful timing because color continues to increase for several hours. With this reagent, color formation is increased with heating. Stannous chloride provides greater color intensity. Hydrazine has been added to stannous chloride to stabilize the reagent and improve the linearity. Methyl-*p*-aminophenol sulfate is acid tolerant, allowing for a one-component acid-molybdate reagent. A method using semidine HCl was published as a "Selected Method" by the American Association for Clinical Chemistry.[97,204]

Phosphate concentrations can also be determined by several other procedures, including the vanadate-molybdate and enzymatic methods. Vanadate and molybdate form a yellow complex with phosphate at acid pH, but the method tends to overestimate inorganic phosphate because of hydrolysis of organic esters. Enzymatic methods are rarely used[272]; for descriptions, see the previous edition of this book.

Specimen Requirements

Serum and heparinized plasma are preferred specimens for the measurement of phosphate. Concentrations of inorganic phosphate are about 0.2 to 0.3 mg/dL or 0.06 to 0.10 mmol/L

lower in heparinized plasma than in serum. Other anticoagulants such as citrate, oxalate, and EDTA may interfere with formation of the phosphomolybdate complex and thus are not suitable.[272]

The apparent concentration of inorganic phosphate in whole blood specimens may decrease or increase with time, depending on the type of specimen, the storage temperature, and the duration of storage. Phosphate concentrations in plasma or serum are increased by prolonged storage with cells at room temperature or 37 °C. Hemolyzed specimens are unacceptable because erythrocytes contain high concentrations of organic phosphate esters, which can be hydrolyzed to inorganic phosphate during storage. Inorganic phosphate increases by 4 to 5 mg/dL or 1.29 to 1.61 mmol/L per day in hemolyzed specimens stored at 4 °C, and more rapidly at room temperature or 37 °C. Glucose phosphate, creatine phosphate, and other organic phosphates may also be hydrolyzed by assay conditions, resulting in overestimation of inorganic phosphate concentrations.

Phosphate is considered to be stable in separated serum for days at 4 °C and for months when frozen, provided evaporation and lyophilization are prevented.

Interferences

Depending on the method used, positive or negative interference has been noted with hemolyzed, icteric, and lipemic specimens.[272] Mannitol,[73] fluoride, and monoclonal immunoglobulins[18,172,231] have also been reported to interfere. Glassware should be properly cleaned and rinsed because phosphate is a common component of many detergents.

Reference Intervals

Phosphate is often referred to as "phosphorus," a practice that is inaccurate and misleading because only phosphate, not elemental phosphorus, circulates in blood and is measured. This practice originated because results were reported as milligrams per deciliter of phosphorus, rather than phosphate. When results are reported in molar units (as in SI), the numeric results and the reference intervals are the same for phosphorus and phosphate, but confusion occurs when results are reported in milligrams per deciliter.

In adults, the reference interval for serum phosphate is 2.5 to 4.5 mg of phosphorus/dL or 0.81 to 1.45 mmol/L. In children, it is 4.0 to 7.0 mg phosphorus/dL or 1.29 to 2.26 mmol/L. Adult plasma reference intervals are about 0.2 mg/dL or 0.06 mmol/L lower than for serum (2.3 to 4.3 mg/dL or 0.75 – 1.39 mmol/l).

Serum phosphate concentrations are about 50% higher in infants than in adults and decline throughout childhood as a consequence of the ability of growth hormone to increase the renal phosphate threshold.[112] The reference interval for serum phosphate in elderly women is similar to that in younger adult women, whereas in elderly men it is lower than in other adult men.[78,281]

Because a diurnal variation in serum phosphate has been reported, fasting morning specimens are recommended (Figure 52-10).[272] Concentrations are higher in the afternoon and evening. Serum phosphate concentrations are influenced by dietary intake and meals and are increased by exercise.

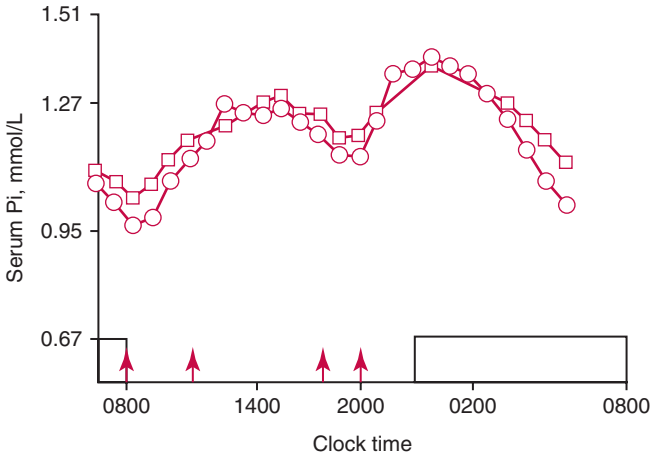

Figure 52-10 Diurnal variation of serum phosphate in men (○) and women (□). Meals and snacks are indicated by *arrows;* the *bar* indicates recumbent posture. *(From Calvo MS, Eastell R, Offord KP, Bergstralh EJ, Burritt MF. Circadian variation in ionized calcium and intact parathyroid hormone: evidence for gender differences in calcium homeostasis. J Clin Endocrinol Metab 1991;72:69-76, © The Endocrine Society.)*

Urinary phosphate excretion varies with age, muscle mass, renal function, PTH, time of day, and other factors. Urinary excretion of phosphate varies widely with diet and is essentially equivalent to dietary intake.[249] On a nonrestricted diet, the reference interval for urinary phosphate is 0.4 to 1.3 g/day or 12.9 to 42.0 mmol/day.

Urine should be collected in 6 mol/L HCl, 20 to 30 mL for a 24 hour specimen, to avoid precipitation of phosphate complexes. Simultaneous measurement of phosphate and creatinine in serum and urine with fasting morning spot or 1 to 2 hour timed collections permits calculation of the renal phosphate threshold ($TmPO_4$/GFR); this calculation is considered the best method for assessing renal tubular reabsorption of phosphate.[272] The clearance of phosphate divided by creatinine clearance can be plotted on a nomogram,[328] and the $TmPO_4$/GFR determined. This index expresses phosphate reabsorption as a function of both serum phosphate concentration and GFR and is more useful than urinary phosphate excretion.

MAGNESIUM

Magnesium is the fourth most abundant cation in the body and the second most prevalent intracellular cation.[258,267] The total body magnesium content is about 25 g or approximately 1 mol, of which about 55% resides in the skeleton (see Table 52-1). One third of skeletal magnesium is exchangeable and is thought to serve as a reservoir for maintaining the extracellular magnesium concentration. About 45% of magnesium is intracellular.

Biochemistry and Physiology

The concentration of magnesium in cells varies from 2.4 to 7.3 mg/dL or 1 to 3 mmol/L. In general, the higher the metabolic activity of a cell, the greater is its magnesium content. Within the cell, most of the magnesium is bound to proteins and negatively charged molecules; 80% of cytosolic magnesium is bound to ATP, and MgATP is the substrate for numerous enzymes. The nucleus, mitochondria, and endoplasmic reticulum contain significant amounts of magnesium. Approximately 0.5 to 5.0% of the total cellular magnesium is free. Transport of magnesium across the cellular membrane is regulated by a specific magnesium transport system.

Extracellular magnesium accounts for about 1% of the total body magnesium content. About 55% of the magnesium in plasma is free, 30% is associated with proteins (primarily albumin), and 15% is complexed with phosphate, citrate, and other anions (see Table 52-2).

Magnesium is a cofactor for more than 300 enzymes in the body.[257,332] It is required for formation of substrates of enzymes (e.g., MgATP is a substrate for numerous enzymes that require ATP). In addition, magnesium is an allosteric activator of many enzyme systems. Examples of enzymes that require magnesium for action include adenylate cyclase, Na^+-K^+-adenosine triphosphatase (ATPase), Ca^{2+}-ATPase, phosphofructokinase, and creatine kinase. The guanine nucleotide containing regulatory proteins Gs and Gi require magnesium for activity. Magnesium is important in oxidative phosphorylation, glycolysis, cell replication, nucleotide metabolism, and protein biosynthesis. A decrease in the serum magnesium concentration lowers the threshold of axonal stimulation and increases nerve conduction velocity. Magnesium also influences neurotransmitter release at the neuromuscular junction by competitively inhibiting the entry of calcium into the presynaptic nerve terminal. Reducing the serum magnesium concentration results in increased neuromuscular excitability. Magnesium deficiency can thus result in a variety of metabolic abnormalities and clinical consequences.[332]

Clinical Significance

Disorders of magnesium metabolism are separated into those causing hypomagnesemia/magnesium deficiency and hypermagnesemia.

Hypomagnesemia/Magnesium Deficiency

Hypomagnesemia is common in patients in hospitals.[257,258,332] Ten percent of patients admitted to city hospitals and as many as 65% of patients in intensive care units may be hypomagnesemic.[320,332] Moderate or severe magnesium deficiency is usually due to loss of magnesium from the gastrointestinal (GI) tract or kidneys (Box 52-7).

Vomiting and nasogastric suction may deplete body stores of magnesium in that upper GI fluids contain approximately 0.5 mmol/L of magnesium. More commonly, magnesium deficiency is associated with losses from the lower intestine. Diarrhea may result in marked losses of magnesium; therefore, acute diarrheal states, regional enteritis, and ulcerative colitis are frequently complicated by magnesium deficiency. Magnesium is most efficiently absorbed from the distal small bowel.

Excessive urinary losses of magnesium from the kidneys are important causes of magnesium deficiency. Clinically important causes include alcohol, diabetes mellitus (osmotic diuresis), loop diuretics (furosemide), and aminoglycoside antibiotics. Increased sodium excretion (parenteral fluid therapy) and increased calcium excretion (hypercalcemic states) also result in renal magnesium wasting.

Because magnesium deficiency is usually secondary to another disease process or to a therapeutic agent, features of the primary disease process may complicate or mask magnesium deficiency. Neuromuscular hyperexcitability with tetany and seizures may be present. These symptoms and signs may also be due to hypocalcemia, and magnesium deficiency is a common cause of hypocalcemia. Magnesium deficiency impairs PTH secretion and causes resistance to PTH in the kidneys and bone; it has been linked to osteoporosis in epidemiologic studies[257] and in animal experiments.[259]

BOX 52-7 Differential Diagnosis of Magnesium Deficiency

Gastrointestinal disorders
- Prolonged nasogastric suction
- Malabsorption syndromes
- Extensive bowel resection
- Acute and chronic diarrhea
- Intestinal and biliary fistulas
- Protein-calorie malnutrition
- Acute hemorrhagic pancreatitis
- Primary hypomagnesemia (neonatal)

Renal loss
- Chronic parenteral fluid therapy
- Osmotic diuresis
  - Glucose (diabetes mellitus)
  - Mannitol
  - Urea
- Hypercalcemia
- Alcohol
- Drugs
  - Diuretics (furosemide, ethacrynic acid)
  - Aminoglycosides
  - Cisplatin
  - Cyclosporine
  - Amphotericin B
  - Cardiac glycosides
  - Pentamidine
- Metabolic acidosis (starvation, ketoacidosis, alcoholism)
- Renal disease
  - Chronic pyelonephritis, interstitial nephritis, and glomerulonephritis
  - Diuretic phase of acute tubular necrosis
  - Postobstructive nephropathy
  - Renal tubular acidosis
  - Post renal transplantation

Primary hypomagnesemia

Phosphate depletion

One of the more serious complications of magnesium deficiency is cardiac arrhythmia. Premature atrial complexes, atrial tachycardia and fibrillation, premature ventricular complexes, ventricular tachycardia, and ventricular fibrillation may be associated with magnesium deficiency. These effects may be caused in part by the hypokalemia, renal wasting, and intracellular depletion of potassium caused by hypomagnesemia.

Although extracellular magnesium accounts for only about 1% of total body magnesium, and plasma magnesium concentrations correlate poorly with total body magnesium, determination of serum magnesium is the most widely used test to assess magnesium deficiency. Hypomagnesemia is often transient and is not an indication of magnesium deficiency. Conversely, intracellular magnesium depletion and magnesium deficiency may exist despite a normal serum magnesium concentration. Consequently, hypocalcemia, hypokalemia, neuromuscular hyperirritability, and cardiac arrhythmias should alert one to the possible presence of magnesium deficiency. Other tests less commonly used include the magnesium loading test (also known as the magnesium tolerance test)[257] and measurements of intracellular magnesium (e.g., in red blood cell, lymphocyte, or skeletal muscle).

Acute symptomatic magnesium deficiency usually is treated with parenteral magnesium; mild depletion may be treated with oral magnesium.[332]

Hypermagnesemia

Magnesium intoxication is not a frequently encountered clinical problem, although a mild to moderate elevation in the serum magnesium concentration may be noted in as many as 12% of hospital patients.[258] Symptomatic hypermagnesemia is almost always caused by excessive intake, resulting from administration of antacids, enemas, and parenteral fluids containing magnesium (Box 52-8). Most of these patients have concomitant renal failure, thereby limiting the ability of the kidneys to excrete excess magnesium. Magnesium used to treat preeclampsia and eclampsia may cause magnesium intoxication in mothers and their neonates.

Depression of the neuromuscular system is the most common manifestation of magnesium intoxication. Deep tendon reflexes disappear at a serum magnesium concentration above 5 to 9 mg/dL or 2.06 to 3.70 mmol/L, whereas depressed respiration and apnea, caused by voluntary muscle paralysis, may occur at serum magnesium concentrations greater than 10 to 12 mg/dL or 4.11 to 4.94 mmol/L. Higher concentrations may result in cardiac arrest. Somnolence, hypotension, nausea, vomiting, and cutaneous flushing may also be seen. Hypermagnesemia induces a decrease in the serum concentration of calcium, presumably because of the inhibition of both PTH secretion and end-organ action of PTH by magnesium.

The possibility of magnesium intoxication should be anticipated in patients receiving magnesium, especially those with renal failure. Replacement therapy should be discontinued in patients with mildly to moderately increased serum magnesium. Higher serum concentrations are used in the treatment of preeclampsia and eclampsia. Because calcium acutely antagonizes the toxic effects of magnesium, patients with severe magnesium intoxication may be treated with intravenous calcium. If necessary, peritoneal dialysis or hemodialysis against a low-magnesium dialysis bath effectively lowers the serum magnesium concentration.[258,332]

BOX 52-8 Causes of Hypermagnesemia

Excessive intake
- Orally (usually in the presence of chronic renal failure)
  - Antacids
  - Cathartic
- Rectally
  - Purgation
- Parenterally
  - Treatment of pregnancy-induced hypertension
  - Treatment of magnesium deficiency

Renal failure
- Chronic (usually with administration of magnesium)
  - Antacid
  - Cathartic
  - Enema
  - Infusion
  - Dialysis
- Acute
  - Rhabdomyolysis

Familial hypocalciuric hypercalcemia
Lithium ingestion

Measurement of Total Magnesium

Serum magnesium has been measured by various techniques including photometry, fluorometry, flame emission spectroscopy, and atomic absorption spectrometry (AAS).[272,327,336] Today, photometric methods are most commonly used by clinical laboratories; although AAS[195,272] is considered the reference method, it is rarely used today.

Photometric Methods

Several metallochromic indicators or dyes change color on selectively binding magnesium and have been used to measure it in biological samples.[272,310,327,336]

Calmagite [1-(1-hydroxy-4-methyl-2-phenylazo)-2-naphthol-4-sulfonic acid] (Figure 52-11), a metallochromic indicator, forms a colored complex with magnesium in alkaline solution, which is measured at 530 to 550 nm.[1,182,270,327] A specific calcium-chelating agent, EGTA (see Figure 52-5), is added to reduce interference by calcium. Reagents may include potassium cyanide (to prevent formation of heavy metal complexes) and polyvinylpyrrolidone and surfactants to reduce interference from protein and lipemia.

Methylthymol blue (see Figure 52-11) forms a blue complex with magnesium, which is measured around 600 nm[310,336]; EGTA is added to reduce interference by calcium.

A formazan dye [1,5-bis(3,5-dichloro-2-hydroxyphenyl)-3-formazan carbonitrile] forms a complex with magnesium

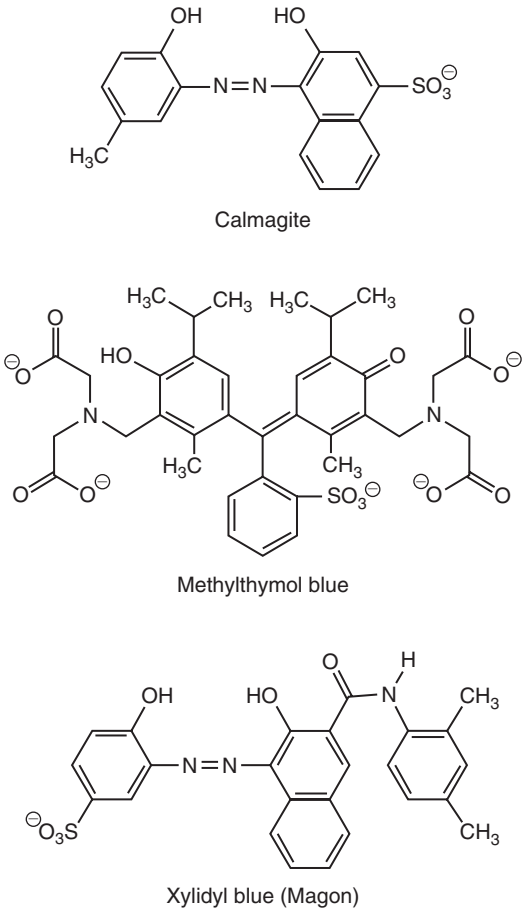

Figure 52-11 Metallochromic indicators for magnesium.

at alkaline pH, which has been measured at 630 nm by thin-film reflectance photometry.[312] *N,N′*-[1,2-ethanediylbis(oxy-2,1-phenylene)bis(N-carboxymethyl)] glycine is used to chelate calcium. This thin-film reflectance method shows relatively little interference from icteric, lipemic, and hemolyzed specimens. Elevated calcium concentrations cause a measurable but small overestimation.

Magon, or xylidyl blue [1-azo-2-hydroxy-3-(2,4-dimethylcarboxanilido)-naphthalene-1′-(2-hydroxybenzene)] (see Figure 52-11), binds magnesium in alkaline solution, causing a spectral shift and forming a red complex.[14,65] Absorbance most often has been measured around 600 nm. Calcium and protein interferences are reduced by EGTA and dimethyl sulfoxide, respectively.

All of these methods have been applied to automated analyzers.[272]

Atomic Absorption Spectrometry

As with calcium, AAS methods provide greater accuracy and precision for magnesium measurements than do photometric methods.[272] For furher information,[195,336] refer to previous editions of this book.

Enzymatic methods have been developed with hexokinase or another enzyme that uses Mg^{2+}-ATP as a substrate. The rate of the enzyme-catalyzed reaction is dependent on the concentration of magnesium. When hexokinase is used with glucose-6-phosphate dehydrogenase, the rate of the dehydrogenase reaction is monitored by measuring the formation of NADPH monitored at 340 nm.[302] A simple one-step reaction using stabilized isocitrate dehydrogenase has been reported.[93,296] This enzyme is activated by magnesium and produces NADPH.

Measurement of Free (Ionized) Magnesium

Instruments for the measurement of free magnesium in whole blood, plasma, or serum were developed in the 1990s.[17,71,242] These instruments use ISEs with neutral carrier ionophores, including ETH5220, ETH7025, or a proprietary ionophore. Current ionophores or electrodes have insufficient selectivity for magnesium over calcium. Thus it is necessary to determine the two ions simultaneously in each sample and to correct the result for Ca^{2+} interference. Also pH should be measured simultaneously, as the binding of Mg in plasma is pH dependent.[331]

Comparisons of instruments for free magnesium determinations have been reported.[47,52,144,146,243] Differences in measured free magnesium were apparent among analyzers, mainly because of interference from free calcium.

Decreased total serum magnesium is a common finding in hospital patients. Magnesium salts are frequently administered to patients for antiarrhythmic, vasomotor, and neuronal actions, and to patients with preeclampsia, myocardial infarction, and ischemic heart disease. Monitoring of free magnesium concentrations has been suggested because both low and high concentrations can be life threatening.[257,258,320,332]

Discordance between total and free magnesium measurements has been reported in selected patient populations, including those with cardiovascular disorders, diabetes mellitus, alcoholism, migraine headaches, asthma, renal transplant, and head trauma, and in pregnant women. Interferences, such as that from thiocyanate in smokers,[71] in measurement of free magnesium may explain some of these discrepancies. Free magnesium determinations may be helpful in some of these disorders, in critically ill patients, and during cardiopulmonary bypass, preeclampsia, neonatal distress, and therapy with a number of drugs.[258,266,267]

Specimen Requirements for Total and Free Magnesium

Serum and heparinized plasma are the preferred specimens for measuring free and total magnesium.[17,242] Zinc heparin, lithium-zinc heparin, and some of the newer heparins developed for free calcium determination should be avoided because they significantly increase the apparent free magnesium concentration.[242,316,335] Other anticoagulants, such as citrate, oxalate, and EDTA, are not acceptable because they form complexes with magnesium. Storage of serum for days at 4 °C and for months frozen does not affect measured concentrations of total magnesium, provided evaporation of the specimen is prevented.

Serum or plasma must be separated from the clot or red blood cells as soon as possible to prevent an increase in serum

magnesium due to cell leakage. Because erythrocytes contain higher concentrations of magnesium than serum or plasma, hemolyzed specimens are unacceptable. Interference by icterus or lipemia depends on the method and can be decreased by the use of bichromatic analysis or blanking with EDTA. Lipemic specimens should be ultracentrifuged.

Factors that alter free calcium concentration by altering the distribution of calcium between free, protein-bound, and complexed pools can also alter free magnesium concentration. Therefore specimens should be handled anaerobically to prevent loss of CO_2 and analyzed without delay to prevent changes in pH caused by metabolism. As with free calcium, high concentrations of heparin should be avoided. Certain silicones or other tube additives as well as thiocyanate (smokers and diet) interfere with free magnesium determinations.

Magnesium is primarily an intracellular ion. Thus magnesium depletion is not necessarily reflected in decreased concentrations of the metal in serum. The magnesium status of an individual is best measured by a parenteral magnesium load test,[227] also known as a magnesium tolerance test.[257] In this test, the percentage magnesium retention is assessed after an intravenous magnesium load. After baseline collection of 24 hour urine, 0.1 mmol/kg body weight of magnesium is administered intravenously in 5% dextrose and another 24 hour urine collection is carried out. In individuals with adequate magnesium stores, 60 to 80% of the magnesium load is excreted within 24 hours.[227,257]

Urine specimens should be collected in acid (e.g., HCl, 6 mol/L, with 20 to 30 mL added to the container for a 24 hour collection) to prevent precipitation of magnesium complexes. As with calcium, if acid must be added after collection, the entire specimen must be acidified, warmed, and mixed thoroughly before a sample is removed for analysis.

Reference Intervals for Total and Free (Ionized) Magnesium

For adults, reference intervals for total serum magnesium of 1.7 to 2.4 mg/dL or 0.66 to 1.07 mmol/L have been reported. However, the adequate reference interval is somewhat a matter of debate, as concentrations from the lower end may be associated with cardiovascular risk.[272] Magnesium concentrations in erythrocytes are approximately three times those of serum. Conversion factors for the units used to express magnesium concentration are given below:

$$\text{mmol/L} = \text{mEq/L} \times 0.5 = \text{mg/dL} \times 0.41$$
$$\text{mEq/L} = \text{mmol/L} \times 2 = \text{mg/dL} \times 0.82$$
$$\text{mg/dL} = \text{mEq/L} \times 1.22 = \text{mmol/L} \times 2.43$$

The reference interval for free magnesium is instrument dependent[71,272]; a typical interval for the CRT (Nova Biomedical, Waltham, Mass) is 0.45 to 0.60 mmol/L.

Reference intervals for total magnesium in infants, children, and adolescents have been published; they do not differ significantly from those of adults.[272]

HORMONES REGULATING MINERAL METABOLISM

PTH and 1,25-dihydroxyvitamin D are the primary hormones regulating bone and mineral metabolism. Calcitonin has pharmacologic actions, but a physiologic role has not been established in adults. PTHrP is the principal mediator of humoral hypercalcemia of malignancy, but it also has physiologic functions in fetuses and in women during pregnancy and lactation.

Parathyroid Hormone

PTH is synthesized and secreted by the parathyroid glands, usually two superior and two inferior, located bilaterally on or near the thyroid gland capsule. The chief cells of the gland are responsible for synthesizing, storing, and secreting the hormone. The chromosomal location of the gene for PTH is 11p15.3-p15.1.

Biochemistry and Physiology

The concentration of PTH in blood is determined by its synthesis and secretion by the parathyroids and its metabolism and clearance by the liver and kidneys. The primary regulators of PTH secretion are calcium, 1,25-dihydroxyvitamin D, and phosphate. PTH acts directly on bone and kidney, and indirectly on intestine, to increase the plasma concentration of free calcium and decrease the plasma concentration of phosphate.

Synthesis and Secretion

Parathyroid cells have relatively few secretory granules for storage of PTH. Thus PTH must be synthesized as needed for secretion. Control of PTH synthesis by calcium and phosphate occurs largely at the post-transcriptional level. Specific proteins bind to a sequence in the 3′-untranslated region of the PTH mRNA with resultant alteration of the stability of the mRNA.[213]

The primary translation product leading to PTH is the 115 amino acid long pre-pro-PTH (Figure 52-12).[85,219] The amino-terminal hydrophobic "pre" or leader sequence is involved in transporting PTH across the endoplasmic reticulum membrane into the cisternae. Both the pre sequence and the six amino acid long N-terminal "pro" sequence are enzymatically cleaved during intracellular processing and before packaging in the Golgi apparatus. After processing, intact PTH (84 amino acids, molecular mass 9425 Da) is secreted, stored, or degraded intracellularly. Intracellular degradation is increased when plasma calcium concentration is high and secretion of PTH is low. When PTH secretion is high (e.g., with low plasma calcium), intracellular degradation of PTH is low. Unlike proinsulin, pro-PTH does not appear to be secreted or to circulate in measurable concentrations. However, together with intact PTH, several C-terminal fragments of the molecule are secreted from the parathyroid.[210]

The classical biological activity of PTH resides in the N-terminal third of the molecule.[136,210] Synthetic PTH(1-34) is at least as potent as intact PTH(1-84) in interacting with

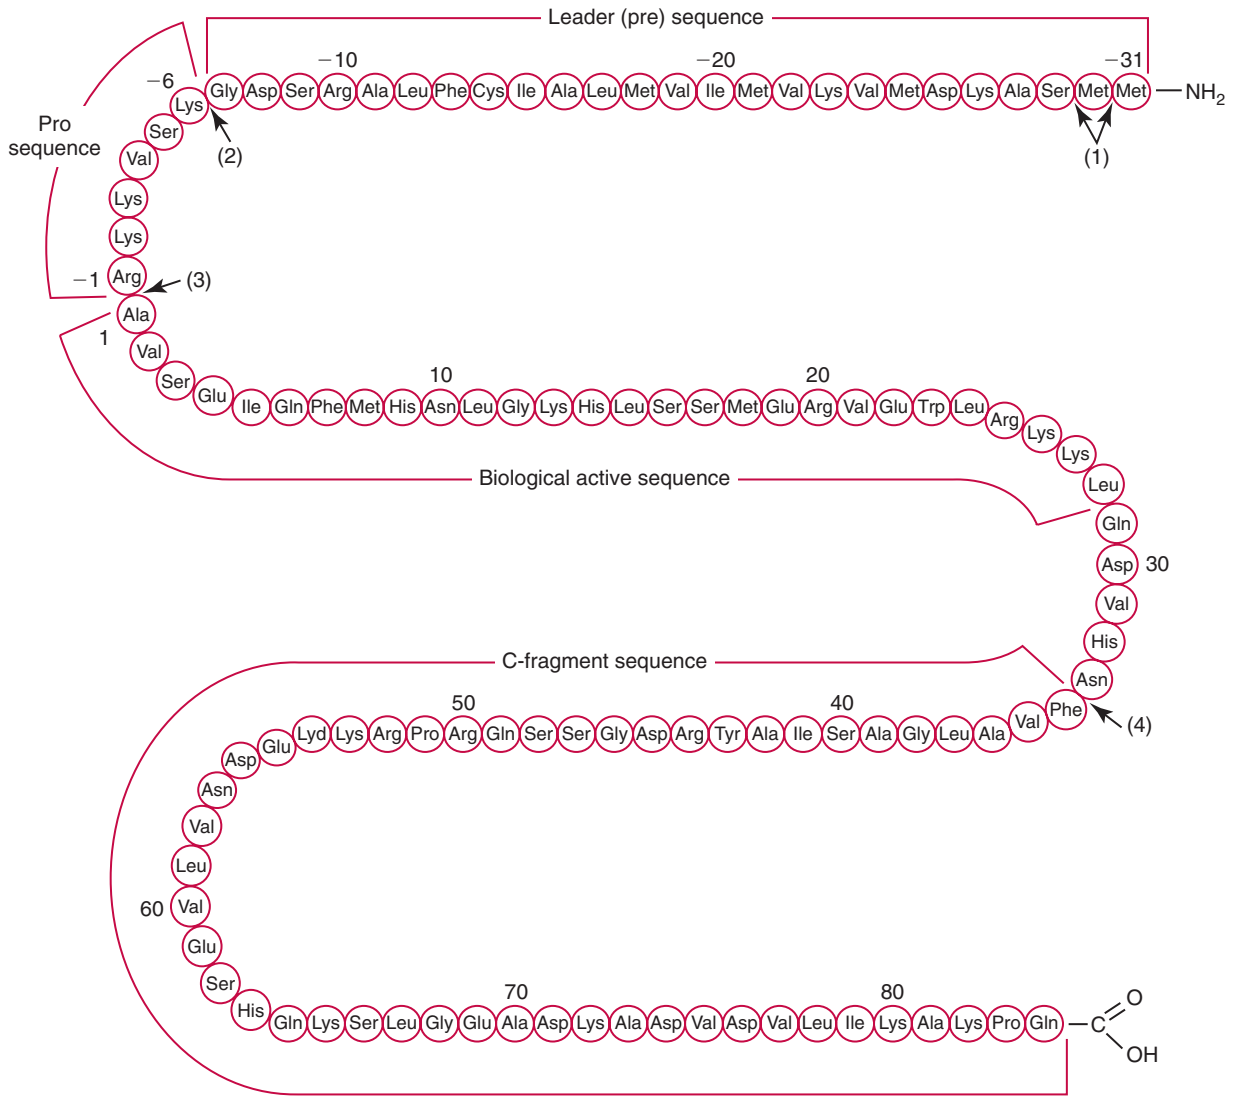

Figure 52-12 Amino acid sequence of human preproparathyroid hormone. ***Arrows*** **indicate the sites of cleavage by proteases to remove the N-terminal methionine and isoleucine** ***(1)*****, the leader (pre) sequence** ***(2)*****, and the pro sequence** ***(3)*****, producing intact PTH(1-84). Cleavage at position 4 produces inactive carboxyl (C)-terminal fragments.** *(From Habener JF, Rosenblatt M, Potts JT Jr. Parathyroid hormone: biochemical aspects of biosynthesis, secretion, action, and metabolism. Physiol Rev 1984;64:985-1053.)*

the PTH/PTHrP receptor (PTH1R, type 1 PTH receptor) and stimulating calcemic, phosphaturic, and other biological responses in kidney and bone. Oxidation of the methionine residues at position 8 or 18 results in loss of biological activity.

The PTH molecule contains a large number of basic amino acids. The middle portion of the molecule is quite immunogenic because of its hydrophobicity and species specificity. The C-terminal part of PTH, PTH(7-84), has some effects that antagonize those of PTH[286] and is involved in some functions of the hormone, having its own receptors in kidney and bone, that are distinct from those mediated by PTH1R.[210]

The concentration of free calcium in blood or extracellular fluid is the primary acute physiologic regulator of PTH synthesis, metabolism, and secretion.[36,85,219] Free calcium is sensed by a G-protein–coupled calcium-sensing receptor (CaSR) in the plasma membrane of parathyroid cells; intracellular signal transduction pathways following activation of the receptor involve release of free calcium from intracellular stores and opening of plasma membrane calcium channels.[35] The 1078 amino acid CaSR (gene symbol *CASR*, gene location chromosome 3q13.3-q21) is a member of subfamily C of the G-protein–coupled receptors. Other subfamily members include gamma-aminobutyric acid type B (GABAB) receptors, metabotropic glutamate receptors (mGluR), and pheromone receptors. The CaSR has a large extracellular domain for the detection of ionized calcium, seven transmembrane domains, and an intracellular domain that couples the receptor to G proteins. An increase in extracellular free calcium concentration inhibits PTH synthesis and secretion and

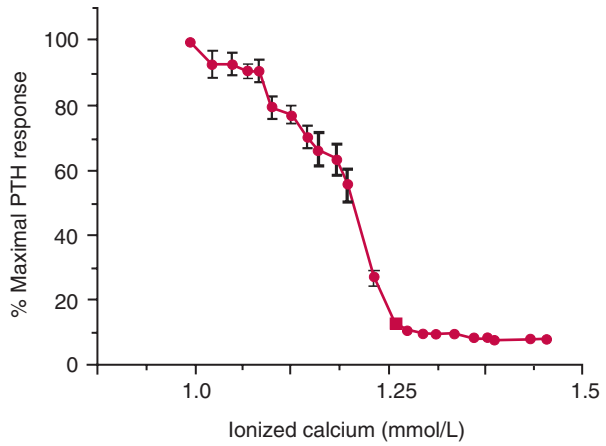

Figure 52-13 Regulation of secretion of intact parathyroid hormone (PTH) by calcium in healthy humans. Calcium and ethylenediaminetetraacetic acid (EDTA) were infused to demonstrate the sigmoidal relationship between PTH secretion and free calcium. *[From Brown EM. Extracellular Ca^{2+} sensing, regulation of parathyroid cell function, and role of Ca^{2+} and other ions as extracellular (first) messengers. Physiol Rev 1991;71:371-411.]*

increases PTH metabolism, whereas a decrease has the opposite effect. An inverse sigmoid relationship exists between PTH secretion and free extracellular calcium (Figure 52-13).[219] Maximal secretion and suppression are attained with mild hypocalcemia and mild hypercalcemia, respectively. The midpoint of this relationship, or the set point, is the calcium concentration at which PTH secretion is half maximal. Set points appear to vary somewhat from individual to individual and may be altered by physiologic or pathologic processes.

$1,25(OH)_2D$, phosphate, and magnesium also influence the synthesis and secretion of PTH.[84,85,219] $1,25(OH)_2D$ interacts with vitamin D receptors in the parathyroid glands to chronically decrease PTH secretion by suppressing PTH gene transcription and subsequent secretion. Hyperphosphatemia and hypophosphatemia increase and decrease PTH synthesis and secretion,[5] respectively, and the hyperphosphatemia of chronic renal failure leads to parathyroid hyperplasia and hyperparathyroidism. Magnesium probably does not play an important role in PTH secretion except at the extremes of magnesium concentration.[84] Chronic severe hypomagnesemia, such as that occurring in alcoholism, has been associated with impaired PTH secretion, whereas acute hypomagnesemia may stimulate secretion. Chronic hypomagnesemia can cause resistance to the effects of PTH.[177] Hypermagnesemia suppresses PTH secretion via the calcium-sensing receptor, although not as effectively as does calcium.[84]

Biological Actions

PTH influences calcium and phosphate homeostasis directly through its actions on both bone and kidney and indirectly through its actions on the intestine through $1,25(OH)_2D$.[85,219] The hormone exerts its actions by interacting with type 1 PTH receptors (PTH/PTHrP receptors) located in the plasma membrane of target cells. This interaction initiates a cascade of intracellular events, including generation of cAMP, activation of kinases, phosphorylation of proteins, increased entry of calcium and intracellular calcium stimulated phospholipase C activity with generation of diacylglycerol and phosphoinositide-activated enzyme and transport systems, and secretion of lysosomal enzymes.[85,228] Two active domains have been identified in the receptor binding region of PTH that activate two separate second messenger pathways upon binding to the receptor[271]; in its classical target cells, PTH normally activates both pathways.

In the kidneys, PTH has several functions: (1) induces 25-hydroxyvitamin D-1α-hydroxylase, increasing the production of $1,25(OH)_2D$, which in turn stimulates intestinal absorption of both calcium and phosphate; (2) increases calcium reabsorption in the distal convoluted tubule of the nephron; (3) decreases reabsorption of phosphate by the proximal tubule; and (4) inhibits Na^+-H^+ antiporter activity, which favors mild hyperchloremic metabolic acidosis in hyperparathyroid states. The effects of PTH on bone are complex, as evidenced by its stimulation of bone resorption or bone formation, depending on the concentration of PTH and the duration of exposure.[85,136] Chronic exposure to high concentrations of PTH leads to increased bone resorption. Bone resorption, a prompt effect, is important for the maintenance of calcium homeostasis, whereas the delayed skeletal effects of PTH are important for extreme systemic needs and skeletal homeostasis.

Despite the extent and rapidity of catabolic effects in bone, it has not been possible to find PTH receptors on osteoclasts, whereas they are found on osteoblasts and adjacent bone marrow stromal cells. These cell types mediate PTH action to osteoclasts via several cytokines.[210] Actions include enhanced differentiation of osteoclast precursors and stimulation of resorbing activity in mature osteoclasts.

PTH also has an anabolic effect on the skeleton. It increases the number of osteoblasts and enhances their differentiation from stromal cells. Different fragments and the intact hormone may have different effects on osteoblast gene expression.[85] Because of its anabolic effect on bone, PTH(1-34) is used as a therapeutic agent for osteoporosis under the name teriparatide (see "Biochemical markers of bone turnover").[136] Osteoblasts, via macrophage-colony stimulating factor (M-CSF), stimulate osteoclast precursor formation from macrophages. Therefore osteoclasts are ultimately derived from the bone marrow and from hematopoietic stem cells located in the bone marrow.

Integration of the direct effects of PTH on bone and kidney, and of the indirect effects on intestine through $1,25(OH)_2D$, results in alterations in calcium and phosphate concentrations in blood and urine. In blood, total and free calcium concentrations are increased, whereas the concentration of phosphate is decreased. In urine, inorganic phosphate and cAMP concentrations are increased. Urinary calcium excretion usually is increased because the larger filtered load of calcium, derived from bone resorption and intestinal calcium absorption, overrides the increased tubular

tahir99-VRG & vip.persianss.ir

reabsorption of calcium. In the absence of disease, the increase in blood calcium reduces PTH secretion through a negative feedback loop, maintaining homeostasis.

Heterogeneity of Circulating PTH

PTH circulates partially as the biologically active hormone and partially as a series of N-terminally truncated fragments containing the midregion and C-terminal amino acids. Many of these fragments have been identified[33,187] (Figure 52-14). The heterogeneity is due to (1) the secretion of both intact hormone and C-terminal fragments by the parathyroids, (2) peripheral metabolism of intact hormone by liver and kidney to C-terminal fragments, and (3) renal clearance of intact hormone and C-terminal fragments (Figure 52-15). In the parathyroids, secretion of intact PTH is increased by hypocalcemia and is greatly reduced or absent in hypercalcemia, whereas some secretion of C-terminal fragments persists in hypercalcemia. Biologically active intact PTH (amino acids 1-84) is rapidly cleared from plasma (half-life <5 minutes) by Kupffer cells of the liver (60 to 70%) and by glomerular filtration in the kidneys (20 to 30%).[85] Peripheral metabolism appears to inactivate intact hormone without releasing measurable concentrations of biologically active N-terminal fragments.[33,210]

Circulating PTH measured by most immunoassays is composed of "inactive" fragments and intact hormone. Fragments consisting of the middle and carboxyl regions of the molecule (e.g., amino acids 34-84, 36-84) are devoid of the N-terminal region and classical PTH biological activity and were earlier considered to be inactive degradation products. However, reports have identified separate receptors for C-terminal PTH in bone cells and have suggested that such fragments may affect the maturation and biological activity of these cells. C-terminal fragments are cleared by glomerular filtration and normally have a half-life of less than 1 hour. Their half-life and circulating concentration are significantly increased in individuals with impaired renal function. In most current assays, 5 to 25% of the total circulating PTH is intact hormone, and 75 to 95% consists of C-terminal fragments in individuals with normal renal function.[85]

Clinical Significance

Determination of PTH is useful in the differential diagnosis of both hypercalcemia and hypocalcemia, for assessing parathyroid function in renal failure, and for evaluating parathyroid function in bone and mineral disorders (see "Calcium, Clinical Significance," "Hypocalcemia," and "Hypercalcemia"; "Metabolic Bone Diseases"; and "Interpretation of PTH Results").

Measurement of PTH

Radioimmunoassay for PTH was among the first modern immunoassays to be put to clinical use in the 1960s, adding a new dimension to diagnosis and treatment of hypocalcemic and hypercalcemic states. However, it soon became clear that not all immunoreactive substances measured in blood by the assay were active PTH—a finding that led to the identification of C-terminal fragments of PTH. The next generation of immunoassays was developed to overcome this problem. To date, there have been three generations of PTH assay, which have yielded partially different results as the result of the presence of a series of immunologic determinants along the molecule and the physiologic heterogeneity of circulating PTH-related antigens (Figure 52-16).[33,95,194,325,342] Noncompetitive (sandwich) immunoassays generally are used now for the measurement of intact PTH. Radioimmunoassays (RIAs) of the first generation of PTH assays were competitive immunoassays involving a single antibody directed toward epitopes in the midregion or the C-terminal half of the molecules, these being the most immunogenic parts. Today, such assays have been largely discontinued because of their limited specificity and/or sensitivity. Midregion and C-terminal methods (1) measure primarily C-terminal fragments, which are present in much higher concentrations than is the biologically active hormone; (2) often provide poor identification of parathyroid function, as the measured concentration is affected by peripheral metabolism and glomerular filtration of the fragments; (3) are difficult to interpret in patients with impaired renal function, as an apparent high value does not necessarily indicate secondary hyperparathyroidism; and (4) produce results that are not suppressed in nonparathyroid hypercalcemia and are often falsely modestly elevated.[79] Other RIAs were developed to recognize epitopes in the N-terminal part of PTH, but these suffered from inaccuracy.[325,342] Competitive immunoassays lacked the sensitivity required to measure intact PTH in patients with normal or modestly elevated concentrations.

The second generation of PTH assays were designed to detect the intact molecule only and were called *intact assays*. This was accomplished by the use of noncompetitive (sandwich) immunometric assays using two antibodies[33,342]: a solid-phase capture antibody directed against the C-terminus, and a labeled detection antibody raised against the N-terminus (amino acids 1-34), or vice versa. The following advances permitted the development of noncompetitive methods for intact PTH: (1) determination of the amino acid sequence of human (h)PTH; (2) increased understanding of the secretion, metabolism, clearance, and circulating forms of PTH; and (3) synthesis of hPTH, fragments of hPTH, and analogs of fragments for use as immunogens, tracers, and calibrators, for characterization of antiserum and antibody specificity, and for affinity purification of antibodies. The clinical utility of the first generation of so-called intact PTH assays in diagnosing primary hyperparathyroidism and in monitoring secondary hyperparathyroidism is well established.[33] Yet, it has become clear that they overestimate the severity of PTH-related bone disease because they also detect several molecular species of PTH, which can be separated when a serum sample is fractionated on high-performance liquid chromatography (HPLC). Indeed, if PTH concentration in the serum of a patient with end-stage kidney disease was decreased to normal as measured by these assays, adynamic bone disease was a possible outcome.[33,342] Again, blood was found to contain N-terminally truncated PTH fragments that are long

tahir99-VRG & vip.persianss.ir

Selected reaction monitoring—mass spectrometric immunoassay responsive to parathyroid hormone and related variants. Clin Chem 2010;56:281-90.)*

tahir99-VRG & vip.persianss.ir

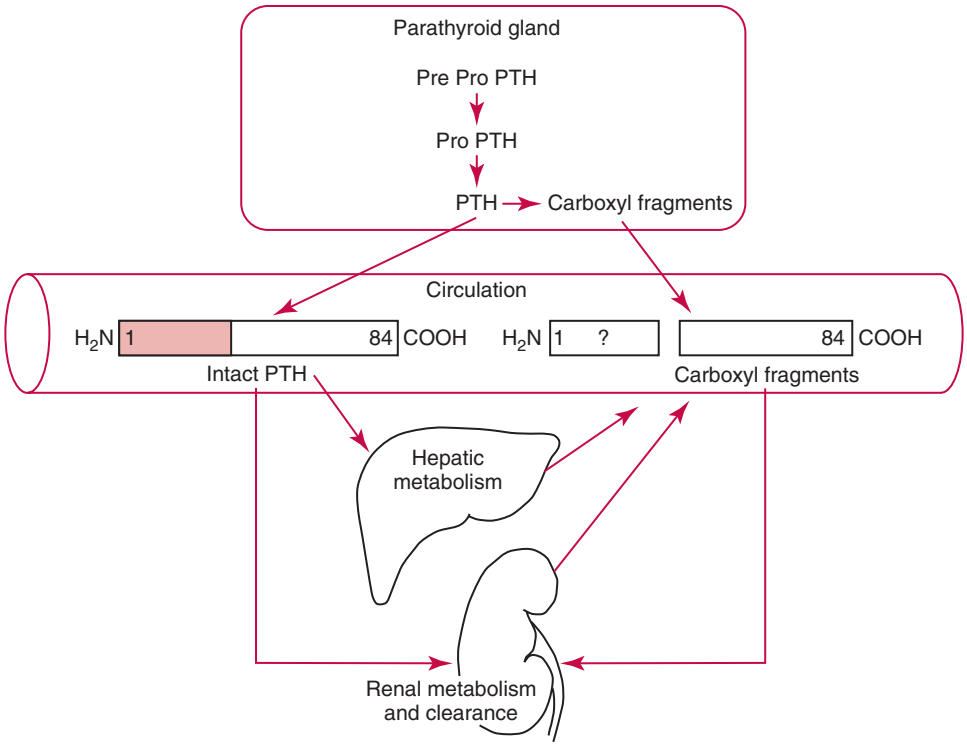

Figure 52-15 Secretion, metabolism, clearance, and circulating forms of parathyroid hormone (PTH). Both intact PTH and inactive fragments containing the middle and carboxyl (C)-terminal amino acids are secreted by the parathyroid glands. These inactive fragments are produced by peripheral metabolism of intact PTH by the liver and kidneys. Carboxy-terminal fragments are cleared by the kidneys by glomerular filtration. The half-life and concentration of intact hormone are small compared with those of inactive fragments. *(From Endres DB, Villanueva R, Sharp CF Jr, Singer FR. Measurement of parathyroid hormone. Endocrinol Metab Clin North Am 1989;18:611-29.)*

enough to react in the intact PTH assays but do not bind to the PTH receptor. Therefore, the term *intact* as applied to these immunometric intact PTH assays is somewhat of a misnomer because non–1-84 PTH fragments [e.g., PTH(7-84)] are detected along with PTH(1-84).

In the newest PTH assays, in third-generation immunoassays in general, and in second-generation intact assays, the epitope of the N-terminally binding antibody consists of the first four to six amino acids of the intact PTH molecule.[292,325] Such assays have been variously termed *true intact* PTH assays, *whole* PTH assays, or *cyclase-activating* PTH assays. Despite the theoretical improvement, in clinical practice they have not shown clear advantages over earlier immunoradiometric assays (IRMAs).[27,33] In addition to intact PTH, these assays have been reported to detect another molecular species in blood, called *amino PTH* by D'Amour and associates,[64] which possibly has its amino-terminal serine residue in a phosphorylated form.

Noncompetitive Methods for Intact PTH

Noncompetitive (also known as two-site, sandwich, or immunometric) methods (see Chapter 16) require two antibodies capable of simultaneously binding two separate epitopes on the PTH molecule (Figure 52-17): (1) a capture antibody immobilized to a solid phase, and (2) a signal or reporter antibody labeled with a measurable substance or an enzyme, changing the concentration (substrate or product) of a measurable substance. Unlike competitive immunoassays, with noncompetitive methods, both antibodies are added in excess, ensuring that all analyte is measured. After formation of the ternary complex or sandwich, excess labeled antibody is removed by washing before quantification of complexes. Noncompetitive immunoassays provide increased sensitivity, specificity, reproducibility, and convenience. In practice, the lower limit of detection for such assays is often lower than that observed in competitive immunoassays, and the upper linear limit is higher than that observed in competitive immunoassays.

For measuring intact PTH, the capture antibody is most often directed against the carboxyl or middle region of the molecule (e.g., amino acid sequences 39-84, 44-84) and the signal antibody against the N-terminal amino acid sequence (1-34).[33] A few methods have reversed this, using capture antibodies against the N-terminal amino acid sequence (e.g., amino acids 26-32) and signal antibodies against the middle or C-terminal amino acid sequence (e.g., 55-64).[292] With the

tahir99-VRG & vip.persianss.ir

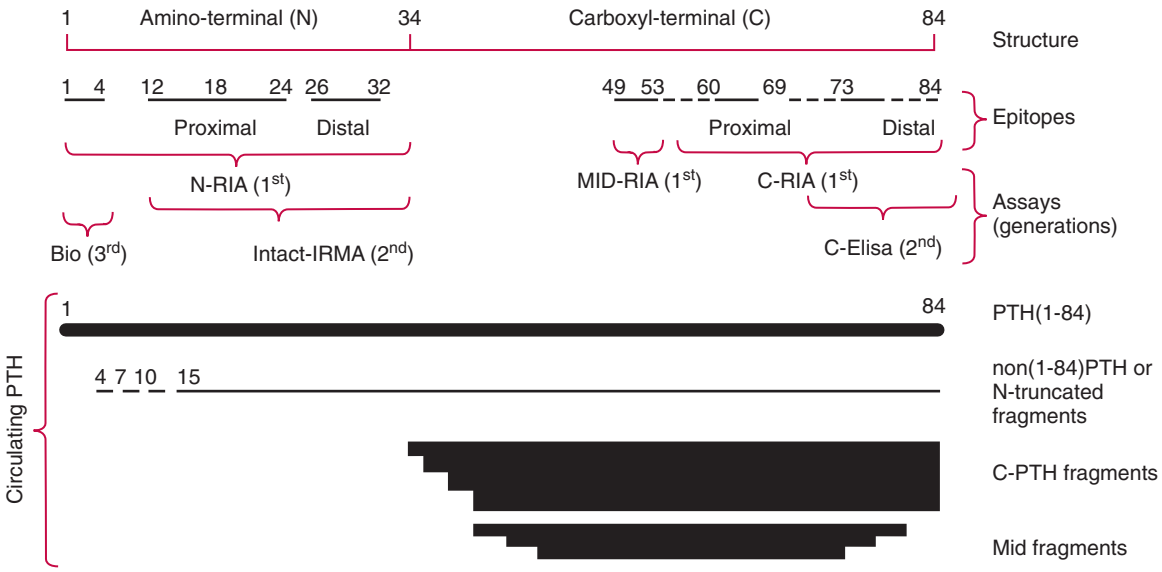

Figure 52-16 Relationship between parathyroid hormone (PTH) assays, PTH assay epitopes, and PTH molecular forms detected in circulation. The *upper panel* depicts the structure of human PTH and epitopes detected by various PTH assays. First-generation PTH assays detect full-length PTH(1-84), in addition to PTH fragments. These assays include radioimmunoassays (RIAs) that use antisera specific for the amino-terminal (N-RIA), middle (MID-RIA), or carboxy-terminal (C-RIA) region of PTH. Second-generation "intact PTH" assays detect full-length PTH(1-84) and non–(1-84)PTH fragments. Third-generation PTH assays (Bio) detect the full-length PTH(1-84). The *bottom panel* depicts the PTH molecular forms present in the circulation. *(Modified from Henrich LM, Rogol AD, D'Amour P, Levine MA, Hanks JB, Bruns DE. Persistent hypercalcemia after parathyroidectomy in an adolescent and effect of treatment with cinacalcet HCl. Clin Chem 2006;52:2286-93.)*

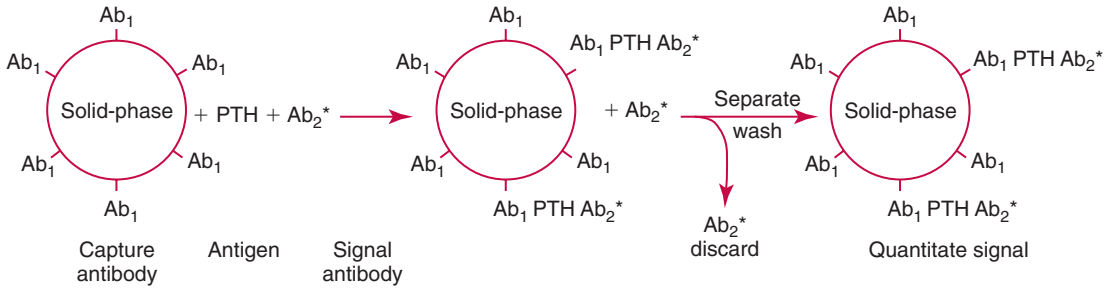

Figure 52-17 Principle of a noncompetitive immunoassay for parathyroid hormone (PTH). PTH is reacted with immobilized capture antibody (Ab_1) against one antigenic determinant and with a labeled signal antibody (Ab_2*) against a second antigenic determinant. PTH forms a bridge between the two antibodies, producing a "sandwich" or ternary complex. Both antibodies are added in excess, ensuring that all PTH reacts and is measured. Free signal antibody is separated, and the solid-phase antibody-PTH-labeled antibody complexes are quantified with an appropriate detection system. The signal increases with increasing concentrations of PTH. *(Modified from Endres DB, Villanueva R, Sharp CF Jr, Singer FR. Measurement of parathyroid hormone. Endocrinol Metab Clin North Am 1989;18:611-29.)*

latter arrangement, a higher concentration of signal antibody is needed because of the high concentration of inactive fragments relative to intact hormone, potentially adversely impacting sensitivity by increasing the blank (signal in the absence of intact PTH). The specificity of these noncompetitive methods depends on the sequence specificity of the antibodies used; they do not measure classical C-terminal fragments that lack the N-terminal amino acid sequence (1-34).

Antibodies used in immunometric assays may be monoclonal or polyclonal antibodies purified by affinity chromatography to produce sequence-specific antibodies.

tahir99-VRG & vip.persianss.ir

Affinity-purified polyclonal antibodies have been widely used, particularly for the signal antibody, because of the difficulty of producing high-affinity monoclonal antibodies against PTH. Capture antibodies are noncovalently bound or are covalently attached to one of a variety of solid phases, including polystyrene beads, plastic tubes, paramagnetic particles, microparticulate cellulose, and sepharose.[290] Signal antibodies most often have been radiolabeled (for IRMAs) with ^{125}I, or labeled with a chemiluminescent [for immunochemiluminometric assays (ICMAs)] compound, such as acridinium ester or isoluminol, or an enzyme [enzyme-linked immunosorbent assay (ELISA) or enzyme immunoassay (EIA)], such as alkaline phosphatase (ALP), which converts a substrate (1,2-dioxetane phosphate) to a chemiluminescent product.[290,292] Other assay formats used on fully automated immunoassay analyzers include electrochemiluminescence detection (ruthenium chelate).

Intact PTH assays available commercially have been listed and compared.[244,292]

N-Terminal–Truncated PTH and Second-Generation Intact PTH Methods

The N-terminal–truncated fragment(s) [also called non-(1-84)PTH and PTH(7-84)], containing all but a few of the N-terminal amino acids of PTH,[34,179] account, on average, for 20 and 50% of intact PTH concentrations measured by first-generation intact PTH assays in healthy subjects and patients with chronic renal failure, respectively. Furthermore, the relative concentration of N-terminal–truncated PTH increases with hypercalcemia and decreases with hypocalcemia. Similar to classical C-terminal fragments, N-terminal–truncated PTH originates from both secretion by the parathyroids and peripheral metabolism of intact hormone.[216]

The first noncompetitive methods used for intact PTH cross-reacted with N-terminal–truncated fragment(s), thus overestimating the concentration of biologically active, truly intact PTH. Synthetic PTH(7-84) has shown cross-reactivities of 40 to 160% in these methods.[96,179] These findings stimulated the development of a new generation of methods for intact PTH, using antibodies against the very N-terminal region of PTH that do not cross-react with synthetic PTH(7-84) (see Figure 52-16).

One of the newest-generation methods uses antibodies against PTH(1-4) and even requires the presence of the most N-terminal amino acid, as evidenced by its failure to recognize PTH(2-34).[96,292]

Studies have suggested that N-terminal–truncated PTH [e.g., PTH(7-84)] may be biologically active and antagonistic to the action of PTH. Synthetic PTH(7-84), used as the available representative of N-terminal–truncated PTH, decreased serum calcium; antagonized the calcemic, phosphatemic, and phosphaturic effects of intact PTH in thyroparathyroidectomized animals; and was bound by a C-terminal PTH receptor distinct from the PTH/PTHrP receptor.[72]

Because first-generation methods for intact PTH measure N-terminal–truncated PTH, they overestimate the concentration of biologically intact hormone. The degree of overestimation is method dependent, but intact PTH is 50% higher on average than PTH(1-84) in patients with primary hyperparathyroidism or end-stage renal disease.[96]

The inability of first-generation intact PTH methods to accurately measure biologically active intact hormone may explain why intact PTH is not a reliable indicator of bone turnover in dialysis patients and often fails to distinguish patients with low-, normal-, and high-turnover bone disease.[193] Furthermore, treatment of patients to suppress their intact PTH value to normal or near normal frequently results in adynamic bone disease. The PTH(1-84)/N-terminal–truncated fragment ratio has been proposed for evaluating bone turnover in renal osteodystrophy on the basis of the ability of PTH(7-84) to antagonize the biological activity of intact PTH and preliminary experimental evidence for the predictive value of this ratio.[209] The ratio is calculated after intact PTH and PTH(1-84) are measured and N-terminal–truncated fragments are calculated by subtracting PTH(1-84) from intact PTH. This issue is still unclear, however, because subsequent studies were unable to substantiate the greater clinical utility of measuring both PTH(1-84) and intact PTH and calculating this ratio to assess bone turnover in end-stage kidney disease.[114,193]

Even second-generation intact PTH assays are not absolutely specific for intact PTH, as evidenced by demonstration of an amino-terminal form of PTH distinct from both the intact hormone and the N-truncated fragment. This form represented approximately 20% of the intact PTH measured with a second-generation intact PTH method.[64] The clinical implications of this form have not yet been established, but it has been reported in patients with hyperparathyroidism and parathyroid carcinoma.

Mass spectrometry has been used to characterize PTH fragments and to measure intact PTH.[169,187] In the mass spectrometric method of Kumar and colleagues used for measurement of PTH in serum,[169] PTH was captured on antibody-coated beads and was digested by trypsin. The N-terminal 13 amino acids were then quantified by selected reaction monitoring in a liquid chromatography-tandem mass spectrometry system. As expected, the assay showed no detectable cross-reactivity with PTH fragments, including PTH(7-84), which was captured on the antibody-coated beads.

Specimen Requirements

Specimen requirements may depend on the specific method. Serum or EDTA plasma generally is preferred, and results may vary with sample type. After separation, serum or plasma should be frozen if analysis is delayed. Lower concentrations of PTH are observed in serum incubated at room temperature for longer than a few hours, or after one to several days at 4 °C. PTH has been reported to be more stable in EDTA plasma; this is a probable consequence of reduced proteolytic activity.

Reference Intervals

Reference intervals for PTH vary greatly with the method used.[292,342] Typical reference intervals are as follows:

Intact PTH: 10 to 65 pg/mL or 1.1 to 6.8 pmol/L
PTH(1-84): 6 to 40 pg/mL or 0.6 to 4.2 pmol/L

Interpretation of PTH concentrations should take into account the patient's circulating calcium concentration at the time of sampling.

The upper limit of the reference interval for PTH may be inappropriately high because of the prevalence of vitamin D insufficiency and mild secondary hyperparathyroidism in the reference group. Significantly lower intervals have been established for these methods by excluding individuals with vitamin D insufficiency (see "Vitamin D, Reference Intervals").[292]

Intact PTH concentrations vary with age and are low or normal during pregnancy,[167] lower in fetuses and umbilical cord blood,[165] and increased during the first few days of life, in response to neonatal hypocalcemia. Concentrations in children and adolescents are reportedly similar, if not identical, to those in adults.[264] In healthy adults, circulating concentrations of intact PTH increase with age.[78]

Intact PTH is secreted in a pulsatile fashion with an overall circadian rhythm characterized by a nocturnal rise. Measurement of PTH on more than one occasion should assist in preventing misinterpretation of parathyroid status as the result of episodic secretion.

Interpretation of PTH Results

PTH is the most important test for the differential diagnosis of hypercalcemia. The serum concentration of intact PTH is increased in most patients with primary hyperparathyroidism (Figure 52-18) and is below normal or close to the lower limit of the reference interval in most patients with nonparathyroid hypercalcemia, including hypercalcemia-associated malignancy. In patients with stable hypercalcemia, a PTH value in the upper half of the reference interval is inappropriately high and is suggestive of primary hyperparathyroidism. Whenever possible, PTH specimens should be obtained before therapy is provided for hypercalcemia, because PTH secretion may be stimulated by declining serum calcium.

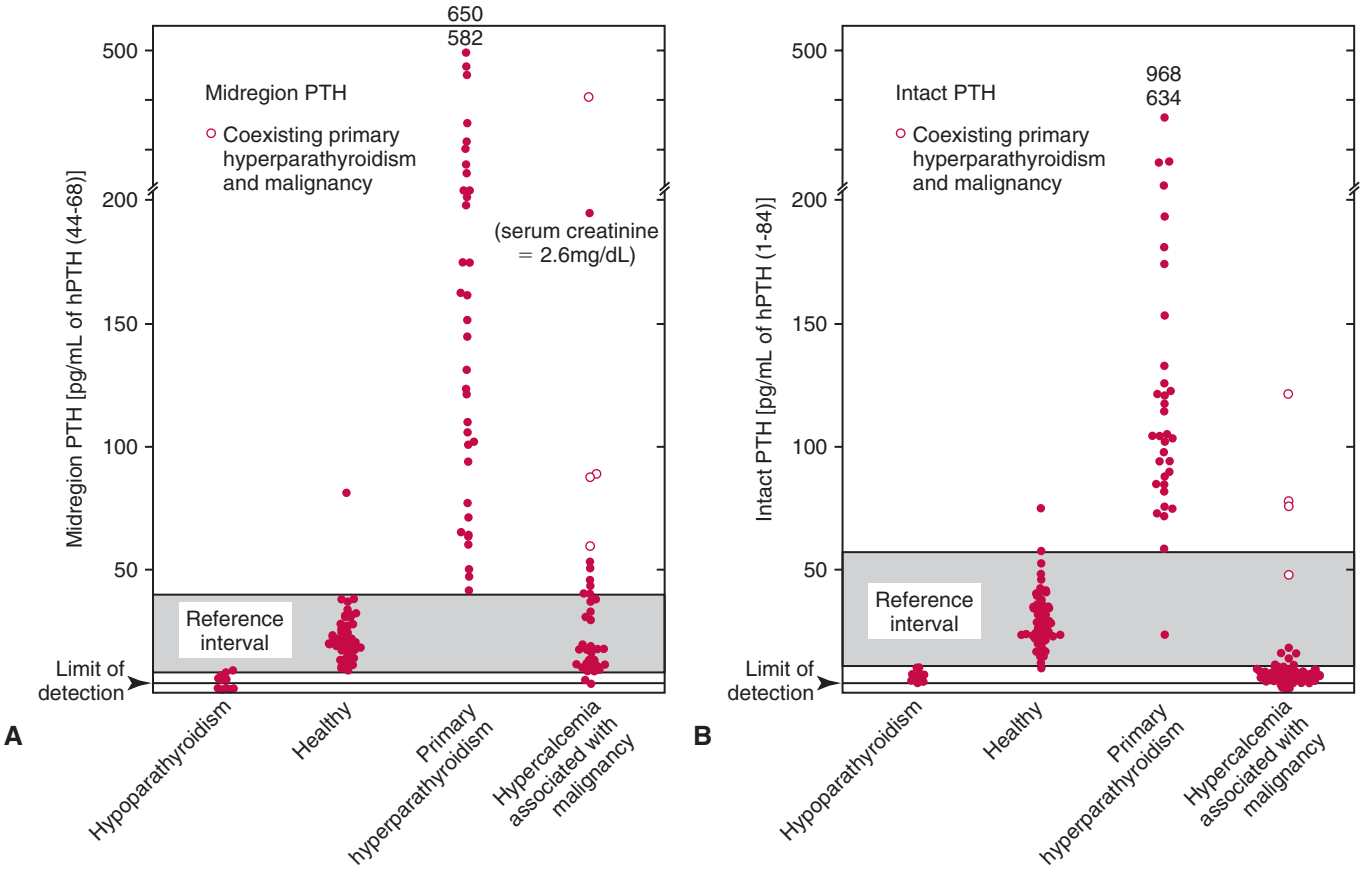

Figure 52-18 Parathyroid hormone (PTH) in healthy individuals and patients with primary hyperparathyroidism, hypercalcemia associated with malignancy, and hypoparathyroidism. PTH was measured with immunoassay for its midregion (A) and for intact PTH (B). *(Modified from Endres DB, Villanueva R, Sharp CF Jr, Singer FR. Measurement of parathyroid hormone. Endocrinol Metab Clin North Am 1989;18:611-29.)*

tahir99-VRG & vip.persianss.ir

Increased PTH in patients with hypercalcemia and malignancy suggests coexisting hyperparathyroidism and malignancy, in that ectopic PTH production appears to be extremely rare. Hypercalcemia in malignancy is usually associated with bone metastases (e.g., local osteolytic hypercalcemia) and/or production of PTHrP (e.g., humoral hypercalcemia of malignancy). PTHrP does not cross-react in any of the PTH immunoassays that have been evaluated. According to a 2003 study, PTH(1-84) is more sensitive in diagnosing primary hyperparathyroidism than intact PTH.[283] In this study, PTH(1-84) and intact PTH were elevated in 96% and 73% of 56 patients with primary hyperparathyroidism, respectively.

Measurements of urinary calcium excretion are necessary to confirm hypocalciuria in cases of suspected familial hypocalciuric hypercalcemia. Such patients do not usually display hypercalcemia above 12 mg/dL or above 0.3 mmol/L. Because having this disorder in the heterozygous state leads to no ill effects, parathyroidectomy is not indicated. However, infants with homozygous familial hypocalciuric hypercalcemia can present with life-threatening hypercalcemia, even requiring emergency parathyroidectomy.

Because of the short half-life of PTH (≤5 minutes), intraoperative determination of intact PTH is useful for assessing the completeness of parathyroidectomy and facilitating minimally invasive parathyroid surgery, thereby improving cost-effectiveness and cosmetic outcomes.[50] PTH is measured just before the incision and again at 10 minutes after resection of the hyperfunctioning parathyroid tissue. The neck should not be massaged by the surgeon at baseline (where PTH could rise) or following parathyroidectomy (when PTH could be released from injured parathyroid glands). A decline of 50% or more is usually considered indicative of the removal of all hyperfunctioning tissue. In contrast to patients with solitary parathyroid adenomas, interpretation of results in patients with multiglandular disease is complicated. Preoperative or intraoperative PTH may be useful for localizing hyperfunctioning parathyroid tissue by sampling multiple veins from the cervical and mediastinal regions. PTH(1-84) may be decreased more rapidly and completely than intact PTH after removal of hyperfunctioning tissue.[339]

Subnormal or low-normal PTH is observed in most patients with hypoparathyroidism (see Figure 52-18); such concentrations are inappropriately low for patients with hypocalcemia. The apparently detectable concentrations observed in many patients with hypoparathyroidism or nonparathyroid hypercalcemia may be a result of the imprecision of methods used at low concentrations, a nonspecific serum (ligand-free matrix) effect, and/or measurement of N-terminal–truncated PTH. More rigorous assessment of the limit of detection of PTH immunoassays and use of PTH(1-84) methods may show that concentrations are undetectable in these patients.

In secondary hyperparathyroidism, PTH is increased before total or free calcium becomes abnormally low—a consequence of homeostatic mechanisms for maintenance of serum calcium. Consequently, PTH is more sensitive than calcium in identifying secondary hyperparathyroidism.

In patients with end-stage renal disease, measurement of PTH is helpful in assessing parathyroid function, in estimating bone turnover, and in improving management. Patients with high-turnover bone disease caused by secondary hyperparathyroidism (advanced osteitis fibrosa) have the highest concentrations of PTH, whereas those with low-turnover, adynamic bone disease, including osteomalacia, have the lowest concentrations (Figure 52-19). Intermediate concentrations are seen in low-turnover adynamic (aplastic) disease and early osteitis fibrosa. Considerable overlap in intact PTH concentrations is apparent among the various forms of renal osteodystrophy. In dialysis patients, cut points ("decision levels") of less than 100 or 150 pg/mL and greater than 250 to 300 pg/mL have been suggested for distinguishing patients with low-turnover and high-turnover bone disease, respectively. The Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines of the National Kidney Foundation

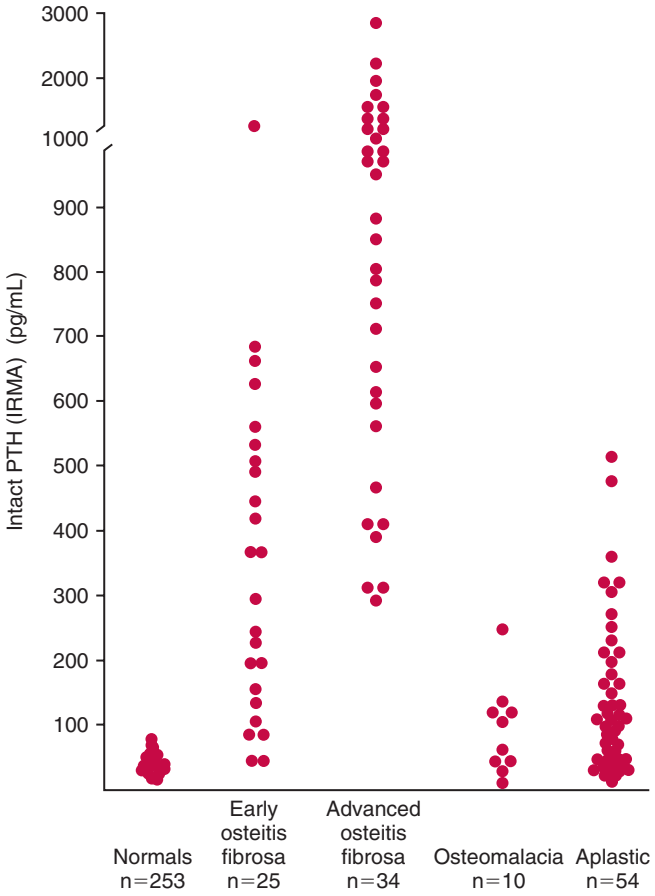

Figure 52-19 Intact parathyroid hormone (PTH) for assessing parathyroid function in end-stage renal disease. Dialysis patients were separated into those with early and advanced osteitis fibrosa, osteomalacia, and aplastic disease by quantitative histomorphometric analysis of undecalcified bone biopsies. *[From Segre GV, Sherrard DJ, Pandian MR, et al. Intact PTH (IRMA) II: New applications to issues in parathyroid hormone and mineral metabolism. San Juan Capistrano, Calif: Nichols Institute, 1989.]*

tahir99-VRG & vip.persianss.ir

define reasonable therapeutic goals for intact PTH concentrations (first-generation IRMA or second-generation assay in general) in end-stage kidney disease as two to four times the upper limit of the reference interval to prevent parathyroid-suppressed, adynamic, and hyperparathyroid bone disease.[76]

Parathyroid status is usually determined by measuring PTH on predialysis specimens because various factors, including changes in serum calcium and the type of dialysis membrane, affect PTH secretion and clearance. Comparison of predialysis and postdialysis specimens has been suggested for determining acute parathyroid responsiveness to alterations in serum calcium concentrations.

The PTH(1-84) assay theoretically should more accurately assess parathyroid status and bone turnover and thus better guide therapy in patients with end-stage renal disease compared with the intact PTH assay [see "Noncompetitive Methods for Intact PTH" and "N-Terminal–Truncated PTH and Second-Generation Intact PTH Methods"].[193,209] However, the benefits of the new generation of PTH assays have not been as expected,[321] and it has not been easy to define the therapeutic targets for PTH(1-84).[163] Noncompetitive immunoassays for intact PTH or PTH(1-84) must have high concentrations of the C-terminal antibody to avoid underestimation of PTH in dialysis patients with secondary hyperparathyroidism who have high concentrations of C-terminal fragments. Absence of interference can be assessed by confirming that specimens from dialysis patients with the highest concentrations of PTH dilute in a parallel fashion. Alternatively, recovery can be determined by adding a known amount of intact PTH to these specimens.

PTH concentrations may be altered in hyperthyroidism, in hypothyroidism, and with lithium carbonate treatment. PTH is decreased and is inversely correlated with T3 concentrations in hyperthyroid patients. Serum PTH is increased in patients who become hypothyroid after radioactive iodine treatment, and is decreased with replacement therapy; these changes apparently are mediated by serum calcium. Long-term lithium carbonate therapy has been reported to increase parathyroid gland size and circulating intact PTH. Lithium may produce a state of relative resistance to calcium negative feedback, raising PTH concentrations.

An uncommon use for PTH methods measuring C-terminal fragments involves analysis of fluid from suspected parathyroid cysts. Parathyroid cyst fluid appears to contain primarily inactive fragments of PTH, not intact hormone.[22]

Vitamin D and Its Metabolites

Vitamin D is produced endogenously through exposure of skin to sunlight, and is absorbed from foods containing or supplemented with vitamin D. The vitamin is metabolized to its biologically active form, 1,25-dihydroxyvitamin D [1,25$(OH)_2$D], a hormone that regulates calcium and phosphate metabolism. Deficiency of vitamin D results in impaired formation of bone, producing rickets in children and osteomalacia in adults.

Biochemistry and Physiology

Vitamin D and its metabolites may be categorized as cholecalciferols or ergocalciferols (Figure 52-20). Cholecalciferol (vitamin D_3) is the parent compound of the naturally occurring family and is produced in the skin from 7-dehydrocholesterol on exposure to the ultraviolet B portion of sunlight.[20,178] Latitude, season, aging, sunscreen use, and skin pigmentation influence production of vitamin D_3 by the skin. Vitamin D_2 (ergocalciferol), the parent compound of the other family, is manufactured by irradiation of ergosterol produced by yeasts. Vitamin D_2 differs from vitamin D_3 by the double bond between carbon 22 and carbon 23 and a methyl group on carbon 24. When vitamin D or its metabolites are written without a subscript, both families are included.

Only a few foods, primarily fish liver oils, fatty fish, egg yolks, and liver, naturally contain significant amounts of vitamin D. Consequently, before foods were supplemented with vitamin D_2 or vitamin D_3, most vitamin D in the body was that produced by synthesis in the skin. In North America, a considerable fraction of vitamin D is acquired by ingestion of fortified foods (some cereals, bread products, and milk) or vitamin D supplements. The recommended daily allowance is 400 IU (10 μg). In some European countries, the recommendation for people older than 60 years is 800 IU or 20 μg. However, some clinicians in the United States are prescribing up to 2000 IU of vitamin D daily to treat or prevent osteoporosis and to ensure optimal dietary calcium absorption.[130]

Metabolism, Regulation, and Transport

Vitamin D_2 and vitamin D_3 are metabolized to 25-hydroxyvitamin D [25(OH)D] in the liver by vitamin D 25-hydroxylase, a cytochrome P450 enzyme (Figure 52-21).[70,178] The concentration of 25(OH)D in serum is approximately 10 to 65 ng/mL or 25 to 162 nmol/L (Table 52-4). The half-life of circulating 25(OH)D is 2 to 3 weeks. At 25(OH)D concentrations near 30 ng/mL, dietary calcium absorption is maximal. Therefore any reference interval for 25(OH)D should not be confused with the "optimal" or "healthy" range for 25(OH)D. At physiologic concentrations, 25(OH)D is biologically inactive in affecting dietary calcium absorption.

25$(OH)D_2$ and 25$(OH)D_3$ are metabolized to 1,25-dihydroxyvitamin D [1,25$(OH)_2$D], the biologically active hormone, by 25(OH)D 1α-hydroxylase, a cytochrome P450 enzyme, in kidney and placenta (see Figure 52-21). Normal circulating concentrations are approximately 15 to 60 pg/mL or 36 to 144 pmol/L—about $\frac{1}{1000}$ that of 25(OH)D (see Table 52-4). The half-life of 1,25$(OH)_2$D is 4 to 6 hours.

Circulating concentrations of 1,25$(OH)_2$D are tightly regulated, primarily by PTH, phosphate, calcium, and 1,25$(OH)_2$D.[49,70] PTH and hypophosphatemia increase the synthesis of 1,25$(OH)_2$D by increasing 25(OH)D-1α-hydroxylase activity, whereas hypocalcemia acts indirectly by stimulating the secretion of PTH. Hypercalcemia, hyperphosphatemia, and 1,25$(OH)_2$D reduce 25(OH)D 1α-hydroxylase and 1,25$(OH)_2$D. 1,25$(OH)_2$D also induces 25(OH)D 24-hydroxylase, an enzyme producing 24,25-dihydroxyvitamin D [24,25$(OH)_2$D], the most prevalent

Ergocalciferol is produced commercially by irradiation of ergosterol. *(Modified from Holick MF, Adams JS. Vitamin D metabolism and biological function. In: Avioli LV, Krane SM, eds. Metabolic bone disease, 2nd edition. Philadelphia, Pa: WB Saunders, 1990:155-95.)*

TABLE 52-4 Vitamin D and Its Metabolites in Plasma

Compound	Concentration	Free, %	Half-life
Vitamin D	<0.2-20 ng/mL <0.5-52 nmol/L	—	1-2 d
25-Hydroxyvitamin D	10-65 ng/mL 25-162 nmol/L	0.03	2-3 wk
1,25-Dihydroxyvitamin D	15-60 pg/mL 36-144 pmol/L	0.4	4-6 h

dihydroxylated vitamin D form in serum. This enzyme is also responsible for inactivating 1,25(OH)vitamin D through the 24-oxidation pathway, leading to formation of calcitroic acid.[270a]

In the circulation, vitamin D, 25(OH)D, and $1,25(OH)_2D$ are bound to vitamin D–binding protein (DBP), a specific, high-affinity transport protein also known as *group-specific component of serum* or *Gc-globulin*.[20,49,119] DBP belongs to the albumin and α-fetoprotein gene family. In humans, DBP contains 458 amino acid residues and has a molecular mass of 51,335 Da. DBP is constitutively synthesized by the liver and circulates in great excess (at about 400 mg/L), with less than 5% of the vitamin D binding sites normally occupied. DBP binds vitamin D and its metabolites, particularly the 25-hydroxylated metabolites 25(OH)D, $24,25(OH)_2D$, and $1,25(OH)_2D$.[20,119] Only 0.03% of 25(OH)D and 0.4% of

tahir99-VRG & vip.persianss.ir

$1,25(OH)_2D$ are normally free in plasma (see Table 52-4). DBP concentrations are increased in pregnancy and with estrogen therapy and are decreased in nephrotic syndrome.

Biological Actions of 1,25-Dihydroxyvitamin D

$1,25(OH)_2D$ helps to maintain calcium and phosphate in blood through its actions on intestine, bone, kidney, and the parathyroids. In the small intestine, $1,25(OH)_2D$ stimulates calcium absorption, primarily in the duodenum, and phosphate absorption by the jejunum and ileum.[20,49,70] Three events serve to absorb calcium from the diet: (1) calcium entry into the brush border cytoplasm, mediated by an epithelial Ca^{2+} transporter or channel (CaT1; gene name *ECAC2;* chromosome 7q34); (2) diffusion of calcium within the cell fostered by calbindin-D9k, which is a cytosolic calcium-binding protein [gene symbol *S100G*, located on the X chromosome, and distinct from calbindin-D28K, located on chromosome 8 (gene symbol *CALB1*)]; and (3) exit of calcium from the cell across its basolateral membrane by the action of a CaATPase (e.g., a Na^+/Ca^{2+} exchanger). CaT1 synthesis is ≈90% vitamin D dependent, and calbindin D synthesis is completely dependent on vitamin D. Because knockout mice lacking calbindin D_{9k} expression do not display deficient calcium absorption and can increase calcium absorption in response to vitamin D, the necessity of calbindin-D9k for calcium absorption has been questioned.[5,170] A diet high in calcium downregulates CaT1 and calbindin D expression by downregulating production of $1,25(OH)_2D$.

At high concentrations, $1,25(OH)_2D$ increases bone resorption by inducing monocytic stem cells in bone marrow to differentiate into osteoclasts and by stimulating osteoblasts to produce cytokines and other factors that influence osteoclast activity. By stimulating osteoblasts, $1,25(OH)_2D$ also increases the circulating concentrations of alkaline phosphatase and osteocalcin. In the kidneys, $1,25(OH)_2D$ inhibits its own synthesis in an ultra-short negative feedback loop and stimulates its own metabolism. $1,25(OH)_2D$ also acts directly on the parathyroids to inhibit the synthesis and secretion of PTH. In addition to a direct transcriptional mechanism, $1,25(OH)_2D$ increases the concentrations of the calcium sensing receptor in the parathyroid gland, thus sensitizing the gland to calcium inhibition.[20]

In target tissues, $1,25(OH)_2D$ exerts its actions by associating with a specific nuclear vitamin D receptor (VDR), analogous to the steroid receptors for androgens, estrogens, and corticosteroids (see Chapters 54 and 56). This receptor is expressed widely in tissues, and most cells respond to $1,25(OH)_2D$.[28] The vitamin D receptor can form heterodimers with members of the retinoid X receptor. The vitamin D receptor is a member of the NR1I family, whose other members include the pregnane X receptor (PXR) and the constitutive androstane receptor (CAR). The gene for the vitamin D receptor is located on chromosome 12q1. The vitamin D_3 receptor is 427 amino acids long and binds to DNA through amino acids 21-96 with NR C4-type zinc fingers at positions 24-44 and 60-84. A hinge region encompasses amino acids 97-191. The ligand-binding region spans amino acids 192-427 with vitamin D–binding regions at amino acids 227-237 and 271-278. The receptor has many natural variations (position 33: G → D; position 35: H → Q; position 45: K → E; position 46: G → D; position 47: F → I; position 50: R → Q; position 73: R → Q; position 80: R → Q; position 230: L → V; position 305: H → Q; position 314: I → S; position 362: T → I; and position 391: R → C). At least one natural variant (position 274: R → L) decreases ligand affinity by a factor of 1000.

In addition to the classical vitamin D effects on calcium metabolism, increasing evidence suggests the role of $1,25(OH)_2D$ in regulation of the immune response and in epithelial differentiation. Inverse relationships have been documented between vitamin D metabolite concentration in blood and the incidence of certain cancers[66] and various other disorders. These findings have led to increased demand for vitamin D testing and have prompted calls for increases in the recommended daily intake of vitamin D. Nevertheless, substantial reductions in the rate of development of various cancers through the use of vitamin D have been difficult to demonstrate in clinical trials.[66]

Clinical Significance

Determination of 25(OH)D may be useful in the differential diagnosis of hypocalcemia, hypercalcemia, or hypercalciuria and for evaluating vitamin D status in health and in bone and mineral disorders (see "Calcium, Clinical Significance," "Hypocalcemia," and "Hypercalcemia"; and "Metabolic Bone Diseases"). Only measurements of 25(OH)D and $1,25(OH)_2D$ have proven clinical value; $1,25(OH)_2D$ measurements are rarely needed in routine or even subspecialty clinical practice.[176,232] The National Kidney Foundation guidelines have emphasized that vitamin D nutrition is assessed by measurements of 25(OH)D, *not* measurements of $1,25(OH)_2D$ [e.g., see http://www.kidney.org/professionals/kdoqi/guidelines_pedbone/index.htm (accessed on September 20, 2011)]. Routine clinical determination of vitamin D, $24,25(OH)_2D$, or other metabolites is not indicated.

Vitamin D nutritional status is best determined through the measurement of 25(OH)D (Box 52-9), rather than vitamin D, (1) because 25(OH)D is the main circulating form of vitamin D (see Table 52-4), (2) because of its longer

BOX 52-9 Abnormal Circulating Concentrations of 25(OH)D

Decreased 25(OH)D
- Inadequate exposure to sunlight
- Inadequate dietary vitamin D
- Vitamin D malabsorption
- Severe hepatocellular disease
- Increased catabolism (e.g., drugs, such as anticonvulsants)
- Increased loss (nephrotic syndrome)

Increased 25(OH)D (hypercalcemia)
- Vitamin D or 25(OH)D intoxication

half-life [as a result of this, 25(OH)D is less affected by day-to-day variation, exposure to sunlight, or food intake], and (3) because measurement of 25(OH)D is relatively easy compared with the more technically complicated methods used to measure vitamin D.[138,140,178] Groups at higher risk for developing nutritional vitamin D deficiency include breast-fed infants, strict vegetarians who abstain from eggs and milk, individuals with darker skin pigmentation, and the elderly.

Measurement of circulating 25(OH)D is useful in selected patients in evaluating hypocalcemia, vitamin D status, bone disease, and other disorders of mineral metabolism. Circulating concentrations of 25(OH)D may be decreased by (1) reduced availability of vitamin D, (2) inadequate conversion of vitamin D to 25(OH)D, (3) accelerated metabolism of 25(OH)D, and (4) urinary loss of 25(OH)D with its transport protein DBP. Reduced availability of vitamin D occurs with inadequate exposure to sunlight, dietary deficiency, malabsorption syndromes, and gastric or small bowel resection. Severe hepatocellular disease has been associated with inadequate conversion of vitamin D to 25(OH)D. Drugs such as phenytoin, phenobarbital, and rifampin induce drug-metabolizing enzymes that accelerate the metabolism of vitamin D and its metabolites. Serum 25(OH)D concentrations may be reduced in patients with nephrotic syndrome because of the urinary loss of DBP and 25(OH)D.

Serum 25(OH)D concentration is generally accepted as the functional indicator of an individual's vitamin D status.[293] Studies of serum concentrations of 25(OH)D have suggested that a significant proportion of adults in Europe or North America do not get sufficient vitamin D.[3,147,184,273] It has been notoriously difficult to harmonize the reference intervals for 25(OH)D used in various laboratories; this may be related in part to differences of opinion regarding the definition of subclinical vitamin D insufficiency in apparently healthy populations.[51,178] (See below under reference intervals.)

In patients with hypercalcemia, measurement of 25(OH)D has limited value. Its most common use in this situation is in confirming intoxication after ingestion of large amounts of vitamin D or 25(OH)D; in such patients, the 25(OH)D concentration is typically greater than 100 ng/mL or 250 nmol/L.

A 2011 guideline from the Endocrine Society[136A] recommends that routine screening for vitamin D deficiency is not warranted on a population basis, but is warranted in those at risk of deficiency. Candidates for screening are listed as patients with (1) rickets, (2) osteomalacia, (3) osteoporosis, (4) chronic kidney disease, (5) hepatic failure, (6) malabsorption syndromes (cystic fibrosis, inflammatory bowel disease, Crohn disease, bariatric surgery, radiation enteritis), (7) hyperparathyroidism, (8) medications (antiseizure medications, glucocorticoids, AIDS medications, antifungals, e.g., ketoconazole, cholestyramine), (9) African-American and Hispanic children and adults, (10) pregnant and lactating women, (11) older adults with history of falls, (12) older adults with history of nontraumatic fractures, (13) obese children and adults with BMI > 30 kg/m^2), (14) granuloma-forming disorders (sarcoidosis, tuberculosis, histoplasmosis, coccidiomycosis, berylliosis), and (15) some lymphomas.

BOX 52-10 Abnormal Circulating Concentrations of 1,25(OH)$_2$D

Decreased 1,25(OH)$_2$D
- Renal failure
- Hyperphosphatemia
- Hypomagnesemia
- Hypoparathyroidism
- Pseudohypoparathyroidism
- Vitamin D–dependent rickets, type I
- Hypercalcemia of malignancy

Increased 1,25(OH)$_2$D
- Granulomatous disease
- Primary hyperparathyroidism
- Lymphoma
- 1,25(OH)$_2$D intoxication
- Vitamin D–dependent rickets, type II

Measurement of 1,25(OH)$_2$D is diagnostic in vitamin D–dependent rickets types 1 and 2, and in disease states associated with overproduction of 1,25(OH)$_2$D such as sarcoidosis, tuberculosis, Hodgkin's disease, fungal infection, Wegener's granulomatosis, and lymphoma. In the last of these, activated macrophages convert 25(OH)D to 1,25(OH)$_2$D. In other situations, the test result gives confirmatory information in the evaluation of hypercalcemia, hypercalciuria, hypocalcemia, and bone and mineral disorders (Box 52-10). Concentrations of 1,25(OH)$_2$D are increased in vitamin D–dependent rickets type 2 (as the result of nonfunctioning VDR) and in 1,25(OH)$_2$D intoxication, and may be elevated in primary hyperparathyroidism, although the diagnosis of primary hyperparathyroidism does not require measurement of 1,25(OH)$_2$D. Patients with primary hyperparathyroidism and high concentrations of 1,25(OH)$_2$D do appear to be more prone to developing hypercalciuria and renal stones. Reduced concentrations of 1,25(OH)$_2$D can be observed in patients with renal failure, hypercalcemia of malignancy, hyperphosphatemia, hypoparathyroidism, pseudohypoparathyroidism, type 1 vitamin D–dependent rickets, hypomagnesemia, nephrotic syndrome, and severe hepatocellular disease. Other than in cases of suspected vitamin D–resistant rickets, measurement of 1,25(OH)$_2$D in such circumstances is not required for diagnostic purposes.

Diagnosis of vitamin D deficiency is not based on measurement of 1,25(OH)$_2$D, however, because the circulating concentration of this metabolite is often normal because of a compensatory hyperparathyroidism.[183] Nor is the assay useful in confirming intoxication with vitamin D or 25(OH)D, because in this situation, 1,25(OH)$_2$ concentrations may be low, normal, or increased.

Measurement of Vitamin D Metabolites

Specific and sensitive assays have been developed for measuring vitamin D, 25(OH)D, and 1,25(OH)$_2$D.[138,140,178] 25(OH)D and 1,25(OH)$_2$D assays should measure D_2 and D_3 metabolites equally (with "equimolar" reactivity), because both D_2 and D_3 are metabolized to produce biologically active 1,25(OH)$_2$D.

Separate measurement of the D_2 and D_3 forms does not necessarily distinguish between dietary and endogenous sources of vitamin D, as food is supplemented with D_3 and D_2.

The hydrophobic natures and small circulating concentrations of vitamin D metabolites together with the possibility of matrix effects have presented enormous challenges for the development of assays that would be both specific and suitable for high-throughput clinical analysis needs.[138,140] In general, two or three of the following steps are needed in any assay for 25(OH)D or 1,25$(OH)_2$D: (1) deproteinization or extraction, (2) purification, and (3) quantification. The first step frees the metabolites from DBP and may partially purify them. Purification steps, most often column chromatography, separate the various forms of vitamin D, lipids, and interfering substances. The method of quantification depends on the metabolite that is being measured.

Extraction and Deproteinization

Before the advent of commercially available methods, it was common to use two-phase, liquid-liquid partitions with organic solvents and solvent mixtures, including methylene chloride, hexane, diethyl ether, ethanol/chloroform/water, methylene chloride/methanol, hexane/isopropanol, and cyclohexane/ethyl acetate. Ethanol and methanol have also been used to free 25(OH)D from DBP when 25(OH)D is measured.

Today, the most widely used commercially available methods use acetonitrile to deproteinize the specimen and to denature DBP, thereby freeing the vitamin D metabolites.[138,140,178] Another method uses immunoextraction for 1,25$(OH)_2$D.

Column Chromatography

Differences in their polarities, related to their numbers of hydroxyl groups, have been used to separate vitamin D and its metabolites. With three hydroxyl groups, 1,25$(OH)_2$D is more polar than 25(OH)D, with its two hydroxyls, which is more polar than vitamin D, with one hydroxyl group.

Extracts have been purified by chromatography on, for example, minicolumns of silica, silicic acid, Sephadex LH-20, hydroxyalkoxypropyl Sephadex LH-20 (Lipidex 5000), celite, and alumina. Solid-phase extraction using octadecyl (C_{18})-silica was widely used for measuring 1,25$(OH)_2$D. The most popular method used both a reversed-phase C_{18}-silica minicolumn and a normal-phase silica minicolumn to separate vitamin D metabolites. This method was modified by eliminating the silica cartridge and using "phase switching" with a single non–end-capped C_{18}OH cartridge.

Measurement of 25-Hydroxyvitamin D

Acceptance of serum 25(OH)D as an indicator of an individual's vitamin D status has resulted in the development of several commercial assays for it over the past 15 years.[178] The metabolite is measured by competitive protein binding assay (CPBA), competitive or noncompetitive immunoassay (RIA, EIA, ICMA), ultraviolet (UV) absorption after separation by HPLC, or by mass spectrometry after separation by chromatography. Determination by HPLC with UV absorption requires appropriate HPLC equipment (see Chapter 13), specialized training, and a larger sample. Most clinical laboratories that measure 25(OH)D have chosen the more familiar competitive immunoassays or CPBAs. These assays are relatively easy to perform, use widely available reagent sets, and require only a small volume of plasma. In a 2011 CAP survey of 151 laboratories (mostly in the United States), two methods accounted for two-thirds of the results: 54 laboratories reported results by LC-MS/MS assays and 50 used the Diasorin Liaison assay (discussed below). Although assays easily recognize supranormal concentrations of 25(OH)D, measurement of subnormal and low-normal concentrations is more difficult, requiring well-validated methods free from interference.

External quality assurance surveys and proficiency testing programs have identified differences of results among the different 25(OH)D assays—RIA, chemiluminescence immunoassay (CLIA), and the newer liquid chromatography-mass spectrometry (LC-MS/MS) methods.[288] The differences in results reflect, in part, (1) differences in calibration of the assays, (2) nonequimolar responses of some assays to 25(OH)D_2 and 25(OH)D_3, and (3) noncommutable materials used in surveys. Nonequimolar responses are common among the automated methods, but not in LC-MS/MS and HPLC assays.

Care must be taken in interpreting results from external quality assurance surveys and proficiency testing programs. Survey materials that have been processed extensively are noncommutable and lead to overestimation of between-assay variability. Moreover, survey materials that lack 25(OH)D_2 will give no indication of assays that under-recover that form. To address these concerns, a 2011 accuracy-based survey was prepared by the College of American Pathologists. Five pools of minimally processed human serum were prepared to cover a range of 25(OH)D concentrations from about 15 to 60 ng/mL. Two of the pools contained increased concentrations of 25(OH)D_2; these were made from serum of volunteers who had taken 25-hydoxyvitamin D_2 [not made by addition of 25(OH)D_2 to serum)]. Target values were determined by the LC-MS/MS assay in the reference laboratory at the CDC. This survey showed that some assays underestimated the total 25(OH)D in the samples with increased 25(OH)D_2, but the gross errors of 100% or more seen in previous surveys were absent. Importantly, the differences laboratories using LC-MS/MS assays were comparable to differences among laboratories using single commercial assays, despite the differences among LC-MS/MS assays. Despite the improved overall results, even with a generous acceptance criterion that allowed differences from the target value of 25%, the overall pass rate for the five individual pools was only 83 to 92%. It is hoped that efforts at the NIST and elsewhere will lead to improvements of accuracy of these assays.

Radioimmunoassay and Chemiluminescence Immunoassay. Development of a useful antiserum permitted the development of a competitive immunoassay (RIA) for 25(OH)D.[138,140] The antiserum was raised against a bovine serum albumin (BSA) conjugate of a vitamin D analog lacking the

side chain [23,24,25,26,27-pentanor vitamin D-C(22)carboxylic acid]. A radioiodinated vitamin D analog [3-aminopropyl derivative of vitamin D-C(22)-amide] was used as the tracer. Samples and calibrators are deproteinized with acetonitrile and analyzed directly without chromatography. Although the antiserum also recognizes 24,25$(OH)_2$D, 25,26$(OH)_2$D, and 25(OH)D-26,23-lactone, the 25(OH)D results obtained are comparable with those obtained by HPLC because of the much lower concentrations of the other metabolites. The RIA has been reported to be less sensitive to interfering substances in serum extracts than is a CPBA that uses DBP.[142] This assay is commercially available as an RIA and as an automated immunoassay based on chemiluminescence (CLIA) detection.[138] The manufacturer replaced the original RIA antiserum in the late 1990s.

Immunoassays for 25(OH)D have appeared from several manufacturers. Some of these assays underestimate the total concentration of 25(OH)D when 25$(OH)D_2$ is present. This is a particular concern in the United States where the available high-dose supplements are vitamin D_2.

Competitive Protein-Binding Assays With Vitamin D–Binding Protein. Before the development of immunoassays, 25(OH)D was measured primarily with CPBA with DBP as the specific binder, and with tritiated 25$(OH)D_3$ (>100 Ci/mmol) as tracer. Assays based on DBP measure both 25$(OH)D_2$ and 25$(OH)D_3$, but it is important to verify that they respond equally to 25$(OH)D_2$ and 25$(OH)D_3$. If the assay procedure does not involve a chromatographic step for isolating 25(OH)D, other metabolites are also measured, including 25$(OH)D_3$-23,26-lactone, 24,25$(OH)_2$D, 25,26$(OH)_2$D, and, to a lesser extent, vitamin D, thus overestimating the 25(OH)D concentration by about 10% in healthy subjects. 25(OH)D concentrations are reported to be significantly higher when measured by CPBA than when measured by RIA or HPLC.[183,184]

HPLC and Ultraviolet Absorption. HPLC methods for 25(OH)D have used normal-phase chromatography on silica, reversed-phase chromatography on C_{18}-silica, or a combination of the two followed by quantification by UV absorption at 254 or 265 nm. Most methods have required both extraction and preparative chromatography before HPLC. Methods without preparative chromatography also have been developed using gradient or isocratic reversed-phase HPLC with photodiode-array UV detection.[6,323] A specimen of 0.5 to 1.0 mL is required because of the limited sensitivity of UV detection. HPLC methods allow 25$(OH)D_2$ and 25$(OH)D_3$ to be separated. HPLC is useful for validating the accuracy of immunoassays and CPBAs.[138,140]

LC-MS/MS Assays. Liquid chromatography coupled with tandem mass spectrometry is widely used in the measurement of 25(OH)D.[140,198,326] The LC-MS/MS methods are capable of relatively high throughput, with some laboratories producing 1000 results per day. LC-MS/MS has become more attractive for 25(OH)D measurement as the instrumentation has become more widely available in clinical laboratories.

Despite the high selectivity of mass spectrometry, the C-3 epimer of 25(OH)D is not differentiated from 25(OH)D as it has the same mass. Thus, unless the epimer is separated chromatographically prior to the mass-spectrometric quantification, results of LC-MS/MS assays are increased by the C-3 epimer. This is rarely a problem in adults as the epimer is normally present in only low concentrations, but it is a problem in pediatric patients under the age of 1 year.[283A]

In LC-MS/MS assays, samples typically are denatured by the addition of alcohol (such as a methanol-propanol mixture) containing a stable-isotope–labeled internal standard such as ($^2H_6$)25(OH) D_3 (26,26,26,27,27,27-hexadeutero-25-hydroxycholecalciferol). Following extraction, drying, and reconstituting in solvent, the 25(OH)D is chromatographed and analyzed by multiple reaction monitoring. Between-day (total) CVs of 5 to 10% have been reported within individual laboratories, but between-laboratory variability has been a problem, perhaps no worse than for commercially available competitive binding assays.

The 25(OH) metabolites related to D_2 and D_3 are quantified separately by LC-MS/MS. This may have some limited clinical value in some settings,[138] but it is important to report the sum of the two concentrations [25$(OH)D_2$ + 25$(OH)D_3$] because vitamin D status depends on the total concentration, not on the individual concentrations. One approach to reporting is to provide the concentrations of both forms, but to provide a reference interval only for the sum of the two.

Measurement of 1,25-Dihydroxyvitamin D

1,25$(OH)_2$D circulates at approximately $\frac{1}{1000}$ of the concentration of 25(OH)D and at significantly lower concentrations than other dihydroxylated metabolites—facts that together with the extreme hydrophobicity and instability of the compound greatly complicate its determination in serum.[138,178] The most widely used methods require extraction, chromatography, and quantification by radioreceptor assay (RRA) or RIA.

Radioreceptor Assay. Assays using vitamin D receptors from calf thymus or chick intestine have been reported but are rarely used in clinical laboratories. Details are available in the previous edition of this book.

Radioimmunoassay. The first radioimmunoassay for 1,25$(OH)_2$D was introduced in 1978 and required a cumbersome purification.[138] After several assays of similar characteristics, in 1996 another RIA was introduced, with an iodinated reporter and use of an equivalent serum matrix. For this method, sample purification is not needed.[138,141]

The RIA is more convenient than the RRA for 1,25$(OH)_2$D because a radioiodinated tracer eliminates the need for liquid scintillation, and the antiserum eliminates the need to prepare VDR from calf thymus. The RIA uses an antiserum with 1 to 2% cross-reactivity with the more abundant, non-1-hydroxylated vitamin D metabolites and a ^{125}I-labeled tracer prepared from 1,25$(OH)_2$-24,25,26,27,tetranor-C(23)-carboxylic acid and radiolabeled Bolton-Hunter reagent. Before analysis, specimens are deproteinized with acetonitrile, oxidized with sodium metaperiodate, and purified using C_{18}-OH and silica cartridges. Sodium metaperiodate is necessary to eliminate interference by 24,24$(OH)_2$D and

25,26$(OH)_2$D by oxidizing them to their aldehyde and ketone forms, which are easily removed by chromatography. A silica column was added to the single C_{18}-OH cartridge used with the radioreceptor assay, to reduce interference in the RIA. With this RIA, 1,25$(OH)_2$ D_2 is about 70% as potent as 1,25$(OH)_2D_3$. Recovery of individual samples is not determined, although calibrators are prepared in a stripped serum base and are treated identically to samples. The method does cross-react (13 to 25%) with numerous 1-hydroxylated metabolites, including 1,24,25$(OH)_3$D, 1,25,26$(OH)_3$D, and 1,25$(OH)_2$D-26,23-lactone. 1,25$(OH)_2$D-26,23-lactone is a significant metabolite with a concentration of 0 to 30% of that of 1,25$(OH)_2D_3$. A modification of this method using a single C_{18}-OH "extra clean" cartridge is commercially available.

Another commercially available RIA has been developed that uses selective immunoextraction of 1,25$(OH)_2$D.[139] This method is reported to have greater cross-reactivity with the 1-hydroxylated metabolites, including 1,25-dihydroxyvitamin D_3-26,23-lactone[137] and calcipotriol,[148] which is used for treating psoriasis. Apparent concentrations of 1,25$(OH)_2$D are significantly higher with this method than with RRA in patients with hypoparathyroidism receiving vitamin D treatment, patients with biliary atresia, vitamin D–intoxicated subjects, and some normal specimens.

Troubleshooting Vitamin D Assays

Methods requiring extraction and chromatography should be monitored for recovery of the vitamin D metabolites of interest and for solvent or column blanks. Care must be taken to ensure that D_2 and D_3 metabolites are recovered equally, providing a total measurement of 25(OH)D or 1,25(OH)D. Solvents, chromatographic materials, and cartridges may contain substances that interfere with quantification of vitamin D metabolites by CPBA, RIA, and RRA or UV absorption after HPLC, resulting in an overestimation of vitamin D metabolites. Any interference can be monitored by treating a water blank identically to the specimens. Undetectable concentrations of vitamin D in this blank verify the absence of positive interference.

Calibrators for vitamin D assays should be prepared from stock solutions whose concentration and purity are checked by UV spectrophotometry. Stock solutions are suitable if the ratio of absorbance at 264 nm to that at 228 nm is greater than or equal to 1.5. Stock solutions are adjusted using a molar extinction coefficient of 18,200 L/mol/cm for vitamin D_3 metabolites at 264 nm. Tracers used for recovery must be pure to determine recovery accurately. Both calibrators and tracers may be purified by HPLC.

Specimen Requirements

Serum is typically used for measuring vitamin D metabolites, although plasma generally is acceptable for assays using extraction and chromatography. Once separated from the clot, serum is relatively stable at both room temperature and 4 °C; specimens should be frozen if the analysis is delayed. Vitamin D metabolites in serum or plasma do not appear to be sensitive to light and do not require special handling in the laboratory.[140]

Reference Intervals

Reference intervals for vitamin D metabolites are method dependent. A representative one for 1,25$(OH)_2$D is:

1,25$(OH)_2$D: 15 to 60 pg/mL or 36 to 144 pmol/L

Lower limits of the reference interval for 25(OH)D of 10 or 15 ng/mL (25 to 37 nmol/L) have been increasingly criticized as inappropriately low, as even above this limit the vitamin D status of the individual can be insufficient (Table 52-5).[185] Concentrations of less than 20 to 30 ng/mL or 50 to 75 nmol/L can be associated with increased serum PTH concentrations and reduced calcium absorption. In late 2010, the United States Institute of Medicine published a recommendation that the lower limit for vitamin D sufficiency be lowered from 30 to 20 ng/mL and that concentrations above 50 ng/mL be considered as cause for concern.

In 2002 and 2003, the National Health and Nutrition Examination Survey (NHANES) III study reported an unexpectedly high prevalence of vitamin D insufficiency in adults and adolescents in North America.[46,186] For example, vitamin D insufficiency [25(OH)D <20 ng/mL or 50 nmol/L] was exceedingly common during the winter in adult (30 years and older) Caucasian men (15%) and women (30%) living in the South of the United States. Similar findings have been reported from Europe.[147]

The concentrations of 25(OH)D in African Americans are lower than in non-Hispanic whites, but the clinical significance of this is uncertain. Compared with non-Hispanic

TABLE 52-5 Reported Associations of Serum 25-Hydroxyvitamin D Concentrations With Serum PTH and Bone Histology

25(OH)D	1,25$(OH)_2$D	PTH Increase	Bone Histology
<5 ng/mL or <12.5 nmol/L	Normal or low	>30%	Incipient or overt osteomalacia
5-10 ng/mL or 12.5-25 nmol/L	Normal	15-30%	High turnover
10-20 ng/mL or 25-50 nmol/L	Normal	5-15%	Normal or high turnover
>20 ng/mL or >50 nmol/L	Normal	—	Normal

From Lips P, van Schoor NM, Bravenboer N. Vitamin D-related disorders. In: Rosen CJ, Compston JE, Lian JB, eds. Primer on the metabolic bone diseases and disorders of mineral metabolism. Washington, DC: American Society for Bone and Mineral Research, 2008:329-35.

whites, African Americans have higher bone mineral density, higher plasma concentrations of PTH and $1,25(OH)_2D$, and lower concentrations of biochemical markers of bone remodeling and lower rates of osteoporosis.

Circulating concentrations of 25(OH)D are increased by exposure to sunlight and show seasonal variation, with the highest concentrations in summer or fall and the lowest concentrations in winter or spring.[281] This has led to the recommendation that testing be done at the end of winter; if results are above the chosen cutoff, the patient is likely to have adequate concentrations throughout the year on his or her usual regimen of sun exposure and oral intake of the vitamin. The concentrations are influenced by latitude, sunscreen use, and skin pigmentation. Serum 25(OH)D concentrations of 100 ng/mL (250 nmol/L) are not uncommon in people with extensive sun exposure, such as lifeguards.

Concentrations of vitamin D metabolites vary with age and are increased in pregnancy.[166,167] Concentrations of $1,25(OH)_2D$ are higher in pregnancy and in children than in adults, with the highest concentrations occurring during periods of greatest growth.[205] Although 25(OH)D and $1,25(OH)_2D$ concentrations have been reported to decrease with age, this decline may be a consequence of poor nutrition, reduced exposure to sunlight, and declining health. Concentrations of these metabolites were unchanged with age in studies limited to healthy and active subjects.

Calcitonin

Release of calcitonin from the parafollicular or C cells of the thyroid gland is stimulated by circulating calcium. The hormone has been used pharmacologically as an inhibitor of bone resorption, but the physiologic role of endogenous calcitonin is less certain. No apparent alterations in bone or mineral metabolism are evident in humans with calcitonin deficiency or excess. However, calcitonin measurements have a role in the diagnosis and follow-up of medullary thyroid carcinoma, a malignant tumor of the C cells, in particular in its familial form.

The C cells of the thyroid arise from the neural crest and are distributed throughout the gland. These cells belong to the APUD (amine precursor uptake and decarboxylation) family, which explains the association of thyroid medullary carcinoma with other tumors such as multiple endocrine neoplasia type 2A and 2B (MEN2A and MEN2B).

Biochemistry and Physiology

Calcitonin is a 32 amino acid peptide, with a molecular mass of 3418 Da, an N-terminal disulfide bond linking the cysteine residues 1 and 7, and a C-terminal proline-amide (Figure 52-22). The hormone interacts with a specific G-protein–coupled receptor that is found on fully differentiated osteoclasts.[2] The structures necessary for biological function are the C-terminal portion of the molecule, with its proline-amide residue, the disulfide bond between residues 1 and 7, and the methionine residue at position 8. The amino-terminal amino acids are highly conserved. In humans, salmon calcitonin is 10 times as potent as the human hormone and thus is used pharmacologically, usually as nasal spray.[2]

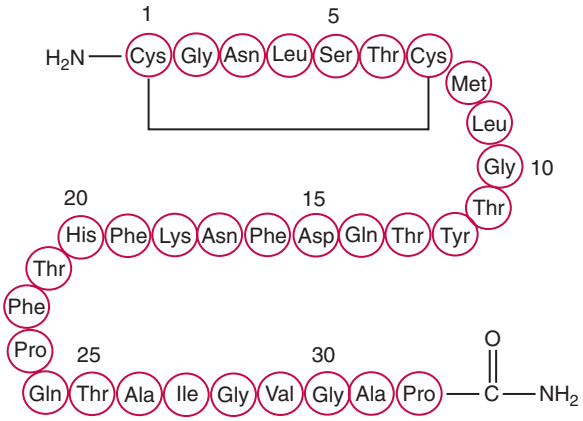

Figure 52-22 Amino acid sequence of human calcitonin.

The physiologic regulation of calcitonin secretion is incompletely understood, but the best known secretagogue is the concentration of free calcium in blood. At least in animals, several other peptide hormones (gastrin, cholecystokinin, glucagon, secretin) can stimulate calcitonin secretion, but their physiologic role in humans is uncertain.

Pharmacologic doses of calcitonin reduce serum calcium and phosphate concentrations primarily by inhibiting osteoclastic bone resorption. Salmon calcitonin has been used to treat Paget disease of bone, osteoporosis, and hypercalcemia due to increased bone resorption. Pharmacologic doses of calcitonin also decrease the renal tubular reabsorption of calcium and phosphate. Calcitonin seems to exert an analgesic effect, which is not necessarily solely explained by its effects on bone.[2]

Higher concentrations of circulating calcitonin can be observed in young children[15] and during pregnancy and lactation,[166,167] suggesting that the hormone may be important in protecting the skeleton during periods of calcium stress. Evidence in favor of such a hypothesis has been gained from knockout mice lacking calcitonin.[337]

In serum, multiple forms of calcitonin can be observed both in healthy individuals and in patients with medullary thyroid carcinoma (MTC) or nonthyroidal malignancies. Much of the immunoreactive calcitonin in the circulation is larger than the monomeric hormone.[39] Several reasons for this heterogeneity have been put forward: sulfoxide modification of the monomer, dimerization, glycosylation, presence of biosynthetic precursors of the monomer, and binding to plasma proteins.

During the biosynthesis of calcitonin, the original product is a larger precursor form known as procalcitonin. Procalcitonin has attracted attention as a potential infection marker, in relation to the acute-phase response.[261]

Clinical Significance

Medullary thyroid carcinoma (MTC) occurs as a sporadic disease and as part of the syndromes MEN2A, MEN2B, and familial MTC (FMTC). Together, these account for 5 to 10%

BOX 52-11 Increased Circulating Concentrations of Calcitonin

- Other malignancies

Acute and chronic renal failure
Hypercalcemia
Hypergastrinemia and other gastrointestinal disorders
Pulmonary disease

of thyroid malignancies, with the sporadic MTC accounting for about 80% of all MTCs. It has been suggested that routine measurement of serum calcitonin in nodular thyroid disease could assist in detecting unsuspected sporadic MTC. After thyroidectomy of MTC patients, calcitonin serves as a tumor marker in the monitoring of treatment response. For more detailed information on the use of calcitonin measurements in oncology, see Chapter 24, "Tumor Markers."

Calcitonin concentrations are increased occasionally in various nonthyroidal cancers (Box 52-11), both in those arising from the neural crest and in others. Increased concentrations or enhanced response to calcitonin secretagogues (calcium, pentagastrin, or both of these) has been reported in cases of nonmalignant disease such as acute and chronic renal failure, hypercalcemia, hypergastrinemia and other gastrointestinal disorders, pulmonary disease, and severe illness.

Assays have been reported also for salmon calcitonin, but it has not been possible to predict the treatment response to this drug by monitoring its circulating concentration. Thus it is advisable to follow the treatment by determining clinical parameters and measuring calcium.

Measurement of Calcitonin

Calcitonin is measured by immunoassay, and interpretation of results in principle can be complicated both by the heterogeneity of the circulating antigen and by the varying characteristics of the different assays.

Historically, the first methods described were RIAs; the different assays showed widely differing reference intervals, sensitivities, and specificities, and they suffered differently from matrix effects. More recently, noncompetitive immunoassays (IRMA, ELISA, EIA, ICMA) have been developed and are available from several diagnostic companies[19]; their results still differ markedly.[318] Some assays may give results that are erroneously low at high concentrations (hook effect); samples with concentrations of 344 ng/L or less (≤344 pg/mL) appear to be unaffected.[318,319]

Reference Intervals

The reference intervals for calcitonin are dependent on the method used. They should be determined for healthy and athyroidal individuals, by gender, in each laboratory for basal and stimulated (calcium and pentagastrin provocation tests) conditions. It is a common finding that men show higher basal and stimulated concentrations than women, but this is not necessarily true for every method.

A typical upper limit for the reference interval for basal calcitonin concentration in adults is about 10 pg/mL or, if the assay gives higher concentrations in men, 5.8 pg/mL (1.7 pmol/L) in women and 8.8 pg/mL (3.8 pmol/L) in men.[15,80] In addition to gender, age, growth, pregnancy, and lactation have been reported to influence[15,159] circulating calcitonin concentrations in healthy people, but reference intervals generally are not given by the assay manufacturer for groups other than healthy adults.

Parathyroid Hormone–Related Protein

Parathyroid hormone–related protein (PTHrP) was discovered as an agent responsible for causing the state known as humoral hypercalcemia of malignancy (HHM) in certain cancers.[43,338] It later proved to be an autocrine/paracrine factor with a multitude of functions in several organ systems.[297,298] Among these are its effects on chondrocyte biology and endochondral bone formation,[110] as well as on calcium metabolism in the fetus[55,206] and during pregnancy and lactation.[338]

Biochemistry and Physiology

PTHrP is derived from a gene on chromosome 12 that is distinct from the *PTH* gene on chromosome 11. Three isoforms of 139, 141, and 173 amino acids are predicted by alternative messenger RNA (mRNA) splicing (Figure 52-23).[110] The N-terminal end of the molecule shows close homology to PTH, with 8 of the first 13 amino acids being identical. The remainder of the PTHrP molecule shows little homology with PTH. The PTH-like activity of PTHrP is contained within the N-terminal amino acids [PTHrP(1-36)].

The primary transcript can undergo a series of post-translational modification reactions, resulting in a series of partially overlapping peptides with biological activities.[55,110,338]

The common N-terminus explains the ability of PTHrP to interact with the PTH/PTHrP receptor, mimicking the biological actions of PTH in classic target tissues, including bone and kidney.[55] Like PTH, PTHrP causes hypercalcemia and hypophosphatemia and increases urinary cyclic AMP. However, when compared with patients with primary hyperparathyroidism, those with PTHrP-induced hypercalcemia have lower concentrations of $1,25(OH)_2D$ and more typically have metabolic alkalosis (instead of hyperchloremic metabolic acidosis), reduced distal tubular calcium reabsorption, and reduced and uncoupled bone formation.

The presence of several basic amino acid residues in PTHrP suggests that it may undergo extensive post-translational processing. Forms of PTHrP containing the following amino acids have been detected in serum[297]: (1) PTHrP(1-36) measured by N-terminal assays; (2) PTHrP containing N-terminal and midregion amino acids measured with noncompetitive immunoassays against PTHrP(1-74 or

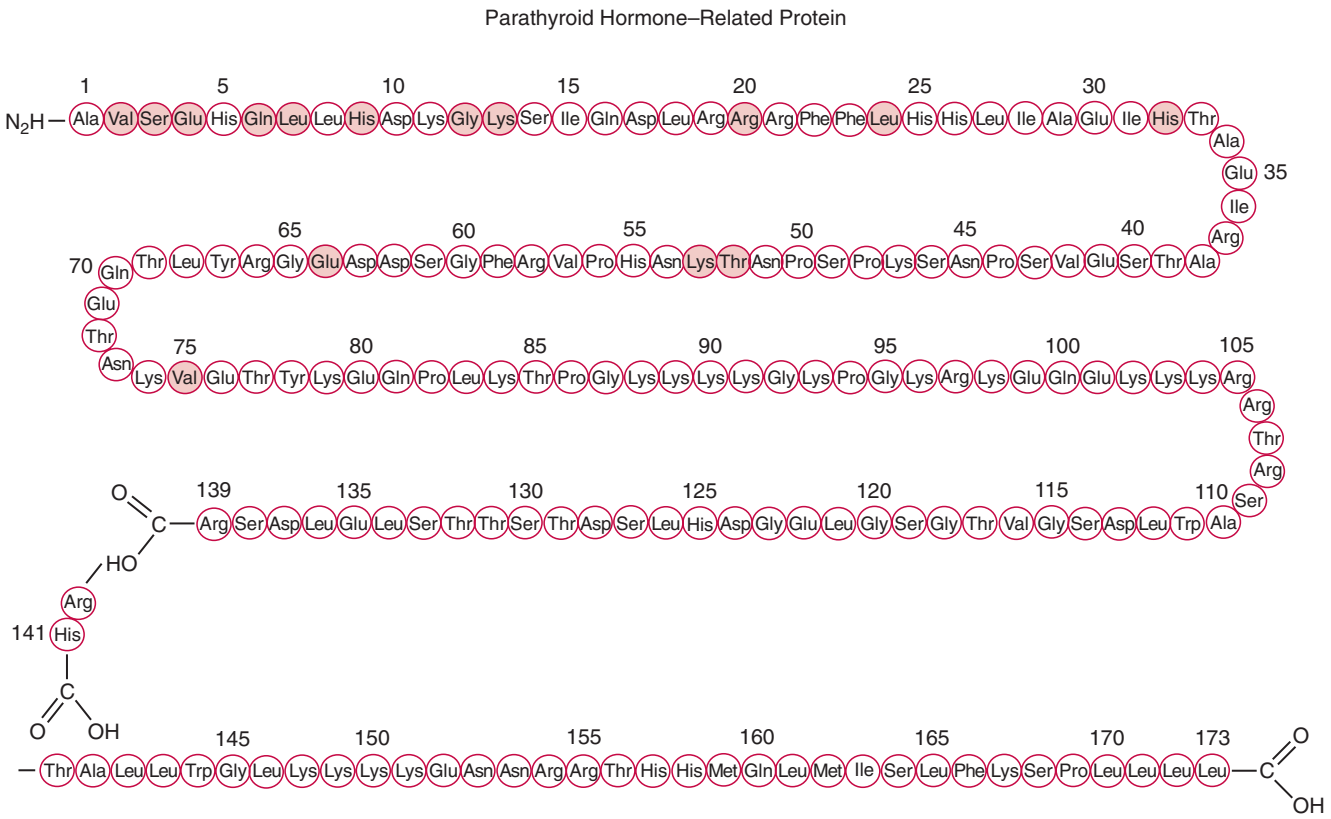

Figure 52-23 Amino acid sequence of human parathyroid hormone–related peptide (PTHrP). Although the exact length of circulating PTHrP is unknown, proteins of 139, 141, and 173 amino acids have been predicted from alternative splicing events. The *shaded circles* show amino acids that are identical in parathyroid hormone (PTH) and PTHrP. *(Modified from Hendy GN, Goltzman D. Parathyroid hormone-like peptide. In: Endocrinology and metabolism inservice, volume 9. Washington, DC: American Association for Clinical Chemistry, 1991:9-24.)*

1-86); (3) midregion fragments, beginning at position 38 and extending 70 to 80 amino acids, measured with midregion assays; and (4) carboxyl fragments, beginning at position 107 or 109, measured with antiserum directed against PTHrP(109 to 138).[338] Midregion and carboxyl forms exert biological actions distinct from the PTH-like actions associated with the N-terminal region.

Besides its endocrine role in the pathophysiology of HHM, PTHrP participates in normal physiology by acting locally on cells or tissues as an autocrine or paracrine factor.[110,298,338] PTHrP is widely expressed in most normal tissues of fetuses and adults. Although it is unlikely that low circulating concentrations of PTHrP have a significant effect on calcium homeostasis in normal adults, PTHrP exerts endocrine effects on skeletal development and calcium homeostasis during fetal life[165,166] and lactation.[167] Breast milk contains extremely high concentrations of PTHrP[338] as does amniotic fluid. Examination of the physiologic effects of PTHrP has identified several themes: (1) PTHrP regulates transepithelial calcium transport; (2) PTHrP is a potent smooth muscle relaxant; and (3) PTHrP regulates growth, differentiation, and development. However, its role of PTHrP in many tissues is unknown.[298]

Clinical Significance

Hypercalcemia associated with malignancy is the second most common cause of hypercalcemia. This frequent paraneoplastic syndrome is believed to occur primarily through two mechanisms: HHM and local osteolysis. HHM is present in approximately 75 to 80% of patients with hypercalcemia associated with malignancy.[143] HHM is common in patients with squamous (lung, head and neck, esophagus, cervix, vulva, and skin), renal, bladder, and ovarian carcinomas. Hypercalcemia due to skeletal metastases and local osteolysis are common in breast cancer and multiple myeloma, lymphoma, and other hematologic malignancies. The hypercalcemia of a subset of lymphomas (human T-cell leukemia virus-1) appears to be caused by HHM. Breast carcinomas may cause hypercalcemia by HHM and/or skeletal metastases with local osteolysis. It is now well established that PTHrP is the principal mediator of HHM, causing dramatic uncoupling of bone resorption from bone formation. After it is secreted by tumors, PTHrP circulates and acts on its target tissues (skeleton and kidney) as an endocrine hormone causing hypercalcemia.

PTHrP determinations usually are considered investigational, because HHM nearly always occurs in advanced

disease when the diagnosis is clear. The need for PTHrP determination may increase if it becomes important in prognosis,[322] selection of therapy, or monitoring.

Measurement of PTHrP

Several competitive immunoassays have been used to measure PTHrP in sera from patients with HHM. For example, N-terminal [PTHrP(1-34)], midregion [PTHrP(37-67, 37-74)], and C-terminal [PTHrP(109-138)] competitive RIAs have been developed.[43] Of the competitive immunoassays, the N-terminal assays have been used most widely. Affinity chromatography with immobilized antisera against PTHrP, reversed-phase chromatography, and other purification techniques have been used to improve the sensitivity and specificity of these competitive RIAs. C-terminal assays give elevated results in patients with renal insufficiency.[43]

More sensitive and noncompetitive immunoassays (IRMAs) have also been developed.[43,91,226,240] Currently available assays use antibodies against PTHrP (sequences 37-74, 1-40, 1-40, 1-34, 1-40, and so on) as capture antibodies. Their radiolabeled signal antibodies are against PTHrP (sequences 1-36, 60-72, 57-80, 37-67, 50-83, and so on), respectively; the idea is to measure molecular species of PTHrP that contain large N-terminal regions. The limit of detection for these assays is reported to be from 0.1 to 1.0 pmol/L.

Specimen Requirements

PTHrP is unstable in serum and plasma at 4 °C and at room temperature unless collected in the presence of protease inhibitors. A combination of aprotinin, leupeptin, pepstatin, and EDTA provides the greatest protection. In general, specimens should be collected with protease inhibitors and kept on ice. Serum or plasma should be promptly separated from the clot and/or cells and frozen.

Reference Intervals

PTHrP: 1.3 pmol/L or less.

PTHrP concentrations in healthy persons are dependent on both the assay and the specimen collection, varying from undetectable to up to 5 pmol/L. With sensitive noncompetitive immunoassays, concentrations of up to approximately 1 to 2 pmol/L have been reported in normal subjects. PTHrP is reported to be detectable in approximately 50 to 80% of healthy individuals with the most sensitive methods.

Interpretation

PTHrP is increased in 50 to 90% of patients with hypercalcemia associated with malignancy (Figure 52-24). In addition to squamous cell carcinoma of the lung, head and neck, esophagus, cervix, skin, and other sites, elevated concentrations have been found in a wide variety of other malignancies, irrespective of their source or histology. Increased concentrations of PTHrP have been found in breast, renal, bladder, and ovarian carcinomas. Concentrations are elevated in a number of endocrine malignancies with hypercalcemia, including pheochromocytoma and islet carcinomas. PTHrP is elevated in hypercalcemic patients with adult T-cell lymphoma/leukemia and B-cell lymphoma. PTHrP concentrations have been elevated less frequently in patients with hypercalcemia and other hematologic malignancies (e.g., multiple myeloma).

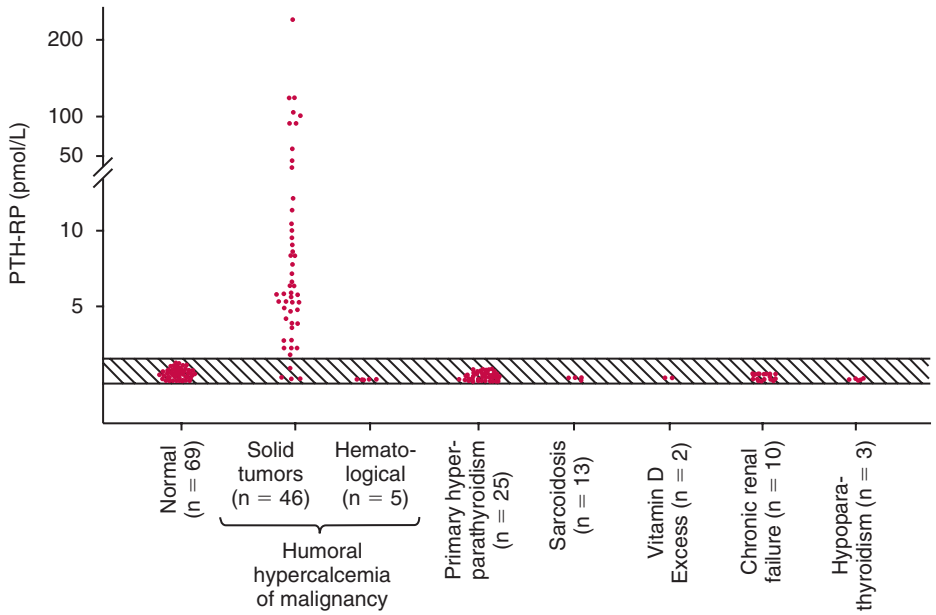

Figure 52-24 Parathyroid hormone–related peptide (PTHrP) in healthy patients and patients with malignancies and other disorders. The *hatched area* indicates the reference interval. *(Adapted from Pandian MR, Morgan CH, Carlton E, Segre GV. Modified immunoradiometric assay of parathyroid hormone-related protein: clinical application in the differential diagnosis of hypercalcemia. Clin Chem 1992;38:282-88.)*

PTHrP is undetectable or normal in most but not all patients with malignancy not associated with hypercalcemia. Increased concentrations of PTHrP have been reported to precede hypercalcemia in some patients with malignancy. Concentrations are normal in patients with primary hyperparathyroidism, hypoparathyroidism, miscellaneous noncancer causes of hypercalcemia, and chronic renal failure (with noncompetitive methods).

SUMMARY OF INTEGRATED CONTROL OF MINERAL METABOLISM

The metabolism of calcium is linked intimately with that of phosphate (Figure 52-25).[84,239,249] The homeostatic mechanisms are directed principally toward the maintenance of normal extracellular calcium and phosphate concentrations, which sustain the extracellular and intracellular processes and provide substrate for skeletal mineralization. The parathyroid gland responds to a decrease in free calcium concentration within seconds. During a time of calcium deprivation, the increase in serum PTH rapidly alters both renal and skeletal metabolism.

Renal Handling of Calcium and Phosphate

Of the about 10 g or approximately 250 mmol of calcium filtered by the kidneys each day, 65% is reabsorbed in the proximal tubule. Calcium reabsorption here is closely linked to sodium and is independent of PTH. Approximately 10 to 20% of calcium is reclaimed in the thick ascending loop of Henle, and 5 to 10% in the distal convoluted tubule. PTH enhances calcium reabsorption at the two latter locations[84] by binding to the PTH receptor.

In contrast to the calcium-conserving effect of PTH on the kidneys, PTH increases renal phosphate excretion at the proximal tubule by directly lowering the renal phosphate threshold. Approximately 6.5 g or 210 mmol of phosphate is filtered by the kidneys each day. Normally, 85 to 90% is reabsorbed by the renal tubules (proximal and distal convoluted tubule). FGF-23 have recently been recognized as a key hormone that lowers serum phosphate.

Intestinal Absorption of Calcium and Phosphate

PTH increases intestinal calcium absorption by increasing $1,25(OH)_2D$ whereas FGF-23 decreases $1,25(OH)_2D$. The effects of PTH and FGF-23 are mediated by opposite effects on renal 25(OH)D 1α-hydroxylase which increases the conversion of 25(OH)D to the active vitamin D metabolite, $1,25(OH)_2D$. About 30 to 40% of a daily calcium intake of 1 g or 25 mmol is absorbed. Approximately 100 to 200 mg (2.5 to 5.0 mmol) of calcium is secreted into the gut lumen by intestinal secretion; therefore, net calcium absorption is 200 mg/d or 5.0 mmol/d. Calcium is absorbed by passive diffusion and by an active transport system. It is estimated that passive diffusion accounts for absorption of about 10% of ingested calcium per day. Active calcium absorption in the duodenum is under the control of $1,25(OH)_2D$.

Dietary phosphate intake is usually 1.2 to 1.4 g/d or 39 to 45 mmol/d, nearly twice the recommended intake, of which approximately 60 to 70% is absorbed, principally in the jejunum. As with calcium, both passive and active transport systems exist; $1,25(OH)_2D$ is the principal regulator of the active transport of phosphate. PTH-stimulated synthesis of $1,25(OH)_2D$ thus offsets the phosphaturic effect of PTH. High serum phosphate concentration stimulates secretion of FGF-23 by bone cells, thus leading to increased phosphate excretion and also decreased $1,25(OH)_2D$. Phosphate depletion or hypophosphatemia stimulates formation of $1,25(OH)_2D$ by the kidneys. At pharmacologic concentrations, calcitonin has the opposite effect to that of PTH. It is unclear, however, whether calcitonin has any physiologic role in mineral homeostasis in adult humans.

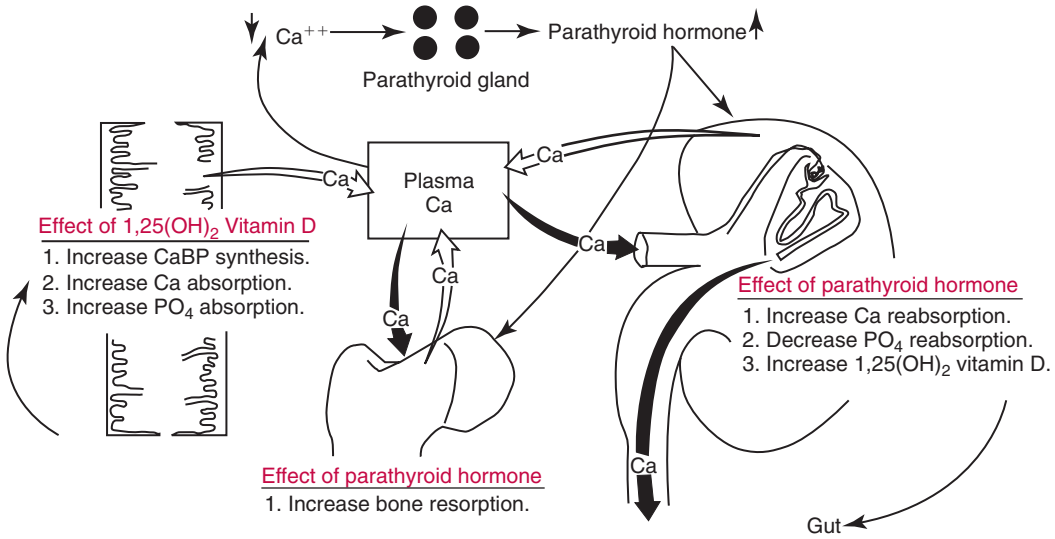

Figure 52-25 Integrated control of mineral metabolism. ***CaBP,*** **Calcium-binding protein.**

Bone Metabolism

PTH also has an acute effect on the skeleton. Acutely, PTH decreases collagen synthesis in osteoblasts, but osteoclastic bone resorption is increased, with a net increase in mineral (calcium and phosphate) release from bone into the extracellular fluid. PTH is able to act directly on osteoblasts by interacting with their PTH receptors. The effect of PTH on osteoclasts appears to be indirect, through local mediators produced by the osteoblast (e.g., RANK ligand and OPG) or released from the bone matrix (e.g., TGF-β). Prolonged calcium deprivation results in enhanced recruitment of osteoclasts and an increased number of mature osteoclasts, which continue to resorb bone, releasing calcium, phosphate, and degradation products of the organic matrix. Prolonged exposure to PTH eventually also increases osteoblast activity. This anabolic effect has been the rationale for designing PTH analogs that specifically increase bone formation.[136,215]

Magnesium

Magnesium is efficiently absorbed in the intestinal tract (most efficiently in the distal small bowel). During normal dietary magnesium intake, approximately 30 to 40% of magnesium is absorbed. Magnesium is absorbed by both active and passive transport.

No hormone or factor has been described as primarily regulating magnesium homeostasis. About 25 to 35% of filtered magnesium is passively reabsorbed in the proximal convoluted tubule, where reabsorption is linked closely to sodium and calcium transport. The major site of active reabsorption is the thick ascending loop of Henle, where 60 to 75% of magnesium is reabsorbed. During times of magnesium deprivation, magnesium essentially disappears from the urine (<0.5 mmol/d). The renal threshold for magnesium is close to the filtered load. When magnesium intake is excessive, any amount greater than this maximum is excreted.

BIOCHEMICAL MARKERS OF BONE TURNOVER

In recent years, a large number of specific markers have been developed for measuring both bone formation and degradation. Markers of bone formation are products of the osteoblast: the amino- or carboxy-terminal propeptides of type I collagen, PINP, and PICP, respectively, bone-specific alkaline phosphatase (BAP/BSAP/BALP are all used as abbreviations), and osteocalcin. Markers of bone resorption are breakdown products of type I collagen in bone and include the amino-terminal (N-terminal) and carboxy-terminal (C-terminal) cross-linked telopeptide parts of collagen [N-telopeptide (NTX), C-telopeptide (CTX), and C-telopeptide of type I collagen (ICTP)] and the pyridinium cross-links [pyridinoline (PYD) and deoxypyridinoline (DPD)]. TRAP5b is an enzyme released from resorbing osteoclasts and measurable in blood. Several reviews on biochemical markers of bone metabolism are available.[37,199,247,275,276] More recently, methods have been developed for the measurement of osteoprotegerin and RANK ligand—proteins synthesized by the osteoblast that can influence osteoclast formation, activation, and bone resorption. However, it is unclear whether these newer analytes add information beyond that provided by the markers listed previously. Additional studies are required to determine the roles of RANK ligand and osteoprotegerin as markers of bone turnover.

Markers of Bone Formation

Bone formation markers, listed in Box 52-12, can be divided into three families, each of them roughly reflecting a specific phase in development of the osteoblast phenotype. During each remodeling cycle, osteoblasts are formed from undifferentiated mesenchymal cells and pass through the phases of proliferation, matrix maturation, and mineralization (see Figure 52-3).[181] In a steady-state situation without specific disturbances in the production of any of the osteoblast products, the protein products of all three phases should in principle correlate with each other, and their measurements should give the same clinical information on the rate of bone formation. However, marker families can give discordant results if bone formation is affected by a disease state that specifically targets a particular developmental phase of the osteoblast.

Propeptides of Type I Procollagen (PINP and PICP)

Type I collagen accounts for ≈90% of the organic matrix of bone and provides it with tensile strength. The type I collagen molecule, a triple helix of two identical α1(I) chains and a slightly different α2(I) chain, is synthesized as a precursor, type I procollagen that contains large additional domains at both ends of the rodlike collagen molecule (see Figure 52-26). These extensions, known as *propeptides,* are enzymatically cleaved from procollagen in the extracellular space by two different enzymes. Cleavage of the bulky, globular C-terminal propeptide (PICP) is necessary before collagen molecules can be assembled into collagen fibers, whereas the N-terminal propeptide (PINP) may remain longer as a portion of the molecules that are deposited on the surfaces of fibers. In bones, PINP is released before mineralization, but in soft tissues, type I collagen may still contain the N-terminal propeptide (type I pN-collagen). In principle, the concentrations of procollagen propeptides reflect the rate of collagen synthesis in a manner analogous to the way that the C-peptide of insulin serves as an indicator of endogenous insulin production.

Properties of the two propeptides of type I procollagen and the corresponding circulating antigens are summarized in Table 52-6. The serum PICP antigen is homogenous and

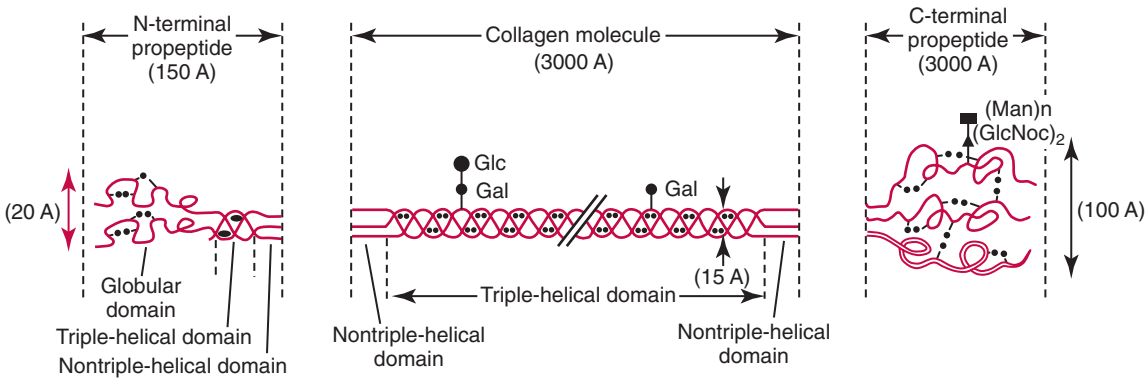

Figure 52-26 Schematic representation of a type I procollagen molecule. The non–triple-helical domains at both ends of the collagen molecule are the telopeptides. The N-terminal propeptide consists of an N-terminal globular domain, a triple-helical domain, and a C-terminal non–triple-helical domain. *(From Prockop DJ, Kivirikko KI, Tuderman L, Guzman NA. The biosynthesis of collagen and its disorders. N Engl J Med 1979;301:13-23, 77-85.)*

TABLE 52-6 Molecular Properties of Propeptides of Type I Procollagen and Corresponding Circulating Antigens

	PINP	PICP
Location	Amino-terminal	Carboxy-terminal
Molecular mass	35,000 Da	100,000 Da
Shape	Elongated	Globular
Chemical nature	Phosphorylated, partially collagenous	Glycoprotein, oligosaccharides of the high-mannose type
Related Serum Antigen		
Homogeneity	One major and one minor form	One form
Size	Same as intact PINP (major) or smaller	Same as PICP
Clearance from blood	Scavenger receptor of liver endothelial cells	Mannose receptor of liver endothelial cells

corresponds in size to the complete propeptide.[202] Also, serum PINP antigen in healthy persons is present mainly in intact, trimeric form.[201] However, in certain situations (e.g., end-stage kidney disease with hemodialysis, bedridden geriatric patients),[163] smaller forms of PINP antigen can be detected in serum. Their exact origin is not known, but in ascitic fluid the molecular mass of a similar antigen (about 10,000 Da) in clearly less than that of a individual monomeric chain of PINP (15,000 Da), suggesting a truncated form such a chain.[193A] In principle this could represent a degradation fragment of tissue type I pN-collagen, an idea strengthened by the finding that the concentration of this smaller antigen correlates with that of the serum marker of type I collagen degradation, ICTP.[163,193A] The PINP assays developed differ with respect to whether they only measure the trimeric form (intact PINP[201]) or both forms (total P1NP[32]) of the serum antigens.

Clearance of Propeptides

For each molecule of type I collagen deposited in the tissues, one molecule of each propeptide is released. For a kilogram of type I collagen synthesized, which is an estimated yearly production rate for adults, about 450 g of propeptide is produced. An efficient recycling mechanism has been noted for this material, which has no known further function once cleaved from procollagen. The intact propeptides are taken up from the circulation via two specific receptor-mediated pathways and are degraded by the endothelial cells of the liver (see Table 52-6).[200,287] PICP and PINP behave differently after exogenous thyroxine treatment, which increases the PINP concentration while PICP is decreased.[317] There are also families with a genetic defect in the uptake mechanism for PICP, which results in an increased concentration of this antigen with no other abnormalities in type I collagen metabolites or other biochemical markers of bone metabolism.[291] When clearance of PINP was studied using an assay that detects both forms of antigens, it was found that renal clearance also occurs for the smaller circulating propeptides.[274]

Clinical Significance

After they are set free from procollagen, the two propeptides behave as two individual proteins, and their fates and metabolism are dependent on their structures. In principle, measurement of either propeptide should give the same information. This is the case when PICP and PINP concentrations are compared in situ (e.g., during the fibroproliferative response in a healing wound, where the concentrations of both propeptides increase up to 1000-fold in 1 week).[201] In children, circulating propeptides closely reflect the somatic

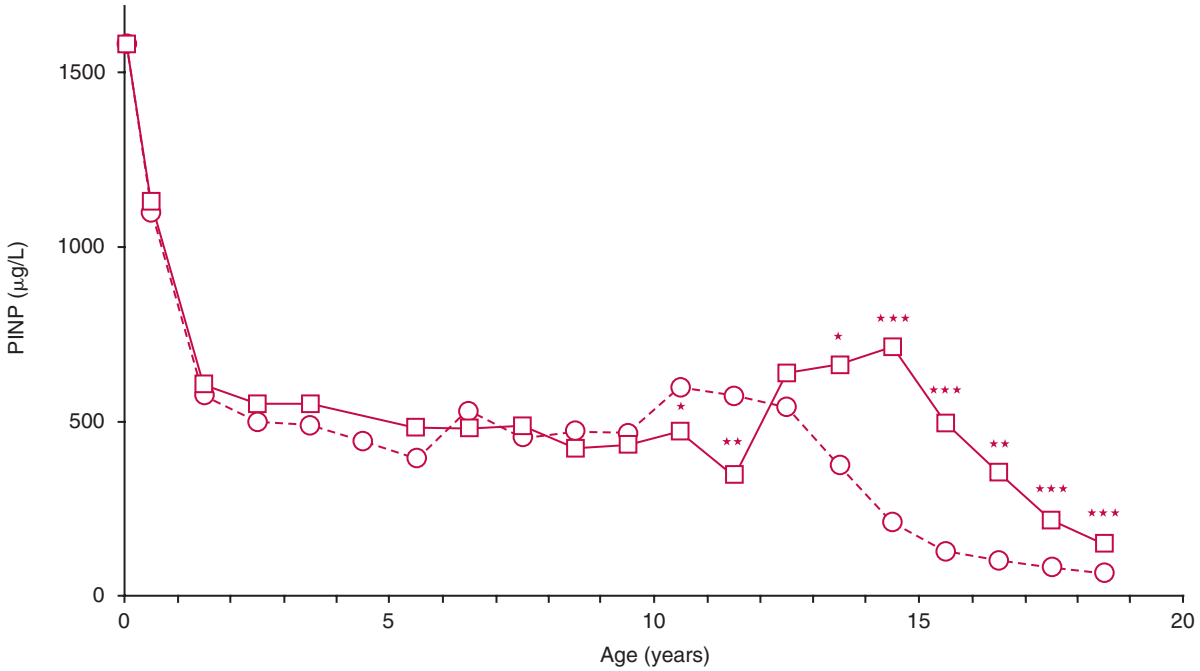

Figure 52-27 Serum concentrations of the amino-terminal propeptide of type I procollagen (PINP) in infants, children, and adolescents in relation to age and gender. Geometric means are shown, defined as the arithmetic mean of log-transformed PINP concentrations, raised to the power of 10. □ ,boys; ○, girls. Geometric means for each age band are plotted at the midpoint of that age band. Unpaired *t*-tests between age-matched boys and girls: *P < 0.05; **P < 0.01; ***P < 0.001. *(From Crofton PM, Evans N, Taylor MRH, Holland CV. Procollagen type I amino-terminal propeptide: pediatric reference data and relationship with procollagen type I carboxyl-terminal propeptide. Clin Chem 2004;50:2173-6.)*

growth rate, and the peak of PICP and PINP concentrations occurs earlier in girls than in boys (Figure 52-27).[62] During puberty, the increase is larger in boys than in girls.

Various drug therapies affect PINP and PICP concentrations. For example, during the first 2 days of teriparatide [PTH(1-34)] treatment, PINP and PICP increase rapidly and continue to increase until the end of 1 month of treatment to a net increase of 110% (Figure 52-28).[108] By contrast, large doses of intravenous methylprednisolone decrease PICP rapidly, reflecting the inhibition of bone formation by glucocorticoids.[230]

Several studies suggest that the serum concentration of PINP is increased more during active bone growth than is the concentration of PICP.[108,299] The ratio of PICP/PINP in serum is expected to be about 3 when the concentrations are expressed as µg/L. In adults, this ratio is indeed about 3, but in children it is less than 1.[303] In Paget disease of bone, a similar discrepancy is seen between circulating concentrations of the two propeptides.[279] A low PICP/PINP ratio is associated with aggressive breast cancer.[154]

Specimen Requirements

The preferred sample for measuring either of the procollagen propeptides is serum. The antigens are very stable in serum or plasma. Storage of a serum sample at room temperature for 1 week does not decrease measurable concentrations.[202]

Assays for PICP and PINP

The PICP antigen has been purified from the cell culture medium of human fibroblasts and used for establishing a radioimmunoassay.[202] A similar EIA is commercially available (called *CICP*). Assays for PINP can be divided into two families: intact PINP[201] and total P1NP.[32,104,225] So far, only a radioimmunoassay for intact PINP has been approved by the U.S. Food and Drug Administration (FDA). This assay has been used in several clinical studies (e.g., for monitoring the effects of alendronate,[75] denosumab,[63] and teriparatide on bone).[108,208,262]

Reference Intervals

The reported reference intervals for PICP are to be 38 to 202 µg/L in men and 50 to 170 µg/L in women.[202] For intact PINP, the original reference intervals reported in men are 20 to 78 µg/L and in women were 19 to 84 µg/L.[201] The reference interval for total P1NP in young healthy premenopausal women (n = 637; age 30 to 39 years) is 16.3 to 72.2 µg/L in France, Belgium, the United States, and the United Kingdom.[109] Significant differences have been noted between countries; the values being significantly higher in France and Belgium than in the United Kingdom and the United States. The reference interval for total PINP in men is 13.9 to 85.5 µg/L.[104] Children have higher concentrations immediately after birth and later during growth spurts (see Figure 52-27); reference

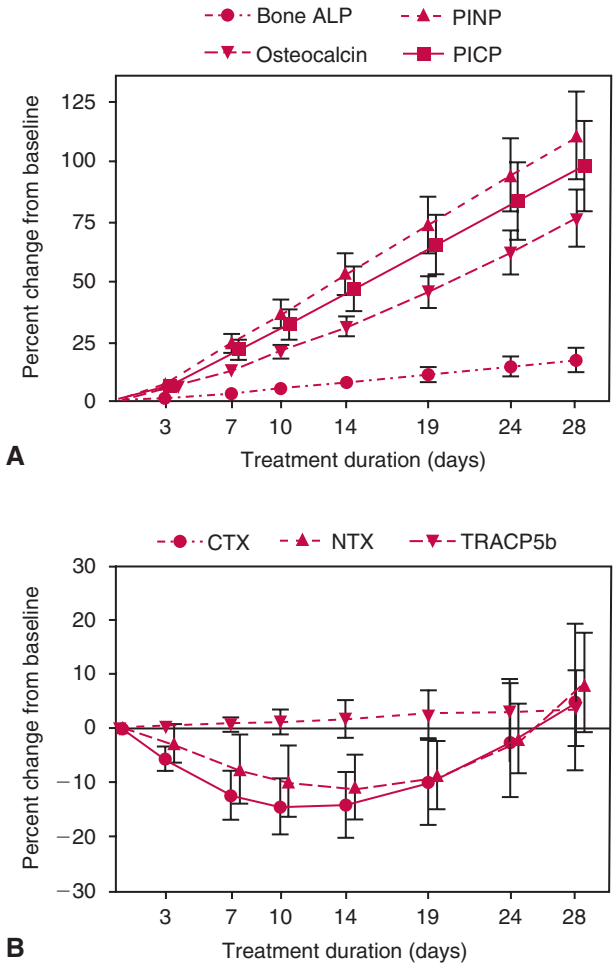

Figure 52-28 Changes in biochemical markers of bone metabolism during 28 days of teriparatide [PTH(1-34)] treatment of osteoporosis. *Line plots* show estimated mean and 90% confidence intervals for percentage change from baseline in (A) markers of bone formation and (B) markers of bone resorption. *Bullet points* at some time points have been slightly shifted horizontally to increase readability. For bone ALP, osteocalcin, PINP, and PICP, all changes from baseline are statistically significant ($P < 0.0001$). For CTX, all changes from baseline until day 19 are statistically significant ($P < 0.0004$). For NTX, all changes from baseline to days 7 to 10 are statistically significant ($P < 0.03$). For TRACP5b, no changes are statistically significant. *(From Glover SJ, Eastell R, McCloskey EV, Rogers A, Garnero P, Lowery J, et al. Rapid and robust response of biochemical markers of bone formation to teriparatide therapy. Bone 2009;45:1053-8.)*

intervals for children have been reported.[62] In neonates (younger than 1 month of age), the reference interval of intact PINP concentration is very high at 770 to 3202 µg/L.

Bone Alkaline Phosphatase (BAP)

Alkaline phosphatases (ALPs; EC 3.1.3.1) are membrane-bound ectoenzymes that catalyze the hydrolysis of monophosphates from ester linkage under alkaline conditions (pH 8 to 10). Four different genes codes are known for

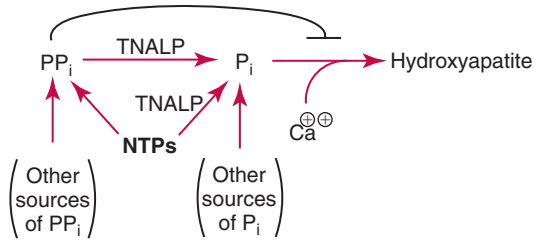

Figure 52-29 Schematic representation of the role of bone alkaline phosphatase in hydroxyapatite formation. Alkaline phosphatase catalyzes the hydrolysis of pyrophosphate (PP_i) produced by the activity of nucleoside triphosphate pyrophosphohydrolase from nucleoside triphosphates (NTPs). Alkaline phosphatase has a positive effect on mineralization primarily by controlling the size of the inhibitory pool of PP_i. The enzyme also generates P_i by using NTPs and PP_i as substrates, but other major sources of P_i (e.g., intestinal absorption) are likely to contribute to the bulk of the P_i needed for hydroxyapatite deposition. *(Modified from Hessle L, Johnson KA, Anderson HC, Narisawa S, Sali A, Goding JW, et al. Tissue-nonspecific alkaline phosphatase and plasma cell membrane glycoprotein-1 are central antagonistic regulators of bone mineralization. Proc Natl Acad Sci U S A 2002;99:9445-9.)*

the tissue-nonspecific, intestinal, placental, and germ cell (placental-like) isoenzymes. The alkaline phosphates of liver, bone, and kidney are isoforms of the same gene product, the tissue-nonspecific gene located in chromosome 1 (TNALP). These isoforms are N-glycosylated, and only the liver ALP does not contain O-linked glycans.[221] ALP is attached to the outer surface of the cell membrane by a glycosylphosphatidylinositol (GPI) anchor. Serum ALP is a homodimer in which the anchor has been removed by the action of endogenous or exogenous (e.g., serum) GPI-specific phospholipase D.[8] Bone ALP can be further separated by anion-exchange HPLC or isoelectric focusing into four isoforms—B/I, B1x, B1, and B2—which differ in their sialic acid content.[123,280] Using the same procedure, liver ALP is divided into three isoforms.[280] As glycoproteins, ALPs are cleared by the liver.

During mineralization of bone, the main function of bone ALP is to hydrolyze inorganic pyrophosphate (PPi) to generate phosphate (Pi) (Figure 52-29).[127,135,153] Matrix vesicles are markedly enriched in tissue-nonspecific alkaline phosphatase.[153] The balance between Pi and PPi is thought to be critical for mineralization because PPi inhibits the formation of hydroxyapatite. Studies on TNALP knockout mice, whose condition resembled the human disease hypophosphatasemia (or hypophosphatasia), have suggested that skeletal ALP is necessary for the propagation step but not for the initiation of mineralization.[7,334]

Bone ALP is produced by the osteoblast during the matrix maturation phase (see Figure 52-3),[181] when the newly formed collagenous matrix is prepared for the deposition of mineral. However, because ALP is firmly bound to the cell membrane, its release to plasma can be delayed, and the increase in plasma activity takes time.

Clinical Significance

Total ALP or BALP provides the highest clinical sensitivity and specificity in the diagnosis and monitoring of Paget disease of bone. Although total ALP is used most often, BALP is more sensitive than total ALP in mild disease. ALP is markedly increased in Paget disease and reflects generally increased bone formation in this condition. In severe osteomalacia, BALP may be markedly increased without an increase in bone mineralization because of a mineralizing defect.

BALP is increased in metabolic bone disease, including osteoporosis, osteomalacia and rickets, hyperparathyroidism, renal osteodystrophy, and thyrotoxicosis, and in individuals with acromegaly, bone metastases, and other disorders with increased bone formation.

Because the half-life of ALP is relatively long (≈40 hours), it is less sensitive than procollagen propeptides or osteocalcin to acute treatment effects, such as the effects of large doses of intravenous methylprednisolone.[230] During teriparatide treatment, ALP is not increased as early or as much as procollagen propeptides or osteocalcin (see Figure 52-28).[108]

ALP and BALP are stable in serum in vitro and do not require special specimen handling. Because of its long half-life, ALP has a long half-life in serum and is relatively unaffected by diurnal variation. BALP is more useful than osteocalcin (see later) in individuals with impaired renal function because it is not cleared by glomerular filtration.

Because 1,25-dihydroxyvitamin D regulates the synthesis of BALP and osteocalcin, both of these markers may be misleading in patients treated with calcitriol and in those with abnormal concentrations of this hormone.

Measurement of Bone Alkaline Phosphatase

Measurement of the enzymatic activities of total and bone ALP was described in Chapter 22. Although internal standards for ALP isoenzymes have been used to increase assay precision in assays of BALP activity,[83] the assays tend to be technically complicated and labor intensive, imprecise, insensitive, and inaccurate. Heat denaturation has been criticized because of its irreproducibility or variability. A method using wheat germ agglutinin (WGA) to precipitate BALP has been criticized because WGA does not precipitate all BAP from serum from Paget disease patients and fails to completely separate bone and liver activity.[158] Lot-to-lot variability of the lectin is also evident.[29]

Several immunoassays have been reported for BALP. However, none of the monoclonal antibodies used is completely specific for bone or liver ALP.[191] Two commercially available immunoassays use monoclonal antibodies against BALP from SaOS-2 cells. One immunoassay is an IRMA using two monoclonal antibodies—a capture antibody and a radioiodinated signal antibody—preferentially reacting with BAP. This two-site immunoassay measures the mass of BALP in μg/L. Subsequently, an immunoenzymatic method was developed by replacing the signal antibody with direct measurement of the activity of immobilized BALP.[38] A modification of this method is available on an automated immunoassay analyzer using chemiluminescence detection. The other assay uses a single monoclonal antibody against BALP. Microtiter plates are coated with this antibody and are used to separate BALP from other isoforms and isoenzymes. After immunoseparation, the activity (U/L) of BALP is determined with a *p*-nitrophenyl phosphate substrate.

The analytical and clinical performances of these BALP immunoassays have been characterized in a series of articles. Unfortunately, current immunoassays are not completely specific for BALP and exhibit 7 to 17% cross-reactivity with ALP from liver.[38,234] It has been difficult to exactly determine cross-reactivity with the liver isoform because of limitations of existing preparations and incomplete understanding of the exact nature of circulating isoforms. BALP immunoassays provide greater sensitivity and specificity for bone formation than does the measurement of total ALP. Current methods for BALP are not reliable in patients with liver disease with increased concentrations of the liver isoform,[191] and BALP may be misleading in liver disease because of this cross-reactivity of current methods with liver ALP.

Reference Intervals

Serum concentrations of BALP are influenced by age and gender. Concentrations are higher in men and increase with age in both men and women, consistent with the age-related increase in bone turnover. The reference interval of BALP with the IRMA is 5 to 20 μg/L. With the immunoabsorption assay, it is 15.0 to 41.3 U/L for men and 11.6 to 29.6 U/L for premenopausal women. For the automated chemiluminescent immunoenzymatic method, the 95th percentile limit is reported to be 14.3 μg/L for men and 20.1 μg/L for premenopausal women. Children have much higher concentrations, especially during growth spurts.[192,241]

Osteocalcin

Osteocalcin (OC), also known as bone gla protein (BGP), is the most abundant noncollagenous protein of human bone. It is a small protein of 49 amino acids with a molecular mass of 5669 Da; its gene, symbol *BGLAP,* is located in chromosome 1. $1,25(OH)_2D$ upregulates OC synthesis. OC contains three glutamyl residues at amino acid positions 17, 21, and 24 (Figure 52-30), which may be converted to γ-carboxyglutamyl residues by a post-translational, vitamin K–dependent enzymatic carboxylation. These unique carboxylated amino acids bind calcium ions and are found in various proteins involved in blood coagulation and in calcium transport, deposition, and homeostasis. OC binds calcium and hydroxyapatite, suggesting a physiologic role in bone mineralization.[118]

Osteocalcin knockout mice have increased bone formation compared with wild-type mice.[74] They develop a phenotype marked by higher bone mass and bones of improved functional quality by 6 to 9 months. This could indicate an inhibitory function of OC on osteoblast activity, but further study has demonstrated that osteocalcin has a small role in bone and dentine mineralization, in contrast to another γ-carboxylated protein of bone, matrix gla protein.[211]

Instead of bone formation defects, these knockout mice show decreased insulin and adiponectin secretion, insulin

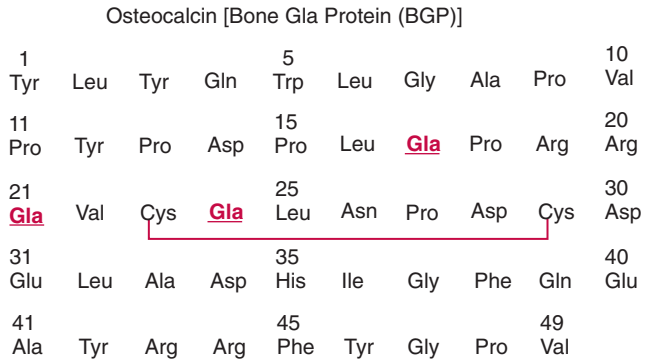

Figure 52-30 Structure of human osteocalcin. Three glutamyl residues at positions 17, 21, and 24 can be carboxylated in a post-translational, vitamin K–dependent, enzymatic step producing γ-carboxyglutamyl (Gla) residues. A disulfide bond formed between cysteines in positions 23 and 29 stabilizes two antiparallel α-helical structures representing 40% of the overall structure.

resistance, higher serum glucose concentrations, and increased adiposity.[176] Osteocalcin in fact may be an osteoblast-secreted hormone regulating insulin secretion and sensitivity.[58,94] Leptin formed in adipose tissues, on the other hand, regulates synthesis of osteocalcin in osteoblasts. Adipose cells can also produce osteocalcin.[89]

Both in mice and in men, osteocalcin can be present in the serum in carboxylated and undercarboxylated forms; it is the undercarboxylated form of osteocalcin that acts as a hormone. The undercarboxylated fraction represents 16 to 21% of the total OC.[324]

Serum OC is cleared by the kidneys and has a half-life of approximately 5 minutes. OC concentrations are increased in individuals with renal failure. OC exhibits a diurnal variation with a nocturnal peak, dropping by as much as 50% to a morning nadir. Circulating OC is heterogenous; in addition to the intact molecule, several fragments are the result of proteolysis at arginine residues in positions 19, 20, 43, and 44 (see Figure 52-30). Intact OC has been estimated to account for about 35% of total OC, N-terminal/midregion for about 30%, and other fragments for much less in the circulation.[103] These proportions are different in some conditions (e.g., osteoporosis).

Clinical Significance

The concentration of OC changes rapidly in situations that affect bone turnover. During teriparatide treatment, OC increases rapidly but less pronouncedly than PINP and continues to increase until the end of the first month of treatment (see Figure 52-28).[108] OC will rapidly decrease in patients who get large doses of methylprednisolone intravenously.[230] Thus OC is increased in metabolic bone disease with increased bone formation, including osteoporosis, hyperparathyroidism, renal osteodystrophy, and thyrotoxicosis, and in individuals with fractures, acromegaly, and bone metastases. OC is decreased in hypoparathyroidism, hypothyroidism, and growth hormone deficiency, and during estrogen therapy and treatment with glucocorticoids, bisphosphonates, and calcitonin.

OC concentrations may be misleading in several situations. They increase in patients with impaired renal function without a similar increase in bone formation, because OC is cleared by the kidneys. OC may be increased during bed rest without an increase in bone formation. Serum OC may not reflect bone formation in patients treated with $1,25(OH)_2D$ or those with abnormalities in this hormone, because OC is regulated by $1,25(OH)_2D$.

About 10 to 30% of OC synthesized by the osteoblast is released into the circulation. OC is not a pure marker of bone formation: freshly synthesized OC is secreted in part into the bloodstream and is incorporated in part into the bone matrix.[235] Osteocalcin is also released from the bone matrix during bone resorption; these fragments of OC may contribute to circulating concentrations of osteocalcin. Thus, serum osteocalcin may be considered a marker of bone turnover rather than bone formation.[149] Measurements of OC are used more in research than in clinical practice.

Measurement of Osteocalcin

Many immunoassay methods have been developed for OC since the first assay was reported in 1980.[235] Early OC assays were competitive immunoassays, but noncompetitive methods have been developed.[175] Noncompetitive methods measuring intact OC, especially those measuring both intact OC plus the N-terminal/midregion (1-43) fragment, are of particular interest. These assays do not measure smaller fragments of OC that can be produced during bone resorption. OC concentrations are more stable when measured with assays that recognize both intact hormone (1-49) and the N-terminal/midregion (1-43), because this fragment is produced in vitro by hydrolysis of intact OC.[255]

For most assays, specificities with respect to carboxylated and undercarboxylated forms of OC are not known. An ELISA assay for N-terminal midfragment is independent of the degree of γ-carboxylation of human OC.[255] If the serum sample is precipitated with hydroxyapatite[203] or barium sulfate,[289] the supernatant contains undercarboxylated OC.

The circulating concentration of OC measured in healthy subjects varies widely between methods and laboratories. One study reported that mean values for healthy individuals ranged from 3 to 27 ng/mL.[69] Such variability may be a consequence of differences in specificities and sensitivities of antisera/antibodies used in the assays, and in the purity, potency, and immunoreactivity of OC calibrators. Another important source of variation between methods may be their dependence on, or independence of, calcium concentration in the assay. Calcium binding to γ-carboxyglutamyl residues induces a conformational change in OC. Although EDTA is added to some assays to eliminate this effect, other assays require the addition of calcium.

An immunoassay for the undercarboxylated form of osteocalcin has also been developed. This assay uses recombinant human undercarboxylated OC for calibration and two

monoclonal antibodies[324]; one of these specifically recognizes the 14-30 sequence, in which the three glutamic acid residues are not carboxylated.

Specimen Requirements

Osteocalcin is rapidly degraded in blood samples at room temperature or at 4 °C.[13,24,103] Measured serum OC concentrations are more stable when assessed with methods measuring both intact OC and the N-terminal/midregion fragment (1-43): measured concentrations were unchanged after 3 hours at room temperature and after 24 hours at 4 °C.[24,103]

Reference Intervals

OC concentrations are influenced by age, gender, and diurnal variation. Men have somewhat higher concentrations of OC than women. OC concentrations have been reported to increase, decrease, or remain unchanged with advancing age as a probable consequence of the heterogeneity of circulating OC and differences in immunoassay specificity. OC concentrations generally are increased during menopause. In a commercially available OC ELISA, the reference interval is 9.6 to 40.8 μg/L in men, 8.4 to 33.9 μg/L in premenopausal women, and 12.8 to 55.0 μg/L in postmenopausal women. Concentrations are higher in children; the highest concentrations are observed during periods of rapid growth.[192,241]

Biochemical Markers of Bone Resorption

Most markers of bone resorption reflect aspects of the degradation of type I collagen. These markers were initially measured in urine, but serum-based methods have been developed. An osteoclast-derived enzyme, serum tartrate-resistant acid phosphatase (TRAP5b), has also been used to assess bone resorption. Bone resorption markers are listed in Box 52-13.

Collagen Cross-Links

Procollagen undergoes extensive intracellular post-translational processing, including hydroxylation of proline and lysine residues, glycosylation of hydroxylysine residues, and formation of the collagenous triple helix.[247] After it is secreted, procollagen is converted to collagen during extracellular processing, with enzymatic removal of PINP and PICP (see Figure 52-26).

Extracellularly, type I collagen molecules are assembled into immature fibrils with limited tensile strength, which then are modified by formation of intramolecular and intermolecular covalent bonds or cross-links.[162] Intermolecular cross-linking sites have been located in short non–triple-helical domains at each end of the type I collagen molecule, called *telopeptides* (see Figure 52-26). Two hydroxylysine and/or lysine residues in the telopeptide at the amino-terminal end (N-telopeptide) can be linked to a helical site at amino acid 930, and two C-telopeptides can be linked to a helical site at amino acid 87. The activities of two enzymes—intracellular lysyl hydroxylase 2b and extracellular lysyl oxidase—regulate which variant structures of cross-links are formed (Figure 52-31).[265] Lysyl hydroxylase 2b forms hydroxylysine in telopeptide sequences, and lysyl oxidase deaminates the ε-amino group of lysine or hydroxylysine to produce allysine or hydroxyallysine. After this enzymatic processing of telopeptides, the other reactions are spontaneous, leading to a series of divalent and later trivalent cross-links. Of the latter, pyridinoline and deoxypyridinoline (Figure 52-32) are stable even in acid hydrolysis, whereas the pyrrole variants are quite unstable (see Figure 52-31). Trivalent cross-links are found in soft tissues and in collagen types other than type I (type II, III, etc.).

In soft tissues, only mature, trivalent cross-links are found, but bone contains immature, divalent cross-links because mineralization occurs at the same locations as telopeptide cross-links. C-terminal telopeptide isolated from human bone contains un–cross-linked as well as divalently and trivalently cross-linked telopeptides.[81] Pyridinolines were the first mature cross-links to be identified, but their quantity in bone is relatively low—≈1 per 3 to 5 collagen molecules—compared with the quantity of their divalent precursors—1 per collagen molecule.[10,125] The pyrrole cross-links are concentrated at the N-terminal end of human bone collagen.[125] More pyrrole is produced if the activity of lysyl hydroxylase 2b is low in the osteoblast.[10]

Both telopeptides have a sequence with an aspartic acid residue, which as the result of a nonenzymatic reaction, can undergo racemization and β-isomerization.[31,86] Immunoassays detect only one form of these structures, thus decreasing the amount or concentration of antigen detected and creating the possibility that changes in concentration (e.g., with treatment) are due in part to changes in the fine structure of the antigen, rather than to changes in total concentration.

Degradation of Bone Collagen

Cathepsin K is the main enzyme that degrades bone collagen within the lacuna of the osteoclast. Its activity alone is sufficient to completely dissolve insoluble collagen of adult human cortical bone.[98] Osteoclasts also produce other proteases, notably several matrix metalloproteinase (MMP) enzymes (e.g., MMP-9, MMP-10, MMP-12, MMP-14).[67] Cross-linked telopeptides are released from type I collagen during bone resorption because cross-links resist proteolysis of adjacent

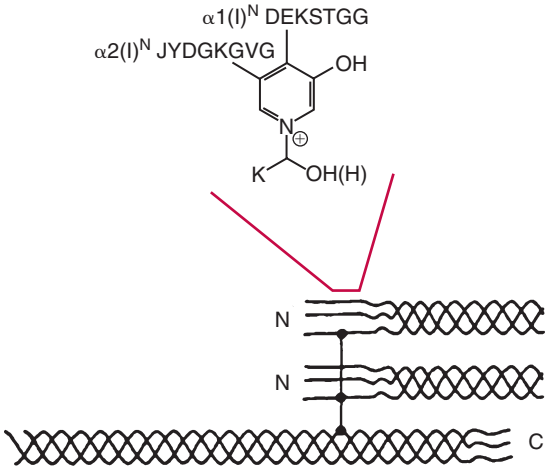

Figure 52-32 Structure and molecular origin of the N-telopeptide (NTX) epitope in type I collagen fibrils. The peptides excreted in urine consist of two telopeptide fragments still linked to the cross-linking residue, which can have a deoxypyridinoline *(as shown here),* a pyridinoline, or a pyrrole structure. *(Modified from Atley LM, Mort JS, Lalumiere M, Eyre DR. Proteolysis of human bone collagen by cathepsin K: characterization of the cleavage sites generating the cross-linked N-telopeptide neoepitope. Bone 2000;26:241-7.)*

polypeptide chains. This may lead to generation of a neoepitope such as NTX that can be detected by an immunoassay (see Figure 52-32).[9]

For C-terminal telopeptides, two distinct immunoassays—ICTP and CTX—reflect different enzymatic pathways of bone breakdown.[100] Cathepsin K releases CTX antigen but destroys reactivity in the ICTP assay (Figure 52-33). ICTP antigen is stable after MMP-1, MMP-9, and MMP-13 digestion.[269] It has been suggested that the ICTP assay could be called the *CTX-MMP assay.*[68] The importance of MMPs is demonstrated by pycnodysostosis, a lysosomal disease caused by cathepsin K deficiency.[107] In this disease, ICTP is the major fragment released during bone resorption.[218]

NTX and CTX reflect normal osteoclastic function,[133] whereas ICTP detects pathologic degradation of bone and soft connective tissue as seen in multiple myeloma, bone metastasis, and rheumatoid arthritis.[248] Thus, in rheumatoid arthritis, CTX is generally within the reference interval, whereas ICTP is increased, correlating with markers of inflammation (CRP and ESR).[268] It seems that MMPs are important in this condition because lack of cathepsin K activity does not abolish erosion.[4]

Excretion of hydroxyproline has been used to assess bone turnover or bone resorption, but it is rarely used today. It is

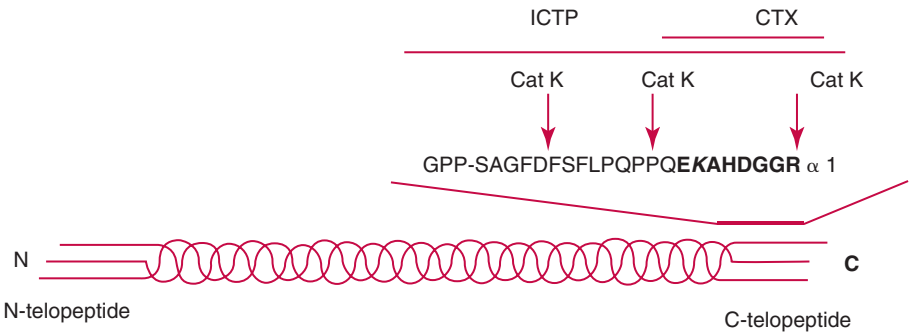

Figure 52-33 Schematic representation of the CTX and ICTP epitopes and cathepsin K (Cat K) cleavage sites in the carboxy-terminal telopeptide of type I collagen. The CTX epitope corresponds to an 8 amino acid sequence in the telopeptide part of an α1(I) chain, whereas the ICTP epitope is a larger conformational epitope, requiring telopeptide parts of two α1(I) chains, both of which contain the phenylalanine-rich region. As shown in the figure, cathepsin K degrades the ICTP phenotype, while generating CTX. The hydroxylysine residue (K) participates in intramolecular and intermolecular covalent cross-links. *(Modified from Garnero P, Ferreras M, Karsdal MA, Nicamhlaoibh R, Risteli J, Borel O, et al. The type I collagen fragments ICTP and CTX reveal distinct enzymatic pathways of bone collagen degradation. J Bone Miner Res 2003;18:859-67.)*

found mainly in collagens, where it accounts for about 13% of total amino acids. It is needed to stabilize the triple-helical structure at body temperature. When the helical collagenous sequence is degraded, this amino acid is released and about 90% of it is catabolized in the liver to urea and carbon dioxide. About 10% is excreted in urine, where it can be analyzed by any one of several methods. However, hydroxyproline is not specific for collagen in that other proteins also contain it (e.g., complement C1q). In addition, the amino-terminal propeptides of type I and III procollagens, markers of collagen synthesis, include in their structure a triple-helical part, which contains hydroxyproline (see Figure 52-26). In addition, ingestion of meat or gelatin increases hydroxyproline excretion.

Comparison of Urine and Serum Analyses

Urine used to be the sample of choice for measuring bone collagen degradation. Urine hydroxyproline analysis was replaced by the more sensitive and specific cross-link and telopeptide assays. Urine measurement needs to be corrected for creatinine excretion to adjust for effects of urine concentration or dilution. This includes a second analyte, which has its own analytical variation that adds to the uncertainty of the result.

Serum and urine telopeptide assays have been compared in several studies; correlation coefficients have varied from 0.6 to 0.9.[134] Kidneys are involved in further degradation of cross-linked peptides; as a result, ≈40% of total cross-links in the urine are free (i.e., not peptide bound).[256] The mean fractional excretion of NTX (0.22) is lower than that of CTX (0.44), indicating that renal degradation is greater for the former analyte.[82]

During antiresorptive treatment, urinary telopeptide assessment may overestimate the decrease in bone resorption because the renal metabolism of these peptides can change. The response to antiresorptive therapy is generally greatest when measured with telopeptide assays, intermediate with total DPD assay, and lowest with free DPD assay.[102,155] Fractional excretion of conjugated cross-links is less than 1, whereas that of the free fraction is greater than 1.[57] It is likely that serum assays will replace urine assays.

Clinical Significance of Telopeptides and Cross-links

Increased urinary telopeptides and deoxypyridinoline have been reported in osteoporosis, Paget disease of bone, primary and secondary hyperparathyroidism, hyperthyroidism, and other diseases (e.g., carcinoma metastases, multiple myeloma), with increased bone resorption or osteolysis.

Inhibition of bone resorption with pharmacologic agents leads to a decrease in serum or urinary telopeptides and urinary deoxypyridinoline. Treatment of postmenopausal women or osteoporotic individuals with bisphosphonates or other antiresorptive drugs decreases bone resorption markers. Although markers of bone formation are also decreased because of the coupling of resorption and formation, their reductions are delayed and are not as great as those observed for markers of bone resorption.

Measurement of Telopeptides and Pyridinium Cross-Links

Several methods are commercially available; the most commonly used are serum and urine assays for NTX and CTX, serum assay for ICTP, and a urine assay for deoxypyridinoline.

N-Telopeptide. NTX in urine is measured with a commercially available ELISA, which uses a monoclonal antibody against the NTX fraction isolated from the urine of healthy adolescents.[126] The antibody recognizes a conformational epitope of the cross-linked α_2(I)N-telopeptide containing the sequence QYDGKGVG, which is a product of osteoclastic proteolysis (see Figure 52-32). It does not recognize a precursor that is not cross-linked, but it does measure both pyridolines and pyrroles.[125] Because the assay does not measure

precursors of cross-links, only degradation of mature collagen is measured, just as with the pyridinolines. Measurement of NTX provides considerable specificity for bone because DPD cross-links primarily involve the α_2(I) chain. By contrast, α_1(I) predominates in other tissues. Moreover, two thirds of deoxypyridinoline cross-links in bone collagen are at the NTX site, whereas one third are at the CTX site. On the other hand, about 85% of the pyrroles are located in the N-telopeptide. The lability and reactivity of pyrroles and their potential for oxidation and hydrolytic ring opening explain the difficulties encountered in isolating and characterizing these structures from NTX antigen.[125] When urine is treated with UV light for 3 days, the apparent concentration of urinary NTX unexpectedly increases by ≈30%, which probably indicates dissolution of aggregated N-telopeptides.[23]

The commercially available urinary NTX ELISA assay measures only nonisomerized α_2(I) N-telopeptide.[31] However, in adult urine, the amount of β-isomerized NTX-peptide is about 10-fold that of nonisomerized forms.

The NTX method has been adapted for the measurement of N-telopeptides in serum.[54] The use of serum eliminates the need to measure urine creatinine to correct for urine concentration and can significantly reduce within-subject day-to-day variation in NTX measurements. Experimental and clinical data have demonstrated this serum assay to provide a useful index of bone resorption; however, mostly for technical reasons, the serum assay has not become as widely used as the assay for NTX in urine.[134]

C-Telopeptide CTX Assay. The first CTX immunoassays were based on a polyclonal antibody produced in rabbits against a synthetic peptide corresponding to residues 15C to 22C (EKAHDGGR) of the α_1(I) chain of type I collagen.[26] This region includes the cross-linking hydroxylysine at residue 16C. Subsequently, several other methods were developed for measuring CTX in urine and serum. The most widely used methods recognize the β-isomer, formed during aging of bone by transfer of the peptide backbone from the α-carboxyl group of aspartic acid to the β-carboxyl group of the same amino acid. In healthy human bone, ≈70 to 80% of C-telopeptides have this β-isomerization, but in Paget disease, it accounts for only about 50 to 60%.[101] This fact introduces additional uncertainly in that β-isomerization and racemization may vary between individuals.[247] All CTX methods require the C-terminal amino acid to be a free arginine.

Serum CTX is measured using two monoclonal antibodies.[254] With two α_1(I) chain telopeptides in each collagen molecule, the use of two antibodies directed against the β-isomer ensures that only the ββ-forms are measured. A modification of this method is now available on an automated immunoassay analyzer using electrochemiluminescence detection.[99]

C-Telopeptide ICTP Assay. A radioimmunoassay for the C-terminal telopeptide of type I collagen (ICTP) detects collagen degradation fragments in serum.[246] Rabbit antibodies were raised against a cross-linked C-telopeptide of type I collagen produced by collagenase digestion of human bone. The epitope measured is vulnerable to digestion by cathepsin K (see Figure 52-33); this method is relatively insensitive to changes in bone resorption caused by normal bone turnover.[100] However, the method is suitable for detecting the osteolytic processes taking place in multiple myeloma[77] or metastatic bone disease, as well as the erosion process in rheumatoid arthritis.

Deoxypyridinoline and Pyridinoline. DPD and PYD were originally measured by HPLC. Today, DPD is measured primarily by immunoassay using automated analyzers or manual ELISA. Unlike most HPLC methods, which measure total DPD and total PYD, the immunoassays for DPD or DPD/PYD measure primarily free, but not peptide-bound, forms. In urine, approximately 40% of PYD and DPD is free and 60% is protein bound.

Comparisons of free and total DPD and PYD suggest that the ratio of free to total pyridinolines varies with physiology, pathophysiology, and treatment.[102,155] Total DPD has been reported to be increased more than free DPD in individuals with disorders involving increased bone resorption (e.g., postmenopausal women; women with osteoporosis, Paget disease, hyperthyroidism). Furthermore, short-term bisphosphonate treatment of patients with Paget disease or osteoporosis reduces the total but not the free DPD.

One commercially available ELISA measures both PYD and DPD with equimolar cross-reactivity.[111] Of greater interest for monitoring bone resorption is the commercially available ELISA that measures DPD but not PYD.[251] This method, a competitive ELISA, uses a streptavidin-coated microtiter plate and biotinylated deoxypyridinoline as the solid phase. Sample or calibrator and the monoclonal antibody against DPD are added and incubated. After washing, a second antibody, goat antimouse immunoglobulin (Ig)G conjugated to ALP, is added. Bound antibody-antibody-enzyme conjugate is measured after addition of *p*-nitrophenyl phosphate.

More recently, automated immunoanalyzer methods for DPD have become commercially available. The most widely used is a solid-phase, competitive EIA with chemiluminescence detection. The solid-phase antibody is incubated with serum or calibrator and ALP conjugated to DPD. After washing, antibody-antigen-enzyme complexes are determined after the addition of substrate.

DPD and PYD can be measured by HPLC with fluorescence detection.[151] Because ≈60% of the pyridinolines in urine are contained in peptides, most methods use acid hydrolysis to generate free amino acids. The hydrolysate is fractionated by column chromatography before resolution of the pyridinolines by reverse-phase chromatography. Because the pyridinolines are highly polar at acid pH, ion-pairing agents have been used to increase their retention by reverse-phase columns. Although most methods have used gradient elution, simpler isocratic methods have been described.[151] Fluorometric detection is used to quantify these naturally occurring fluorescent pyridinium compounds. Lack of synthetic calibrators, controversy over the molar fluorescence yield of pyridinolines, and variability of acid hydrolysis have been suggested as factors contributing to differences observed between laboratories.[250]

Specimen Requirements

Serum is collected after overnight fasting. Both timed and random urine tests have been used for pyridinolines and telopeptides. Although early studies used 24 hour urine samples, timed or early-morning voided urine has also been used. A second morning void, collected by 1000, is most commonly recommended.[37] For treatment monitoring, the specimens should be collected at the same time as the baseline specimen. Peak urinary excretion of pyridinolines occurs at about 0500 to 0800, reflecting the nocturnal peak in bone turnover. Urinary pyridinolines reach a nadir between 1400 and 2300.

DPD and telopeptides are relatively stable in urine. Exposure to UV light, but not laboratory lighting, decreases DPD and PYD.[23] Free pyridinolines are especially vulnerable to UV lighting. It is recommended that prolonged exposure to light and exposure to direct sunlight should be avoided.

Reference Intervals

Concentrations of collagen cross-links are influenced by age and gender. Reference intervals for NTX, CTX, ICTP, and DPD are listed in Table 52-7. Concentrations are markedly higher in children, with highest concentrations observed during early infancy and adolescence—periods of rapid bone growth. In adults, concentrations of collagen cross-links are relatively constant between the ages of 30 and 45, but they increase significantly after menopause in women. Age-related increases have also been reported in men.

Tartrate-Resistant Acid Phosphatase (TRACP5b)

Osteoclasts produce and secrete a tartrate-resistant acid phosphatase (see Figure 52-2) during bone resorption (EC 3.1.3.2).[233] In cell culture, its activity is used to detect and enumerate osteoclasts.[133] Osteoclast number can be elevated in bone disorders and is decreased by antiresorptive treatment (such as bisphosphonates and selective estrogen receptor modulators).[340] The activity of this acid phosphatase in serum has been measured by a number of methods, but most previous methods failed to distinguish between two isoforms: TRACP5b produced by the osteoclasts, and TRACP5a produced by inflammatory macrophages and dendritic cells. These isoforms differ in their carbohydrate content: 5a contains a sialic acid and mannose, but 5b only mannose. In addition, isoform 5b is a dimer, whereas 5a is a monomer. Only about 10% of TRACP circulates in enzymatically active form, and the remaining 90% circulates as inactive fragments.[122]

Several approaches may be used to measure only TRACP5b activity. In a kinetic method, TRACP5b activity is estimated by subtracting tartrate-resistant fluoride-resistant acid phosphatase activity from total activity.[212] Two commercial immunoassays are also available for TRACP5b. In one of them, monoclonal antibody (O1A) binds both isoforms but no inactive fragments; the activity of bound enzymes is then detected with *p*-nitrophenyl phosphate as a substrate at pH 6.1, which is selective for TRACP5b activity.[120,121] In another assay, two monoclonal antibodies are used. One antibody binds the active 5b isoforms of 5b; the other binds inactive fragments, and the activity of bound enzyme is then detected with the TRACP 5b-selective substrate, 2-chloro-4-nitrophenyl phosphate.[224] The two assays have similar TRACP5b specificity and clinical performance in monitoring antiresorptive treatment.[340]

Specimen Requirements

The preferred sample for measuring TRACP5b is serum. Diurnal variation is minor, probably indicating that the half-life of TRACP5b is longer than those of the other markers of bone resorption.[124] TRACP5b may be relatively unstable on storage, although it has been shown that TRACP5b can be stored for up to 8 hours at room temperature and up to 3 days at 4 °C. For long-term storage, it is essential that samples be

†Mean (SD).

stored at −80 °C.[121] Six months' storage at −20 °C reduces activity by at least 40%.[121]

Clinical Significance

In response to alendronate, TRACP5b decreased by a mean (SE) of 39% (4%), compared with 49% (4%) to 69% (5%) for urinary telopeptides (CTX and NTX), and 75% (8%) for serum CTX.[124] TRACP5b activity changes in children; boys aged 13 to 17 years have higher concentrations than girls in the same age groups.[241]

Reference Interval

An immunoassay for TRACP5b has upper limits of reference intervals of 4.15 U/L for women and 4.82 U/L for men.

Preanalytical and Analytical Variables of Bone Turnover Marker

Controllable sources of preanalytical variability include sampling time, sample preservation procedures, and food intake. Bone marker concentrations in urine and serum vary with the time of day because of the diurnal variation of bone resorption and formation. Because of the nocturnal peak in bone turnover, most bone markers peak in the early morning hours (0400 to 0800) and reach their nadir in the afternoon (1300 to 2300). The amplitude of this variation is greatest for resorption markers, with nadir values averaging 70% of peak values. Consequently, specimens should be collected at a standardized time of day to minimize the impact of diurnal variability. For urinary markers, collection of the second morning void is often recommended.

Concentrations of urinary resorption markers are usually normalized by dividing by the urinary creatinine concentration. Variability (within- and between-method) in creatinine measurements, within-subject variability in urinary creatinine, and its dependence on muscle mass contribute to the overall variability of urinary resorption markers.

Long-term, within-individual variability of urine markers is generally higher (15 to 60%) than that of serum markers (5 to 10%). Compared with other bone markers, BALP and TRACP5b do not demonstrate much diurnal variation because of their long half-lives in serum.

Food intake has a marked effect only on serum CTX concentration.[56] The diurnal variation of serum CTX has a magnitude of about ±40% around the 24 hour mean; the only variable that has been recognized as influencing circadian variation is fasting, which reduces variation to about one fourth.[237] With other bone markers, the clinical impact of feeding versus fasting is small. However, in clinical practice, collection of samples in the fasting state is standard practice.

METABOLIC BONE DISEASES

Metabolic bone disease results from a partial uncoupling or imbalance between bone resorption and formation. Decreased bone mass, or *osteopenia,* is more common than abnormal increases in bone mass. The most prevalent metabolic bone diseases are osteoporosis, osteomalacia and rickets, and renal osteodystrophy. Osteoporosis, the most prevalent metabolic bone disease in developed countries, is characterized by loss of bone mass, microarchitectural deterioration of bone tissue, and increased risk of fracture. Rickets and osteomalacia, which are more common in the less-developed countries, are characterized by defective mineralization of bone matrix. Renal osteodystrophy is a complex condition that develops in response to abnormalities of the endocrine and excretory functions of the kidneys. In addition to these three diseases that affect the skeleton in general, two diseases characterized by localized bone involvement are discussed here: Paget disease of bone and bone metastases.

Osteoporosis

Osteoporosis, the most prevalent metabolic bone disease in the United States, results in 1.5 million fractures each year.[128] Osteoporosis is associated with increased risk for vertebral, hip, and distal forearm fractures. At age 50, women have a lifetime fracture risk (at any of these three sites) of about 40%. Men have a lifetime fracture risk of approximately one third that of women. Because trabecular bone turns over at five to seven times the rate of cortical bone, fractures of bones that are predominantly trabecular (vertebra and distal forearm) occur earlier in life. One third of women who are older than 65 years suffer vertebral crush fractures. Vertebral crush fractures can occur acutely and result in disabling pain and discomfort. Long-term complications include immobility and loss of height. Secondary problems include protuberant abdomen, chronic constipation, and loss of self-esteem. Many mild vertebral fractures may be clinically silent when they occur, only to manifest much later as an incidental finding on an x-ray.

Fractures of bone with more cortical bone (proximal femur or hip) occur later in life. For women, the lifetime risk of hip fracture is 15% and for men 3%. The mortality rate accompanying hip fracture may be as high as 20%. Hip fracture mortality is higher in men than in women, increases with age, and is higher for those with coexisting illness and poor prefracture functional status.[128] Twenty-five percent of survivors are confined to long-term care in nursing homes. The cost of medical care for osteoporosis in the United States is estimated to be close to $20 billion.

Peak bone mass normally is attained by 30 years of age and begins to decrease slowly after age 40 in both men and women. The amount of bone attained during growth is an important determinant of whether clinical osteoporosis develops later in life. Exercise and adequate nutrition play important roles in attaining and maintaining skeletal mass. During early adult life, bone formation is coupled with bone resorption so that bone mass remains stable. Aging is a major risk factor for bone loss because after 40 years of age, bone resorption slightly exceeds bone formation, so that approximately 0.5% of the skeletal mass is lost per year. In women, the decrease in sex steroids at menopause accelerates bone loss (postmenopausal osteoporosis) to about 2% per year. Osteoporosis is usually due to inadequate bone formation

BOX 52-14 Causes of Osteoporosis

Failure to develop normal skeletal mass during growth and development because of poor nutrition or inadequate exercise
Endocrine deficiency or excess
- Estrogen or testosterone deficiency
- Cushing syndrome
- Hyperthyroidism
- Hyperparathyroidism

Immobilization or weightlessness
Hematologic malignancies (multiple myeloma)
Inherited defects of collagen synthesis (osteogenesis imperfecta)
Systemic mastocytosis
Heparin therapy
Rheumatoid arthritis
Idiopathic juvenile osteoporosis

during growth or a pathophysiologic process that impairs osteoblastic bone formation or increases bone resorption. Clinically, osteoporosis is most commonly encountered in postmenopausal women. Advanced age, female gender, and sex steroid deficiency are prominent risk factors. Other risk factors include a family history of osteoporosis, alcohol abuse, smoking, and chronic disease.

After decreased bone mass is documented by bone mass measurements, the diagnostic work-up is directed at determining the cause (Box 52-14). Most often, the cause is attributed to age ("senile" osteoporosis), postmenopausal osteoporosis, or both, but it may be secondary to chronic disease, drug therapy, or other causes. If osteoporosis is inconsistent with age or gender (such as in a middle-aged man or a premenopausal woman), laboratory testing should be performed to exclude other secondary causes of osteoporosis, including hyperthyroidism, Cushing syndrome, hypogonadism, primary hyperparathyroidism, and multiple myeloma. Chronic excess of thyroid hormone, cortisol, or PTH may cause osteoporosis. Long-standing hyperthyroidism or excessive thyroid hormone replacement increases bone resorption to a greater extent than is seen with formation leading to osteoporosis. Cortisol markedly decreases bone formation and causes an increase in bone resorption. Patients with Cushing syndrome may have severe osteoporosis. More commonly, patients receiving glucocorticoid therapy for diseases like asthma and rheumatoid arthritis may have disabling osteoporosis. Hyperparathyroidism occurs most commonly in postmenopausal women and may lead to osteoporosis. Multiple myeloma not uncommonly presents with vertebral crush fracture, and osteoporosis must be considered in these patients.

Bone markers can be used to assess bone turnover in patients with osteoporosis, because the rate of bone turnover (spontaneous or modified by the therapy) is considered an important determinant of bone fragility in postmenopausal and older women.[301] Elevated markers of bone turnover indicate increased bone turnover but are not diagnostic for osteoporosis. Markers for both bone resorption and bone formation can, because of coupling of bone formation and resorption, be useful in monitoring the effects of antiresorptive therapy.[21,301] Teriparatide treatment is best monitored by PINP or osteocalcin, but resorption markers may change later during therapy (see Figure 52-28). International Osteoporosis Foundation and IFCC recommend one bone formation marker (serum PINP) and one bone resorption marker (serum CTX) to be used as reference markers.[323A]

Prevention of osteoporosis is an important goal. Adequate nutrition and exercise during growth allow achievement of optimal bone mass. High calcium intake (1000 to 1500 mg/d), adequate vitamin D (at least 400 to 800 U/d), sufficient protein intake, and a regular exercise program are helpful in maintaining bone mass and preventing osteoporosis.

Treatment of osteoporosis depends on the cause. In secondary osteoporosis, treatment is directed at the underlying condition. Most therapies for the treatment of postmenopausal osteoporosis are directed at decreasing osteoclastic bone resorption. Antiresorptive therapies approved by the U.S. Food and Drug Administration (FDA) in the United States include bisphosphonates (alendronate and risedronate, ibandronate, and zoledronic acid), selective estrogen receptor modulators (raloxifene), and calcitonin (nasal spray or injection). Estrogen is approved for management of menopausal symptoms and has an effect on slowing down early postmenopausal bone loss that appears as robust as that of the bisphosphonates. Recombinant hPTH(1-34), also known as teriparatide, is the only FDA-approved therapy for stimulating bone formation, but strontium ranelate has been approved for this purpose in Europe and in several other countries.

Osteomalacia and Rickets

Osteomalacia and rickets are caused by a mineralization defect that occurs during bone formation, resulting in an increase in osteoid, the unmineralized organic matrix of bone.[185] Defective mineralization produces rickets in children and osteomalacia in adults. Osteomalacia or rickets is usually due to vitamin D deficiency or phosphate depletion.

The causes of decreased 25(OH)D and $1,25(OH)_2D$ are listed in Boxes 52-9 and 52-10, respectively. Vitamin D deficiency may be secondary to dietary deprivation and/or inadequate exposure to sunlight, vitamin D malabsorption, disorders of vitamin D metabolism, or end-organ resistance to the action of vitamin D. In spite of supplementation of milk, bread, and some cereals with vitamin D, vitamin D insufficiency may be more common than was previously thought, in both North America and Europe.[46,186] Breast-fed infants, the elderly, strict vegetarians, and individuals with darker skin pigmentation are at increased risk. Although clinical osteomalacia caused by vitamin D deficiency appears to be uncommon, the prevalence of subclinical or mild osteomalacia in the overall population is unknown. Subclinical osteomalacia may coexist with osteoporosis in elderly patients with poor diets and little exposure to sunlight. It has also been shown that mild to moderate vitamin D deficiency may be

associated with reduced muscle strength, impaired physical performance, and falls—all factors contributing to osteoporotic fracture.[185] Vitamin D deficiency may develop in patients with malabsorption caused by postgastrectomy syndrome, small bowel disease (e.g., celiac sprue), hepatobiliary disease, or pancreatic insufficiency.

Vitamin D resistance is rare. Vitamin D–dependent rickets type I is an inherited defect in 25(OH)D-1α-hydroxylase that causes impaired formation of $1,25(OH)_2D$.[185] The disease is manifested in infancy and can be treated with physiologic doses of $1,25(OH)_2D$. Vitamin D–dependent rickets type II is an inherited disorder that is characterized by very high serum concentrations of $1,25(OH)_2D$.[185] This syndrome is caused by resistance to $1,25(OH)_2D$, secondary to defects in the $1,25(OH)_2D$ receptor.

Osteomalacia and rickets may also occur as the result of phosphate depletion. The most common cause of rickets in the United States is hypophosphatemic osteomalacia (also known as *hypophosphatemic vitamin D–resistant rickets* and *vitamin D–resistant rickets*).[260] This disorder is an X-linked dominant inherited trait characterized by renal phosphate wasting. Tubular phosphate wasting can also occur sporadically in adults and as part of Fanconi syndrome. Certain rare mesenchymal tumors may produce a phosphaturic factor (phosphatonin or FGF-23), resulting in renal phosphate wasting and osteomalacia.

In developing countries, dietary calcium deprivation may lead to the clinical picture of rickets, without clear vitamin D or phosphate deficiency.[223]

Drugs have also been associated with osteomalacia. Anticonvulsants increase the hepatic catabolism of vitamin D metabolites and also produce end-organ resistance. Phosphate-binding antacids used for treatment of peptic ulcer disease cause osteomalacia by preventing the intestinal absorption of phosphate. Etidronate treatment (e.g., of Paget disease, osteoporosis, hypercalcemia of malignancy) can cause a mineralization defect, resulting in osteomalacia.

Clinical manifestations of rickets and osteomalacia are a consequence of the defect in mineralization. Rachitic manifestations include bowing of the extremities, short stature, costochondral junction swelling, indentation of the lower ribs, and flattening of the skull. In adults, bone pain is the most common symptom, and stress fractures and frank skeletal fractures may occur. X-rays show classic findings in rickets, such as cupping and fraying of the epiphyseal and diaphyseal ends of the long bone. Pseudofractures are common among adults.

Vitamin D deficiency is diagnosed by measuring serum 25(OH)D (see Table 52-5). Other laboratory findings in rickets and osteomalacia include increased serum ALP, with other alterations in bone and mineral metabolism dependent on the cause and severity of the disorder. ALP is usually increased because of increased osteoblastic activity associated with producing unmineralized osteoid. Calcium may be low-normal or low in vitamin D deficiency, depending on the severity of the disease. Phosphate may be normal or low but falls with the development of secondary hyperparathyroidism. Serum calcium and PTH concentrations are usually normal in renal tubular defects of phosphate transport. Renal phosphate defects can be best assessed through determination of the renal phosphate threshold.

Treatment of rickets and osteomalacia is dictated by the cause of the disorder. Nutritional rickets and osteomalacia are healed by treatment with physiologic doses of vitamin D, whereas higher doses may be required in malabsorption. Adequate dietary intakes of calcium and phosphorus are critical during therapy. Renal phosphate-wasting syndromes require frequent pharmacologic administration of oral phosphorus.

Disorders of Bone and Mineral in Chronic Kidney Disease (Renal Osteodystrophy)

Chronic renal failure is associated with a multitude of disorders of bone and mineral metabolism.[113,145] Renal bone diseases include both high-turnover bone disease (osteitis fibrosa or secondary hyperparathyroidism) and low-turnover bone disease (osteomalacia and adynamic bone disease). Quantitative histomorphometric analysis of bone biopsies, measurement of bone formation by double tetracycline labeling, and special stains are often necessary for correct diagnosis of patients with osteitis fibrosa, osteomalacia, adynamic bone disease, and mixed bone disease of renal osteodystrophy.

Osteitis fibrosa (hyperparathyroid bone disease) is the most common high-turnover bone disease. This disorder is caused by high concentrations of serum PTH in secondary hyperparathyroidism. Secondary hyperparathyroidism is a consequence of the hypocalcemia associated with hyperphosphatemia and $1,25(OH)_2D$ deficiency. Hyperphosphatemia is a result of the inability of the kidneys to excrete phosphate. $1,25(OH)_2D$ deficiency results from the inability of the kidneys to synthesize $1,25(OH)_2D$ because of decreased renal mass and suppression of 25(OH)D-1α-hydroxylase activity by high concentrations of phosphate. Deficiency of $1,25(OH)_2D$ leads to reduced intestinal absorption of calcium and reduced inhibition of PTH secretion by $1,25(OH)_2D$. Skeletal resistance to PTH also contributes to hypocalcemia and secondary hyperparathyroidism.

Low-turnover bone diseases include osteomalacia and adynamic (also known as *aplastic*) bone disease. Osteomalacia and adynamic bone disease are distinguished by the extent of unmineralized bone matrix or osteoid: osteoid is increased in osteomalacia and normal or low in adynamic bone disease. Osteomalacia in chronic renal failure may reflect vitamin D deficiency caused by decreased renal synthesis of $1,25(OH)_2D$ (see "Osteomalacia and Rickets") or aluminum-related disease. In the 1970s and 1980s, aluminum intoxication was a significant contributing factor to the development of osteomalacia and adynamic bone disease. Aluminum intoxication was commonly caused by aluminum contamination of dialysis water and by therapeutic use of oral aluminum-containing antacids to reduce serum phosphate by binding phosphate and preventing its intestinal absorption. The inability of patients with renal failure to

excrete aluminum leads to high concentrations in serum (see section on aluminum toxicity in Chapter 48) and deposition in bone, inhibiting bone cell function and bone mineralization. Aluminum-related disease is less common today because of reduced use of aluminum-containing antacids and the use of effective means to decrease the concentrations of aluminum in dialysis water. Other causes of adynamic renal bone disease include calcium supplementation, excessive vitamin D administration, treatment of hyperparathyroidism, advanced age and osteoporosis, diabetes, corticosteroid therapy, and immobilization. Today, oversuppression of parathyroid function (brought about by the use of oral calcium carbonate to control hyperphosphatemia and treatment with vitamin D and dialysate solutions containing high calcium to control hyperparathyroidism) is believed to be the main cause of adynamic renal bone disease.

Amyloid deposition may be noted in bone and in other tissues. It is thought to result from reduced degradation of α_2-microglobulin by the kidneys. The amyloid in renal failure is primarily composed of α_2-microglobulin. The fraction of patients with amyloidosis increases with the duration of dialysis therapy; 70 to 80% of patients have clinical features of amyloidosis after 10 or more years of hemodialysis. Amyloidosis may coexist with high-turnover or low-turnover bone disease.

Bone pain is the most common complaint of patients with renal osteodystrophy. The weight-bearing bones are the site of greatest discomfort, with leg and hip pain and back pain being common. If the patient is a growing child, skeletal deformities may result, with bowing of the extremities, kyphoscoliosis, and slipped femoral epiphyses. Extracellular calcification is also commonly found in periarticular areas, in the medial layer of arteries, and in internal organs (lungs, heart muscle, and other tissue).

The central role of serum PTH in guiding therapy requires that the PTH assay used can be relied on to measure only the active hormone. This is not true for any of the assay generations (see "Parathyroid Hormone, Measurement of PTH"), and kidney disease leads to accumulation of inactive PTH fragments well above the concentrations seen in healthy individuals. Treatment guidelines take this problem into account, but inconsistencies among assays can still lead to situations in which opposite therapeutic decisions could be made for a single patient, depending on the assay used.[292] Studies are clearly needed to test whether modern biomarkers of bone turnover, when used with measurements of circulating PTH concentrations, could more adequately define the type of osteodystrophy.[145]

Biochemical findings in chronic renal failure include hyperphosphatemia and hypocalcemia. The measured concentration of immunoreactive PTH is generally increased, often dramatically, and $1,25(OH)_2D$ is decreased. Serum ALP is increased in patients with hyperparathyroidism or osteomalacia. Because magnesium is cleared by the kidney, modest elevations (2 to 4 mg/dL or 0.08 to 0.16 mmol/L) are common, especially in those taking magnesium-containing antacids.

Early management of renal failure calls for dietary restriction of phosphate and administration of phosphate-binding agents. Calcium supplements added to the diet to prevent secondary hyperparathyroidism may also serve as phosphate binders. Administration of $1,25(OH)_2D$ or other active forms of vitamin D enhances intestinal calcium absorption and may act directly on the parathyroid gland to reduce PTH secretion. Ultimately, dialysis or renal transplantation may be necessary.

Paget Disease of Bone

Paget disease is a localized disease of bone characterized by osteoclastic bone resorption, followed by replacement of bone in a chaotic fashion.[284,285] This disease has a restricted geographic distribution; it is most common in Europe, North America, Australia, and New Zealand in persons of Anglo-Saxon descent—the prevalence may be up to 4% among people older than 40 years—whereas it is extremely uncommon in Asia, Africa, and Scandinavia. Its origin has been linked to genetics, as a family history of Paget disease is reported by 20 to 30% of patients, but also to environmental factors, in particular to a possible viral infection. The disease typically has late onset, spotty involvement, and inclusions that resemble viral nucleocapsids in the nuclei of osteoclasts. An apparent decline in the frequency and severity of the disease has been reported; this change is too rapid to be explained by genetics alone.[59,285]

Paget disease may affect one bone or several bones. Signs and symptoms depend on which skeletal site is affected; the skull, femur, pelvis, and vertebrae are most commonly affected. In most affected individuals in the United States, the disease is diagnosed from radiographs or laboratory tests (ALP) performed for another reason. With more extensive disease, localized bone pain and increased warmth may be noted in or over the affected bone. Advanced disease can produce deformities such as skull enlargement and bowing of the weight-bearing bones (femur and tibia). Complications of deformed bone include arthritic symptoms, nerve compression, deafness, spinal nerve compression, and, in rare cases, osteogenic sarcoma.

Laboratory and other findings include increased markers of bone turnover[278] and abnormal radiographs and bone scans. Radiologic examination demonstrates the characteristic findings of Paget disease: lytic areas in sites of active osteoclastic bone resorption and thickened, expanded, and sclerotic areas in the sites where osteoblasts have formed woven bone. The radioisotopic bone scan is the most sensitive test for detecting small, early lesions. The most common finding leading to the diagnosis of Paget disease is increased serum ALP (up to 10-fold and higher).

Other biochemical markers of bone formation and degradation give information about the pathologic process taking place. Discrepancies have been noted between the formation markers that reflect different phases of the normal osteoblast phenotype: PINP and total and bone ALP all perform similarly,[278] whereas osteocalcin is less consistently elevated. Paget disease leads to a disproportionate increase in serum PINP

compared with that of PICP.[279] This finding is yet to be explained.

Increases in biochemical markers of bone resorption reflect the osteoclastic nature of the disease. In untreated Paget disease, the αCTX derived from relatively newly formed collagen, is raised more (16-fold) than the βCTX (threefold), which dominates in diseases with generally increased resorption of normal bone such as hyperparathyroidism or hyperthyroidism.[278]

Bone markers are used in diagnosis and therapeutic monitoring. Total ALP (TALP) is usually sufficient, but in patients with hepatocellular injury, a measurement of bone ALP (BALP) or PINP may be helpful.[285]

Therapy is directed at decreasing osteoclastic bone resorption. Bisphosphonates and calcitonin are effective in decreasing bone pain, serum ALP, and other biochemical markers of bone turnover. Patients occasionally may need surgery for skeletal deformity that limits mobility or for arthritic changes, fractures, or nerve compression.

Involvement of Bone in Malignancies

Bone metastases are the most common skeletal complication of malignancy, occurring in up 70% of patients with advanced breast or prostate cancer, and in 15 to 30% of patients with carcinoma of lung, colon, stomach, bladder, uterus, rectum, thyroid, or kidney.[252] Metastases can have a markedly osteolytic or osteoblastic character, but often they are mixed. Most patients with breast cancer have predominantly osteolytic lesions,[116] but about 15 to 20% of metastases have a predominantly osteoblastic nature. Metastases of prostate cancer are generally regarded as osteoblastic.[117] In most carcinoma metastases, however, both bone degradation and formation take place to some extent. The lesions of multiple myeloma are purely osteolytic; the tumor cells secrete factors that suppress bone formation; generalized osteoporosis is also a feature of the disease (see Box 52-14).[197,253]

Many biochemical bone markers, reflecting bone formation or bone resorption, have been investigated for their potential for early detection or treatment monitoring of bone metastases and myeloma.[276] In addition to localized malignant lesions, generalized osteoporosis can complicate the interpretation of most resorption markers, with the possible exception of ICTP. In multiple myeloma, serum ICTP and urinary NTX are the most sensitive tools for estimating increased bone breakdown and may be clinically useful for identifying patients with increased risk of progression of bone disease.[77,132] Resorption markers [e.g., deoxypyridinoline (DPD)] respond promptly to antiresorptive therapy (e.g., with bisphosphonates) for multiple myeloma,[276] whereas serum ICTP has been reported to predict the overall clinical outcome.[77] TRACP5b activity is increased in various carcinomas with bone involvement,[53,120] but evidence for its clinical value is still quite limited.

In carcinomas with predominantly or partially osteoblastic metastases, bone formation markers such as PINP can help in early detection of skeletal involvement.[160,161,164]

CHAPTER 53

Pituitary Function and Pathophysiology

*William E. Winter, M.D., Ishwarlal Jialal, M.D., Ph.D., F.R.C.Path(London), D.A.B.C.C., Mary Lee Vance, M.D., and Roger L. Bertholf, Ph.D.**

The pituitary gland (also called the *hypophysis*) regulates the endocrine system by integrating chemical signals from the brain with feedback from the concentration of circulating hormones to stimulate intermittent hormone release from target endocrine glands.[115,156] The pituitary clearly serves as the master gland in maintaining homeostasis by orchestrating the many processes necessary for survival of the individual, as well as for survival of the species.

The hypophysis is composed of the adenohypophysis (the anterior lobe of the pituitary; ≈75% of the mass of the pituitary) and the neurohypophysis (the posterior lobe of the pituitary, ≈25% of the mass of the pituitary; also called the pars nervosa) (Figure 53-1).[10] In turn, the adenohypophysis has three parts: (1) the pars distalis, where most hormone-producing cells are located; (2) the pars tuberalis, which is part of the hypophyseal stalk; and (3) the pars intermedia. The pars intermedia may be referred to as the intermediate lobe of the pituitary, although it is really part of the adenohypophysis.

The biology of the adenohypophysis is distinctly different from that of the neurohypophysis: the adenohypophysis is controlled by the hypothalamus via releasing or inhibiting hormones, whereas the cell bodies of the neurohypophysis are anatomically located in hypothalamic nuclei, with oxytocin or antidiuretic hormone (ADH) reaching the neurohypophysis through neurohypophyseal nerve axons.[96] Thus the neurohypophysis is not a discrete endocrine organ, but rather functions as a reservoir for these two hormones.

The roles of the various hormones secreted by the pituitary are exceedingly diverse and include regulation of (1) the body's response to stress [adrenocorticotropic hormone (ACTH, or corticotropin) and growth hormone (GH)], (2) the metabolic rate [thyroid-stimulating hormone (TSH, or thyrotropin)], (3) growth (TSH and GH), (4) reproduction [luteinizing hormone (LH) and follicle-stimulating hormone (FSH)], (5) nourishment for the newborn and infant (prolactin), (6) parturition and milk let-down during breast feeding (oxytocin), and (7) fluid balance (ADH, or vasopressin). Some of the pituitary hormones have specific targets (e.g., ACTH, TSH, LH, or FSH), whereas other hormones have multiple targets (e.g., GH, prolactin, oxytocin, and ADH).

A newly recognized product of the pituitary gland detected in some perimenopausal and postmenopausal women is human chorionic gonadotropin (hCG).[185] Usually, hCG is associated with pregnancy or gestational trophoblastic disease. In early pregnancy, hCG doubles approximately every 48 hours, whereas the concentration of hCG from pituitary or gestational trophoblastic disease origin is relatively stable and does not increase in the pattern seen in pregnancy. If an elevated hCG of 5 to 14 IU/L is detected in a postmenopausal woman, it is likely to be of pituitary origin if (1) the FSH is elevated (>45 IU/L), (2) the hCG is suppressed after 2 weeks of estrogen replacement, and (3) gestational trophoblastic disease has been excluded.

The placenta produces several hormones that are similar to pituitary hormones: hCG has functional and structural similarity to LH; human placental lactogen (hPL, or somatomammotropin) has actions similar to prolactin and GH; placental GH becomes the predominant maternal GH during gestation; and placental corticotropin-releasing hormone (CRH) concentration rises in the fetus throughout gestation.[131] Placental GH (GH-V) differs from pituitary GH in 13 of 191 amino acids. Furthermore, GH-V exists in glycosylated and nonglycosylated forms, whereas pituitary GH is not glycosylated. The site of glycosylation in GH-V is asparagine at residue 140.

ANATOMY

The pituitary is located at the base of the brain and is protected anteriorly, inferiorly, and posteriorly by the bony sella turcica. Inferior and anterior to the sella is the air-containing

*The authors gratefully acknowledge the contributions of Ronald J. Whitley, A. Wayne Meikle, Nelson B. Watts, and Laurence M. Demers, on which portions of this chapter are based.

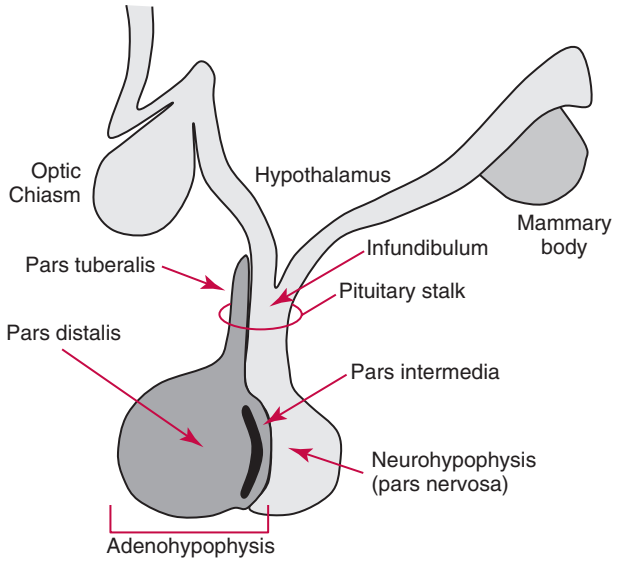

Figure 53-1 The hypophysis (pituitary gland) is composed of the adenohypophysis (the anterior lobe of the pituitary) and the neurohypophysis (the posterior lobe of the pituitary; pars nervosa). The adenohypophysis has three parts: the pars distalis, where most of the hormone-producing cells are located; the pars tuberalis, which is part of the pituitary stalk; and the pars intermedia.

sphenoid sinus, which communicates with the nasopharynx. Neurosurgeons take advantage of the proximity of the sphenoid sinus to the pituitary; the preferred surgical route to the pituitary is transsphenoidal (an incision is made in the mucosa of the oral cavity above the gum line, and the skin covering the upper lip and lower nose is dissected free of the underlying tissue; next the nasal septum is removed with entry into the sphenoid sinus; by removal of the floor of the sella, the pituitary is exposed).

The pituitary weighs only 0.5 to 0.6 g. The gland is larger in women than in men; its size increases during pregnancy, and it is largest in multiparous women. At the completion of pregnancy, when the pituitary is largest, it is susceptible to infarction if hypovolemic shock develops from hemorrhage following delivery, producing a postpartum hypopituitarism called *Sheehan syndrome*.

If the pituitary is greatly reduced in size or is apparently absent on magnetic resonance imaging (MRI) studies, the sella is said to be "empty."[125] In the empty sella syndrome, the sella may be normal in size or enlarged. An incompetent diaphragma sella with compression of the pituitary gland by herniating arachnoid can cause an empty sella, or the pituitary may be reduced in size as the result of some form of injury, radiotherapy, or surgery.

Arterial blood is supplied to the pituitary via the superior and inferior hypophyseal arteries, both of which are branches of the carotid arteries. The superior hypophyseal arteries supply the anterior pituitary and hypophyseal stalk, whereas the inferior hypophyseal arteries supply the posterior pituitary.

Direct delivery of hypothalamic regulatory hormones to the adenohypophysis occurs through the hypothalamic-pituitary portal system, which invests the adenohypophysis (pars distalis). A portal system is a vascular apparatus in which blood that initially passes through one capillary network (e.g., the hypothalamus) is collected into vessels that subsequently supply a second capillary network (e.g., the anterior pituitary). In this way, the hypothalamus controls the secretion of adenohypophyseal hormones via delivery of hypothalamic venous blood to the anterior pituitary gland. There is also retrograde flow from the pituitary to the hypothalamus via the portal system.

Via the lateral hypophyseal veins, pituitary venous drainage is moved to the cavernous and intercavernous sinuses. The cavernous sinus drains to the superior and inferior petrosal sinuses, which join the transverse sinus to form the jugular vein. This anatomic relationship is clinically important because access to pituitary secretions can be afforded by cannulation of the inferior petrosal venous sinuses.[193] Usually, the neuroradiologist places a catheter into a femoral vein that traverses an iliac vein, inferior vena cava, or superior vena cava to the jugular vein to enter the inferior petrosal venous sinus. Inferior petrosal venous sinus sampling can be helpful in the evaluation of patients with Cushing syndrome, to differentiate between Cushing disease (an anterior pituitary corticotropinoma) and ectopic ACTH syndrome.

The internal carotid arteries are located laterally to the pituitary. Above the pituitary is the diaphragma sella, which comprises circular (intercavernous) sinuses containing venous blood. Anterior and superior to the pituitary is the optic chiasm. These relations are clinically important because pituitary neoplasms can invade or compress these structures, as well as the bony sella turcica. For example, expanding anterior pituitary adenomas can compress the optic chiasm, producing bilateral hemianopsia.[202] In this condition, both lateral visual fields are lost. While walking, affected patients will bump into lateral structures in the environment because of loss of their lateral vision.

PITUITARY EMBRYOLOGY

The adenohypophysis develops in utero from a dorsal evagination of the roof of the stomodeum, which becomes the Rathke pouch.[204] The superior portion of the Rathke pouch constitutes the pars tuberalis (see earlier), whereas the posterior portion of the Rathke pouch develops into the pars intermedia (or intermediate lobe). Transcription factors that regulate the development of the anterior pituitary gland include HESX, LHX3, LHX4, SOX3, Pit-1, PROP1, RIEG, and GLI2.[54,55,117] The pars intermedia, which is active only late in pregnancy and in utero, secretes alpha-, beta-, and gamma-melanocyte stimulating hormone (MSH), corticotropin-like intermediate lobe peptide (CLIP), gamma-lipotropin, and beta-endorphin. MSH is believed to promote melanin synthesis. Lipotropins mobilize fat from adipose tissue, and endorphins are endogenous opioids.[128] The clinical significance of these products as causes of disease is not well understood.

TABLE 53-1 Hypothalamic Releasing or Inhibiting Hormones, Their Target Cells, and the Hormone That Is Regulated

Hypothalamic Hormone/ Abbreviation	Amino Acids	Anterior Pituitary Target Cell	Hormone Regulated	Amino Acids	MW
Corticotropin-releasing hormone (CRH)	41	Corticotroph	ACTH	39	4.5 kDa
Thyrotropin-releasing hormone (TRH)	3	Thyrotroph	TSH*	alpha: 92 beta: 118	28 kDa
Growth hormone–releasing hormone (GHRH)	44	Somatotroph	GH	191 176	22 kDa 20 kDa
Somatotropin release–inhibiting hormone† (SRIH)	14	Somatotroph	GH		(see above)
Gonadotropin-releasing hormone (GnRH)	10	Gonadotroph	LH*	alpha: 92 beta: 121	32 kDa
			FSH*	alpha: 92 beta: 111	30 kDa
Prolactin release-inhibiting hormone (PRIH)	1	Lactotroph	Prolactin	199	22 kDa

*All alpha glycoprotein chains are identical, including the alpha chain of human chorionic gonadotropin (hCG).
†a.k.a. somatostatin.
MW, Molecular weight.

Regulation of Function of the Adenohypophysis

The synthesis and release of the following anterior pituitary hormones are stimulated by hypothalamic releasing hormones: ACTH, TSH, GH, LH, and FSH.[96] Prolactin is the sole anterior pituitary hormone whose release is predominantly regulated through suppression. Corticotrophs secrete ACTH, thyrotrophs secrete TSH, somatotrophs secrete GH, gonadotrophs secrete both LH and FSH, and lactotrophs (or mammotrophs) secrete prolactin. Except for LH and FSH, each hormone is normally produced by a unique cell type. However in pathologic circumstances, both GH and prolactin may be secreted by an anterior pituitary adenoma. The molecular composition of the anterior pituitary hormones is summarized in Table 53-1.

Multiple levels of control of the hypothalamic-pituitary-end organ-hormone axis are known (Figure 53-2).[42] Except for prolactin and LH at the midpoint of the menstrual cycle, negative feedback controls secretion of the adenohypophyseal hormones. The long feedback loop involves suppression of the hypothalamic releasing hormone and the anterior pituitary trophic hormone by the hormonal product of the target tissue. The major site of negative feedback for cortisol (regulated by ACTH), insulin-like growth factor-I (IGF-I; regulated by GH), and sex steroids and inhibins (regulated by LH and FSH) is the hypothalamus. In contrast, for thyroid hormone (regulated by TSH), the major site of negative feedback is the anterior pituitary. Retrograde flow from the pituitary to the hypothalamus via the portal system permits the existence of short negative feedback loops where pituitary hormones suppress the secretion of hypothalamic releasing hormones. Ultra-short feedback loops also exist in which pituitary hormones inhibit their own secretion.

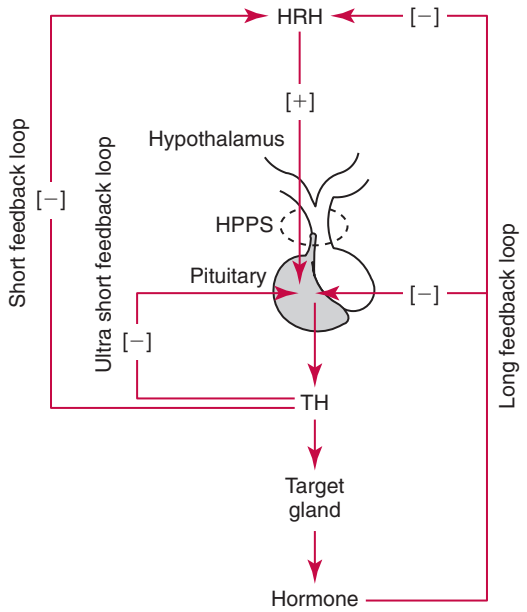

Figure 53-2 Many anterior pituitary trophic hormones (THs) (e.g., ACTH, TSH, GH, LH, FSH) are regulated by hypothalamic releasing hormones (HRHs). Releasing hormones secreted by the hypothalamus reach the pituitary via the hypothalamic-pituitary portal system (HPPS). Long feedback loops involve negative feedback of the target cell hormone at the pituitary gland and hypothalamus. The short feedback loop involves the anterior pituitary trophic hormone feeding back at the hypothalamus, whereas the ultra-short feedback loop involves the anterior pituitary hormone feeding back at the anterior pituitary. [+], Stimulation; [–], suppression.

HYPOTHALAMIC REGULATION

The hypothalamus is an area of the brain that produces hormones that control a number of bodily functions including the release of hormones from the pituitary gland. It is located in the middle of the base of the brain, and encapsulates the ventral portion of the third ventricle.

Hormones released by the hypothalmus that regulate the anterior pituitary hormones are listed in Table 53-1. With the exception of ACTH, hypothalamic hormones are structurally smaller than all of the anterior pituitary hormones.

CRH has wide distribution throughout the brain and brainstem.[86] In the hypothalamus, it is released by the paraventricular nucleus (PVN). CRH secretion is stimulated by systemic physiologic stress via (1) neurons of subfornical origin, (2) neurons of the nucleus tractus solitarius (NTS), (3) hypothalamic glutamatergic neurons, and (4) 5-hydroxytryptamine–secreting neurons of the raphe nucleus. Neurogenic stress to release CRH also acts via hypothalamic glutamatergic neurons. Stress inhibits hypothalamic GABAergic neurons of the PVN that otherwise would suppress CRH release. GABA (gamma-aminobutyric acid) serves as an inhibitory neurotransmitter. GABAergic neurons that innervate CRH-secreting neurons also originate from the lateral septum and the bed nucleus of the stria terminalis (BST). ACTH release is stimulated by serotonin, endorphins, and acetylcholine, and suppressed by GABA. Physiologically, stress, inflammation, and hypoglycemia stimulate ACTH release.

Thyrotropin-releasing hormone (TRH) is a tripeptide the product of the PVN of the hypothalamus.[155] TRH-secreting neurons in the PVN are innervated by axons that release (1) norepinephrine, (2) leptin, (3) neuropeptide Y, (4) agouti-related protein (AgRP), (5) MSH, (6) CRH, or (7) somatostatin. Leptin is produced by adipose tissue and acts to reduce appetite and raise energy expenditure as body fat stores rise. Leptin receptors are expressed in the ventromedial nucleus (VMN) of the hypothalamus. Neuropeptide Y and AgRP promote food intake.

The energy state and temperature of the organism influence TRH secretion. In addition to TRH, TSH secretion is suppressed by (1) thyroid hormone, (2) glucocorticoids, (3) estrogens, and possibly (4) GH. Acute inflammatory cytokines stimulate ACTH release but suppress TRH and TSH. Norepinephrine stimulates TSH release, whereas endorphins, serotonin, and dopamine suppress TSH.

Growth hormone–releasing hormone (GHRH) is produced by neurons in the arcuate nucleus of the medial basal hypothalamus. Simulators of GHRH include dopamine- and galanin-secreting neurons, and brainstem neurons with catecholaminergic inputs.[143] Galanin is a neuropeptide that is widely expressed in the endocrine, central nervous, and peripheral nervous systems. Hypothalamic somatostatin release–inhibiting hormone (SRIH) suppresses both GHRH release and anterior pituitary GH release. Leptin from adipose tissue and ghrelin from the stomach overall have the effect of increasing GHRH secretion and directly increasing GH concentrations. However, the clinical relevance of these influences and of other growth hormone–releasing peptides (e.g., GHRP-6) is not well understood. Ghrelin binds to GH secretogogue receptors (GHS-R) that increases food intake. Hormones that affect GH secretion include estrogen, testosterone, and glucocorticoids. Physiologically, amino acids and hypoglycemia stimulate GH release. In turn, the secretion of IGF-I in response to GH is influenced by nutrition, sex steroids, thyroid hormone, and the presence of chronic disease. Dopamine, endorphins, serotonin, and norepinephrine stimulate GH secretion.

Gonadotropin-releasing hormone (GnRH) regulation is complicated by the fact that GnRH must differentially control LH and FSH secretion, which vary greatly during the menstrual cycle in women.[129] GnRH-secreting neurons are not located in a discrete nucleus, but instead are diffusely distributed in the hypothalamus. Embryologically, these neurons are unusual in that they originate outside the central nervous system. GnRH secretion is stimulated by neurons that secrete (1) galanin-like peptide (GALP), (2) kisspeptin, (3) glutamate, (4) neuropeptide Y, and (5) norepinephrine. Kisspeptin is a neuropeptide that regulates puberty and reproduction. Neurons secreting GABA, beta-endorphins, and CRH inhibit GnRH. Gonadotropin release is stimulated by norepinephrine, GABA, and acetylcholine, and is suppressed by endorphins, dopamine, and serotonin.

GnRH pulsatility is essential to gonadotroph responsiveness. Tonic release of GnRH will downregulate GnRH receptors on gonadotrophs, leading to hypogonadism. Therapeutically, downregulation is accomplished with a long-acting GnRH agonist such as leuprolide acetate (Lupron Depot, Abbott Laboratories, Abbott Park, Ill) in the treatment of central precocious puberty in children, or the induction of hypogonadism in males with prostate cancer. Conversely, pulsatile GnRH administration is used to initiate puberty and to induce ovulation or spermatogenesis in GnRH deficiency. The rate of pulsatility may influence the relative secretion of LH and FSH. In primate studies, GnRH at one pulse per hour preferentially released LH, whereas one pulse every 3 hours caused a decline in LH and a mild rise in FSH.

Anterior Pituitary

In the anterior pituitary, (1) CRH receptors are expressed on corticotrophs, (2) TRH receptors are expressed on thyrotrophs, (3) GHRH receptors are expressed on somatotrophs, (4) GnRH receptors are expressed on gonadotrophs, and (5) prolactin-inhibiting hormone (PRIH) receptors are expressed on lactotrophs. In pathologically high concentrations, TRH stimulates the release of LH and prolactin. Otherwise, TRH does not appear to play a major role in regulating LH or prolactin secretion.

Corticotrophs are stimulated by high concentrations of proinflammatory cytokines such as interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)-alpha.[209] This emphasizes the interrelationship of the endocrine and immune systems in a hypothalamic-pituitary-adrenal-immune system axis. Through vasopressin type 3 receptors (V1b receptors), high

TABLE 53-2 Hypothalamic Hormones, Anterior Pituitary Hormones That They Regulate, Target Organ or Tissues Regulated by the Anterior Pituitary Hormone, and Hormonal Product of the Target Organ or Tissues

Hypothalamic Hormone(S)	Anterior Pituitary Hormone	Target Organ/Tissue	Target Hormone
CRH	ACTH	Adrenal cortex: zona fasiculata and zona reticularis	Cortisol
TRH	TSH	Thyroid follicular cell	Thyroxine (T_4) and 3,5,3′-triiodothyronine (T_3)
GHRH and SRIH	GH	Liver and many tissues of the body	Insulin-like growth factor-I (IGF-I), IGF binding protein-3 (IGFBP-3), and acid-labile subunit (ALS)
GnRH	LH, FSH	Gonad	Sex steroids and inhibins
PRIH	Prolactin	Breast	Not applicable

concentrations of ADH stimulate corticotrophs to release ACTH.

The hormonal products of each anterior pituitary target cell (if applicable) are listed in Table 53-2 along with a summary of each system. Many of these hormones display circadian (daily), ultradian (>daily) or infradian (<daily) variation that reflects changes in hypothalamic control. Deficiency of an individual pituitary hormone is typically called *hypopituitarism,*[13,179,194] whereas deficiency of all anterior pituitary hormones is termed *panhypopituitarism.*

Growth Hormone and Insulin-like Growth Factors

Linear growth is the consequence of (1) genetic potential, (2) nutrition, (3) the presence or absence of disease, and (4) hormonal effects.[212] Many hormones influence growth, but the most important are GH, thyroid hormone, and sex steroids. Excess glucocorticoids can impair growth in children. GH deficiency produces disease in adults, thus GH is essential for health throughout life.

Growth Hormone–Releasing Hormone (GHRH)

PreproGHRH is a polypeptide chain of 108 amino acids (12.4 kDa). Removal of the 20 amino acid signal (leader) sequence yields the 88 amino acid proGHRH. Cleavage of the 11 amino acid N-terminal pro-sequence and the 31 amino acid C-terminal pro-sequence, with release of 2 free amino acids (positions 76-77 with reference to preproGHRH), produces the 44 amino acid mature GHRH. The terminal leucine of GHRH is amidated. Alternative splicing of the mRNA (isoform 2) produces a preproGHRH protein of 107 amino acids, which is missing amino acid 103.

Somatotropin Release–Inhibiting Hormone

Somatotropin release–inhibiting hormone (SRIH) also is known as *somatostatin.*[195] It is widely distributed throughout the body (CNS, gut, and delta cells of the islets of Langerhan) and produces multiple physiologic effects. Somatostatin receptors are widely distributed (see later). Somatostatin that functions as SRIH is produced by the paraventricular nucleus of the hypothalamus. In the islets, somatostatin suppresses glucagon and insulin secretion, whereas somatostatin release is stimulated by both of these hormones. In this way, delta cell somatostatin modulates islet function by smoothing out extremes in the secretion of glucagon and insulin to maintain a stable blood glucose concentration. Somatostatin in the gut is found in highest concentration in the duodenum and jejunum.

Expression of the somatostatin gene produces the 116 amino acid polypeptide preprosomatostatin. Cleavage of the signal sequence (24 amino acids) produces prosomatostatin (92 amino acids), and subsequent cleavage of the N-terminal pro-sequence (64 amino acids) yields a 28 amino acid form of somatostatin (SST-28). SST-28 has an intrachain disulfide bond between amino acids 17 and 28. In many tissues, SST-28 undergoes cleavage to a 14 amino acid form (SST-14) through removal of the N-terminal 14 amino acid sequence by the enzymes prohormone convertase 1/prohormone convertase 2 (PC1/PC2) and carboxypeptidase E (CPE). SST-14 is the major form of somtatostatin in the CNS and delta cells, whereas SST-28 is the major form in the gastrointestinal tract. SST-28 is also the major circulating form of somatostatin. Therefore, somatostatin measurements in peripheral blood do not reflect SRIH secretion. Somatostatin is highly conserved in nature: all vertebrates have the identical sequence for SST-14.[195]

In addition to GH suppression, somatostatin also suppresses TRH, TSH, CRH, and ACTH. However, the effect of somatostatin on regulation of the adrenal cortical and thyroid axes ordinarily is minor. In the gastrointestinal tract, somatostatin reduces the secretion of multiple hormones including (1) gastrin, (2) secretin, (3) cholecystokinin, (4) vasoactive intestinal polypeptide, (5) motilin, (6) neurotensin, and (7) pepsin and reduces gastric pH, intestinal motility, ion and nutrient absorption, and proliferation of the mucosa (see Chapter 51). Calcitonin, catecholamines, renin, and pancreatic exocrine function are suppressed by somatostatin. Somatostatin analogs (e.g., octreotide) are used pharmacologically to suppress a variety of hormone overproduction conditions.[28]

TABLE 53-3 Biology of the Somatostatin Receptors

SSTR	Gene Location	Amino Acids/ Molecular Wt	SST Binding	Distribution
SSTR1	14q1	391 aa 42.7 kDa	SST-14 > SST-28	Fetal kidney, fetal liver, adult pancreas, brain, lung, jejunum, stomach
SSTR2	17q2	369 aa 41.3 kDa	SST14 and SST-28	Cerebrum, kidney
SSTR3	22q13.1	418 aa 45.8 kDa	SST-14 and SST-28	Brain, pituitary, pancreas
SSTR4	20p11.2	388 aa 42 kDa	SST-14	Fetal and adult brain, lung, stomach, less in kidney, pituitary, adrenals
SSTR5	16p13.3	364 aa 39.2 kDa	SST-28 > SST-14	Adult pituitary, heart, small intestine, adrenal, cerebellum, fetal hypothalamus

Growth Hormone–Releasing Hormone Receptor (GHRHR)

The anterior pituitary somatotroph GHRH receptor (GHRHR) is a member of family B-III of the G-coupled receptor superfamily (the "secretin" family).[7] Receptors for (1) secretin, (2) vasoactive intestinal polypeptide (VIP), (3) parathyroid hormone (PTH), and (4) calcitonin share partial sequence identity with GHRHR.

PreGHRHR is a 423 amino acid polypeptide that is converted to the mature 401 amino acid form of GHRHR by removal of the 22 amino acid signal peptide. The N-terminal extracellular domain is 110 amino acids. GHRHR has seven transmembrane domains and a 42 amino acid cytoplasmic domain. Amino acid 50 may be glycosylated.

Somatostatin (SRIH) Receptor

Throughout the body, there are five receptors for somatostatin (SSTR1 through SSTR5; Table 53-3). Each receptor is encoded by a gene located on a separate chromosome. SSTR2 has two alternatively spliced isoforms. All of the SSTR receptors have seven transmembrane domains, and are coupled with a pertussis toxin–sensitive G protein. SSTR3, SSTR4, and SSTR5 are expressed in the pituitary.

Growth Hormone (GH)

GH has two disulfide bridges (amino acids 54 and 165, and amino acids 182 and 189).[59] Structurally, GH has four main alpha-helices, and within the connecting loops three mini-helices. Two circulating forms of GH are present: a 22 kDa form that is a 191 amino acid chain (full-length GH) representing 85 to 90% of circulating GH, and a 20 kDa GH that lacks amino acids 32 through 46.[184] The 20 kDa form of GH results from alternative splicing of the GH mRNA transcript. In addition to the 22 kDa and 20 kDa forms, circulating GH exists as aggregates and oligomers. "Big GH" is a dimer of GH monomers, and "big-big GH" is GH associated with its binding protein (GHBP). GHBP is the external domain of the GH receptor (GHR), which binds GH with high affinity and is produced by cleavage of the GHR. Approximately 55% of all circulating GH forms are monomeric; big GH and big-big GH represent ≈27% and ≈18% of circulating GH, respectively. Approximately 50% of GH is not bound to GHBP, ≈45% is bound to GHBP, and the remaining 5% of GH is bound to low-affinity binding proteins. Considering the multiple forms of GH, it is not surprising that significant analytical biases are observed between different immunoassays for GH.

The gene for GH (chromosome 17q24.2) is a member of the GH subfamily that includes (–5′ to 3′ direction) (1) GH (the *GH1* gene), (2) a chorionic somatomammotropin (human placental lactogen) pseudogene designated *CSHP*, (3) a chorionic somatomammotropin-A designated *CSH1*, (4) the placentally produced 22 kDa GH variant (GH-V; gene designation *GH2*), and (5) chorionic somatomammotropin-B (gene designation *CSH2*).[40] Somatomammotropin (hPL) is a placental hormone with growth-promoting properties. Prolactin (199 amino acids) shares a homologous amino acid sequence with GH, but prolactin, encoded on chromosome 6p22, is not part of the GH complex on 17q24.2.

GH has both direct and indirect activity. Its direct actions will be described in the following sections.[118] The indirect activity of GH is mediated by IGF-I. To initiate its direct and indirect activity, GH binds to tissue receptors (GHR) that appear to be expressed by all tissues.

Growth Hormone Receptor (GHR)

The GHR is a member of the class 1 hematopoietic cytokine family.[142] Other members of this family include receptors for erythropoietin, granulocyte-macrophage colony-stimulating factor, and various interferons. Structurally, the GHR is a single-chain, 620 amino acid protein (130 kDa). PreGHR includes an 18 amino acid leader sequence. The GHR structure includes an extracellular domain (246 amino acids), a transmembrane domain (24 amino acids), and a cytoplasmic domain (350 amino acids).[31] When the extracellular portion of the GHR is shed, the 55 kDa GHBP moiety is released into the circulation.

Four isoforms of the GHR are expressed by alternative splicing of the nascent mRNA. Isoform 1 is the full-length receptor. Isoform 2 differs in the sequence of amino acids 292-297 (with reference to preGHR) and lacks amino acids

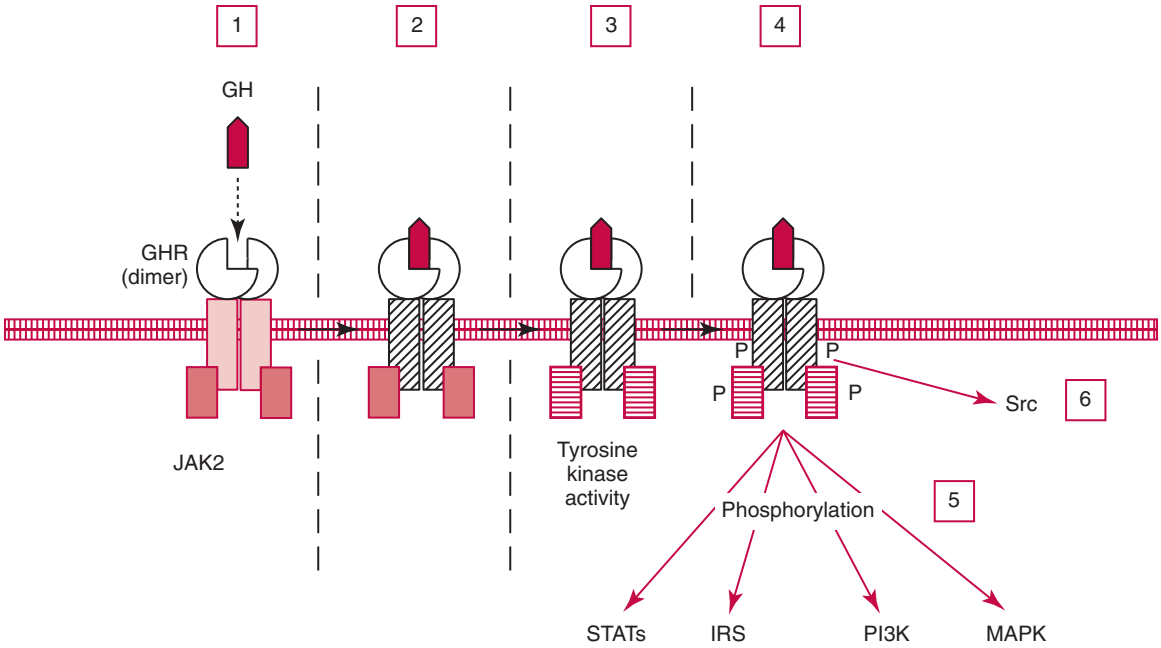

Figure 53-3 The growth hormone receptor (GHR) exists as a cell surface dimer in its inactive state. With GH binding to the GHR *[1]*, the GHR recruits or activates Janus-associated kinase molecules (JAK2) *[2]*. JAK2 then achieves tyrosine kinase activity *[3]*, and JAK2 and the GHR are phosphorylated *[4]*. Activated JAK2 now triggers several intracellular pathways involving STATs (signal transducers and activators of transcription), the insulin receptor substrate (IRS), phosphatidylinositol 3′-kinase (PI3K), and a mitogen-activated protein kinase (MAPK) *[5]*. Independent of JAK2, GHR signaling can proceed via Src *[6]*.

298-638. Isoform 3 differs in the sequence of amino acids 292-294 and lacks amino acids 295-638. An alanine at position four is replaced by aspartic acid, and amino acids 25 to 46 are missing in isoform 4.

The GHR exists as a cell surface dimer in its inactive state (Figure 53-3). When GH binds to the GHR, the receptor recruits or activates 120 kDa Janus-associated kinase enzymes (JAK2, a type of adapter tyrosine kinase). JAK2 then exerts tyrosine kinase activity by phosphorylating itself and the GHR.[132] Phosphorylation activates JAK2, which triggers several intracellular pathways involving (1) STATs (signal transducers and activators of transcription), (2) the insulin receptor substrate (IRS), (3) phosphatidylinositol 3′-kinase (PI3K), and (4) a mitogen-activated protein kinase (MAPK). STAT5b is involved, but it is unclear whether STAT5a is also involved. In its role as a transcription factor, phosphorylated, dimerized STAT5b enters the nucleus to promote gene transcription. Independent of JAK2, GHR signaling can be effected via Src, which is a tyrosine kinase. (*Note:* Src is the Rous sarcoma virus proto-oncogene.)

Insulin-like Growth Factors

IGF-I is a member of the insulin-related peptide family whose other members include IGF-II, insulin, and relaxin. Stimulated by hCG during pregnancy, relaxin is produced by the corpus luteum verum (the corpus luteum of pregnancy), the decidua (the uterine lining during pregnancy), and the placenta. Relaxin increases collagenase activity to soften and lengthen the cervix and pubic symphysis and facilitate parturition. Relaxin also reduces uterine contractility by inhibiting myosin kinase activity. In humans, there are three nonallelic relaxin genes: *RLN1, RLN2,* and *RLN3.*

Proinsulin, IGF-I, IGF-II, and relaxin are all composed of two domains (A and B) joined by a connecting domain. The connecting domains vary in sequence and length much more than the A and B domains. The connecting domain of proinsulin is cleaved to release C-peptide (connecting peptide), producing insulin A and B chains. Insulin, IGF-I, IGF-II, and relaxin have two disulfide bridges. IGF-I and IGF-II share 62% homology, and they each share 50% homology with insulin.

The 110 amino acid sequence of preproinsulin includes a signal peptide (amino acids 1-24), the insulin B chain (amino acids 25-54), C-peptide (amino acids 57-87), and the insulin A chain (amino acids 90-110). The two interchain disulfide bonds are between amino acids 31 and 96, and 43 and 109. The single intrachain disulfide bond is between amino acids 95 and 100.

Two forms of prepro-IGF-I are expressed as a consequence of alternative mRNA splicing: IGF-IA and IGF-IB. The IGF-IA preprohormone is 153 amino acids, including a signal peptide (amino acids 1-21), an N-terminal propeptide

(amino acids 22-48), IGF-I (70 amino acids), and a C-terminal propeptide (the E domain, amino acids 119-153). The IGF-I polypeptide includes the B domain (amino acids 49-77), the C (connecting) domain (amino acids 78-89), the A domain (amino acids 90-110), and the D domain (amino acids 111-118). Three disulfide bonds are present between amino acids 54 and 96, 66 and 109, and 95 and 100. IGF-I is not glycosylated.

The 195 amino acid IGF-IB preprohormone is composed of a signal peptide (amino acids 1-21), a propeptide (amino acids 22-48), IGF-I (70 amino acids), and another propeptide region (the E domain, amino acids 119-195). Differences in the D versus E domain of the prepro-IGF-I distinguish IGF-IA from IGF-IB; the tertiary structure of the IGF-I proteins and the placement of disulfide bonds are identical between IGF-IA and IGF-IB.

The IGF-II preprohormone comprises 180 amino acids. The first 24 residues constitute the signal (or leader) peptide. After their removal, IGF-II is derived from pro-IGF-II after cleavage of the C-terminal E peptide (amino acids 92-180). Therefore, amino acids 25 to 91 include the B region (amino acids 25-52), the C region (amino acids 53-64), the A region (amino acids 65-85), and the D region (amino acids 86-91) of IGF-II. Isoform I is the full-length prepro-IGF-II (180 amino acids). Formed by alternative splicing, isoform II lacks amino acid 25 (alanine) and is therefore 179 amino acids in length. IGF-II is glycosylated at amino acid 99 and has three intrachain disulfide bonds between amino acids 33 and 71, 45 and 84, and 70 and 75. A potential glycosylation site is amino acid 163.

Prorelaxin is a 185 amino acid protein that contains a signal sequence (amino acids 1-22), a B chain (amino acids 23-53), a connecting propeptide (amino acids 56-158), and an A chain (amino acids 163-185). A-B interchain disulfide bonds can occur between amino acids 35 and 172, and 47 and 185. An additional disulfide bridge may occur between amino acids 171 and 176.

IGF-I and IGF-II circulate together with an IGF binding protein, IGFBP (specifically IGFBP-3), and the acid-labile subunit (ALS) to form a 150 kDa trimeric protein complex. About 75 to 80% of IGF-I/IGFBP-3 complexes are trimeric; the remaining IGF-I/IGFBP-3 complexes are dimeric and may include other IGFBPs. Less than 1% of the total IGF-I is free (the biologically active form). The binding affinity of IGF-I for the insulin receptor is low (≈7% of insulin affinity), but circulating IGF-I concentrations exceed insulin by three orders of magnitude. Without binding proteins, therefore, IGF-I could cause potentially devastating hypoglycemia.

The trimeric IGF-I-IGFBP-3-ALS complexes do not normally cross capillary membranes because of their size. However, the 50 kDa binary complex and free IGF-I are able to enter the interstitium, where binding to type I IGF receptors can occur.

Most of the circulating IGF-I is produced by hepatocytes.[139] However, IGF-I is also produced locally throughout the body and thus acts as a paracrine and an autocrine hormone. The possible endocrine (systemic) influence of IGF-I on growth is discussed later.

Similar to IGF-I, IGF-II does not normally produce hypoglycemia. However, reports have described tumors that secrete a larger than normal form of IGF-II. This big IGF-II did not bind normally to IGFBP-3, and therefore the free IGF-II concentration was greatly elevated. As a result of IGF-II binding to the insulin receptor, the clinical syndrome was similar to hypoglycemia caused by hyperinsulinism (i.e., free fatty acids were not elevated, ketones were absent, and lactate and alanine were not elevated), yet insulin itself was suppressed because the beta cells were normal. Removal of the tumor resolved the patient's hypoglycemia.[44]

Insulin-like Growth Factor Binding Proteins

Because of their very high affinity (K_d 10^{-10} to 10^{-11} M) for IGFs, IGFBPs are regarded as inhibitors of IGF action.[136] IGFBPs have higher affinity for IGFs than the IGF receptors. Currently under study is the possibility that IGFBPs may directly influence growth. Receptors for IGFBPs have been described. Proteolysis of IGFBPs releases IGF-I; therefore IGFBP proteases can influence free IGF-I concentrations. Table 53-4 summarizes the features of the seven known IGFBPs.

TABLE 53-4 Characteristics of Insulin-like Growth Factor Binding Proteins (IGFBPs)

IGFBP	Chromosome Gene Location	Amino Acids	Affinity for IGF-I vs. IGF-II	Specific Features
1	7p13	234	1 = 2	RGD sequence*
2	2q3	289	1 < 2	RGD sequence*
3	7p13	264	1 = 2	N-glycosylation
4	17q	237	1 = 2	Extra cysteines
5	2q3	252	1 < 2	Ternary complex with ALS
6	12q13	216	1 < 2	O-glycosylation
7	4q12	282	†	Stimulates prostacyclin production

*RGD sequence = Arg-Gly-Asp.
†Binds IGF-I and IGF-II with low affinity.
ALS, Acid-labile subunit.

Receptors for Insulin-like Growth Factors

Two types of receptors for IGFs have been identified: the type I IGF receptor and the type II IGF receptor (Figure 53-4).[134] Structurally, the type I IGF receptor is similar to the insulin receptor. Because this receptor does not exclusively bind IGF-I, the terminology "IGF-I receptor" is not recommended. The type I receptor is derived from a single precursor protein of 1367 amino acids that includes the 30 amino acid signal peptide. The 706 amino acid (130 kDa) alpha chain is extracellular and is bound by a disulfide bond to the transmembrane 90 kDa (627 amino acids) beta chain. Cleavage of the alpha and beta chains releases a tetrapeptide (707 to 710: arginine-lysine-arginine-arginine). Beta chain amino acids 906 to 929 form a transmembrane domain. The receptor exists as a homodimer (beta-alpha-alpha-beta) with the two alpha chains bound to each other by two disulfide bonds. Similar to the type I IGF receptor, the insulin receptor is a homodimer of two 135 kDa alpha chains and two 95 kDa beta chains.

Tyrosine kinase activity in the cytoplasmic portion of the type I IGF receptor beta chain results from binding of an IGF molecule to the cysteine-rich portion of the alpha chains (amino acids 148-302), which causes conformational changes in both alpha and beta chains. Intracellular signaling involves autophosphorylation and phosphorylation of the 185 kDa insulin receptor substrate 1 (IRS1), which is the predominant target of the active type I IGF receptor. The type I IGF receptor binds IGF-I with higher affinity than IGF-II, and affinity for insulin is lower than the affinity of the receptor for IGF-I or IGF-II. The affinities of the insulin receptor are the opposite: insulin >> IGF-II > IGF-I.

The type II IGF receptor is structurally dissimilar from the type I IGF receptor and the insulin receptor. The 270 kDa, 2451 amino acid, type II IGF receptor is a monomeric protein that is similar to the epidermal growth factor (EGF) receptor.

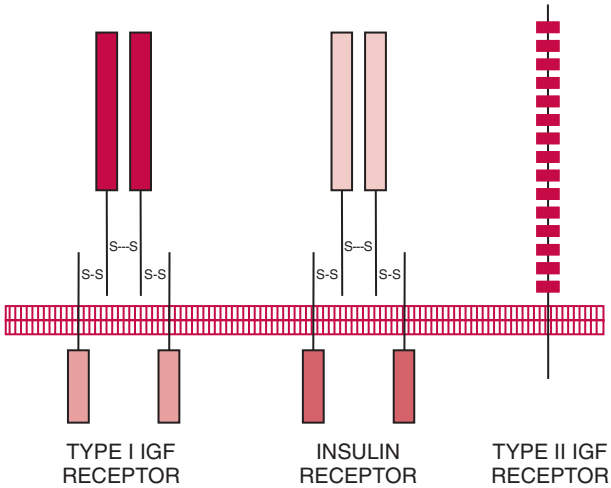

Figure 53-4 The type I IGF receptor is structurally similar to the insulin receptor. The structure of the type II IGF receptor is similar to that of the epidermal growth factor receptor.

(*Note:* The leader sequence is 40 amino acids.) The EGF receptor itself is also known as ErbB1 or HER1. The external portion of the receptor is 2264 amino acids, the transmembrane domain is 23 amino acids, and the cytoplasmic domain is 164 amino acids. Beginning at the N-terminus, thirteen ≈150 amino acid repeats and a 47 amino acid fibronectin type II domain are followed by two more repeats. Evidence indicates at least five glycosylation sites: amino acids 112 (with preference for the pre-type II IGF receptor), 581, 626, 747, and 1246. Two disulfide bonds are found between amino acids 1903 and 1927, and between amino acids 1917 and 1942.

Ligand binding to EGF receptors results in dimerization and tyrosine kinase activation. The external ligand-binding domain of EGFs is composed of numerous short amino acid repeats. The type II IGF receptor removes IGF-II from the circulation, and its engagement leads to activation of transforming growth factor (TGF)-beta. The type II IGF receptor binds mannose-6-phosphate, in addition to IGFs, permitting the uptake and intracellular movement of mannose-6-phosphate–containing lysosomal enzymes. The binding sites for IGFs and mannose-6-phosphate are found on different parts of the receptor. The affinities of the type II IGF receptor are as follows: IGF-II >> IGF-I > insulin. Because this receptor does not exclusively bind IGF-II, the terminology "IGF-II receptor" is not recommended.

A hybrid receptor consisting of the alpha-beta chain of the insulin receptor and the alpha-beta chain of the type I IGF receptor has been described. It has been suggested that these hybrid receptors may allow cancers to respond to insulin.[23] Increasing evidence suggests that IGF-I may enhance the growth of many tumors. Thus, the casual use of IGF-I injections in children to enhance growth in short but otherwise normal children is problematic and potentially carcinogenic.

Regulation of Growth Hormone (GH) Secretion

GH ultimately stimulates release of IGF-I, which negatively feeds back to regulate GH release via two hypothalamic hormones: somatotropin-release inhibiting hormone (SRIH, or somatostatin; from the hypothalamic paraventricular nucleus) and growth hormone–releasing hormone (GHRH; from the hypothalamic infundibular nucleus) (Figure 53-5). These hypothalamic GH-regulating hormones are carried to the anterior pituitary via the specialized hypothalamic-pituitary portal vascular system. Somatotrophs of the anterior pituitary gland have receptors for both hormones. Somatostatin inhibits GH release, whereas GHRH promotes the release of GH. However, GH release is the predominant hypothalamic effect, because surgical interruption of the pituitary stalk with destruction of the hypothalamic-pituitary portal system leads to GH deficiency, not excess. In addition to its hypothalamic negative feedback effects, IGF-I directly suppresses pituitary release of GH.

Physiologically, GH secretion is episodic.[138] Consequently, random measurements cannot exclude GH deficiency; between pulses, GH concentrations can be quite low and do

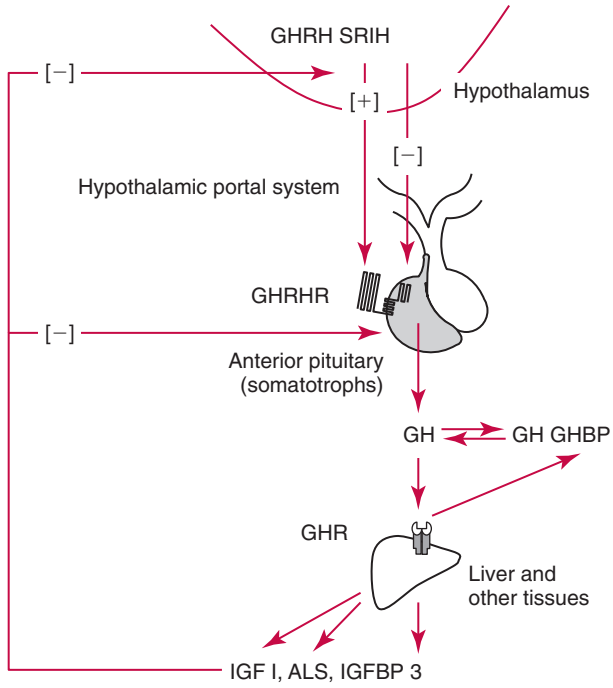

Figure 53-5 The hypothalamus secretes growth hormone–releasing hormone (GHRH) and somatotropin release–inhibiting hormone (SRIH; somatostatin), which regulate growth hormone (GH) release. The receptor for GHRH (GHRHR) is illustrated because mutations in this receptor can cause some forms of inherited GH deficiency. GH circulates unbound and bound to its binding protein (GHBP). GHBP is the extracellular domain of the GHR, which is cleaved from the GHR to circulate in the plasma. GH releases insulin-like growth factor-I (IGF-I), insulin-like growth factor binding protein 3 (IGFBP-3) and the acid-labile subunit (ALS). IGF-I negatively feeds back at the anterior pituitary somatotrophs and at the hypothalamus. Because transection of the pituitary stalk leads to GH deficiency, the predominant hypothalamic control of GH is stimulatory via GHRH.

not distinguish GH insufficiency from normal production of the hormone. During daytime hours, the plasma concentration of GH in healthy adults remains stable and relatively low (<2 µg/L), with several secretory spikes occurring approximately 3 hours after meals (particularly meals high in protein and arginine) and after exercise. In contrast, during the evening hours, adults and children show a marked rise in GH secretory activity ≈90 minutes after the onset of sleep; GH concentrations reach a peak value during the period of deepest sleep. This pattern of GH secretion may be important for anabolic and repair processes, and for proper skeletal growth. GH is also increased by psychologic or physical stress and hypoglycemia. Normal GH secretion requires thyroxine and age-appropriate concentrations of testosterone or estrogen.

GH is suppressed by elevations in blood glucose. One of the tests for GH excess measures GH following an oral glucose load; the normal response is a GH concentration of less than 1 to 2 µg/L, depending on the lower limit of detection of the GH immunoassay (Box 53-1). GH also declines with increases in free fatty acid concentrations, rapid eye movement sleep, and aging. In the presence of abnormally high concentrations of glucocorticoids, GH secretion is suppressed. In addition, circulating GH is thought to influence the release of hypothalamic hormones through the short feedback loop. Other hypothalamic hormones, such as TRH and GnRH, do not affect GH release in normal subjects but may provoke GH release in patients with acromegaly.

Age-associated decline in GH production has spawned an industry of dietary supplements purported to "support" growth hormone secretion.[97] These supplements are amino acid preparations that theoretically stimulate release of the subject's own GH. Such dietary supplements have no proven medical value. Use of GH by athletes to enhance strength or promote recovery from injury is prohibited in most sports.

The role of non-GHRH GH secretogogues (e.g., ghrelin, various synthetic hexapeptides) in the physiologic control of GH and growth is highly debated.[6] One such secretogogue is ghrelin (28 amino acids, 3.4 kDa; gene name: *GHRL;* chromosome 3p2). Although ghrelin is produced in the hypothalamus, its highest concentration is found in stomach tissue. In addition, ghrelin is widely distributed in the gastrointestinal tract, heart, lung, and adipose tissue. Ghrelin appears to stimulate food intake and obesity.[65]

Ghrelin binds to the somatotroph GH-secretogogue receptor (gene name: *GHSR;* isoform 1A: 366 amino acids, 41 kDa; isoform 1B: 289 amino acids, 32 kDa; chromosome 3q26.31), which is distinct from the GHRHR. *GHRL,* the gene that encodes ghrelin, also encodes the 23 amino acid peptide obestatin. Obestatin may decrease food intake and increase

BOX 53-1 Protocol for Glucose Suppression of Growth Hormone Test

Rationale
Normal subjects show suppression of serum growth hormone (GH) concentrations after oral administration of glucose. Subjects with acromegaly fail to exhibit appropriate GH suppression.

Procedure
The test should be performed after an overnight fast with the patient maintained at bed rest. After a baseline blood specimen is collected for GH and glucose measurement, a solution of 75 g of glucose is given orally. Glucose and serum GH are measured again on specimens collected 30, 60, 90, and 120 minutes later.

Interpretation
Serum GH concentrations in normal individuals fall to less than 1 to 2 µg/L (i.e., below the lower limit of detection of the GH assay used). Subjects with acromegaly fail to show this suppression and sometimes show a paradoxical increase in GH concentration. Patients with liver disease, uremia, or heroin addiction may have false-positive results with this test (failure to suppress serum GH concentrations after oral glucose load).

satiety, but this has been debated. Obestatin is a ligand for the orphan GPR39 receptor (453 amino acids, 51 kDa; chromosome 2q21). However, despite obestatin binding to the GPR39 receptor, receptor activation may not follow.[133]

Physiologic Actions

GH effects can be classified as indirect or direct.[173] GH directly raises blood glucose by stimulating gluconeogenesis and reducing insulin sensitivity. Also, it causes adipose tissue lipolysis and the resulting GH-induced elevations in free fatty acids provide an alternative energy source that serves to spare glucose for CNS utilization. Therefore when glucose and free fatty acid concentrations are raised at times of stress, in partnership with epinephrine, glucagon, and cortisol, fuels for the fight-or-flight response are provided. GH has other effects on intermediary metabolism: GH stimulates the uptake of nonesterified fatty acids by muscle and accelerates the mobilization and metabolism of fat from adipose tissue to the liver.

At the epiphysis of growing bone, GH promotes epiphyseal prechondrocyte differentiation. GH directly stimulates the production of IGF-I, IGFBP-3, and the acid labile subunit (ALS). In turn, after entering the interstitium, unbound IGF-I binds to type I IGF receptors.

Indirect effects of GH are mediated through IGF-I production, which (together with GH) is necessary for linear growth in childhood. IGF-I is mitogenic and antiapoptotic. Epiphyseal prechondrocyte differentiation stimulated by GH, along with the local effects of IGF-I (also under the control of GH), stimulates the clonal expansion of differentiating chondrocytes.

Thus, the overall effect of GH is to promote growth in soft tissue, cartilage, and bone. This action results from stimulation of protein synthesis that is induced in part by an increase in amino acid transport through cell membranes. The effects of GH on bone and muscle are exerted both directly and through the effects of IGF-I under the influence of GH. Increased growth of soft tissue and the skeleton is accompanied by changes in electrolyte metabolism, including positive nitrogen and phosphorous balance, a rise in plasma phosphorous concentration, and a fall in blood urea and amino acid concentrations. Additional responses to GH include increased intestinal absorption of calcium and decreased urinary excretion of sodium and potassium. The metabolic changes most likely are caused by increased uptake of these ions by growing tissue.

IGF-I increases glucose oxidation in adipose tissue and stimulates glucose and amino acid transport into diaphragmatic muscle and heart muscle. Synthesis of collagen and proteoglycans is enhanced by IGF-I, which also has positive effects on calcium, magnesium, and potassium homeostasis. The insulin-like effects of this growth factor have been ascribed in part to its structural similarity to insulin.

Evidence indicates that the local effects of IGF-I (autocrine or paracrine) are predominant in stimulating growth, when compared with the systemic effects of IGF-I produced by the liver. When the hepatic *IGF-I* gene was knocked out in mice (although nonhepatic tissues expressed IGF-I), growth was normal, and IGFBP-3 and ALS concentrations were low. IGF-I may function as a growth factor in utero; however, its secretion in utero is not under the control of GH.

In the absence of GH, IGF-I is not as effective a growth stimulant as it is when both are present. IGF-I treatment alone is not recommended as therapy for GH deficiency; IGF-I therapy is reserved for cases of GH resistance due to GHR deficiency.[95]

GH (through IGF-I) and insulin induce growth in a similar manner because both have protein anabolic effects and stimulate the transport of amino acids into peripheral cells. Their respective effects on glucose homeostasis, however, oppose each other. Most growth-promoting GH effects are delayed rather than immediate and are exerted primarily through IGF-I.

IGF-I concentrations vary widely with age and gender.[83] IGF-I rises during childhood, and during puberty, IGF-I concentrations can be two to three times the adult concentration. Following adolescence, IGF-I concentrations show a gradual decline, reaching a steady state in the third decade of life.

GH is not the only determinant of IGF-I concentration in the circulation. Transformation of the GH stimulus to IGF-I production and secretion is modulated by (1) nutrition, (2) the presence or absence of chronic inflammation, (3) thyroid function, (4) glucocorticoids, and (5) sex steroids. IGF-I secretion is reduced by (1) malnutrition, (2) malabsorption (e.g., inflammatory bowel disease), (3) celiac disease, (4) cystic fibrosis, (5) chronic disease, (6) hypothyroidism (e.g., Hashimoto thyroiditis), and (7) sex hormone deficiency during adolescence. Therefore a decreased IGF-I concentration is not necessarily synonymous with GH deficiency.

In cases of acquired GH resistance and genetic GH resistance (*GHR* mutation or signaling disorder), GH concentrations will rise, and high concentrations of GH produce hyperlipidemia and hyperglycemia.[75] Cases of acquired GH resistance are not treated with GH or IGF-I, but instead are treated through resolution of the underlying disorder.

The actions and regulation of IGF-II have been debated.[160] IGF-II is believed to be important for intrauterine growth. Mice display intrauterine growth retardation when the IGF-II gene is knocked out. Although IGF-II–producing tumors are very rare, such tumors can produce hypoglycemia. The tumors produce an aberrant form of IGF- II ("big" IGF-II) that does not associate normally with IGFBPs. The production of big IGF-II, in combination with a reduction in an IGFBP concentration, results in higher concentrations of free IGF-II, which causes hypoglycemia by associating with the insulin receptor. Both IGF-I and IGF-II are of great interest to cancer researchers, but a detailed discussion of this topic is beyond the scope of this chapter.

Clinical Significance

Clinically important states of GH excess or deficiency are uncommon and are often difficult to diagnose.[90] GH concentrations vary widely under normal circumstances; therefore random measurements of GH, in general, are not diagnostically useful. A single GH measurement cannot distinguish

between normal fluctuations and the low or high concentrations that are typical of various diseases. GH measurements are best determined as part of dynamic testing: physiologic or pharmacologic provocative stimuli are used to help diagnose GH deficiency, whereas GH suppression (or lack thereof) following glucose administration is useful in evaluating GH excess.[71] IGF-I concentrations often correlate better with the clinical severity of acromegaly than with glucose-suppressed or basal GH concentrations.[49]

In contrast to GH, a single measurement of IGF-I is considered to be an accurate reflection of GH-IGF-I production, irrespective of the time of the day or meals. IGF-I has a much longer half-life than GH, so its concentration is more stable. The half-life of GH is slightly longer than 15 minutes, whereas the half-life of the trimeric IGF-I-IGFBP-3-ALS complex is 17 to 22 hours. The half-life of unbound IGF-I is only 10 to 20 minutes, but the unbound form of the hormone accounts for less than 1% of the total concentration. Serum concentrations of IGF-I are influenced by (1) age, (2) gender, (3) degree of sexual maturity, (4) thyroid status, and (5) nutritional status. As mentioned previously, IGF-I concentrations are low in GH deficiency and in patients with acute or chronic protein or caloric deprivation. In pediatric endocrinology, measurements of IGFBP-3 have been used in addition to IGF-I measurements to assess GH; however, the value of this approach has not been established. The diagnostic use of GH to stimulate IGF-I production is controversial and is not currently included in standard medical practice.[161]

Growth Hormone Excess

Acromegaly is the rare clinical syndrome in adults that results from GH excess.[57,214] Even less common is gigantism, which results from GH excess in childhood. The clinical features of acromegaly involve overgrowth of the skeleton and soft tissue, producing (1) acral enlargement (enlargement of the extremities), (2) organomegaly (enlarged heart and/or liver), (3) facial coarsening, (4) intestinal polyposis, (5) premature cardiovascular disease, (6) hyperhidrosis (increased sweating), (7) skin tags, (8) joint disease, (9) myopathy with weakness, (10) insulin resistance, and often (11) diabetes mellitus. Premature cardiovascular disease is the most common cause of death in individuals with acromegaly. Gigantism is characterized by extreme tall stature, in addition to the clinical features of acromegaly, as pathologic GH excess occurs before epiphyseal fusion is complete.

Most cases of acromegaly (≈95%) result from anterior pituitary GH-secreting tumors (somatotropinomas).[58] Somatotropinomas are usually large macroadenomas (>10 mm in diameter); approximately 75% of these tumors are visualized by computed tomography (CT) or magnetic resonance imaging (MRI) (the preferred method for pituitary imaging is MRI). Some anterior pituitary tumors secrete both GH and prolactin (somatomammotropinomas). Approximately 5% of acromegaly cases result from GHRH-secreting hypothalamic tumors, and less than 1% of cases result from extrapituitary somatotropinomas, GHRH-secreting islet cells, or lung or breast tumors.

In severe or advanced cases of GH excess, the diagnosis may be nearly certain on the basis of physical appearance alone. However, in less severe or early cases, the physical changes may be subtle and gradual, so a high degree of clinical suspicion is needed to make an early diagnosis. The reversibility of tissue changes depends largely on the duration of the disease. In addition to soft tissue changes, acromegaly may cause severe disability or death from cardiac, pulmonary, and/or neurologic sequelae. The most important requirement for the diagnosis of acromegaly is the demonstration of inappropriate and excessive GH secretion.[150]

As many as 10% of patients with active acromegaly have random serum GH concentrations that fall within the normal reference interval. Essentially all patients with acromegaly have an abnormal GH response to oral glucose (53-1). Patients with acromegaly typically show no change in their basal concentration of GH or demonstrate a paradoxical increase in GH[70]; normal individuals, on the other hand, show suppression of GH concentrations to less than 1.0 μg/L after the oral glucose load. Serum IGF-I concentrations are also elevated in active acromegaly, and often correlate better with the clinical severity of acromegaly than do glucose-suppressed or basal GH concentrations.

Growth Hormone Deficiency and Growth Retardation

In children, short stature with a normal growth velocity (≥4 to 5 cm/y) results from (1) familial short stature, (2) primordial growth failure (prenatal-onset growth failure), or (3) constitutional delay in growth and adolescence (delayed maturation). Short stature with a low growth velocity (<4 to 5 cm/y) results from genetic short stature, chronic illness, malnutrition, deprivation (nutritional or psychologic), Turner syndrome in girls, or endocrine disorders (e.g., hypothyroidism, disorders of the GHRH-GH-IGF-I axis, poorly controlled diabetes, rickets, pseudohypoparathyroidism, pseudopseudohypoparathyroidism, and Cushing syndrome).[167]

GH deficiency is not a common cause of growth retardation. About one half of children evaluated for growth retardation have no specific organic cause; about 15% have an endocrine disorder, of which approximately half (about 8% of all children with short stature) have GH deficiency. However, short children with low growth velocities with no clear explanation should be screened for GH deficiency once hypothyroidism has been excluded.

GH deficiency in children is characterized by (1) short stature, (2) low growth (3) velocity, (4) immature facial appearance, (5) retarded bone age on radiologic examination, and (6) increased adiposity. In cases of congenital GH deficiency, size at birth is usually normal because in utero, IGF-I does not appear to be under GH control. Micropenis (an abnormally short penis) is evident in some boys with congenital GH deficiency and will resolve with GH replacement in childhood. Adults with GH deficiency experience (1) reduced muscle mass, (2) increased adiposity, (3) osteoporosis with decreased bone density, (4) an increase in fracture risk, (5) decreased quality of life, (6) dyslipidemia,

TABLE 53-5 GH Deficiency of Genetic Etiology

Gene/Classification/Inheritance	Mutation	Phenotype
GH1; IA; AR	Deletion, FS, NS	Absent GH expression; immune resistance to GH treatment is common
GH1; IB; AR	Splicing?	Reduced GH; responds to GH treatment*
GHRHR; IB; AR	Possible MS	Reduced GH; responds to GH treatment*
GH1; II; AD	DN	Reduced GH; responds to GH treatment; MPHD is possible
Unknown; III; XLR	—	Reduced GH; responds to GH treatment; agammaglobulinemia is possible

*One third of heterozygotes may be short.
AD, Autosomal dominant inheritance; *AR,* autosomal recessive inheritance; *DN,* dominant negative; *FS,* frameshift; *MS,* missense mutation; *NS,* nonsense mutation (stop codon); *XLR,* X-linked recessive; *?,* otherwise not defined.

and (7) an increased risk for cardiovascular disease.[113] GH deficiency is probably the most common identifiable abnormality in adults with large pituitary adenomas[33] and in patients who have undergone pituitary irradiation. Thus GH replacement therapy is an important clinical intervention in GH-deficient adults and children and is considered the standard of care.

GH insufficiency can be a consequence of (1) hypothalamic disease, (2) disruption of the portal system between hypothalamic nuclei and the anterior pituitary, (3) GHRHR loss-of-function mutations, or (4) somatotroph disease. GH deficiency can occur in isolation [isolated GH deficiency] or together with other pituitary deficiencies [multiple pituitary hormone deficiencies (MPHD) or combined pituitary hormone deficiencies (CPHD)]. Patients with isolated GH deficiency should be followed clinically for the development of other pituitary hormone deficiencies because MPHD can evolve over time. Biochemical testing is necessary to establish the diagnosis of GH deficiency, growth hormone resistance, or MPHD. In most affected children, the cause of GH deficiency is unknown [idiopathic GH deficiency].[159] Approximately one in four children with proven GH deficiency has an organic origin for their GH deficiency; half of these children will be diagnosed with a CNS tumor.

Any type of hypothalamic disease or dysfunction can lead to GHRH deficiency, including (1) tumor, (2) inflammation, (3) previous infection, (4) trauma (including previous surgery),[124] (5) bleeding, (6) irradiation, and (7) malformation [septo-optic dysplasia (SOD)].[116] Low-dose irradiation of the hypothalamus/pituitary can cause idiopathic GH deficiency, whereas higher doses of irradiation can cause MPHD. SOD is defined by the triad of (1) midline brain defects such as agenesis of the septum pellucidum and/or corpus callosum, (2) hypoplasia of the optic nerve, and (3) anterior and/or posterior pituitary hormone abnormalities. A small number of cases of SOD are explained by mutations in *HESX1, SOX2,* and *SOX3,* all of which are transcription factors. *HEXS1* (chromosome 3p14.3) is a paired-like homeobox gene, *SOX2* (chromosome 3q26.3) is the SRY (sex-determining region on the Y chromosome) box 2 gene, and *SOX3* (chromosome Xq27.1) is the SRY box 3 gene. Midline brain tumors, such as meningiomas, gliomas, germinomas, third ventricle colloid cysts, ependymomas, and optic nerve gliomas, also affect the hypothalamus. Disruptions in the hypothalamic-pituitary portal system can result from tumor, inflammation, previous infection, trauma (including previous surgery), and irradiation.

Congenital GH deficiency from pituitary disease has many causes, including *GHRHR* gene mutations (idiopathic GH deficiency type IB), *GH1* mutations (idiopathic GH deficiency types IA, IB, II, and III, and bioinactive GH), and transcription factor mutations (usually causing MPHD: *LHX3, LHX4, PROP1, Pit-1, RIEG*) and malformations (anencephaly and holoprosencephaly) (Table 53-5).[168] Homozygous *LHX3* mutations have caused panhypopituitarism, with the exception that ACTH was not affected. Heterozygous *LHX4* mutations have caused deficiencies of GH, TSH, and ACTH. *PROP1* (name derived from "PROphet of Pit-1"; POU1F1; Pit-1 stands for "paired-like homeodomain transcription factor")[157] mutations causes deficiencies of GH, prolactin, TSH, and gonadotropins. ACTH deficiency has also occurred in some families. *PROP1* gene mutations are inherited as autosomal recessive traits. *Pit-1* gene mutations cause GH, prolactin, and variable degrees of TSH deficiency. These transcription factor mutations may be inherited as autosomal recessive or dominant traits. Heterozygous *RIEG* gene mutations (*PITX2,* a paired-like homeobox gene) are the cause of Rieger syndrome, which may include GH deficiency. Features of Rieger syndrome encompass developmental abnormalities of teeth, the anterior chamber of the eye, and the umbilicus. Mutations in *GLI1, GLI2, Shh, ZIC2, SIX3, tgif, PATCHED1, DGF1,* and *FAST1* have variously been cited as causes of holoprosencephaly.[88] Children with midline facial clefts (cleft lip, cleft palate, or combined) or a single central incisor can exhibit GH deficiency. Two *GH1* gene mutations have been identified to cause bioinactive GH.[189] In these mutations, GH does not have full biological activity but retains normal immunoreactivity. Therefore, in contrast to other forms of pituitary or hypothalamic disease, the GH concentration is not deficient. At least one reference laboratory provides *GHRHR, GH1,* and *GHR* gene sequencing services (Athena Diagnostics, Worcester, Mass).[7,62,207]

Acquired causes of pituitary disease include (1) tumor (craniopharyngioma, Rathke cleft cyst, arachnoid cyst, or anterior pituitary adenoma), (2) infiltrative disease—amyloidosis, (3) inflammation (autoimmune hypophysitis and granulomatous inflammation), (4) infection, (5) trauma (including surgery), (6) bleeding, (7) irradiation, (8) infarction (pituitary apoplexy from Sheehan syndrome), and (9) metabolic derangement (hemochromatosis, iron overload from long-term transfusion therapy, or certain anemias, such as sideroblastic anemia).[5] Hemochromatosis does not cause hypopituitarism until many decades have passed.[35] Some investigators believe that all patients with "idiopathic" hypopituitarism should be screened for hemochromatosis.[141]

A staged approach to the evaluation of GH secretion is advised.[166] Initial screening can involve one of the following tests: (1) measurement of IGF-I (with or without IGFBP-3), (2) GH measurement following exercise, or (3) pharmacologic GH screening. All forms of GH testing should be performed after the subject has fasted overnight. If a GH screening test is abnormal, definitive testing should be pursued.[201] If GH adequacy is demonstrated by GH screening tests, definitive GH testing need not be performed unless there is a very high index of suspicion for GH deficiency. In children, the likelihood of a falsely abnormal GH screening test can be reduced by pretreatment of both boys and girls with a short course of sex steroids [ethinylestradiol: for body weights <50 lb, 20 μg/dose 18 hours, 12 hours, and 1 hour before testing; for body weights ≥50 lb: 50 μg/dose 18, 12, and 1 hour before testing, or 100 μg/d for 3 days; Premarin: for body weights <30 lb: 2.5 mg twice daily for 3 days; for body weights ≥30 lb, 5 mg twice daily for 3 days; diethylstilbestrol (DES): 5 mg/d for 3 days; or, exclusively in boys, testosterone enanthate 50 mg injected intramuscularly 2 or 3 weeks before testing]. The mechanism is unclear; however, sex steroids appear to play a major role in increasing the response of IGF-I to GH at the time of puberty. From clinical experience, GH deficiency is overdiagnosed in some peripubertal children who are tested without the benefit of sex hormone priming.

Exercise physiologically enhances GH release.[72] Typically, in the fasting state, the subject exercises vigorously for ≈20 minutes (e.g., running up and down stairs, running on a treadmill). At the completion of the exercise, when the subject is tachycardic and sweating, a sample is collected for GH measurement (Box 53-2). A baseline GH measurement is not required. A GH concentration may also be obtained 40 minutes after exercise, in case of delayed GH release. Finally, screening for GH deficiency can be performed by measuring GH 60 to 90 minutes following clonidine, glucagon, or L-dopa administration. (*Note:* L-dopa is not currently available in the United States.) Doses of clonidine, glucagon, and L-dopa are identical to doses used in formal GH testing scenarios (see later).

It has been argued that measuring GH during sleep is a physiologic assessment of the hypothalamic-somatotroph-GH axis. Some authorities suggest electroencephalographic (EEG) monitoring with GH measured during deep sleep (e.g., stage III, stage IV). More simply, GH could be measured 1 hour after the onset of sleep. However, in reality these types of sleep studies are cumbersome because they require hospitalization or overnight boarding in a sleep laboratory. In practice, this is rarely done. Furthermore, the high cost of hospitalization or the sleep laboratory suggests that an exercise tolerance test or a simple pharmacologic stimulus would be a more cost-effective approach to initial GH testing.

Reference intervals for IGF-I and IGFBP-3 are age and gender dependent.[73] If IGF-I is within its reference interval for age and gender in children, GH deficiency is excluded. If IGF-I is low, definitive GH testing is required. Because IGF-I concentrations can be depressed in states of (1) malnutrition, (2) malabsorption, (3) chronic disease, (4) hypothyroidism, and (5) sex hormone deficiency, a low IGF-I concentration does not confirm GH deficiency. IGFBP-3 is less dependent on good nutrition to achieve normal concentrations, so it may be a superior marker of GH deficiency compared with IGF-I. However, one study failed to demonstrate that measuring IGFBP-3 alone or together with free IGF-I was superior to measuring IGF-I alone as a screening test for GH deficiency.[48] In another study, only ≈50% of GH-deficient children had a low IGFBP-3 concentration; this finding calls into question its value as a sensitive screening test.[198]

Analytical advantages of IGFBP-3 over IGF-I include the following: (1) IGF-I must be separated from its binding proteins to be measured, but IGFBP-3 does not require a dissociation step; (2) IGFBP-3 is present in higher concentration than IGF-I; and (3) less age dependency is seen for IGFBP-3 compared with IGF-I.[47] Because of their stability over the course of a day, IGF-I and IGFBP-3 measurements may be obtained randomly. However, some researchers have concluded that IGFBP-3 measurements are too nonspecific to be used for the evaluation of GH deficiency.[45] Furthermore, reports indicate that IGF-I and

BOX 53-2 Protocol for the Exercise Stimulation Test for Growth Hormone

Rationale
Brisk exercise normally causes an increase in serum growth hormone (GH) concentrations.

Procedure
The test is best performed in the morning after an overnight fast, but may be done at any time. Vigorous physical exercise (running or calisthenics) is performed for 20 minutes. A venous blood specimen for determination of GH is drawn immediately after termination of exercise.

Interpretation
If the serum GH concentration is 7 to 10 μg/L or greater (depending on the specific GH immunoassay used), GH deficiency is unlikely in children. A normal response in adults is a GH concentration of 5 μg/L or greater. In children, a single subnormal response is not diagnostic for GH deficiency and should be confirmed with a second provocative test.

BOX 53-3 Protocol for the Insulin-Induced Hypoglycemia Stimulation Test [Insulin Tolerance Test (ITT)]

Rationale
The stress of insulin-induced hypoglycemia triggers the release of growth hormone (GH) and adrenocorticotropin hormone (ACTH) from the pituitary gland in normal subjects. The GH response is measured directly. Cortisol is measured as the indication of the ACTH response.

Procedure
The test is done after an overnight fast with the patient at bed rest. An indwelling intravenous line is inserted. Sampling is begun after a 30 minute rest period. Baseline samples are drawn for determination of glucose, GH, and cortisol. Regular insulin, 0.1 to 0.15 units/kg body weight, is injected intravenously. Samples are then obtained at +10, +20, +40, and +60 minutes for glucose, GH, and cortisol determinations. Optional time points are +30, +75, +90, and +120 minutes. To be confident that adequate stress has been applied, the patient must become symptomatic (exhibit sweating or tremor), or the glucose concentration must fall to below 40 to 45 mg/dL. Additional IV insulin may be given if this has not occurred by 30 minutes, in which case sampling should be prolonged by 30 minutes. The physician should be in attendance throughout the test, and 50% dextrose for IV administration should be kept on hand to be used in the event of severe hypoglycemic reaction and after adequate hypoglycemia has been documented. Glucagon (1 mg) should be available for parenteral administration in case IV access is lost. The test is contraindicated in patients with seizure disorder, ischemic heart disease, or cardiovascular insufficiency.

Interpretation
The serum cortisol concentration should increase to a peak value of 18 to 20 μg/dL or greater. The serum GH concentration should rise to a peak value of 7 to 10 ng/mL or greater. No response or inadequate response may be due to pituitary hormone deficiency or a hypothalamic lesion.

IGFBP-3 exhibit imperfect sensitivity and specificity for the diagnosis of GH deficiency.[169]

IGF-I measurements in adults often are not diagnostically helpful.[130] For reasons that are unclear, IGF-I concentrations can be normal in GH-deficient adults. Therefore, a normal IGF-I does not rule out adult GH deficiency. If the IGF-I concentration is very low and suspicion for GH deficiency is high (MPHD or childhood-onset severe GH deficiency), some experts would diagnose GH deficiency in the absence of GH testing.[87]

GH responses to insulin-induced hypoglycemia [insulin tolerance test (ITT); Box 53-3] and GH responses to centrally acting pharmacologic or biological agents (Box 53-4) are considered definitive tests. The stimuli can be sequential or administered on different days. The classical diagnosis of pediatric GH deficiency requires that GH responses to two different stimuli (Table 53-6) be deficient. In research settings, GHRH and GHRP-6 have been used to stimulate GH

BOX 53-4 Protocol for the Arginine Stimulation Test for Growth Hormone

Rationale
In normal subjects, IV administration of arginine hydrochloride stimulates growth hormone (GH) release.

Procedure
The test should be done after an overnight fast with the patient maintained at bed rest. A 10% solution of arginine hydrochloride, 0.5 g/kg body weight (maximum dose = 30 g), is infused intravenously over 30 minutes. Blood samples are drawn for determination of GH before the infusion is started, and 30, 60, and 90 minutes after the infusion is begun. Optional time points are +15 and +120 minutes.

Interpretation
The serum GH concentration should rise to a peak value of 7 to 10 ng/mL or greater. A subnormal response is seen in GH-deficient subjects, but a single subnormal GH response is not diagnostic for GH deficiency and should be confirmed with a second provocative test.

TABLE 53-6 Growth Hormone (GH) Stimuli

GH Stimulus	Dose	GH Sampling, Minutes*
Glucagon	0.03-0.1 mg/kg, IM, max 1 mg	0, 30, 60, 90, 120, 150, 180, ±240 (maximum response ≈2-3 hours)
L-dopa	500 mg/M^2 (15 mg/kg) max 500 mg (or) <15 kg: 125 mg 15-30 kg: 250 mg >30 kg: 500 mg	0, 40, 60, 90, 120
Clonidine	0.15 mg/M^2 <30 lb: 0.05 mg >30 lb: 0.1 mg (0.1 mg/tab)	0, 30, 60, 90
Arginine HCl	0.5 g/kg, max 30 g (10% solution IV over 30 min)	0, ±15, 30, 60, 90, ±120
Insulin tolerance test (ITT)	0.1 U/kg (0.05-0.15) IV push insulin	0, 10, 20, ±30, 40, 60, ±75, ±90, ±120
Arginine-insulin tolerance test (AITT)	Arginine: begin at time zero, give insulin at +60 minutes	0, 30, 60, 70, 80, 100, 120

*Experts may differ on the best interval of GH measurements; ± indicates an optional time point.

release. However, because these agents are not available for clinical use, they are not included in Table 53-6. Note that many variations of these protocols are available because endocrinologists often customize these tests. Diazepam and pentagastrin have been studied as GH secretogogues; however, experience with these agents is limited, and they are not included in Table 53-6.

Of children with appropriate stature for age, approximately 80% will have normal GH responses to one stimulus, and at least 95% will have normal GH responses to at least one of two stimuli. This is why two stimuli are generally recommended—to avoid overdiagnosis of GH deficiency. However, the GH Research Society advises that a single definitive abnormal test is adequate to diagnose GH deficiency if the child has (1) confirmed CNS pathology, (2) a history of CNS irradiation, (3) multiple pituitary hormone deficiencies, or (4) a genetic defect.[1]

A history of childhood GH deficiency, CNS disease, trauma, or irradiation is an indication to test adults for GH deficiency.[39,190] Retesting of adults with the diagnosis of childhood GH deficiency is necessary because not all adults with childhood GH deficiency remain deficient as adults. In adults, a single abnormal GH response to a stimulus is diagnostic of GH deficiency if the deficiency is congenital or genetic, or if multiple pituitary hormone deficiencies are due to organic disease. Guidelines published in 2009 recommended that a low IGF-I concentration in a patient with three or more pituitary hormone deficiencies is sufficient to diagnose GH deficiency.[8] Unfortunately GH testing is not very reproducible.[103]

Insulin-induced hypoglycemia (ITT) is often considered to be the "gold standard" stimulus when hypoglycemia is indeed achieved (glucose <40 to 45 mg/dL).[112] The risk associated with this type of test is that untreated severe hypoglycemia can be life threatening. Venous access for infusion of glucose is very important during the ITT. Should vascular access be lost during the ITT, glucagon should be readily available for IM injection (the dose of glucagon is 1 mg). If intravenous access cannot be ensured, stimuli other than insulin should be considered. In general, GH stimulation tests are not conducted by laboratory personnel because of the risks and complexities of testing. Arginine infusion presents the danger of acidosis and even death.[183]

Stimulated GH concentration less than 7 to 10 μg/L defines GH deficiency in children.[26] In adults, GH deficiency is present when stimulated GH is less than 5 μg/L. GH deficiency in adults can be parsed according to the stimulus. For ITTs, a deficient peak GH response is less than 3 μg/L. For GHRH plus arginine, a deficient peak GH response is less than 11 μg/L when the body mass index (BMI) is less than 25 kg/m^2. However if the BMI is 25 to 30 kg/m^2, deficient is defined as less than 8 μg/L, and for BMI greater than 30 kg/m^2, deficient is identified at less than 4 μg/L. Because GHRH is not commercially available, and clonidine and arginine alone are not helpful in defining GH deficiency in adults, the ITT remains the best test of GH secretion in adults.

Controversy continues as to what constitutes a "normal" GH response to stimuli, because insulin-induced hypoglycemia is considered by some to be a nonphysiologic stimulus. Discordance between normal stimulated GH concentration and a deficient spontaneous rise in GH concentration has been described as neurosecretory GH deficiency.[53] Neurosecretory GH deficiency can result from CNS or hypothalamic disease. The diagnosis of neurosecretory GH deficiency requires overnight, every 20 minute blood sampling with GH measurements—a protocol that ordinarily requires hospitalization. The combined costs of GH assays, physician fees, and inpatient services would exceed several thousand dollars.

The definition of *partial GH deficiency* is especially problematic because the definition of *simple GH deficiency* is itself controversial.[91,110] Eliminating GH stimulation testing has been proposed, with the diagnosis of GH deficiency based on growth parameter, IGF-I and IGFBP-3 measurements, neuroradiologic investigation, and genetic considerations.[14,137,211]

Growth Hormone Resistance

In children with short stature and low growth velocity, if IGF-I is (1) below the reference interval for the child's bone age and gender, (2) if the GH concentration is normal or elevated, and (3) if non–GH-dependent causes of IGF-I deficiency (malnutrition, malabsorption, chronic disease, hypothyroidism, and sex hormone deficiency compared with the patient's bone age) have been excluded, GH resistance should be considered.[171] As uncommon as GH deficiency is in the general pediatric population (1 in 10,000 children), GH resistance as a primary problem is far less frequent.

GH resistance can be congenital, resulting from loss-of-function *GHR* mutations or GHR signaling defects (*STAT5b* mutations),[123,215] or from defects in the production of IGF-I itself. Most *GHR* mutations involve the extracellular domain that involves GH binding to the GHR. Some *GHR* mutations affect homodimerization. Loss of the intracellular GHR domain can result from splice-site mutations. GHR is not expressed on the cell surface if the transmembrane domain is defective. Recall that circulating GHBP is derived from the extracellular domain of the GHR. Most cases of GHR deficiency display low or absent concentrations of GHBP. STAT5b is necessary for normal GH-GHR signaling to the cell nucleus. These are autosomal recessive disorders. Size at birth is normal because in utero IGF-I production is independent of GH.

IGF-I gene inactivating mutations or deletions are rare, and only two such mutations have been described. In contrast to GH receptor and signaling defects, when IGF-I itself cannot be produced because of intrinsic *IGF-I* gene mutations, intrauterine growth retardation will result, in addition to extrauterine growth failure. Other consequences of *IGF-I* gene mutations include severe mental retardation, deafness, and micrognathia (mandibular hypoplasia).[206,216]

IGF-I and IGFBP-3 concentrations are very low in rare cases of ALS deficiency, while baseline and poststimulation

GH concentrations are normal.[67] Although adolescence was delayed, adult stature was nearly normal in persons with ALS deficiency.

Acquired GH resistance is far more common than congenital GH resistance. In cases of acquired GH resistance, the IGF-I is low (despite sufficient GH secretion) because of malnutrition, malabsorption, chronic disease, hypothyroidism, or sex hormone deficiency. An acquired form of GH resistance is also observed in patients with idiopathic GH deficiency type I, who develop GH-inhibitory antibodies when treated with exogenous GH. Because GH is absent in this form of congenital GH deficiency, exogenous GH is seen by the immune system as foreign. Apparently, the resulting antibodies directed against exogenous GH bind to, and inactivate, the GH. This is reminiscent of the development of factor VIII antibodies in some boys with severe hemophilia A, who are treated with exogenous factor VIII.

A number of criteria for GH resistance have been proposed, including (1) height more than 3 standard deviations below the mean for age; (2) basal GH greater than 2.5 ng/mL; (3) basal IGF-I less than 50 ng/mL; (4) basal IGFBP-3 more than 2 standard deviations below the mean for age; (5) an increase in IGF-I of less than 15 ng/mL after 4 days of GH treatment (0.05 mg/kg/d); and (6) increase in IGFBP-3 of less than 0.4 μg/mL after GH treatment. The largest concentrations of subjects with GH resistance are found in Israel and southern Ecuador.[170]

IGF-I Resistance

Even less common than GH resistance as a cause of growth failure is IGF-I resistance.[3,76] IGF-I resistance is characterized by growth failure despite elevations in GH and IGF-I. In contrast to GH deficiency and GH resistance states, and in common with *IGF-I* gene mutations, IGF-I resistance causes intrauterine growth retardation and growth failure in childhood. IGF-I resistance can result from mutations in the type I IGF receptor (IGFR), or from downstream signaling mutations.

Rare cases of familial short stature have been ascribed to hemizygosity for the type I IGF receptor gene.[205] Approximately 1 in 50 children with intrauterine growth retardation, short stature, and normal IGF-I concentrations have heterozygous type I IGF receptor mutations.

Measurement of Growth Hormone in Blood

Development of immunochemical methods for measuring GH has followed the same path as those for most other peptide hormones, progressing from radioimmunoassay to immunoradiometric assay, and then to nonisotopic methods involving two antibodies and enzyme, fluorescent, or chemiluminescent labels. Today, a variety of isotopic and nonisotopic assays are commercially available; most of the modern GH assays use mouse monoclonal antibodies and recombinant-derived GH as the competing (labeled) antigens, or as calibrators. Gravimetrically prepared international reference preparations (IRPs), such as the World Health Organization (WHO) international standard of IRP 80/505 human growth hormone recombinant (hGHr), which has a potency of 3.3 IU/mg of r-hGH, or other reference preparations, such as WHO IRP 66/217 or 88/624, have been developed. An international collaborative group currently recommends use of the WHO IRP 98/574 to harmonize GH assays,[196] and at least one commercially available two-site noncompetitive immunoassay has been harmonized to this IRP.[17]

Noncompetitive two-site immunoassays for GH are widely available; most include monoclonal antibodies coupled to an enzyme, chemiluminescent, or fluorescent label. The most sensitive of these GH assays have a detection limit of 1 to 2 μg/L. Of note, although GH is filtered in the glomerulus and excreted in the urine, measurement of urinary GH concentration is not clinically useful.

Analytical Challenges

GH is not a single molecular species, but instead exists in the circulation as a heterogeneous mixture of structural isoforms, including monomeric, dimeric, and oligomeric forms, as well as post-translationally modified monomers with molecular weights ranging from 20 to 22 kDa.[163] Two genes on chromosome 17q code human GH: the product of one is designated GH-N (or GH1) and is expressed primarily in the pituitary; the other is designated GH-V (or GH2) and is derived from the placenta. Both products are 22 kDa proteins, but they differ at 13 residues, and the GH-N isoform is susceptible to deletion of an internal 15 amino acid sequence, producing a 20 kDa GH isoform that accounts for 5 to 10% of the total GH and has a propensity to dimerize. Normally, the human gene for GH that directs the synthesis of a monomeric 22 kDa protein accounts for most of the GH found in the circulation. The 20 kDa variant has less biological activity and does not react with some GH assays, but antibodies that specifically recognize the 20 kDa variant are available.[140] No clinical indications are known for measuring the 20 kDa form of GH, but it has been suggested that it can be used to detect GH doping in sports (see later). Because recombinant GH is the 22 kDa isoform, and exogenous GH suppresses endogenous secretion of the hormone, administration of the recombinant hormone should suppress production of the 20 kDa variant; this effect has been demonstrated.[208] The immunoreactivity of the oligomeric (up to pentameric) isoforms of GH has not been well characterized, although it is known that they have reduced bioactivity and clearance. Approximately half of circulating GH is bound to GHBP derived from the extracellular domain of the GH receptor,[18,19] and a small amount (5 to 8%) is bound to a low-affinity protein.[127] Generally, anti-GH antibodies have sufficiently higher affinity for GH to compete with GH-binding proteins when enough time is allowed for the GH-protein complexes to dissociate. Therefore, immunoassays provide a good approximation of total hormone concentration. Assays for measuring unbound (free) GH also have been developed.[84] Free GH concentrations are proportional to total GH and are inversely proportional to

GH-binding protein, but the clinical usefulness of free GH measurements has not been established.

Variability between GH immunoassays has been reviewed,[26] and it is apparent that significant challenges remain.

Detecting GH Doping in Athletes

Because GH promotes anabolic and lipolytic activities, it has been used by athletes to enhance their physical size, strength, and endurance. In response, the World Anti-Doping Agency has banned the use of GH by athletes competing in sanctioned events. Detecting GH use is challenging, however, because recombinant forms of the hormone are available that are identical to endogenous GH, and normal GH concentrations vary significantly because of the pulsatile nature of hormone release from the pituitary.[74] Although suppression of the 20 kDa GH isoform has showed some promise as a marker of GH doping, most current strategies focus on secondary markers, including IGF and IGFBP.[2]

Specimen Collection and Storage

The preferred specimen is serum; plasma with ethylenediaminetetraacetic acid (EDTA) or heparin added to prevent coagulation may also be used, but values are method dependent. Serum specimens should be stored at 2 to 8 °C if they are not to be tested within 8 hours. If specimens must be stored for longer periods, they should be frozen at −20 °C or colder.

Comments

A single basal or random concentration of GH provides limited diagnostic information. As has been discussed earlier in this chapter, secretion of GH by the pituitary gland is both episodic and pulsatile, and transient concentrations of up to 40 µg/L have been observed in normal, healthy subjects. Serum concentrations are low between pulses in healthy individuals, and some immunoassays are not sensitive enough to distinguish patients with abnormally low concentrations from healthy individuals who have concentrations that happen to fall in the low-normal reference interval. In some individuals, spontaneous GH secretion is better monitored by using a continuous withdrawal pump or by drawing specimens for GH assay every 20 to 30 minutes over a 12 to 24 hour period (e.g., during evaluation of neurogenic GH deficiency). Several stimulation tests have been developed to assess the adequacy of GH secretion (as discussed previously), including the ITT, arginine and GHRH, GHRH and GH-releasing peptide (GHRP), and glucagon stimulation tests. Consensus guidelines have been published for diagnosis of GH deficiency; the commonly accepted ITT cutoff for GH deficiency in adults is less than 3 µg/L following insulin suppression of glucose concentrations to less than 40 mg/dL.[104]

Measurement of Insulin-like Growth Factors

Insulin-like growth factor I (IGF-I; somatomedin C) produced in the liver in response to GH represents the major source of circulating IGF-I. However, it is the autocrine and paracrine production of IGF-I (as controlled by GH) that is responsible for growth. Thus IGF-I is the principal mediator of somatotropic activity of GH.

IGF-I has a longer biological half-life than GH, so its measurement provides an integrated estimate of GH secretion; it is also a more sensitive measure of GH excess in acromegaly. IGF-II is a fetal growth hormone, and the clinical usefulness of measuring IGF-II is very limited.

Historically, radioisotope-based immunoassays for IGF-I were double-antibody methods (competitive or noncompetitive) that used ^{125}I as the tracer. Older IGF-I methods were calibrated with hormone isolated from human serum, but recombinant IGF-I is now available and is used in most procedures. Current IGF-I methods should use a reference material that is traceable to the International Reference Preparation IGF-I 87/518, or the newer WHO First International Standard 02/254.[36] To avoid interference from IGF-binding proteins, many assays isolate IGF using a variety of extraction methods, including (1) gel filtration, (2) acid-ethanol precipitation, (3) cryoprecipitation, (4) C-18 column extraction, or (5) reversed-phase chromatography.[32] Direct (no extraction) procedures are also available, but extraction methods prevent the formation of complexes with carrier proteins and serum proteases. Moreover, extraction procedures are better able to discriminate between GH-deficient patients and age-matched controls. Commercial assays that include chemiluminescent labels are available for measuring IGF-I, usually with minimal cross-reactivity to IGF-II (0 to 3%). It is important to establish age-related reference intervals for IGF-I because of marked differences in hormone concentrations between adults and children.

IGF-binding protein 3 (IGFBP-3) is the major protein carrier of circulating IGF-I and is an indirect measure of GH activity. IGFBP-3 measurements therefore provides additional evidence in cases of suspected GH deficiency. This protein has been measured in unextracted plasma by radioimmunoassay (RIA) using rabbit antihuman IGFBP-3; cross-reactivity with other binding proteins is less than 0.2%.[27]

Measurement of IGF-I has become a staple in the evaluation of growth hormone abnormalities, but problems with interassay agreement remain, mostly related to binding proteins. The availability of reliable reference materials against which immunoassays for IGF-I may be calibrated has been problematic. These difficulties have been reviewed.[85]

Specimen Collection and Storage

Serum or plasma (with heparin or EDTA added to prevent coagulation) is used, depending on the assay method. Samples should be centrifuged within 1 hour of collection and stored frozen at −20 °C or colder for up to 30 days. Some procedures use dried whole blood or serum collected on filter paper.[151]

Prolactin

Prolactin is secreted by lactotrophs of the adenohypophysis.[92] Prolactin stimulates and sustains lactation in postpartum mammals after the mammary glands have been prepared by

other hormones, including estrogens, progesterone, growth hormone, corticosteroids, and insulin.

Biochemistry

Hypothalamic prolactin release inhibitory hormone (PRIH) is dopamine, which is a product of the tuberoinfundibular cells and the hypothalamic tuberohypophyseal dopaminergic system. In lactotrophs, dopamine binds to the type 2 dopamine (D2) receptor, one of five dopamine receptors. Dopamine receptors are located in the caudate putamen, nucleus accumbens, and olfactory tubercle, affecting (1) locomotion, (2) learning, (3) memory, (4) reward, and (5) reinforcement.

The gene for the D2 receptor is located on chromosome 11q2, contains 443 amino acids, and has a mass of 50.6 kDa. The extracellular domain is 37 amino acids, and seven transmembrane domains are present, along with a 14 amino acid cytoplasmic domain. A large extracellular loop is evident between amino acids 211 and 373. Three potential sites of N-glycosylation are noted: amino acids 5, 17, and 23. A disulfide bridge may occur between amino acids 107 and 182. Three isoforms of the D2 receptor have been identified: the full-length isoform is referred to as D2 (long); isoform 2 is D2 (short) and lacks amino acids 242-270; isoform 3, D2 (longer), contains a val → trp-glu substitution at position 270. Mutations in the D2 receptor cause dystonia type 11 (myoclonus dystonia, or alcohol-responsive dystonia).

The gene that encodes prolactin was described in the section concerning the *GH1* gene. Initially, preprolactin is synthesized (227 amino acids), and following cleavage of the leader sequence, the 199 amino acid prolactin hormone is liberated. Amino acid 59 is the site of putative N-glycosylation. Intra-chain disulfide bonds are located between amino acids 32 and 39, 86 and 202, and 219 and 227.

Circulating prolactin exists in several forms: monomeric prolactin (23 kDa, "little" prolactin), dimeric prolactin (48-56 kDa, "big" prolactin), and polymeric prolactin (>100 kDa, "big, big" prolactin). Occasionally, and independent of the presence or absence of disease, immunoglobulin G (IgG) autoantibodies against prolactin can bind to prolactin, forming macroprolactin. The presence of macroprolactin elevates the total prolactin concentration, as the result of lower clearance, in the absence of excess prolactin secretion by the anterior pituitary lactotrophs. Failure to recognize macroprolactin can lead to the inappropriate diagnosis of hyperprolactinemia. In nature, many examples of macroproteins resulting from the complex of an antibody and a protein can be found, including macro-creatine kinase, macroamylase, macro-lactate dehydrogenase, and macro-aspartate aminotransferase.

The gene for the prolactin receptor *(PRLR)* is located at chromosome 5p13.2. Pre-PRLR is 622 amino acids (69.5 kDa). Upon removal of the signal peptide, the full-length PRLR is released (598 amino acids). The first 210 amino acids of the receptor are extracellular, 24 amino acids are present in the transmembrane domain, and the cytoplasmic domain consists of 364 amino acids. Amino acids 27-121 (with reference to preprolactin) represent a fibronectin type III-1 domain, whereas amino acids 127-227 represent a fibronectin type III-2 domain. Amino acids 215-219 display a WSXWS motif, and amino acids 267-275 display a box 1 motif. The WSXWS motif is the tryptophan-serine-wild card-tryptophan-serine sequence located near the lipid bilayer. Box 1 motifs are expressed in the cytoplasmic domain of receptors that engage in Janus kinase 2 (Jak2) receptor signaling. Glycosylation may occur at amino acids 59, 104, and 233, and intrachain disulfide bonds occur between amino acids 36 and 46, and 75 and 86. The PRLR forms a homodimer upon binding prolactin.

Eight isoforms of the PRLR have been described. Isoform 1 is the full-length PRLR. In isoform 2, amino acids 24 to 124 are missing. In isoform 3, amino acids 229 (aspartate) and 230 (phenylalanine) are replaced, respectively, by alanine and tryptophan (amino acids 231 to 622 are missing; therefore this protein lacks a transmembrane domain and the protein is soluble). This isoform has been reported as the product of a breast cancer cell line. Isoform 4 has changes in the amino acid sequence of amino acids 338-376, with the remaining amino acids deleted, and is nonfunctional. Because of a deletion of part of exon 10, and a frameshift mutation, the sequence of isoform 5 is altered among amino acids 337-349; thereafter the remaining amino acids are absent. In isoform 6, amino acids 286-288 (lysine-glycine-lysine) are replaced, respectively, by valine, tyrosine, and proline, and the amino acids distal to 288 are absent; this receptor is nonfunctional. Isoform 7 is secreted with changes in amino acids 229 to 268, and amino acids 269-622 are absent. Last, isoform 8 begins at amino acid 72, and amino acids 286-288 are replaced, respectively, by valine, tyrosine, and proline; the amino acids distal to 288 are absent, as in isoform 6.

Physiology

The biological importance of prolactin in men is unclear.[180] In women, prolactin is necessary for lactation following delivery of the newborn. Prolactin is stimulated by breast-feeding, chest wall disease, and stress. Although prolactin is higher during the day than at night, and a night-to-day prolactin ratio greater than 1:2 is considered normal, the ratio has no diagnostic value. Prolactin is measured in its basal state without stimulatory or suppressive manipulation. As with other adenohypophyseal hormones, the release of prolactin is episodic and varies predictably during the day, with lowest concentrations found at midday and highest values shortly after the onset of deep sleep.

Receptors for prolactin are located in the hypothalamus, breast, and ovary. Breast development during puberty can occur in the absence of prolactin, but estrogen is required, along with GH and GH-stimulated IGF-I. Fetal breast development is stimulated by parathyroid hormone–related peptide (PTHrP), which shares the N-terminal active domain of parathyroid hormone but has extraparathyroidal origins.

Prolactin secretion by lactotrophs is controlled predominantly through suppression by PRIH.[80] In addition, prolactin

may provide feedback centrally to stimulate PRIH in a short negative feedback loop, but this has been difficult to confirm. An ultra-short feedback loop is present where prolactin suppresses its own release. Besides very high concentrations of TRH, other factors that may stimulate prolactin secretion include oxytocin, VIP, basic fibroblast growth factor, EGF, hypothalamic prolactin-releasing peptide (PrRP), galanin, and neurotensin. Identified in the hypothalamus, amygdala, basal ganglia, and dorsal gray matter of the spinal cord, neurotensin is a 13 amino acid peptide neurotransmitter. Neurotensin affects gastrointestinal function and has a role in pain perception.

Estrogen increases prolactin gene transcription and secretion; this explains why prolactin concentrations are higher in women than in men. The upper limit of the prolactin reference interval for women is 20 ng/mL, whereas in men it is 10 ng/mL. Prolactin is lowest while awake and highest during sleep. Prolactin rises during pregnancy because of elevated concentrations of sex steroids (predominantly estradiol). The average serum prolactin during pregnancy is approximately 200 ng/mL. Because of increased lactotrophs, the pituitary approximately doubles in size during pregnancy.

The breast is prepared for lactation during pregnancy through the actions of (1) estrogen, (2) progesterone, (3) prolactin, (4) GH-V, (5) hPL, and possibly (6) IGF-I.[102] Just as the visible size of the breast increases during pregnancy, many microscopic changes occur in breast tissue. Typically, lactation is not active until after delivery, when estrogen and progesterone concentrations have declined. Prolactin increases amino acid and glucose uptake by breast tissue, and synthesis of alpha-lactalbumin and beta-casein, lactose, and milk fats is increased.

Postpartum, a positive feedback loop is seen between suckling and milk production. Transmitted via nerve fibers from the nipple to the CNS, suckling reduces PRIH, which increases prolactin release. With suckling, prolactin can rise by more than eightfold over baseline. The positive feedback loop of suckling, prolactin secretion, and milk production is a "stimulus-secretion" reflex. However, with continued breast-feeding, prolactin concentration declines. One report observed mean prolactin concentrations of 162 ng/mL 2 to 4 weeks postpartum, 130 ng/mL 5 to 14 weeks postpartum, and 77 ng/mL 15 to 24 weeks postpartum. Suckling also stimulates oxytocin release, which is discussed in the section of this chapter concerning the posterior pituitary.

Because elevated prolactin concentrations reduce LH and FSH by inhibiting GnRH release (a short feedback loop between prolactin and the hypothalamus), breast-feeding delays the onset of menses following delivery.[148] Lactation amenorrhea is beneficial because it temporarily ensures that the mother can adequately breast-feed her newborn before she becomes pregnant again. It is understood that oligomenorrhea, amenorrhea, and infertility in hyperprolactinemic women, and impotence and oligospermia in hyperprolactinemic men, result from prolactin suppression of GnRH secretion. Prolactin has direct effects on prolactin receptors in the ovary.

The role of prolactin in the immune system is controversial. At this time, it is difficult to ascribe any major, specific immune function to prolactin.

Hyperprolactinemia

Hyperprolactinemia is the most common hypothalamic-pituitary disorder encountered in clinical endocrinology.[114] Prolactin concentrations may be elevated in women who have only subtle alterations in fertility, such as (1) anovulation with or without menstrual irregularity, (2) amenorrhea and galactorrhea, or (3) galactorrhea alone. Prolactin excess in men is frequently manifested as oligospermia, or impotence, or both. Hyperprolactinemia can also cause galactorrhea in men. In addition, men with prolactin-secreting pituitary adenomas more often than women present with macroadenomas and visual field disturbances resulting from a large tumor pressing on the optic chiasm. Men, of course, do not have the subtle symptom of an irregular menstrual period that frequently reveals a microadenoma (≤10 mm in diameter) in women. Elevated prolactin concentrations are observed in as many as 30% of women with polycystic ovarian syndrome and patients with clinically silent pituitary adenoma. If a borderline elevation of prolactin is found, it is advisable to repeat the measurement on at least two other occasions, taking care to obtain a morning specimen under conditions of minimal excitement or stress to the patient, that is, no trauma and no breast stimulation. The patient should not be on any medication that could stimulate prolactin release. The differential diagnosis of hyperprolactinemia is extensive (Table 53-7).

An extremely important cause of hyperprolactinemia is a prolactinoma.[50,78] The higher the prolactin concentration, the greater is the likelihood that hyperprolactinemia is the result of a prolactinoma. Hyperprolactinemia due to a macroprolactinoma (>10 mm in diameter) can produce prolactin concentrations into the tens of thousands (ng/mL). Prolactin

TABLE 53-7 Differential Diagnosis of Hyperprolactinemia

PRIH (dopamine) deficiency	Hypothalamic disease
	Interruption in the hypothalamic-pituitary portal system
Drugs	Dopamine antagonists
	Cholinergic antagonists
	Serotonergic antagonists
Hormones	Estrogen, pregnancy
Neurogenic	Nursing (nipple stimulation)
	Chest wall disease
	Spinal cord injury
Other diseases	Hypothyroidism (pathologically elevated TRH can release prolactin)
	Chronic renal disease
	Cirrhosis

concentrations greater than 200 ng/mL usually indicate a macroprolactinoma. Prolactinomas are diagnostically challenging. Because any degree of hyperprolactinemia can be seen in cases of prolactinoma, if hyperprolactinemia is otherwise not explained, a thorough search for a prolactinoma, including MRI imaging, should be undertaken. Mass displacement effects from an anterior pituitary tumor include destruction of the sella turcica, invasion of other structures, compression of the stalk, or optic nerve compression with bitemporal hemianopsia.

Early diagnosis of a prolactinoma is critical because therapy with dopamine agonists, such as bromocriptine, can reduce tumor size and control tumor progression.[108] Surgical excision of a prolactinoma usually is considered only when a destructive invasion of adjacent structures and/or serious optic nerve compression occurs.

Macroprolactinemia is a common cause of an elevated plasma prolactin concentration; this benign condition should be ruled out before additional diagnostic studies are performed.[101] Macroprolactinemia can result from elevated circulating concentrations of the polymeric forms of prolactin and/or from prolactin-immunoglobulin complexes with molecular masses in excess of 100 kDa.

Polymeric forms of prolactin lack biological activity; thus, none of the sequelae associated with an elevated prolactin concentration (sexual dysfunction and galactorrhea) are present. In addition, macroprolactinemia is not associated with negative or positive feedback effects at the hypothalamus. Because macroprolactin is formed outside of lactotrophs, it is not found in pituitary tissue, and its size prevents entry into the cerebrospinal fluid. Therefore, macroprolactin appears to be confined to the vascular compartment.

Macroprolactinemia, although asymptomatic, is troublesome for clinicians and the laboratory because it is detected by most prolactin immunoassays. In one report, almost 20% of patients who presented for a clinical work-up for prolactinoma had hyperprolactinemia attributable to the presence of macroprolactin. Although the prevalence of macroprolactinemia was approximately 1.5% in the population studied, the report suggested that macroprolactinemia is more common than was previously realized. Thus, clinical laboratories must be able to rule out the presence of a macroprolactin.[188] Macroprolactin can be precipitated by the addition of polyethylene glycol (PEG) to serum; this is the most common laboratory approach to detecting macroprolactin.[192]

Another diagnostic challenge in the investigation of hyperprolactinemia is the presence of a pituitary incidentaloma in a patient with elevated prolactin that could potentially lead to inappropriate surgery.[152-154] A lesion identified by MRI cannot unequivocally be associated with hyperprolactinemia because of the possibility of an incidentaloma. Compression of the optic chiasm, or destruction of bone, argues against an incidentaloma, but mild to modest elevations in prolactin concentration (50 to 200 ng/mL) are possible when other anterior pituitary tumors compress the hypothalamic-pituitary portal system, impairing the delivery of PRIH to the lactotrophs; these conditions are called *pseudoprolactinomas.* Treatment with a dopamine agonist should lower prolactin concentration in cases of a true prolactinoma, but will not reduce prolactin concentration with pseudoprolactinoma. Prolactin measurements are also susceptible to a high-dose hook effect that may lead to a missed diagnosis of hyperprolactinemia. If a macroadenoma is present by MRI yet the prolactin is only modestly elevated, clinicians may request that the prolactin be remeasured at 1 to 10 and 1 to 100 dilution. If a hook effect is present, the concentration of the diluted sample will be significantly greater than that of the undiluted sample.

MRI of the pituitary gland is performed as part of the clinical assessment when a prolactinoma is suspected. Unless a pituitary tumor can be demonstrated by MRI, prolactin-secreting microadenoma (≤10 mm in diameter) is diagnosed by exclusion. Because half of all prolactin-secreting microadenomas are too small to be detected by imaging methods, differentiating between a small pituitary tumor, prolactin-cell hyperplasia, and idiopathic hyperprolactinemia may not be possible without surgical exploration.

Medications that stimulate prolactin release (through PRIH suppression) are the most common cause of hyperprolactinemia in otherwise healthy individuals.[41] When significant elevation of prolactin is confirmed, a careful history should rule out the possibility that medications are the cause. In addition to estrogens, dopamine receptor blockers (such as the phenothiazines) and dopamine antagonists (such as metoclopramide and domperidone used to treat gastrointestinal diseases) cause significant increases in prolactin. Certain psychiatric drugs, including haloperidol and risperidone, cause elevated prolactin. Antihypertensive agents (such as beta blockers and calcium channel blockers) and antihistamines (such as cimetidine and ranitidine) are associated with modest elevations in prolactin. Thyrotropin (TSH) measurements should be considered in patients suspected of a prolactinoma, to rule out primary hypothyroidism; in rare cases of severe primary hypothyroidism, TRH will promote release of prolactin. A pregnancy test should be performed in women of reproductive age because pregnancy is a cause of hyperprolactinemia.

Prolactin Deficiency

Prolactin is of great clinical importance in the postpartum period, because prolactin is required for lactation.[175] Without the availability of infant formulas or wet nurses, failure of maternal lactation can be fatal to the newborn. Other than the necessity of breast-feeding, however, prolactin deficiency in humans does not appear to have adverse consequences.

Measurement of Prolactin

Similar to most hormone assays, RIA was the first practical method for measuring prolactin, but performance of the early assays was variable, and they have been mostly replaced by nonisotopic methods. Modern prolactin assays typically involve noncompetitive, heterogeneous "sandwich" techniques that make use of two antibodies that recognize different epitopes on the prolactin polypeptide.

Structural variations in circulating prolactin result in biases between immunoassays for this hormone. Monomeric prolactin accounts for more than 85% of the total circulating hormone, but glycosylated and inactive complexed forms (sometimes referred to as "big" and "big-big" prolactin, respectively) constitute a significant fraction, and immunoreactivity of these prolactin complexes is variable. IgG-bound prolactin, now referred to as *macroprolactin,* is a relatively common finding in healthy patients and, according to one study, may account for up to 10% of misdiagnoses in hyperprolactinemic patients,[188] because renal clearance of the immunoglobulin-bound hormone is reduced. IgG-bound prolactin can be separated by gel chromatography, or more conveniently by precipitation of immunoglobulin complexes with the addition of PEG. PEG precipitation removes a small fraction of monomeric prolactin as well, but remains a useful method for distinguishing between clinical hyperprolactinemia and prolactin elevations due to prolactin-IgG complexes.[24]

Prolactin methods should be calibrated against reference materials with known international unit potency, such as the WHO first IRP 75/504, the second international standard (IS) 83/562, or the third IS 84/500, to allow assay-to-assay comparison. Despite the heterogeneity of prolactin, immunoassays correlate well with bioassay-validated prolactin standards.

Specimen Collection and Storage

Prolactin is measured in serum or plasma, although individual assays may recommend serum only. Special handling procedures are not necessary; specimens can be stored at 4 °C for at least 24 hours, but should be frozen if analysis is delayed for longer than 24 hours. Prolactin concentrations rise rapidly during sleep and peak in the early morning hours, so attention should be given to the appropriate reference interval. Emotional stress, exercise, ambulation, and a protein-rich diet all stimulate prolactin secretion; thus specimens collected after an overnight fast when the patient is resting provide the most reliable prolactin concentrations.

Adrenocorticotropic Hormone and Related Peptides

Adrenocorticotropic hormone (ACTH; corticotropin) is secreted by the adenohypophysis as a derivative of proopiomelanocortin (POMC).[186,213] ACTH acts primarily on the adrenal cortex, stimulating its growth and the secretion of corticosteroids (specifically cortisol). ACTH production is increased during physiologic or psychologic stress.

Biochemistry

The biochemistry of ACTH, with its origin from POMC and POMC-derived peptides, is described in detail in Chapter 54.

Regulation of ACTH Secretion

Many variables affect the secretion of ACTH, which is both pulsatile and circadian in nature. Thus, regulation of pituitary secretion of ACTH by the hypothalamus is complex. The control of ACTH release by the pituitary is an integral part of the neuroendocrine regulation of stress homeostasis.

Cortisol is the major negative feedback hormone for the tonic inhibition of hypothalamic CRH and pituitary ACTH secretion. However, endogenous opioids such as met-enkephalin and beta-endorphin, produced by the adrenal glands, have a downregulatory effect on the hypothalamic-pituitary-ACTH axis as well. Regulation of ACTH is discussed at length in Chapter 54.

Clinical Significance

Because ACTH synthesis originates from the POMC precursor peptide, its production by the pituitary is closely linked with the secretion of endogenous opioid peptides, such as beta-endorphin.[178] The physiologic effects of endogenous opiates include (1) sedation; (2) an increased threshold of pain; and (3) autonomic regulation of respiration, blood pressure, and heart rate. These peptides are also involved in modifying endocrine responses to stress and water balance, and may play a role in the regulation of reproduction and the immune system.

Gonadotropin secretion by the pituitary is under inhibitory control by opioid peptides, as is evident by the effects of beta-endorphin analogs on the pulse frequency and amplitude of pituitary LH release. In contrast, beta-endorphin antagonists (such as naloxone) can elicit an increase in the amount and pattern of gonadotropin secretion. ACTH secretion is similarly downregulated by endogenous opioid peptides; therefore naloxone causes an increase in plasma ACTH concentrations.

No diseases have been clearly associated with disordered metabolism of opioid peptides, but changes in their plasma concentrations may accompany other disorders, such as Cushing disease and depression (increased beta-endorphin concentrations)[60] or pheochromocytoma (increased enkephalin concentrations). Altered concentrations of opioids in cerebrospinal fluid may reflect disorders such as chronic pain syndrome, schizophrenia, and depression.

In summary, the only POMC derivative that is measured in the diagnosis of certain human disease states is ACTH. Further discussion of adrenal disorders, including disorders of ACTH secretion, is found in Chapter 54.

Measurement of ACTH

ACTH has been measured by bioassay, receptor assay, and immunoassay. Previous editions of this textbook contain details of bioassays and receptor assays for ACTH, which now are mostly of historical interest.

Immunoassays that measure the concentration of ACTH are more common than bioassays or receptor assays. Competitive binding RIAs have been developed for ACTH; they differ in (1) the choice of radioactive label (^{125}I is most common), (2) separation system (charcoal adsorption, PEG, or second-antibody precipitation), (3) antibody (N-terminal or C-terminal specificity), and (4) whether pre-extraction of ACTH is required. Most polyclonal antibodies recognize a segment of the biologically active N-terminal portion of the

molecule and react with intact ACTH (amino acids 1-39), N-terminal ACTH fragments (amino acids 1-24), and ACTH precursors such as POMC and pro-ACTH.

Immunoradiometric ACTH assays that use labeled monoclonal antibodies in noncompetitive formats have also been developed.[79] In these assays, two monoclonal antibodies (or a polyclonal/monoclonal combination) are directed toward different sites on the ACTH molecule (e.g., the N-terminal and C-terminal domains). These double antibody (sandwich) immunoassays can detect ACTH concentrations of 1 to 4 pg/mL. Monoclonal immunoassays have improved analytical specificity for intact ACTH but may not recognize biologically active precursors and fragments.[165] Less specific ACTH immunoassays are sometimes used to detect the presence of these peptide fragments in patients with cancer-related syndromes (e.g., ectopic ACTH Cushing syndrome); a two-site IRMA has been developed for measuring ACTH precursors in plasma.[52] A direct (unextracted) immunoradiometric test kit for ACTH is commercially available that uses a polyclonal antibody–monoclonal antibody sandwich to detect ACTH; the monoclonal antibody is radiolabeled with ^{125}I. A nonisotopic time-resolved immunofluorometric method has also been reported.[66] ACTH assays have been developed for automated immunoassay platforms using chemiluminescent labels. These methods are more precise than manual methods [coefficients of variation (CVs) <8%], and, analytically, they are sensitive enough to distinguish between low-normal and suppressed hormone secretion.

Quantitative results from different ACTH immunoassays may demonstrate bias as the result of calibration. Currently, manufacturers of commercial ACTH immunoassays usually calibrate their assays with ACTH preparations obtained from research centers, such as human purified ACTH 1-39 (MRC 74/555, 6.2 IU/25 μg), supplied by the National Institute for Biological Standards and Control (United Kingdom), or synthetic ACTH 1-39 (4.71 IU/50 μg), supplied by the U.S. National Hormone and Pituitary Program, which was formerly known as the National Pituitary Agency. For comparison between assays, the calibrators used in a particular assay system must be clearly specified.

Specimen Collection and Storage

Some precautions are necessary in the collection, transportation, and storage of specimens. ACTH is easily oxidized, adsorbs to glass surfaces, and is rapidly degraded by plasma proteases into nonreactive fragments during freezing and thawing of the specimen. Factors that influence plasma ACTH, such as prior administration of corticosteroids, the time of day at which the specimen is collected (diurnal variation), and stress from the venipuncture procedure, should be taken into account. To minimize these problems, it is recommended that blood specimens should be collected into prechilled polystyrene (plastic) tubes containing EDTA, immediately placed on ice, and centrifuged at 4 °C. Some laboratories recommend the use of protease inhibitors, such as aprotinin (Trasylol). The plasma should be transferred to another plastic tube and frozen at −20 °C or colder if analysis is delayed. Antioxidants, such as mercaptoethanol, may be used to stabilize ACTH. Immediately before the ACTH assay is set up, frozen specimens should be thawed and centrifuged to remove any fibrin clots that can interfere with the assay.

Measurement of Endogenous Opioid Peptides

Beta-endorphin is a cleavage product of POMC, which is also the precursor to ACTH and beta-lipotropin. Both RIAs and immunoradiometric assays (IRMAs) have been developed for measurement of beta-endorphin. Commercial assays are widely available, and most reference laboratories offer beta-endorphin assays. The concentration of beta-endorphin is usually very low or undetectable in healthy subjects, and some analytical methods require extraction procedures to detect meaningful concentrations in plasma. The specificity of commercial antibodies for beta-endorphin (relative to beta-lipotropin) can be variable, and some assays cross-react as much as 50% with beta-lipotropin. Assays based on polyclonal antibodies may produce spuriously high results as the consequence of cross-reactivity with serum IgG (e.g., in patients with an IgG myeloma).[99]

Met-enkephalin shares a 5 amino acid N-terminal sequence with beta-endorphin but is thought to be derived from pro-enkephalin, rather than POMC. Measurement of met-enkephalin in plasma is difficult because of its very short half-life (2.5 minutes at 37 °C). Even if blood is immediately chilled on ice and centrifuged under refrigeration, about 50% of met-enkephalin is lost unless the specimen is collected in 23 mmol/L of citric acid. Commercial assays for met-enkephalin have been developed, and anti-enkephalin antibodies are available.

Gonadotropins (Follicle-Stimulating Hormone, Luteinizing Hormone)

Luteinizing hormone and follicle-stimulating hormone are synthesized by gonadotrophs in the adenohypophysis. The actions of FSH are to (1) stimulate the growth and maturation of ovarian follicles, (2) stimulate estrogen secretion (estradiol), (3) promote via estrogen the endometrial changes characteristic of the first portion (proliferative or follicular phase) of the menstrual cycle, and (4) stimulate spermatogenesis in males. FSH is also called *follitropin.*

LH and FSH act synergistically to promote ovulation and secretion of androgens (androstenedione) and progesterone. The actions of LH are to (1) promote and maintain the second (secretory or luteal) portion of the menstrual cycle; (2) in females, to assist in the formation of the corpus luteum; and (3) in males, to stimulate the development and functional activity of testicular Leydig cells that produce testosterone. LH is also called *interstitial cell–stimulating hormone (ICSH),* or *lutropin.*

Biochemistry

Under the generic term *gonadotropins,* LH and FSH control the functional activity of gonads. In males and females, gonadotropin secretion is regulated via GnRH.[51] Pituitary gonadotropin secretion is controlled by feedback from the

gonadotropic hormones. In females, estrogen and inhibin regulate LH and FSH secretion, respectively, and in males, testosterone and inhibin regulate LH and FSH release.

Two *GnRH* genes are present: *GnRH1,* located at chromosome 8p21, and *GnRH2,* located at chromosome 20p13. PreproGnRH1 is a 92 amino acid, 10.4 kDa polypeptide with a 23 amino acid leader sequence. Removal of the leader sequence produces ProGnRH1, which comprises 69 amino acids. Release of the C-terminal GnRH-associated peptide-1 yields *GnRH1* (amino acids 24-33). Amino acid 24 is modified as a pyrrolidone carboxylic acid, and amino acid 33 is modified as a glycine amide.

GnRH2 is expressed in higher concentrations outside than within the CNS. GnRH2 is principally produced in the prostate, bone marrow, and kidney. PreproGnRH2 is a 120 amino acid (12.9 kDa) polypeptide. Cleavage of the 23 amino acid leader sequence generates proGnRH2, which is 97 amino acids in length. Release of the C-terminal GnRH-associated peptide 2 yields GnRH2 (amino acids 24-33). Similar to GnRH1, amino acid 24 is modified as a pyrrolidone carboxylic acid, and amino acid 33 is modified as a glycine amide. GnRH2 has three isoforms: isoform 1 is the full-length protein; isoform 2 lacks amino acids 52-59; and isoform 3 is missing amino acids 52-58.

The receptor for GnRH (GnRHR) is expressed on anterior pituitary gonadotropic cells. The gene for GnRHR is located at chromosome 4q. GnRHR is a 328 amino acid protein; the first 38 amino acids are extracellular, and seven transmembrane domains are present. Only two amino acids are cytoplasmic. The GnRHR is possibly glycosylated at amino acids 18 and 102, and a disulfide bond is probably present between amino acids 114 and 196. Two isoforms of GnRHR are expressed: the full-length protein (isoform 1) and isoform 2, which differs in the amino acid sequence between residues 176 and 328. A putative second GnRHR (GnRH2R) exists, comprising 178 amino acids. However, the gene for GnRH2R (located on chromosome 1) may be a pseudogene.

Both LH and FSH are secreted by gonadotrophs. Similar to TSH and hCG, LH and FSH are glycoprotein alpha/beta heterodimers.[77] The alpha chain is shared among all four hormones. The glycoprotein alpha chain gene is located on chromosome 6q1. The alpha chain includes 116 amino acids and weighs 13.1 kDa, including a leader sequence of 24 amino acids; the secreted chain is 92 amino acids. Amino acids 76 and 102 in the alpha chain are glycosylated. Five disulfide bonds are present at amino acids 31-55, 34-84, 52-106, 56-108, and 83-111.

The gene for the LH beta chain is located at chromosome 19q13.3. The leader sequence (amino acids 1-20) is followed by the 121 amino acid beta chain, which is the secreted form. The beta chain is glycosylated at amino acid 50, and six disulfide bonds are present at amino acids 29-77, 43-92, 46-130, 54-108, 58-110, and 113-120.

The gene for the FSH beta chain is located at chromosome 11p1. The 129 amino acid pre-FSH beta chain is 14.7 kDa, including an 18 amino acid leader sequence; the secreted FSH beta chain is 111 amino acids. FSH-β is glycosylated at amino acids 25 and 42 and contains six disulfide bonds at amino acids 21-69, 35-84, 38-122, 46-100, 50-102, and 105-112. Isolated alpha-subunits are devoid of biological activity; the beta-subunit of FSH may have slight intrinsic biological activity, but full activity is attained when alpha- and beta-subunits are recombined. This suggests that the presence of both alpha- and beta-subunits is important for specific receptor recognition, and that the beta-subunit is responsible for eliciting the specific biological response.

In men, the LH receptor (LHR) is expressed by Leydig cells, whereas in women, the LHR is expressed on theca cells and is induced by FSH on granulosa cells during the follicular phase of the menstrual cycle. The gene for the LHR is located at chromosome 2p21. The pre-LHR protein is 699 amino acids (78.6 kDa). After removal of the leader sequence, LHR comprises 673 amino acids. The extracellular domain is 337 amino acids, followed by seven transmembrane domains and a cytoplasmic domain of 72 amino acids. Seven leucine-rich repeats are present at amino acids 48-71, 97-121, 122-147, 149-171, 172-196, 197-220, and 221-244. Cysteines at positions 643 and 644 are lipidated to S-palmitoyl cysteine. Potential glycosylation sites exist at amino acids 99, 174, 195, 291, 299, and 313. A disulfide bond is likely between amino acids 439 and 514. Two isoforms of LHR are expressed: the long isoform is the full-length LHR, and the short isoform lacks amino acids 227-289.

The FSH receptor (FSHR) is expressed on Sertoli cells in men and on granulosa cells in women. Following the 17 amino acid leader sequence is the 678 amino acid FSHR. The extracellular domain is 349 amino acids, with seven transmembrane domains. The cytoplasmic domain is 65 amino acids. Ten leucine-rich repeats are present at amino acids 18-48, 49-72, 73-97, 98-118, 119-143, 144-169, 170-192, 193-216, 217-240, and 241-259. The FSHR has four proven or suspected sites of glycosylation at amino acids 191, 199, 293, and 318; two definitive disulfide bonds (amino acids 18-25 and 23-32); and one possible disulfide bond (amino acids 442-517). Two isoforms of the FSHR are expressed: isoform 1 is the full-length FSHR, and isoform 2 lacks amino acids 224-285.

Physiologic Activity

In men, LH stimulates testosterone synthesis and secretion by Leydig cells. In response to FSH, Sertoli cells nourish developing sperm during spermatogenesis.

Based on the two-cell model of estradiol and progesterone production by the adult ovary, androstenedione is produced by theca cells in response to LH stimulation (Figure 53-6). Granulosa cells do not have direct access to the circulation; therefore low-density lipoprotein cholesterol is not readily available to granulosa cells in the follicular phase of the menstrual cycle. Consequently, granulosa cell synthesis of sex steroids is dependent on theca cell androstenedione. Granulosa cells initially respond to FSH, and later to FSH plus LH.

FSH has several effects on the ovary during the follicular phase of the menstrual cycle (see Chapter 56). When bound to granulosa cell FSHRs, FSH stimulates granulosa cell

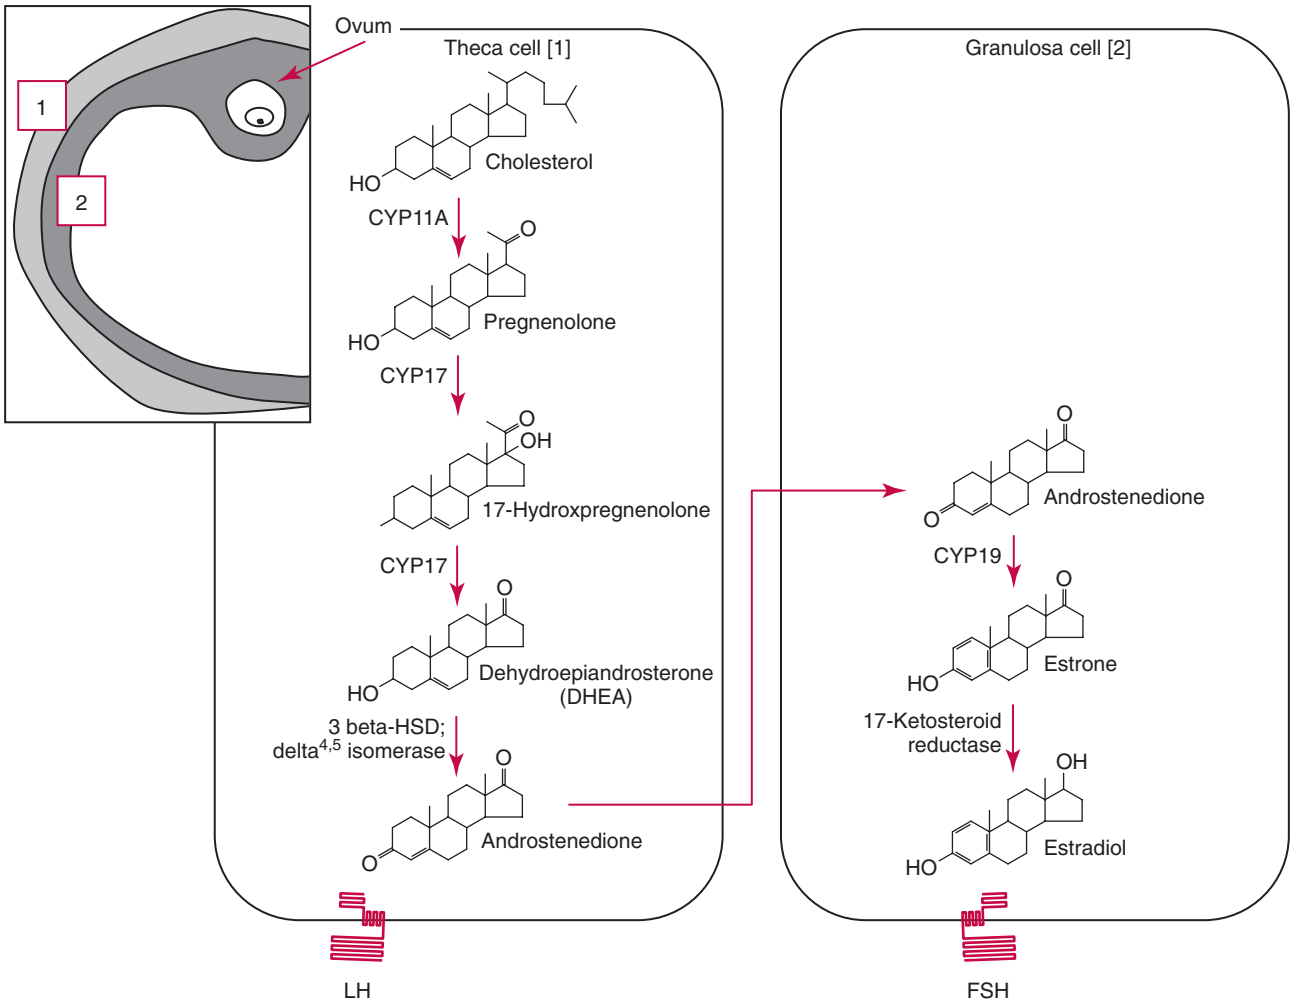

Figure 53-6 In the follicular (proliferative) phase of the menstrual cycle, under the influence of luteinizing hormone (LH), theca cells *[1]* produce androstenedione from cholesterol (the intermediary steps are illustrated). Under the influence of follicle-stimulating hormone (FSH), granulosa cells utilize the androstenedione produced by the theca cells to synthesize estradiol (the intermediary steps are illustrated) *[2]. 3 Beta-HSD,* 3 Beta-hydroxysteroid dehydrogenase; *CYP11A,* 20,22 desmolase; *CYP17,* 17-hydroxylase activity; and *CYP19,* aromatase.

proliferation. As a result, a dominant follicle develops containing the ovum that will be expelled midcycle (ovulation). When stimulated by FSH, granulosa cells use theca cell androstenedione as the precursor for estradiol synthesis. FSH also stimulates the expression of LHRs on the granulosa cells. Estradiol and inhibins from the ovary provide negative feedback for hypothalamic release of GnRH.

At midcycle, as a consequence of the LH surge, the follicle ruptures with release of the ovum (ovulation). The corpus luteum of the ovary (Figure 53-7) is formed from the remaining theca and granulosa cells. The theca cells (responsive to LH) become the theca lutein cells, and the granulosa cells (now responsive to LH and FSH) are converted to the granulosa lutein cells, which now are vascularized and gain access to low-density lipoprotein (LDL) cholesterol from the circulation. With an adequate supply of cholesterol from LDL, the granulosa lutein cells generate progesterone and estradiol. Estradiol and progesterone convert the proliferative endometrium of the first half of the menstrual cycle to the secretory endometrium of the second (luteal) half of the menstrual cycle.

In the absence of pregnancy (i.e., in the absence of hCG), progesterone concentrations decline and menstruation occurs because the corpus luteum atrophies to become the corpus albicans. However, if a fertilized ovum implants in the uterine wall, the syncytiotrophoblast, via hCG, will maintain the corpus luteum, and menstruation is avoided because of continued secretion of estradiol and progesterone. The corpus luteum (supported by hCG) then becomes the corpus luteum of pregnancy.

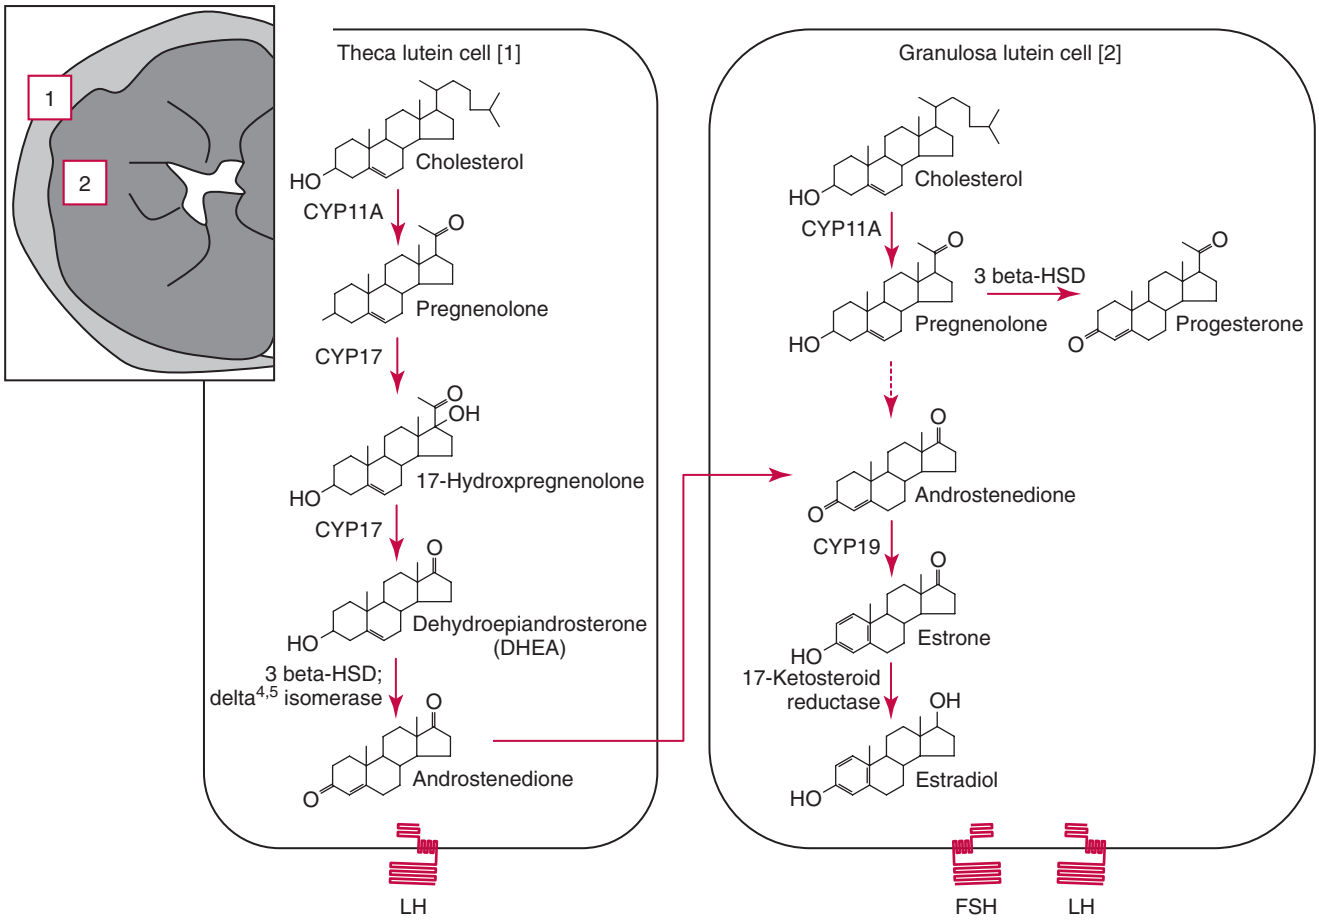

Figure 53-7 **In the luteal (secretory) phase of the menstrual cycle following ovulation, under the influence of luteinizing hormone (LH), theca lutein cells *[1]* produce androstenedione from cholesterol (the intermediary steps are illustrated). Under the influence of follicle-stimulating hormone (FSH) and LH, granulosa lutein cells utilize androstenedione produced by the theca cells to synthesize estradiol, and utilize cholesterol available from LDL to synthesize progesterone (the intermediary steps are illustrated) *[2]*. *3 Beta-HSD,* 3 Beta-hydroxysteroid dehydrogenase; *CYP11A,* 20,22 desmolase; *CYP17,* 17-hydroxylase activity; *CYP19,* aromatase; and *LDL,* low-density lipoprotein.**

Regulation and Clinical Significance

In hypogonadal patients, if gonadotropin concentrations are greatly elevated, hypergonadotropic hypogonadism is diagnosed, indicating that gonadal (end-organ) failure has occurred.[46] Alternatively, if gonadotropin concentrations are consistently low in hypogonadal patients, the diagnosis of hypogonadotropic hypogonadism is likely. To ensure that the pituitary is unable to respond to GnRH, a GnRH stimulation test can be performed.[107,174] In children (especially boys), in whom hypogonadotropic hypogonadism versus constitutional delay in growth and adolescence (delayed puberty) is a diagnostic dilemma, and basal LH and FSH may be low, GnRH testing should be performed. If basal LH and FSH concentrations are low, but LH and FSH rise substantially following GnRH stimulation, constitutional delay in growth and adolescence is likely, and hypogonadotropic hypogonadism can be excluded. The therapeutic approach to these two conditions is very different. Children with constitutional delay in growth and adolescence eventually will enter puberty (although later than their peers), whereas hypogonadotropic hypogonadism will require sex hormone replacement therapy for initiation of puberty. If hypogonadotropic hypogonadism is diagnosed, a thorough search for its cause (e.g., a CNS tumor) is essential. Induction of fertility in patients with hypogonadotropic hypogonadism requires gonadotropin replacement. A protocol for performance of the GnRH test is discussed in the following section.

Hypogonadotropic hypogonadism has also been found to result from loss-of-function mutations in the *GnRHR* gene.[22] Isolated FSH deficiency can result from mutations in the FSH beta chain. However, isolated FSH deficiency is a rare cause of infertility in men or women. Men with FSH deficiency (but LH sufficiency) will have normal testosterone concentrations because LH and responding Leydig cells are normal.

Gain-of-function mutations in the LHR cause a hypogonadotropic, familial, male precocious puberty, in which the

testes autonomously and prematurely produce testosterone (testotoxicosis).[181] Leydig cell adenomas with *LHR* mutations can cause precocious puberty.

LHR loss-of-function mutations cause Leydig cell hypoplasia and inadequate virilization of males in utero, leading to ambiguous genitalia.[217] In females, *LHR* loss-of-function mutations cause oligomenorrhea, amenorrhea, or infertility. *FSHR* loss-of-function mutations in females result in ovarian dysgenesis.

Central precocious puberty occurs with early activation of the hypothalamic-pituitary-gonadal axis, leading to gonadotropin-driven early puberty (onset of breast development or pubic hair before age 8 years or menses before age 9.5 years in girls, and puberty onset in boys before age 9).[38] In most girls (≈95%), no specific cause is identified (idiopathic precocious puberty). Central precocious puberty is uncommon in boys. However, when central precocious puberty occurs in boys, the likelihood of CNS pathology is greater than in girls.

Other details concerning the regulation and clinical significance of LH and FSH are discussed in Chapter 56.

Measurement of LH and FSH

The alpha subunit of LH and FSH is a member of the "cystine knot" superfamily of polypeptides that includes growth hormone, chorionic gonadotropin, and thyrotropin. Therefore, analytical methods for measuring LH and FSH must recognize the unique beta subunits of these hormones, because the alpha subunit is shared among several homologous pituitary products.

Two-site (double antibody) heterogeneous immunoassays are currently the most common methods for measuring gonadotropins, and a wide variety of assays have been adapted to automated platforms. Some commercially available methods attach a capture antibody to the surface of test tubes or plastic beads, whereas others use a paramagnetic label or a microparticle to capture the antibody-antigen complexes. Numerous labels have been used for the second antibody, including radioisotopes, enzymes,[82] fluorophores,[120] and chemiluminescent molecules. In modern immunometric assays, hCG interference has been mostly eliminated (<0.008% cross-reactivity), better assay precision has been achieved (between-assay CVs <10%), and sensitivity has been improved (detection limits <0.2 IU/L).[21] The analytical sensitivity of LH assays is especially important in the evaluation of prepubertal children and patients with hypothalamic disorders, because LH concentrations are very low.

Calibration of gonadotropin assays is difficult because LH and FSH undergo post-translational modifications that produce a mixture of closely related compounds. The earliest reference material used for calibration of LH and FSH assays was the second IRP for human menopausal gonadotropins, isolated from the urine of postmenopausal women. Alterations during metabolism and excretion, however, limited the comparability of this preparation with circulating forms of the hormones, and subsequent calibrators were prepared from extracts derived from the human pituitary gland. Purified pituitary extracts, such as the first and second IRPs for FSH and LH, were available for many years but have been replaced by highly purified extracts that have minimal contamination with cross-reacting glycoproteins. Manufacturers of older immunoassays for LH and FSH used one or more pituitary-derived reference materials for their working calibrators, but recombinant gonadotropin calibrators are now available.

Biases in analytical results still exist between different immunoassay systems (most notably in LH assays), and results can differ by more than 50%, even when calibrated with the same reference preparation.[203,210] The most likely explanation for the bias is the specificity of the antibodies used in each method. Gonadotropic hormones are glycosylated, and this affects their antigenicity.[105] For example, LH immunoassays using monoclonal antibodies generate considerably lower LH concentrations than RIAs using polyclonal antibodies, presumably because of the greater specificity of monoclonal antibodies, which may recognize only a subset of LH isoforms and epitopes. Other factors that contribute to method-dependent biases include differences in calibration procedures and the assay matrix itself.

Specimen Collection and Storage

Serum is the preferred specimen for gonadotropin measurements. Hemolyzed, lipemic, and/or icteric specimens should not be used. Both hormones are stable for 8 days at room temperature, and for 2 weeks at 4 °C; for longer periods, the serum specimen should be frozen at or below −20 °C. Because of episodic, circadian, and cyclic variations in the secretion of gonadotropins, meaningful clinical evaluation of these hormones may require determinations in pooled blood specimens, multiple serial blood specimens, or timed urine specimens. Urine specimens should not contain preservatives; storage at or below −20 °C is recommended.

Measurement of Urinary FSH and LH

Clinically, the pulsatile and episodic release of gonadotropins makes a single blood concentration of FSH or LH difficult to interpret. In adults, concentrations of gonadotropins in blood, particularly LH, may differ as much as threefold between blood specimens collected from the same individual 20 minutes apart. In addition, the lower detection limit of many FSH and LH immunoassays may be within the reference interval for these hormones in normal adults. In prepubertal children, most blood assays are not capable of measuring normal concentrations because they are so low. To optimize detection limits for gonadotropin assays in children, urinary FSH or LH assays have been used.[177] Some pediatric endocrinologists favor urine assays when investigating pubertal disorders of gonadotropin secretion.

Thyroid-Stimulating Hormone (TSH)

TSH (thyrotropin), which is synthesized in thyrotrophs of the adenohypophysis, promotes the growth of thyroid follicular cells and sustains and stimulates the hormonal secretion of

thyroid gland hormones 3,5,3′,5′ tetraiodothyronine (thyroxine; T_4) and 3,5,3′-triiiodothyronine (T_3).[121]

Biochemistry and Physiology

TSH binds to TSH receptors (TSHRs) located on the surfaces of thyroid follicular cells.[126] TSH (1) stimulates growth and vascularity of the thyroid gland, (2) stimulates growth of thyroid follicular cells, (3) promotes thyroid hormone synthesis by increasing the uptake of iodine (via the sodium-iodide transporter), (4) promotes the organification (reduction) of iodine, (5) promotes the coupling of tyrosines, and (6) promotes the proteolytic release of stored thyroid hormone from thyroglobulin. TSH release is stimulated by TRH and is suppressed by thyroid hormone (principally, circulating T_4).

TRH is a modified tripeptide produced by the hypothalamus. The thyroid-releasing hormone receptor (TRHR) is expressed on anterior pituitary thyrotrophs. TRHR is a 398 amino acid protein, and 28 of its amino acids constitute an extracellular domain. Seven transmembrane domains are present, along with a 79 amino acid cytoplasmic domain. Two possible glycosylation sites exist at amino acids 3 and 10, and a disulfide bridge is present between amino acids 98 and 179. Details of TRH and TRHR production are discussed in Chapter 55.

The glycoprotein alpha chain, shared with FSH, LH, and hCG, was described earlier in this chapter. The beta chain of TSH is encoded on chromosome 1p13. Following removal of the 20 amino acid leader sequence, the proTSH beta chain consists of 118 amino acids. Cleavage of the six C-terminal residues released from the propeptide yields the TSH beta chain (112 amino acids). TSH is glycosylated at residue 43, and disulfide bonds are likely at amino acids 22-72, 36-87, 39-125, 47-103, 51-105, and 108-115.

Regulation, Clinical Significance, and Analytical Methods

Details concerning the regulation, clinical significance, and measurement of TSH are discussed in Chapter 55.

Assessment of Anterior Pituitary Lobe Reserve

Evaluation of endocrine function is an important part of the management of patients with pituitary disease.[25,34] Detection of hormone deficiencies before and after treatment and recognition of hormone-producing tumors are the two objectives of testing of pituitary function in patients with pituitary disease.[56]

Assessment of anterior and posterior pituitary function in patients with a pituitary tumor is important in the identification of clinically significant hormone deficiency states caused by the tumor, and in the re-evaluation of patients after pituitary surgery or irradiation to detect hormone deficiencies that occur as a result of invasive treatment. Testing of pituitary function usually is performed under basal conditions, but it can be performed under provocative conditions to expose subtle or mild deficiencies observed in disorders of the adrenal gland or gonads. The primary relevance of prolactin deficiency relates to Sheehan syndrome, in which postpartum hemorrhage results in pituitary infarction and panhypopituitarism; this is still an important problem in developing countries.

BOX 53-5 Assessment of Pituitary Reserve in Surgical Patients

Before Pituitary Surgery
Adrenal function: measurement of morning serum cortisol concentration or cosyntropin stimulation test
Thyroid function: free T_4
Gonadal function: sex hormone determinations (estradiol in women and testosterone in men) and gonadotropins (LH and FSH) if sex steroids are low

Shortly After Pituitary Surgery (2 to 4 Days After Surgery)
Adrenal function: morning serum cortisol concentration
Thyroid function: deferred
Gonadal function: deferred

One Month After Pituitary Surgery
Adrenal function: cosyntropin stimulation test or insulin tolerance test (ITT)
Thyroid function: free T_4
Gonadal function: sex hormone determinations (estradiol in women and testosterone in men)

The lower detection limits of the newer two-site immunoassays for the measurement of pituitary hormones make it possible to distinguish an abnormally low value from the lower end of the normal reference interval. Although assessment of a particular aspect of pituitary function should include clinical signs and symptoms of hormone deficiency and measurement of hormones secreted by the pertinent endocrine gland (e.g., T_4, cortisol, testosterone), newer, ultrasensitive assays for TSH, FSH, LH, and ACTH allow accurate distinction between a pathologically low result and a low-normal result. A scheme for testing of pituitary reserve is proposed in Box 53-5.

Hypothalamic-Pituitary-Adrenal Axis

A morning serum cortisol concentration in excess of 18 to 20 μg/dL usually provides adequate evidence that the hypothalamic-pituitary-adrenal (HPA) axis is intact and is functioning properly. A typical reference interval for morning cortisol is 7 to 25 μg/dL. Therefore, a morning cortisol results can fall within the reference interval, yet may not prove that the patient has a normal HPA axis.

If AM cortisol is frankly low (<5 μg/dL) or equivocal (5 to <17 μg/dL), or if a strong clinical suspicion of adrenal insufficiency is present, the cosyntropin stimulation test is helpful (see Box 54-1). Cosyntropin provocation of cortisol release is performed by obtaining a baseline blood specimen for cortisol followed by intravenous (IV) administration of 250 μg of cosyntropin (an active ACTH analog). Blood specimens are collected 30 and 60 minutes after IV administration of cosyntropin. A normal response to cosyntropin is a peak cortisol of 18 to 20 μg/dL or greater, with an increase in

cortisol over the baseline of 7 μg/dL or greater. When the two criteria are compared, the absolute cortisol concentration is believed to be more important. A lower-dose cosyntropin test (1.0 μg IV) has been proposed as a more sensitive test of impaired pituitary reserve, but its utility is still unclear and controversial.[81]

Tests of the entire HPA axis, such as the insulin tolerance test (also called the insulin-induced hypoglycemia stimulation test; see Box 53-3), occasionally are abnormal in patients who have (1) a normal morning cortisol result, (2) a normal response to cosyntropin, and (3) no signs of adrenal insufficiency. Although an abnormality in these sensitive tests suggests some diminution of ACTH reserve, the clinical significance is most relevant when the patient encounters a major stress, such as gastroenteritis. These tests should be reserved for patients who are strongly suspected of having adrenal insufficiency, or whose morning cortisol concentration or response to ACTH has been found to be abnormal. Standard protocols for the performance and interpretation of these tests have been published. These tests involve some patient risk and discomfort and should be performed only under the direct supervision of an experienced physician.

Measurement of ACTH in blood collected at baseline or after stimulation with insulin adds little to the utility of the tests discussed previously and generally is not recommended. In fact, in patients who have undergone pituitary surgery, the cortisol negative feedback loop to ACTH secretion may take time to normalize. ACTH and cortisol measurements after administration of CRH potentially are a direct test of pituitary ACTH reserve. The insulin-induced hypoglycemia test is currently the definitive test of ACTH and/or cortisol reserve; however, this test is contraindicated in patients with a history of coronary heart disease, seizure disorder, or general debility. Metyrapone testing is discussed in Chapter 55 as another test of pituitary ACTH reserve.

Hypothalamic-Pituitary-Thyroid Axis

Because the current generation of TSH assays provide limits of detection extending to 0.01 IU/mL or less, which is sufficient to distinguish between low-normal and pathologically suppressed TSH secretion, TRH testing usually is not required for assessment of thyroid function.[158] Pharmaceutical TRH currently is not available in the United States.

The sole value of the TRH test is in the diagnosis of a TSH-secreting tumor in a patient presenting with increased free T_4 and an inappropriately elevated TSH.[9] In these patients, the TSH response to TRH is impaired. Such patients may also have elevated concentrations of free alpha subunits.

TRH testing involves the bolus IV administration of TRH (1 μg/kg, 100 μg/m^2, or 500 μg total in adults), along with the measurement of TSH at baseline and at 30 minutes. (*Note:* Some protocols extend TSH measurements to 45 and 60 minutes.) The expected (normal) response is an increase in TSH concentration over baseline of 5 to 30 IU/mL. Some sources report that a normal response to TRH is a fivefold to tenfold increase in serum TSH concentration within 60 minutes after TRH administration. A TSH change less than 5 uIU/mL indicates TSH suppression (primary hyperthyroidism) or inability of the pituitary to respond (secondary hypothyroidism). TSH responses greater than 30 IU/mL are consistent with primary hypothyroidism. In tertiary hypothyroidism, TSH will rise slowly in a delayed response pattern.

Hypothalamic-Pituitary-Gonadal Axis

History and physical examination are extremely helpful in evaluating the status of the hypothalamic-pituitary-gonadal axis, particularly in women during their reproductive years.[12,146] Normal menstrual cycles usually indicate an intact hypothalamic-pituitary-gonadal axis in women of reproductive age. A serum progesterone concentration greater than 10 ng/mL during the luteal phase of the menstrual cycle supports ovulation.

Baseline laboratory assessment for hypothalamic-pituitary-gonadal dysregulation should include measurement of serum gonadotropins (LH and FSH) and sex steroids (estradiol in females and testosterone in males). Provocative testing of this axis with GnRH administration and measurements of FSH and LH (Box 53-6) are useful in selected patients. However, the definition of an appropriate response to GnRH is controversial and depends on the stage of sexual maturation of the subject. Following GnRH injection, LH normally rises more than FSH. Two shortened variations of

BOX 53-6 Protocol for the Gonadotropin-Releasing Hormone Stimulation Test for Luteinizing Hormone and Follicle-Stimulating Hormone Reserve

Rationale

The hypothalamic releasing hormone GnRH stimulates the pituitary release of both LH and FSH in normal individuals. Subnormal responses are seen in some patients with pituitary or hypothalamic disorders. However, the magnitude of LH and FSH responses to GnRH is usually predictable from basal LH and FSH concentrations. This test may be useful in patients in whom the clinical picture and basal gonadotropin measurements are inconclusive.

Procedure

The test may be performed without regard to previous feeding or time of day. After baseline specimens are obtained for LH and FSH measurement, 100 μg or 2.5 μg/kg (to a maximum of 100 μg) GnRH is given intravenously. Samples for LH and FSH determination should be drawn every 15 to 20 minutes for 1 to 2 hours.

Interpretation

LH response should increase by threefold to tenfold. The FSH response is of lesser magnitude (usually a 1.5- to 3-fold increase). Peak responses for both LH and FSH occur between 15 and 30 minutes.

the GnRH test are available: in one variation, leuprolide (a GnRH agonist; 500 μg or 20 μg/kg) is injected subcutaneously, and LH and FSH are measured 3 hours later; in the other variant, 100 μg of GnRH is injected subcutaneously, and LH and FSH are measured 40 minutes later. These tests, however, can be unreliable in differentiating pituitary disorders from hypothalamic dysfunction; the physician usually is dependent on an accurate determination of gonadotropins and sex steroids, along with clinical judgment, in differentiating hypothalamic from pituitary disease.

Pituitary Assessment in Surgical Patients

Initial Assessment

Preoperative testing is indicated in patients with large pituitary tumors or specific clinical indications such as suspected ACTH deficiency, when glucocorticoids may be required preoperatively (see Box 53-5), but the gonadal axis may be compromised in patients with microadenomas as well. In addition to the history and physical examination, patients at risk for pituitary insufficiency should be evaluated for endocrine function before surgery is performed, including laboratory measurements of serum prolactin, free T_4, LH, FSH, sex steroids (testosterone in males and estradiol in females), serum sodium, and urine specific gravity (or serum and urine osmolality), and a morning serum cortisol or cosyntropin stimulation test.

Perioperative Assessment

The optimum time for retesting endocrine function after pituitary surgery is not known. Many protocols (often based on sparse data) explain how potential cortisol deficiency is managed in the perioperative period. Some neurosurgeons provide "stress" doses (high doses) of glucocorticoids immediately before, during, and after surgery. If the patient had ACTH deficiency preoperatively, IV glucocorticoids can be substituted with oral replacement doses (e.g., the equivalent of 12 mg/m^2 per day of hydrocortisone in children, or 20 to 30 mg in adults in divided doses) after 2 to 3 days. If the patient had normal adrenal function preoperatively, exogenous glucocorticoids can be discontinued on the second or third postoperative day. Morning cortisol should be measured 24 hours later; if the result is less than 5 μg/dL, ACTH deficiency is likely and glucocorticoid replacement is indicated. If the 24 hour postoperative cortisol is 10 μg/dL or greater, the HPA axis is normal and glucocorticoid replacement is not required. If cortisol is between 5 and 10 μg/dL, the patient should be treated with glucocorticoids, or provocative testing (ITT) should be performed; the ITT can be used concurrently to assess GH deficiency.

Some neurosurgeons do not treat with glucocorticoids if preoperative adrenal function is normal,[106] instead assessing the patient's postoperative morning cortisol concentration. If cortisol concentration is less than 3.6 μg/dL, ACTH deficiency is present and glucocorticoid treatment is necessary. If cortisol is greater than 16 μg/dL, ACTH deficiency is not present and glucocorticoid treatment is not required. Definitive testing is indicated only for patients with a morning cortisol of 3.6 to 16 μg/dL; pituitary function in these patients can be evaluated with an ITT or glucagon stimulation test. Patients with a morning cortisol between 3.6 and 9 μg/dL usually receive daily glucocorticoid treatment, whereas those with an AM cortisol between 9 and 16 μg/dL are treated only at times of stress.

In the first 4 weeks after pituitary surgery, the cosyntropin test may not be a reliable indicator of HPA axis integrity. During this period, the adrenal response to cosyntropin may be normal, yet endogenous ACTH may be insufficient in the basal state or at times of stress to avoid glucocorticoid insufficiency. Once the adrenal gland atrophies from a deficiency of endogenous ACTH (which may take ≈4 weeks), the cosyntropin challenge becomes abnormal, reflecting endogenous ACTH deficiency.

Postoperative Assessment

It is advisable to wait until 1 month after surgery to evaluate thyroid function (TSH and free T_4) and gonadal function (testosterone in males and estradiol in females; see Box 53-5). Early treatment of thyroid and gonadal deficiencies is not critical, and misleading test results might be observed in the early postoperative period. Adrenal function should be reassessed with a 250 μg cosyntropin stimulation test 1 month after surgery even if immediate results are subnormal, because ACTH deficiency after pituitary surgery is often transient. Periodic clinical follow-up and laboratory assessment should be tailored to individual circumstances.

Stimulation tests for the secretion of ACTH, GH, and GnRH can be combined. For example, the ITT can be combined with the GnRH stimulation test. The ITT assesses GH and ACTH secretion, whereas the GnRH stimulation test assesses the ability of the anterior pituitary to secrete gonadotropins in response to GnRH.

After pituitary irradiation, patients should be evaluated every 6 months with measurement of free T_4, sex steroids, cortisol, and cosyntropin stimulation.

The Neurohypophysis

The neurohypophysis (posterior pituitary) is derived from the brain neuroectodermis. Embryologically, ventral evagination of the floor of the third ventricle forms the neurohypophysis.[63] Antidiuretic hormone (ADH; vasopressin) and oxytocin are secreted from the neurohypophysis, the cell bodies of which are located in hypothalamic supraoptic and paraventricular nuclei. These neurons are located in, and travel through, the median eminence and pituitary stalk, with nerve endings projecting to the posterior lobe of the pituitary gland.

Antidiuretic Hormone

Disorders of ADH involve excess hormone [syndrome of inappropriate ADH (SIADH)] or deficient ADH action [diabetes insipidus (DI)]. DI can result from ADH deficiency, ADH resistance, or renal tubular disease; the latter two conditions are termed *nephrogenic DI*. Disorders of oxytocin secretion have not been described.

Biochemistry

Both ADH and oxytocin are nonapeptides consisting of a cyclic hexapeptide and a 3 amino acid side chain (Figure 53-8). At the physiologic pH of plasma, ADH and oxytocin circulate mainly as unbound (free) hormones.

The gene for ADH is located at chromosome 20p13. PreproADH consists of 164 amino acids (17.3 kDa). The gene also encodes neurophysin 2 and copeptin. The first 19 amino acids of preproADH are the leader sequence. Amino acids 20-28 constitute the ADH nonapeptide hormone; amino acids 32-124 represent neurophysin 2; and amino acids 126-164 represent copeptin (C-terminal provasopressin). The glycine residue at position 28 is amidated, and amino acid 131 is glycosylated. Disulfide bonds are definitive or possible at amino acids 20-25, 41-85, 44-58, 52-75, 59-65, 92-104, 98-116, and 105-110. The disulfide bridge at residues 20-25 is within ADH.

The ADH receptor in the renal tubules (specifically the collecting ducts) is termed the *arginine vasopressin receptor 2 (V2 receptor)*. The V2 receptor is a member of the seven-transmembrane domain G-protein–coupled receptor (GPCR) superfamily, whose other members include the V1a and V1b vasopressin receptors and the oxytocin receptor.

The gene for the V2 receptor is located on chromosome Xq28. The receptor is 371 amino acids (40.3 kDa), including a 38 amino acid extracellular domain, seven transmembrane domains, and a 43 amino acid cytoplasmic domain. Amino acid 22 may be glycosylated, and amino acids 341 and 342 are lipidated as S-palmitoyl cysteines. Two isoforms of the V2 receptor are known: isoform 1 is the full-length receptor, whereas isoform 2 varies in the sequence of amino acids 305 to 309, and amino acids 310 to 371 are absent.

The V1a receptor (V1 receptor) gene is located at chromosome 12q14. The protein is 418 amino acids and weighs 46.8 kDa. A 52 amino acid extracellular domain is present, along with seven transmembrane domains and a 67 amino acid cytoplasmic domain. Glycosylation is possible at amino acids 27 and 196. Amino acids 365 and 366 may be lipidated as S-palmitoyl cysteines. A serine residue at position 404 may be phosphorylated to phosphoserine, and a disulfide bond is likely between amino acids 124 and 203.

The V1b receptor (V3 receptor) is encoded by a gene located on chromosome 1q32. The V3 receptor is composed of 424 amino acids (47.0 kDa). A 35 amino acid extracellular domain is present, along with seven transmembrane domains and an 83 amino acid cytoplasmic domain. The receptor is possibly glycosylated at amino acid 21, and a disulfide bond is likely between amino acids 107 and 186.

Aquaporin-2 is a 271 amino acid protein (28.8 kDa).[100] The gene encoding aquaporin-2 is located on chromosome 12q1. The external domain contains 16 amino acids, along with seven transmembrane domains and a 47 amino acid cytoplasmic domain. Phosphoserines are possible or definitive at amino acids 256, 261, and 264, and amino acid 123 is a possible site of glycosylation. Amino acids 68-70 and 184-186 are NPA (asparagine-proline-alanine) motifs.

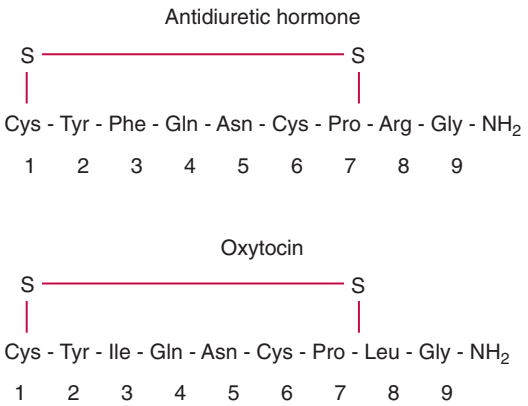

Figure 53-8 The amino acid sequences of antidiuretic hormone (ADH) and oxytocin are compared.

Regulation of ADH Secretion

ADH secretion is controlled predominantly by plasma osmolality (tonicity).[16] Plasma osmolality is sensed by osmoreceptors located in cell bodies in or near the magnocellular nuclei of the hypothalamus. Increased osmolality results in ADH release; even relatively small changes in osmolality affect ADH secretion. A 2% increase in extracellular fluid osmolality can stimulate the osmoreceptor to release ADH. Plasma osmolality above 280 mOsm/kg is thought to be the osmotic threshold for triggering ADH release.

In addition to the osmoreceptor mechanism of vasopressin release, physiologic regulation of ADH secretion involves a pressure-volume mechanism that is distinct from the osmotic sensor. High-pressure arterial baroreceptors of the aortic arch and carotid sinus, and low-pressure volume receptors in the pulmonary venous system and atria, also regulate ADH release. Therefore, ADH is secreted in response to decreased circulating blood volume, or decreased blood pressure. Other nonosmotic stimuli for ADH release include pain, stress, nausea and vomiting, sleep, exercise, and chemical agents such as catecholamines, angiotensin II, opiates, prostaglandins, anesthetics, nicotine, and barbiturates.

The thirst center is regulated by many of the same factors that determine ADH release. This center has a higher set point than the osmoreceptors and responds to osmolalities above 290 mOsm/kg. Responses involving ADH, thirst, and renal reabsorption of sodium and water are coordinated in a complex scheme that maintains plasma osmolality in healthy individuals within a narrow interval (284 to 295 mOsm/kg).

Physiologic Activity

Both ADH and neurophysin 2 are present in secretory vesicles that reach the terminal portion of the axon 12 to 14 hours after they are synthesized (this is also true for oxytocin and neurophysin 1). Upon nerve stimulation, release of neurohypophyseal hormones into the portal circulation occurs via calcium-dependent exocytosis. When a stimulus for secretion of ADH or oxytocin occurs, the stimulus acts on the appropriate magnocellular cell body in the hypothalamus, sending

an action potential down the long axon to the posterior pituitary, causing an influx of calcium and the release of hormone from neurosecretory granules.

The exact role of the neurophysins is unclear, but their proper synthesis is necessary for ADH secretion. The biological role of copeptin is unknown. Because of analytical difficulties in measuring ADH, some investigators have suggested measuring copeptin as a surrogate for ADH, because copeptin is secreted in amounts stoichiometrically equivalent to ADH, and copeptin is stable in plasma.

The actions of ADH are to conserve free water (via V2 receptors) and stimulate vasoconstriction (via V1a receptors).[30] These effects combine to maintain proper osmolality of the extracellular space (the major action of ADH) and blood pressure through maintenance of circulating blood volume and prevention of dehydration and excessive loss of water.

ADH increases the permeability of renal collecting ducts to water, thereby increasing water reabsorption and concentrating the urine (Figure 53-9).

An alternative name for ADH is *vasopressin* (or *arginine vasopressin*), which emphasizes the vasoconstrictive effects of high concentrations of ADH.[197] These vasoconstrictive effects are manifested when ADH binds to V1a receptors on arterial smooth muscle cells. Note that the major endocrine system regulating blood pressure is the renin-angiotensin-aldosterone system. ADH, however, is believed to play an important role in the maintenance of arterial blood pressure during blood loss. Release of ADH into the pituitary portal system also augments the release of ACTH from the adenohypophysis, but does not appear to affect the release of other anterior pituitary hormones.

ADH binding to the V1a receptor stimulates the secretion of vascular endothelial growth factor (VEGF). The V1a receptor may also affect platelet aggregation, coagulation factor release, and glycogenolysis by its expression on platelets and hepatocytes.

The V1b receptor (V3 receptor) is expressed in the CNS. In this way, ADH can release ACTH to aid in the response to stress. The V1b receptor also has been reported to be expressed in islet cells, influencing insulin secretion.

Clinical Significance

Disorders of ADH activity have been divided into hypofunction (DI) and hyperfunction (SIADH) (Figure 53-10).[176,182]

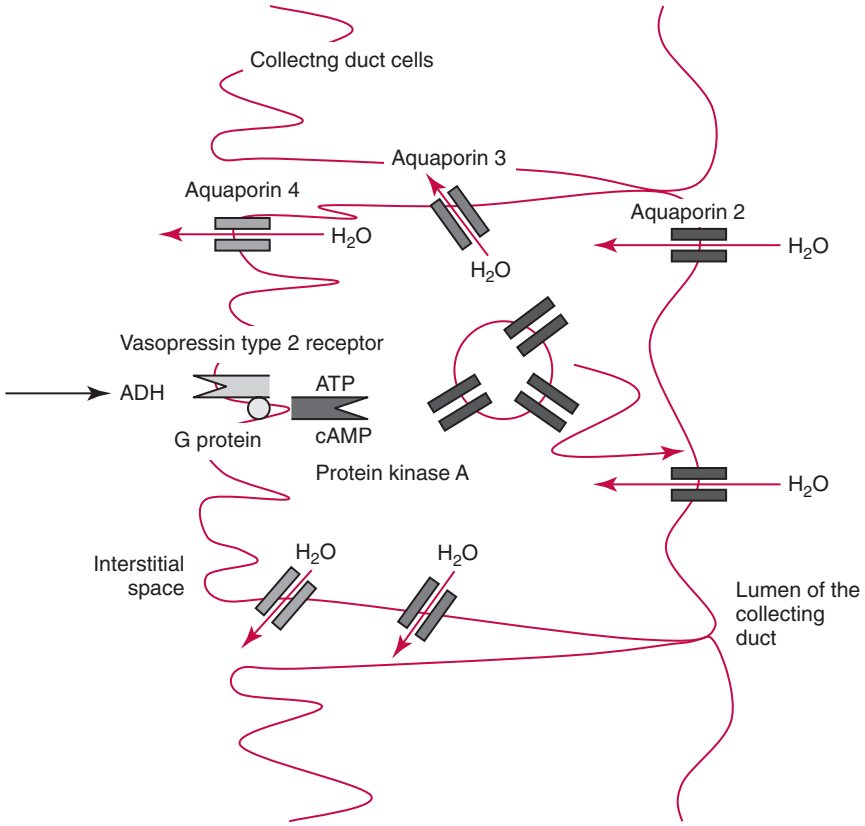

Figure 53-9 Vasopressin type 2 receptors on collecting duct cells bind antidiuretic hormone (ADH). Via a G-protein system, ATP is converted to cAMP via adenylate cyclase with protein kinase A activation. This leads to translocation of aquaporin-2 water channels from an intracellular pool to the apical plasma membrane, allowing free water uptake by cells of the collecting duct. Via the basolateral plasma membrane aquaporin-3 and aquaporin-4 water channels, free water then leaves these cells.

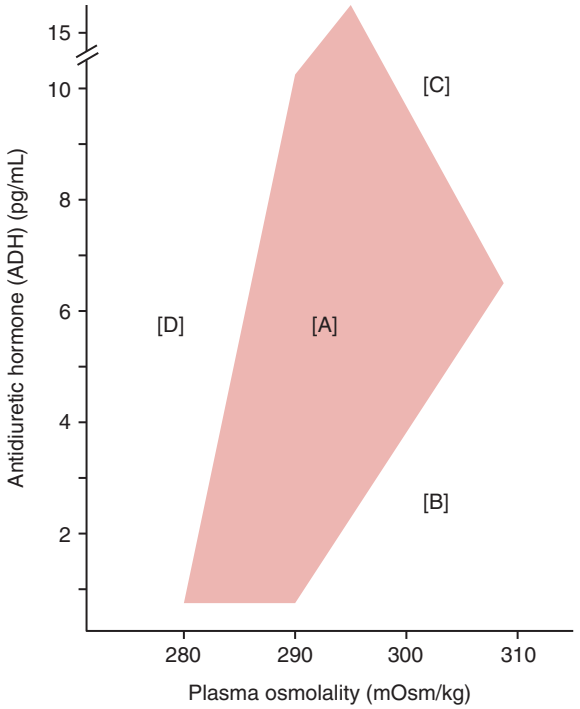

Figure 53-10 The relationship of plasma antidiuretic hormone (ADH) to plasma osmolality. Region *[A]* is the reference interval and the results observed in subjects with psychogenic polydipsia and excessive water intake. Region *[B]* represents findings in central diabetes insipidus, whereas region *[C]* represents findings in nephrogenic diabetes insipidus. Region *[D]* represents findings in the syndrome of inappropriate ADH (SIADH) secretion. *(Modified and abstracted from Zerbe RL, Robertson GL. A comparison of plasma vasopressin measurements with a standard indirect test in the differential diagnosis of polyuria. N Engl J Med 1981;305:1539-46.)*

TABLE 53-8 Causes of Central Diabetes Insipidus

Congenital	Midline malformations: septo-optic dysplasia, holoprosencephaly, single central incisor, cleft lip and/or palate
	Malformation of the pituitary (ectopia or hypogenesis)
	Diabetes insipidus-diabetes mellitus-optic atrophy syndrome (DIDMOA; Wolfram syndrome)
	Familial diabetes insipidus (autosomal dominant and recessive forms)
Acquired	Tumors (craniopharyngioma, germinoma, pinealoma, optic glioma, pituitary adenoma, metastatic tumor, leukemia)
	Trauma (e.g., stalk section)
	Infarction (e.g., septic shock, Sheehan syndrome, hypoxic injury)
	Infiltrative disease (sarcoidosis, hypophysitis, histiocytosis)
	Cysts and aneurysms
	Drugs (opiates, alcohol, phenytoin, alpha-adrenergic agents, etc.)
	Infection
	Increased metabolism of ADH (vasopressinase in pregnancy)

Polyuric states are divided into two main categories: (1) deficient ADH action, producing DI (sometimes called "water diabetes"), and (2) excessive oral water intake (psychogenic polydipsia).[191] Inadequate ADH activity can result from ADH deficiency or ADH resistance. An osmotic diuresis may also produce polyuria and polydipsia. Uncontrolled diabetes mellitus with a high glucose load to the kidney is a common cause of osmotic diuresis.

In DI, polyuria results from excessive loss of water into the urine.[147] Under normal circumstances, urine output is mostly dependent on fluid intake; thus an arbitrary upper limit for normal urine output cannot be defined. When urine output is greater than 2.5 L/d, an investigation is usually indicated. In the absence of ADH, urine output may approach 1 L/h. Increased osmolality normally stimulates thirst. Therefore if a patient with DI has an intact thirst mechanism and free access to water, excessive urinary loss of water will be matched by excessive intake of fluids. This is why DI patients report polydipsia in addition to polyuria. The major laboratory finding is urine of low osmolality and serum sodium within the upper half of the reference interval, with a corresponding high-normal serum osmolality. If water is not available, or the individual with DI is physically impaired or lacks a normal thirst mechanism, serum osmolality rises, serum sodium rises (producing hypernatremia), urine osmolality remains low, and polyuria continues. With dehydration, weight loss is acute (because of fluid loss) and blood pressure falls, inducing tachycardia.

Central DI can result from any destructive hypothalamic lesion or infundibular lesion (Table 53-8). DI resulting from such lesions can equally be termed *hypothalamic, neurogenic, central,* or *cranial DI.* Central DI is caused by failure of the posterior pituitary gland to secrete appropriate amounts of ADH in response to rising plasma osmolality. Increased fluid intake promoted by thirst mechanisms usually prevents dehydration. When the thirst center is also abnormal, severe dehydration can occur. Destruction of 80% of ADH-secreting neurons is required to produce central DI. Surgical or traumatic injury to the neurohypophysis may cause transient DI.

The incidence of central DI is about 1 in 25,000 people. In 30% of patients, central DI occurs without apparent cause. Remaining cases are associated with (1) neoplastic disease, (2) neurologic surgery, (3) head trauma, (4) ischemic or hypoxic disorder, (5) granulomatous disease, (6) infection, or (7) autoimmune disorder. A hereditary form of the disorder is transmitted as an autosomal dominant trait. Inborn errors in the ADH gene cause deficiency of the hormone.

Individuals with familial neurohypophyseal diabetes insipidus (FNHDI) are typically recognized before the age of 6 years and display worsening polyuria and compensatory polydipsia.[43] More than 50 mutations have been identified as causes of FNHDI. Although rare, diabetes insipidus can develop during pregnancy as a result of high circulating concentrations of the enzyme cysteine aminopeptidase (vasopressinase), which inactivates ADH.[111] The vasopressinase may be of placental origin.

DI can result from tubular diseases that affect the responsiveness of renal tubules to ADH (nephrogenic DI). In X-linked congenital diabetes insipidus, an inactivating mutation of the V2 receptor is noted.[187] Loss-of-function mutations in aquaporin-2 cause autosomal recessive and autosomal dominant forms of congenital nephrogenic DI.[144] Chronic hypokalemia and hypercalcemia produce a form of nephrogenic DI that results from downregulation of aquaporin-2 expression.[119]

In the broadest sense, any form of tubular injury with impaired water reabsorption including (1) polycystic kidney disease, (2) medullary cystic kidney, (3) chronic pyelonephritis, (4) acute tubular necrosis, (5) obstructive uropathy, (6) sickle cell nephropathy, and (7) renal amyloidosis causes nephrogenic DI. A large number of drugs can cause nephrogenic DI, including (1) lithium, (2) various antimicrobials (amphotericin B, rifampin, methicillin, demeclocycline, and foscarnet), and (3) several antineoplastic drugs (cisplatin and ifosfamide). In psychogenic polydipsia (primary polydipsia), excessive water intake eventually begins to impair the concentrating ability of the kidney.

Pathologic ADH excess produces SIADH (Table 53-9).[20] SIADH causes excessive water retention, resulting in reduced plasma osmolality, hyponatremia, elevated urine osmolality, and reduced urine output. Water retention can cause edema. Presumably because of suppression of the renin-angiotensin-aldosterone system from relative fluid overload, urinary sodium loss is not restricted, and the usual urinary sodium concentration in SIADH is 20 to 40 mEq/L. By contrast, dehydration fully activates the renin-angiotensin-aldosterone system, and urinary sodium is usually less than 10 mEq/L. Causes of SIADH are legion (see Table 53-9). A rare form of nephrogenic SIADH results from a gain-of-function mutation in the V2 receptor.

TABLE 53-9 Causes of the Syndrome of Inappropriate Antidiuretic Hormone

CNS disease	Brain tumor
	Infection (e.g., meningitis, encephalitis, abscess)
	Prolonged seizure
	Psychiatric disease
	Stress (e.g., prolonged nausea)
Non-CNS tumor (e.g., leukemia)	
Pulmonary disease	Hypoxia (e.g., neonatal)
	Infection (e.g., pneumonia, emphysema)
Nonpulmonary infection (e.g., AIDS)	
Drugs	Drugs with CNS effects (anticonvulsants, antiparkinsonian drugs, antipsychotics, antipyretics, antidepressants)
	Angiotensin-converting enzyme (ACE) inhibitors
	Antineoplastic drugs
	First-generation sulfonylureas

Diagnostic Studies

ADH usually is not measured for diagnostic purposes because ADH excess and deficiency are evident in changes in serum and urine osmolality, serum sodium, and urine volume.[64] Less precise measures of fluid balance include clinical evaluation for dehydration, blood pressure (supine and upright), heart rate, and body weight. Hormone concentration is not measured in some endocrine disorders because the consequent metabolic abnormality is more important. The best example is diabetes mellitus. Diagnosis and management of diabetes mellitus center on measurement of glucose (and now hemoglobin A_{1c})—not on measurement of insulin or C-peptide.

Serum osmolality can be estimated from serum sodium, glucose, and urea (BUN), but is more reliably measured directly by freezing point depression. Various formulas are available for estimating serum osmolality; all are based on the fact that sodium represents approximately half of all the ions in serum (each sodium is balanced by an anion, and sodium accounts for almost 95% of all cations); among all nonionic solutes, only glucose and urea have high enough concentrations to substantially affect (alone) osmolality. Hence, osmolality can be estimated by adding together twice the sodium, the glucose, and the urea concentrations (in the United States, glucose and BUN, measured in mg/dL, must be converted to mmol/L by dividing their concentrations by 18 and 2.8, respectively).

Several variations may be seen in the calculation of serum osmolality (see Chapters 28 and 49). The simple equation,

$$\text{mOsmol/kg} = 2 \times [Na^+] + \frac{[Glu]}{18} + \frac{[BUN]}{2.8}$$

underestimates the true osmolality by 5 to 10 mOsm/kg because of the remaining constituents in serum that do not, individually, have significant concentrations, but when combined contribute approximately that amount. Some laboratories provide a reference interval that accounts for the difference, whereas others add an average factor (often 8 or 9 mOsm/kg) (and use a different reference interval) to make the calculated osmolality a closer estimate of measured osmolality. The equation assumes that the activity

coefficient for Na^+ is 1.0, and this is not the case. Regression analysis of sodium versus measured osmolality produces a slope that corresponds to a factor of approximately 1.86, so some calculations of osmolality (particularly automated calculations) use that factor instead of 2, which results in a bias of approximately 5% between the two equations. As discussed in Chapter 28, the following equations are often recommended:

$$\text{mOsmol/kg} = 1.86[\text{Na}^+\,(\text{mmol/L})] + \text{Glucose}\,(\text{mmol/L}) + \text{Urea}\,(\text{mmol/L}) + 9$$

or

$$\text{mOsmol/kg} = 1.86[\text{Na}^+\,(\text{mmol/L})] + \text{Glucose}\,(\text{mg/dL}) + \text{Urea}\,(\text{mg/dL})/2.8 + 9$$

In the absence of proteinuria, hematuria, glycosuria, and other osmotically active substances (such as radiocontrast dyes), urine specific gravity is a rough estimate of urine osmolality.

Investigation of Polyuria

Assuming that diabetes mellitus is excluded, a differential diagnosis of polyuric states can be made using measurements of plasma and urine osmolality and plasma ADH concentrations (if the findings are equivocal).[89] A recommended strategy is shown in Box 53-7. A screening test for ADH sufficiency is measurement of the urine specific gravity in the first morning-voided urine sample. The specific gravity should be 1.010 or greater in patients with adequate ADH secretion. Failure to demonstrate an appropriate urine specific gravity in a subject with a history of polyuria and polydipsia should trigger assessment of a basic metabolic panel, urinalysis, serum osmolality, and urine osmolality. Hyperglycemia or glycosuria would suggest diabetes mellitus (see Chapter 46).

Urine osmolality below 300 mOsm/kg combined with serum osmolality above 300 mOsm/kg (or with hypernatremia) is diagnostic for diabetes insipidus. If urine osmolality is above 600 mOsm/kg and serum osmolality is below 270 mOsm/kg, DI is unlikely.

If the diagnosis of DI is unclear, a water deprivation test should be performed, although this is rarely needed.[4] Prior to a water deprivation test, uncontrolled diabetes mellitus should be corrected, and thyroid and adrenal function should be normal (or treated if deficient). Water deprivation testing should not be carried out if the subject is dehydrated at baseline or has renal insufficiency. The overnight water deprivation test is usually conducted in a hospital setting because of immediate concerns of profound hypotension and possible mortality.[149,164] Hypertonic saline infusion testing is dangerous and is not used clinically.

The water deprivation test is usually begun on the morning after an overnight fast, unless the history describes large volumes of water ingested and urine produced, in which case the test should begin after breakfast. The subject remains fasting throughout the entire test. A heparin lock is inserted intravenously, so that serial blood samples are obtained easily. Baseline laboratory tests include (1) sodium, (2) potassium, (3) chloride, (4) serum CO_2, (5) BUN, (6) creatinine, (7) glucose, (8) calcium, and (9) serum osmolality. Potassium and calcium are measured to exclude hypokalemia and hypercalcemia as causes of nephrogenic DI (see later).

Measurements of serum sodium, chloride, CO_2, and urine pH provide an assessment of the patient's renal tubular acid-base function.[93] Renal function and hydration status are evaluated with creatinine and BUN measurements. A urine specimen is obtained for measurement of urine sodium, urine osmolality, and urine specific gravity. Body weight and vital signs at baseline are recorded. Thereafter, each hour, serum and urine tests are repeated with measurement of hourly urine output, body weight, and urine volume. If ADH measurements are requested, they can be performed at the beginning, middle, and completion of the test; however, ADH measurements are not required for making the diagnosis of DI. The test is continued for 8 to 10 hours unless the diagnosis of DI is confirmed before the full time has elapsed.

One approach that reduces laboratory charges is to perform serum and urine measurements every 4 hours until plasma osmolality reaches 280 mOsm/kg, when the frequency is increased to every 2 hours. When plasma osmolality reaches 290 mOsm/kg (or serum sodium exceeds 140 mEq/L, or weight loss nears 3%), the tests are performed hourly. During the water deprivation test, if urine osmolality exceeds 600 mOsm/kg on two samples 1 hour apart, or a single urine sample exceeds 1000 mOsm, DI is effectively ruled out, and the test can be concluded. If urine osmolality is below 600 mOsm and serum osmolality is above 300 mOsm/kg, DI is diagnosed and the test can be concluded. If serum osmolality does not exceed 300 mOsm/kg, the test should be

BOX 53-7 Diagnosis of Diabetes Insipidus (DI)

Document polyuria (urine volume >2.5 L/d in adults) and exclude glycosuria. If desired, creatinine excretion can be measured as an estimate of the completeness of the urine collection. Substances that influence antidiuretic hormone (ADH) secretion should be avoided (e.g., nicotine, alcohol, caffeine). If plasma osmolality is greater than 295 mOsm/kg, or if the serum sodium concentration is greater than 145 mEq/L, primary polydipsia is unlikely. If the diagnosis of DI is unclear, proceed with the overnight water deprivation test (see text for a description of this test).

Overnight water deprivation test: If the ratio of urine to plasma osmolality is less than 1.5 at the end of the test, primary polydipsia is unlikely. Measure plasma and urine osmolalities and plasma ADH concentrations at the end of the test; use these relationships to differentiate normal, nephrogenic, and hypothalamic diabetes insipidus, as well as psychogenic polydipsia. If urine osmolality is greater than 400 mOsm/kg at the end of the test, give 5 U of aqueous vasopressin subcutaneously (minimum, 1 U/m^2). If urine osmolality increases by more than 10%, central diabetes insipidus is probable; if urine osmolality does not increase, nephrogenic diabetes insipidus is highly probable.

continued. If mental status changes or hypotension occurs, or weight loss exceeds 3%, the test should be terminated.

If DI is diagnosed during a water deprivation test, aqueous vasopressin is injected subcutaneously (1 U/m^2), or desamino-D-arginine vasopressin (dDAVP, desmopressin) is given IV or IM (2 μg). A decline in urine volume with doubling of urine osmolality over the next 1 to 2 hours identifies the DI as central in origin with the patient ADH deficient. Following exogenous ADH administration, some references define an increase in urine osmolality of 10% or greater over 60 minutes as evidence of ADH deficiency. Failure to respond to exogenous ADH defines nephrogenic DI. Most patients with psychogenic polydipsia have normal urine osmolality after water deprivation, but some fail to produce concentrated urine unless the water deprivation is prolonged. When psychogenic polydipsia is suspected, the patient should be given a minimum of 1 L of normal saline IV to re-establish the renal medullary concentrating gradient, so that the patient can respond appropriately to ADH.

The diagnosis of "partial" DI, in which test results fall between normal and frank DI, is difficult, because no clear-cut boundaries are evident between normal and partial DI, or between partial DI and complete DI.[200] In some cases, measurement of ADH in plasma or urine may be required to reach the correct diagnosis. After water deprivation, patients with central DI have low or inappropriately normal plasma ADH concentrations relative to high plasma osmolality or low urine osmolality, whereas patients with nephrogenic DI have high plasma concentrations of ADH when plasma osmolality exceeds 300 mOsm/kg and urine osmolality is low. Patients with primary polydipsia have normal concentrations of ADH relative to their plasma osmolality. Because ADH concentrations are most discriminatory when plasma osmolality is high, in the past ADH was measured after hypertonic saline was administered to the patient. However, this saline infusion test is potentially dangerous and currently is not used by clinical endocrinologists.

Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH)

The autonomous, sustained production of ADH in the absence of recognized and appropriate stimuli (such as hyperosmolality) is termed *SIADH*.[15] In this syndrome, plasma ADH concentrations are "inappropriately" elevated relative to decreased plasma osmolality, and relative to normal or increased plasma volume.

SIADH may be the result of one of several factors including (1) production of ADH by a malignancy (such as small cell carcinoma of the lung), (2) the presence of acute or chronic disease of the central nervous system, (3) pulmonary disorders, or it may occur as (4) a side effect of certain drug therapies. In addition, as many as 10% of patients undergoing pituitary surgery have transient SIADH (for 2 to 3 days) approximately 8 to 9 days after surgery (typically when the patient is at home) that responds to water restriction and resolves spontaneously. This may represent the release of ADH from the posterior pituitary or hypothalamus following surgical trauma.

In SIADH, primary excess of ADH, coupled with unrestricted fluid intake, promotes increased reabsorption of water by the kidney. The consequences are decreased urine volume and increased urine osmolality. As a result of water retention, patients become modestly volume expanded. The increase in intravascular volume causes hemodilution accompanied by dilutional hyponatremia and low plasma osmolality. Volume expansion also decreases renal sodium reabsorption, thus the urine sodium concentration is increased.

SIADH is a common cause of hyponatremia in hospitalized patients.[11] However, other disorders can cause dilutional hyponatremia and must be differentiated from SIADH. These conditions include (1) congestive heart failure, (2) renal insufficiency, (3) nephrotic syndrome, (4) liver cirrhosis, and (5) hypothyroidism. Excessive administration of hypotonic fluids and treatment with drugs that stimulate ADH (chlorpropamide, vincristine, carbamazepine, nicotine, phenothiazines, and cyclophosphamide) can also cause dilutional hyponatremia. Additionally, hyponatremia may occur from renal or extrarenal sodium loss (depletional hyponatremia) as a result of vomiting, diarrhea, excessive sweating, diuretic abuse, salt-losing nephropathy, or mineralocorticoid deficiency. In these latter conditions, plasma BUN is generally increased. Hyponatremia is increasingly recognized as a marker of disease severity.[172] However, selectively increasing the patient's plasma sodium through fluid manipulation will not improve the outcome; it is the underlying disorder that most likely is responsible for the hyponatremia.

Clinical manifestations of hyponatremia are nonspecific and include weakness and apathy in mild cases, and CNS changes such as lethargy, coma, and seizures in more severe cases.[68] No signs or symptoms are specific for SIADH. History, physical examination, and routine laboratory test results often suggest that hyponatremia is dilutional (decreased BUN, hemoglobin, or albumin) or depletional (increased BUN, hemoglobin, or albumin).

Measurements of sodium and osmolality in blood and urine, combined with clinical assessment of volume status, usually permit the appropriate differential diagnosis of hyponatremic conditions (Box 53-8). The diagnosis of SIADH usually is explored solely on the basis of the clinical scenario and the routine laboratory studies discussed previously.[61] SIADH is diagnosed when hyponatremia (<135 mEq/L) and reduced serum osmolality (<270 to 280 mOsm/kg) are present, together with an inappropriately concentrated urine (urine osmolality >100 mOsm/kg). Maximally dilute urine normally is 50 to 80 mOsm/kg, and this is expected in the setting of hyponatremia and hypo-osmolality. However in SIADH, despite serum hypo-osmolality, urine osmolality is typically 250 to 1400 mOsm/kg. It is important to point out that the urine osmolality does not need to exceed the serum osmolality for the diagnosis of SIADH to be made: the urine need only be inappropriately concentrated with respect to the

BOX 53-8 Diagnosis of the Syndrome of Inappropriate Antidiuretic Hormone

Document plasma hypo-osmolality (≤275 mOsm/kg) and hyponatremia (sodium concentration ≤130 mEq/L). Use the history, physical examination, and appropriate laboratory tests to exclude cardiac, hepatic, renal, thyroid, or adrenal failure, along with the effects of pituitary surgery, diuretic therapy, or medications known to stimulate ADH release. (SIADH cannot be diagnosed unless these factors are corrected.) Measure the urine sodium concentration and osmolality. Urine osmolality greater than plasma osmolality and without correspondingly low urine sodium concentration (usually greater than 40 to 60 mEq/L) indicates that SIADH is probable (see the text for details). If the cause of DI is unclear, consider measuring plasma ADH and plasma renin concentrations. SIADH is characterized by high ADH concentration and low renin concentration. If both plasma ADH and renin concentrations are low, a primary defect in renal water excretion is present.

serum. Urine sodium in SIADH is usually 40 to 60 mEq/L or greater.

Patients with dilutional hyponatremia resulting from excess water intake (psychogenic polydipsia) have a hypotonic plasma, an unremarkable urine sodium concentration (<20 mEq/L), and a dilute urine (urine osmolality less than that of plasma).[69] Patients with depletional hyponatremia caused by extrarenal sodium loss have hypotonic plasma, a low urine sodium concentration (usually <10 to 20 mEq/L), and urine osmolality greater than that of plasma. Patients with depletional hyponatremia caused by impaired renal sodium conservation have similar results, except that their urine sodium concentrations are inappropriately elevated in the setting of volume depletion.

Water load testing is not recommended in cases of suspected SIADH, as it may cause acute hyponatremia with significant adverse consequences. Water load testing involves the administration of water orally (20 mL/kg to 1.5 L maximum) with subsequent observation of the volume of urine passed over the next 4 hours (normal response: >90% of ingested volume excreted). With SIADH, less than 70% of the volume is excreted.

Measurement of ADH

Measurement of ADH typically requires extracting and concentrating the hormone from biological fluids because of its low (pmol/L) concentration and the presence of potentially interfering compounds. ADH can be extracted into acetone, petroleum ether, or ethanol,[37] or it can be chromatographically isolated using octadecyl silica (C-18) columns.[29,122,218] Although nonisotopic (enzyme) immunoassays have been described,[98,199] most laboratories measure ADH by RIA. Most ADH RIA methods are noncompetitive, and separation of bound and free ligand is commonly achieved using second-antibody precipitation techniques.

An ADH method described by Kluge and colleagues[122] extracts the hormone from 0.5 mL of acidified plasma onto a C-18 column preconditioned with methanol/water. After washing with 0.67 mol/L acetic acid, ADH is eluted from the column with 1.0 g/L trifluoracetic acid in methanol. The extract is dried and reconstituted in 0.25 mL of phosphate buffer containing 2.5 g/L bovine serum albumin, 0.01 mol/L EDTA, and 1 g/L neomycin sulfate. A 100 µL aliquot of reconstituted extract is mixed with 25 µL of polyclonal ADH antisera, and after incubation for 24 hours at 4 °C, ^{125}I-labeled ADH is added, followed by incubation for 16 hours. Antigen-antibody complexes are adsorbed on activated charcoal, and following centrifugation, radioactivity is measured in the pellet. This method had an average CV of 3.4% over an analytical range of 0.25 to 5.1 ng/L and a minimum detectable concentration of 0.06 ng/L, determined by 3 SD above the mean result for an ADH-free calibrator.

Specimen Collection and Storage

Blood specimens for ADH should be collected into prechilled tubes containing EDTA as an anticoagulant. Most procedures recommend that specimens be delivered to the laboratory on ice and centrifuged at 4 °C within 30 minutes of collection. The plasma is then removed and stored or shipped frozen at −20 °C until analysis is performed. Random urine specimens may be collected without preservatives; alternatively, complete 24 hour urine specimens may be collected in 10 mL of 6 mol/L hydrochloric acid.[162] Significant deterioration of ADH occurs after prolonged storage.

Oxytocin

Oxytocin is a nonapeptide secreted by the magnocellular neurons of the hypothalamus and stored in the neurohypophysis along with ADH. It promotes uterine contractions and milk ejection and contributes to the second stage of labor.[135]

Biochemistry

The structure of oxytocin is similar to that of ADH (see Figure 53-8), but with a phenylalanine → isoleucine substitution at residue 3, and an arginine → leucine substitution at residue 8.

The gene for oxytocin is located on chromosome 20p13. Prepro-oxytocin is 125 amino acids (12.7 kDa). Similar to the ADH gene, the oxytocin gene encodes two proteins: oxytocin and neurophysin 1. In contrast to preproADH, prepro-oxytocin lacks a sequence analogous to copeptin in ADH. Following the leader sequence of 19 amino acids, the nonapeptide oxytocin is encoded, followed by the 94 amino acid C-terminal propeptide neurophysin 1. The glycine residue at position 28 is amidated. Suspected or definitive disulfide bonds are at amino acids 20-25 (within oxytocin), 41-85, 44-58, 52-75, 59-65, 92-104, and 105-110. ADH and oxytocin are highly conserved throughout a variety of species, suggesting that mutations in the genes that encode them are likely to produce serious consequences.

Oxytocin receptors are expressed in the uterine myometrium and myoepithelial cells of the breast. More myometrial receptors are expressed toward the end of pregnancy. The gene for the oxytocin receptor is encoded on chromosome 3p25. Of its 389 amino acids (42.8 kDa), the first 38 amino acids are extracellular, followed by seven transmembrane domains and a 57 amino acid cytoplasmic domain. Three potential sites of glycosylation are known: amino acids 8, 15, and 26. A disulfide bond may be found between amino acids 112 and 187. Oxytocin receptors occur throughout the CNS, and it is thought that these receptors affect behaviors related to stress, socialization, and maternity.

Regulation of Oxytocin Secretion and Physiologic Activity

Oxytocin is present in both males and females, but its physiologic effects are known only for females.[145] Afferent nerve fibers from the uterus and cervix (and possibly the vagina) communicate with the paraventricular (PVN) and supraoptic nuclei (SON) in the hypothalamus; these are the sites of cell bodies that synthesize oxytocin. Near the conclusion of pregnancy, mechanical stimulation of the cervix by the growing fetus stimulates stretch mechanoreceptors that, in turn, promote oxytocin release from the hypothalamus. Next, uterine contractions during labor trigger additional release of oxytocin. The effect of oxytocin is to increase the strength of uterine contractions, providing positive feedback to oxytocin release until the time of delivery of the fetus. For the myometrium to respond to oxytocin, it must be estrogen primed. Thus, increasing responsiveness of the myometrium to oxytocin is noted near term. Increased sensitivity to oxytocin in the myometrium may reflect changes in oxytocin receptor number and/or responsiveness. Centrally, estrogens enhance the response of oxytocin to these stimuli. The influence of oxytocin on other parts of the brain has been reported. For example, emotional stress inhibits lactation.

With delivery of the newborn and placenta, declining concentrations of sex steroids allow prolactin to trigger active lactation. The role of oxytocin is to stimulate the smooth muscle cells of the breast to propel the milk toward the nipple. These smooth muscle cells (myoepithelial cells) surround the milk-producing cells. With suckling, afferent fibers that travel to the PVN and SON trigger oxytocin release. Contraction of the myoepithelial cells causes "milk let-down" (milk ejection), and milk can leak from the nipple if suckling is not continued.

In summary, oxytocin stimulates uterine smooth muscle contraction during labor and milk duct constriction during suckling that propels milk toward the nipple. Therefore oxytocin is critical for delivery of the newborn. Likewise, oxytocin is exceedingly important for nourishment and hydration of the newborn and infant.

Clinical disorders involving oxytocin have not been reported. However, oxytocin and its derivatives (pitocin) are used as pharmaceuticals to increase the intensity of uterine contractions during labor (e.g., as treatment for prolonged or failed labor) and to prevent or treat postdelivery uterine hemorrhage.

TABLE 53-10 Disorders of Overproduction and Underproduction of Pituitary Hormones

Pituitary Hormone	Consequences of Hormone Excess	Consequences of Hormone Deficiency
ACTH	Cushing disease	Cortisol deficiency
TSH	Central hyperthyroidism	Central hypothyroidism
GH	Children: gigantism	Children: short stature
	Adults: acromegaly	Adults: adult GHD
LH, FSH	Alpha chain overproduction	Hypogonadism
Prolactin	Galactorrhea, hypogonadism	Inadequate lactation or lactation failure in mothers after delivery
ADH	SIADH	DI

Measurement of Oxytocin

Immunoassays for measuring oxytocin in plasma or urine have been developed but are mostly of research interest, because no clinical indications for measuring oxytocin are known. With most plasma oxytocin assays, a preliminary extraction procedure is required to concentrate the hormone and remove interfering substances.

SUMMARY OF PITUITARY RELATED DISORDERS

Disorders that result from overproduction or underproduction of pituitary hormones are tremendously diverse (Table 53-10). Pituitary adenomas may be secretory or nonsecretory.[109] Corticotropinomas secrete ACTH; somatotropinomas secrete GH; and prolactinomas secrete prolactin. Gonadotropinomas usually do not secrete intact LH and/or FSH but may secrete free alpha subunits.[94] These topics are reviewed in depth in many chapters in this textbook. Understanding pituitary function and the various diseases that result from pituitary dysfunction is a fundamental and essential aspect of clinical and laboratory medicine practice.

CHAPTER 54

The Adrenal Cortex

*Roger L. Bertholf, Ph.D., Ishwarlal Jialal, M.D., Ph.D., F.R.C.Path(London), D.A.B.C.C., and William E. Winter, M.D.**

The adrenal cortex and gonads produce steroid hormones. Steroids are a class of organic compounds that contain the cyclopentanoperhydrophenanthrene nucleus that is characterized by four aliphatic rings produced by the biosynthetic cyclization of a linear triterpene, squalene, which is produced by the mevalonate pathway (Figure 54-1). Three rings (A, B, and C) are made up of six carbons, and one ring (ring D) is made up of five carbons. Sterols are steroids that have been hydroxylated at position 3 on the A ring; cholesterol is a sterol. Cholesterol has a double bond between carbons 5 and 6 and contains an eight carbon aliphatic side group at position 17. Cholesterol is the precursor for all human steroid hormones. In humans, cholesterol is derived from both dietary sources and de novo synthesis, and is transported principally in low-density lipoproteins (LDLs). As cellular cholesterol concentrations rise, LDL receptor (LDLR) expression declines in an autoregulatory fashion. The synthesis of cholesterol is reviewed in Chapter 27.

ANATOMY

The adrenal glands are pyramidal in shape, 2 to 3 cm wide, 4 to 6 cm long, and about 1 cm thick. Because each gland sits atop the kidney, the adrenal glands are also referred to as the *suprarenal glands.* Arterial blood is supplied to the adrenal gland by (1) the superior adrenal (or suprarenal) artery from the inferior phrenic artery (a branch of the aorta); (2) the middle adrenal artery, which is directly from the aorta; and (3) the inferior adrenal artery, a branch of the renal artery. Possibly of more clinical importance than the arterial supply, especially when adrenal function is assessed via catheterization, is the venous drainage of the adrenal gland. Adrenal veins are present for each gland: the right adrenal vein enters directly into the vena cava at an acute angle, whereas the left adrenal vein enters into the left renal vein.

The adrenal cortex and the gonads share many metabolic pathways in the synthesis of steroid hormones because both are embryologically derived from nearby mesodermal anlagen.[148] Two important transcription factors in development of the adrenal cortex are steroidogenic factor-1 (SF-1) and the dosage-sensitive sex reversal adrenal hypoplasia congenita (AHC) on the X-chromosome gene 1 *(DAX-1).*[78] SF-1 regulates *DAX-1.*

The postnatal adrenal cortex is composed of three layers: the glomerulosa (10 to 15% of the cortex), the fasciculata (up to 75% of the cortex), and the reticularis (5 to 10% of the cortex). The fetal adrenal gland is proportionately much larger than adrenal glands observed later in life because of the presence of the fetal cortex (which wanes by 18 months of age). The fetal adrenal layer is situated between the definitive cortex and the medulla, and is characterized by large steroid-secreting cells arranged in a reticular pattern. At birth, the adrenal gland is nearly equal in weight to that of an adult (8 to 12 grams). The large size of the fetal adrenal (≈250 mg/100 g body weight) may explain the propensity of the gland to be occasionally traumatized during delivery. Between 3 and 18 months of age, the adrenal glands involute to approximately half their size at birth. Later in life, the adrenal glands are less susceptible to trauma and represent less than 50 mg/100 g of body weight. Adult adrenal glands weigh 4 to 6 g each.

Table 54-1 shows the location and action of major products of the adrenal gland.

STEROID BIOCHEMISTRY

Major hormones produced by the adrenal cortex include (1) mineralcorticoids, (2) glucocorticoids, and (3) adrenal androgens.

Mineralocorticoids (Aldosterone)

Mineralocorticoids bind to the mineralocorticoid receptor (MR) in the distal convoluted tubule and collecting duct of the nephron, the colon, and the salivary glands to promote sodium reabsorption and potassium and hydrogen ion excretion.[352] Similar to receptors for other steroid hormones and thyroid hormone, the MR functions as a transcription factor. When mineralocorticoid binds to the cytoplasmic MRs, the mineralocorticoid-MR complex relocates to the nucleus, where it influences cellular DNA regulating gene transcription. The principal mineralocorticoid is aldosterone, but

The authors gratefully acknowledge the contribution of Professor Laurence M. Demers to the previous edition of this textbook, on which portions of this chapter are based.

other compounds with mineralocorticoid activity include 11-desoxycorticosterone (DOC), 18-hydroxycorticosterone, corticosterone, and cortisol.

The *MR* gene encodes a 107 kDa protein and is officially labeled nuclear receptor subfamily 3, group C, member 2 (NR3C2), located on chromosome 4q31.1-31.2. Alternative splicing yields an alpha and beta MR mRNA. Aldosterone stimulates epithelial sodium channel (ENaC) activity via serum and glucocorticoid-induced kinase (SGK) and K-ras, increases expression of mitochondrial ATP-producing genes, and stimulates the basolateral Na^+/K^+-ATPase pump. ENaC, a highly selective epithelial sodium channel that is amiloride sensitive (amiloride is a K^+-sparing diuretic), has three subunits: the alpha subunit (most important of the three subunits: the sodium channel, non–voltage-gated protein 1, alpha coded by *SCNN1A,* chromosome 12p13), the beta subunit (sodium channel, non–voltage-gated 1, beta *SCNN1B,* chromosome 16p13-p12), and the gamma subunit (sodium channel, non–voltage-gated 1, gamma *SCNN1G,* chromosome 16p13-p12).[178] All ENaC subunits are similar and contain a large N-terminal extracellular domain, two transmembrane spanning domains (M1 and M2), and a C-terminal, short intracellular domain.[140] Although the binding of aldosterone to the MR occurs in the cytoplasm with transit of the complex to the nucleus, some free MR is present in the nucleus. The MR binds cortisol and 11-desoxycorticosterone with affinity equal to that of aldosterone. However, the MR is protected from cortisol and 11-desoxycorticosterone by 11 beta-hydroxysteroid dehydrogenase-2 (HSD11B2), where, for example, HSD11B2 catalyzes the conversion of cortisol to cortisone (Figure 54-2). Cortisone does not bind to the MR. Variations in HSD11B2 may be involved in some cases of otherwise "essential" hypertension.[86] Chronic elevations in angiotensin, which controls aldosterone synthesis and release, produces pathologic changes in the heart and kidney by eliciting myocardial fibrosis and inflammatory changes in the renal vasculature.[139] The actions of mineralocorticoids are summarized in Table 54-2.

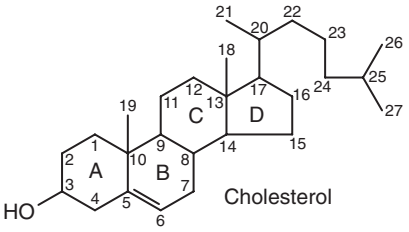

Figure 54-1 Steroids are a class of compounds that are characterized by four interconnected rings labeled *A* to *D*. The carbons are numbered in a standard fashion as illustrated. A sterol is a type of steroid wherein a hydroxyl group is attached to the ring (e.g., cholesterol where the hydroxyl group is attached to carbon 3). Cholesterol has a double bond between carbons 5 and 6 and contains an eight-carbon R group.

Glucocorticoids (Cortisol)

Glucocorticoids bind to the glucocorticoid receptor (GR) located in a large number of tissues, including lymphocytes, hepatocytes, and bone.[34] The *GR* gene contains 10 exons (exons 1 through 8 plus 9 alpha and 9 beta). Alternative splicing yields GR alpha and GR beta transcripts. Because of the wide distribution of the GR, glucocorticoid effects are diverse, including changes in intermediary metabolism and immunoregulation. Glucocorticoids raise blood glucose concentrations by enhancing the synthesis of gluconeogenic enzymes

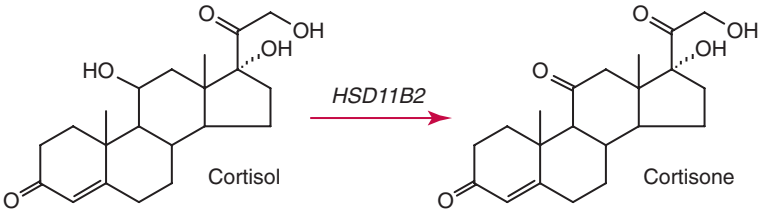

Figure 54-2 Normally, the mineralocorticoid receptor is protected from cortisol by 11 beta-hydroxysteroid dehydrogenase-2 (HSD11B2), which inactivates cortisol to cortisone. Cortisone does not bind to the mineralocorticoid receptor.

TABLE 54-1 Anatomy and Products of the Adrenal Gland

Adrenal Layer	Major Product(s)	Action
Cortex		
Zona glerulosa	Aldosterone	Mineralocorticoid
Zona fasciculata	Cortisol	Glucocorticoid
Zona reticularis	Dehydroepiandrosterone Androstenedione	Adrenal androgen
Medulla	Epinephrine	Catecholamine

(e.g., glucose-6-phosphatase and phosphoenol pyruvate carboxykinase), increase liver glycogen content through activation of glycogen synthase, and inhibit glycogen phosphorylase, producing insulin resistance in both muscle and adipose tissue that further raises blood glucose concentrations. Excessive catabolism of skeletal muscle causes myopathy and consequent weakness. Protein catabolism causes thinning of the skin and loss of strength in connective tissues. With excess glucocorticoids, bone loss may result from collagen catabolism and loss of osteoid, which can lead to fractures and compressed vertebrae.

Glucocorticoids cause adipose tissue redistribution centrally to the trunk, neck, and face, increased adipocyte differentiation, and promotion of lipogenesis in these tissues. Insulin resistance raises very low-density lipoprotein (VLDL) and triglyceride concentrations and lowers high-density lipoprotein (HDL) concentrations. The activity of adipose tissue hormone-sensitive lipase (HSL) is decreased because of insulin resistance, allowing triglyceride breakdown to free fatty acids and increased free fatty acid delivery to the liver, which provides substrate for hepatic triglyceride resynthesis and VLDL production and export. Glucocorticoids increase appetite, and a subsequent increase in caloric intake causes weight gain.

TABLE 54-2 Major Actions of Mineralocorticoids

Action	Adverse Outcome Excessive Action	Deficient Action
Sodium retention*	Hypertension	Hypotension
Urinary potassium wasting	Hypokalemia	Hyperkalemia
Urinary hydrogen ion wasting	Alkalosis	

*With consequent H_2O retention.

When glucocorticoids bind to the cytoplasmic GR, heat shock proteins (HSPs) are released (HSP70 and HSP90).[63] Glucocorticoids are powerful anti-inflammatory hormones that inhibit nuclear factor kappaB (NFkappaB) through the induction of IkappaB synthesis.[91] IkappaB binds to NFkappaB in the cytoplasm, impairing the entrance of NFkappaB into the nucleus. Within the nucleus, the GR-cortisol complex binds NFkappaB, preventing its binding to DNA. Finally, within the nucleus, GR-cortisol and NFkappaB compete for cofactors that are available in limited quantities. Although IkappaB synthesis is enhanced, many proinflammatory genes are repressed, such as cyclo-oxygenase 2 (COX-2), inducible nitric oxide synthase (iNOS), various interleukins (IL-1, IL-2, and IL-6), tumor necrosis factor-alpha, interferon-gamma, and E-selectin. Adrenocorticotropic hormone (ACTH) also stimulates the release of IL-1, IL-6, and tumor necrosis factor-alpha.[275]

Glucocorticoids help maintain vascular tone and cardiac output, and stabilize lysosomal membranes.[44] Glucocorticoids suppress hypersensitivity responses by inhibiting the production of histamine by basophils and mast cells. Modest doses of glucocorticoids may improve one's mood, yet in pharmacologic concentrations, they may produce psychosis. Pathologically elevated concentrations of glucocorticoids are discussed further under the heading of "Cushing syndrome." The relative potencies of corticosteroids in terms of glucocorticoid and mineralocorticoid activity are given in Table 54-3. The actions of glucocorticoids are summarized in Table 54-4.

Adrenal Androgens (DHEA and Androstenedione)

The adrenal androgens dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEA-S), and androstenedione provide androgenic effects through their peripheral conversion to testosterone, which in turn binds to the androgen receptor (AR) that is described in Chapter 56.[149] Between ages 7 and 8, the urinary excretion of 17-ketosteroids (the breakdown products of adrenal androgens) increases as an early sign that puberty will begin in the coming 3 to 5 years.[239]

TABLE 54-3 Relative Potencies of Corticosteroids

Corticosteroid	Glucocorticoid Activity	Mineralocorticoid Activity
Aldosterone	0.1	400
Corticosterone	0.2	2

Skin	Thinning (catabolism)	NSE
Bone	Osteoporosis	NSE
Immune System	Immunosuppression	NSE

NSE, No specific effect.

In males, adrenal androgens, such as DHEA and androstenedione, are normally of negligible importance because testosterone is a much more potent androgen. However, adrenal androgens are important in pubertal and adult women because they produce axillary and pubic hair. Women with Turner syndrome are an excellent example of the effects of adrenal androgens in women. Because of streak gonads (hypoplastic and dysfunctioning gonads mainly composed of fibrous tissue), adolescents with Turner syndrome do not experience gonadarchy (the period during which the gonads begin to secrete sex hormones) because all of their ovarian follicles are atretic before birth. Estrogen deficiency during adolescence is manifest in lack of breast development, primary amenorrhea, and failure of fat redistribution to the hips and buttocks. However, because adrenarchy (the increase in activity of the adrenal glands preceding puberty) is normal in adolescents with Turner syndrome, they will develop axillary and pubic hair despite their lack of estrogenization.

Throughout life, DHEA is sulfated, and circulating concentrations of DHEA-S exceed those of DHEA by 100-fold or more. For example, a typical DHEA reference interval in males is 180 to 1250 ng/dL, whereas the DHEA-S reference interval is 125 to 619 µg/dL.

PHYSIOLOGY AND REGULATION OF ADRENOCORTICAL HORMONES

Steroid hormones are not stored in hormone-producing cells and therefore must be produced as needed. As lipophilic molecules, steroids pass through cell membranes to exit the hormone-producing cells, enter the circulation to be distributed throughout the body, and enter target cells passing through the target cell membrane into the cytoplasm, where they bind to receptors. Translocation of the hormone-receptor complex to the nucleus initiates the action of the hormone. Growing evidence suggests that steroid hormones may concurrently act independently of their effect on DNA transcription. In the circulation, steroids exist as free and bound species. This is discussed in greater detail in Chapter 56.

Aldosterone

Aldosterone production and secretion are controlled through the renin-angiotensin system (Figure 54-3).[216,342] The rate-limiting component in this system is renin release, which is regulated by the juxtaglomerular apparatus. Anatomically, the juxtaglomerular apparatus is composed of (1) the juxtaglomerular cells of the afferent arteriole that immediately leads to the glomerulus, (2) lacis cells (extraglomerular mesangial cells located at the vascular pole of the renal corpuscle), and (3) the macula densa.

The juxtaglomerular cells are modified smooth muscle cells that synthesize and secrete renin. Preprorenin is a 406 amino acid protein. Removal of the 20 amino acid presequence yields prorenin (386 amino acids). Cleavage of the 46 amino acid pro-segment produces the active hormone (340 amino acids, 37 kDa). Both prorenin and renin are released by the juxtaglomerular cells, which function as baroreceptors that detect arterial wall stretch produced by renal perfusion pressure. Therefore, decreased renal perfusion leads to renin release. This is the most important mechanism regulating renin concentrations in the circulation.

The macula densa consists of specialized cells that line the distal convoluted tubule (DCT). Compared with other tubular cells, these cells are unique in that their nuclei are near the apical (luminal) pole of the cell, whereas the Golgi apparatus is near the basolateral pole of the cell. Acting as

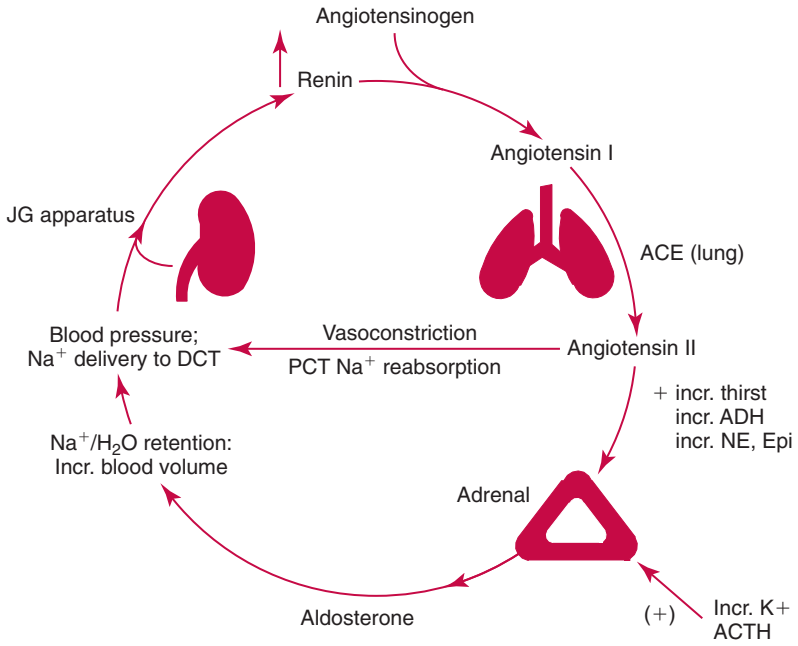

Figure 54-3 The juxtaglomerular (JG) apparatus monitors the perfusion pressure of the glomerulus and the sodium concentration in the distal convoluted tubule (DCT). Renin is released in cases of decreased renal perfusion or decreased sodium concentration in the DCT. Renin cleaves angiotensinogen to angiotensin I. Angiotensin-converting enzyme (ACE) converts angiotensin I to angiotensin II predominantly in the lung. Angiotensin II has direct vasoconstrictive effects, stimulates sodium reabsorption by the proximal convoluted tubule (PCT), and stimulates thirst, antidiuretic hormone (ADH) release, catecholamine release (*Epi,* epinephrine; *NE,* norepinephrine), and aldosterone synthesis and secretion. Aldosterone increases sodium reabsorption, and as water follows salt, blood volume increases along with blood pressure. Overall these effects act to restore renal perfusion. Adrenocorticotropic hormone (ACTH) and increased potassium have minor effects in stimulating aldosterone synthesis and secretion.

a chemoreceptor, the macula densa monitors the sodium concentration in the DCT. If a decline in sodium concentration occurs in the DCT, the macula densa signals the juxtaglomerular cells via prostacyclin to release renin. Anatomically, the DCT passes between the afferent and efferent arterioles of the nephron, which, respectively, supply blood to and drain blood from the glomerular capillaries.

Decreased sodium delivery to the DCT occurs in states of decreased renal perfusion. Decreased sodium delivery to the DCT can result from hyponatremia or a decreased glomerular filtration rate, both of which would elicit renin release. Sympathetic innervation of the juxtaglomerular cells also influences renin secretion via $beta_1$-adrenoreceptors. For this reason, norepinephrine and dopamine stimulate renin release. Thus, with upright posture and catecholamine release, renin release is enhanced. Potassium also directly stimulates renin release. Overall, renin is physiologically released in response to hypovolemia, reduced cardiac output, systemic vasodilatation, selectively reduced renal perfusion, hyponatremia, and stress (mediated by catecholamines).

Angiotensinogen (≈60 kDa) is an $alpha_2$-globulin synthesized in hepatocytes.[211] Renin acts as an aspartyl proteolytic enzyme cleaving the 10 N-terminal amino acids of

TABLE 54-5 Angiotensinogen and Derived Peptides

Molecule	Size (Amino Acids; Abbreviation)
Angiotensinogen	485
↓ Renin	
Angiotensin I	10 (A1-10)
↓ Angiotensin-converting enzyme (ACE)	
Angiotensin II	8 (A1-8)
↓ Amino peptidase A	
Angiotensin III	7 (A2-8)
↓ Arginyl aminopeptidase	
Angiotensin IV	6 (A3-8)

angiotensinogen to form the decapeptide angiotensin I (Table 54-5). Angiotensin I has no endocrine, paracrine, or autocrine effects. Angiotensin-converting enzyme (ACE), a zinc metallopeptidase, removes the two C-terminal residues from angiotensin I to generate the octapeptide angiotensin II.[315] High concentrations of ACE are expressed in the lung. ACE is pathologically expressed in conditions involving macrophage activation such as sarcoidosis. Further degradation of angiotensin II by aminopeptidase A (a glutamyl aminopeptidase) yields the heptapeptide angiotensin III. The ratio of angiotensin II to angiotensin III is usually 4 to 1. An arginyl aminopeptidase generates angiotensin IV from angiotensin III.

Angiotensin II acts to preserve circulating blood volume and maintain blood pressure through several mechanisms: (1) stimulation of aldosterone synthase (CYP11B2) to produce aldosterone; (2) direct vasoconstriction; (3) increased release of epinephrine and norepinephrine from the adrenal medulla, which will also act as vasoconstrictors; (4) stimulation of sodium reabsorption in the proximal convoluted tubule (PCT); (5) stimulation of thirst; and (6) stimulated release of antidiuretic hormone (ADH). Angiotensin III has equivalent potency in stimulating aldosterone secretion.

The best characterized of the angiotensin receptors are AT1 and AT2 that involve multiple second messenger systems.[134] Most functions of angiotensin II are mediated via the AT1 receptor. Some actions of the stimulated AT2 receptor oppose those of the AT1 receptor (e.g., AT2 receptor engagement causes vasodilatation).

Cortisol

Cortisol is controlled through a traditional hypothalamic-pituitary-end organ negative feedback system (Figure 54-4). Corticotropin-releasing hormone (CRH) is released by stress, exercise, and hypoglycemia. Examples of physiologic stress include pain, trauma, surgery, and hemorrhage. Examples of psychologic stress include severe anxiety and major depression. Prolonged administration of supraphysiologic doses of glucocorticoids orally or parenterally will suppress the hypothalamic-pituitary-adrenal axis, leading to adrenal atrophy. As a result, abrupt termination of exogenous steroids may induce an acute and possibly life-threatening glucocorticoid insufficiency.

CRH is produced by the paraventricular nucleus of the hypothalamus. Prohormone convertase-1 (PC1) and PC2 liberate a C-terminal, 43 amino acid CRH precursor from the 196 amino acid preprohormone. Peptidylglycine alpha-amidating mono-oxygenase (PAM) removes the two C-terminal residues and adds an amine group, producing the 41 amino acid polypeptide, CRH.

Following hypothalamic secretion, CRH reaches the anterior pituitary gland through the hypothalamic pituitary portal system.[244] Corticotrophs represent about 20% of functional anterior pituitary cells and express receptors for CRH that promote synthesis, storage, and release of corticotropin (ACTH; 4.5 kDa).[110] ACTH is also released by ADH stimulation but to a lesser degree than CRH. The proinflammatory

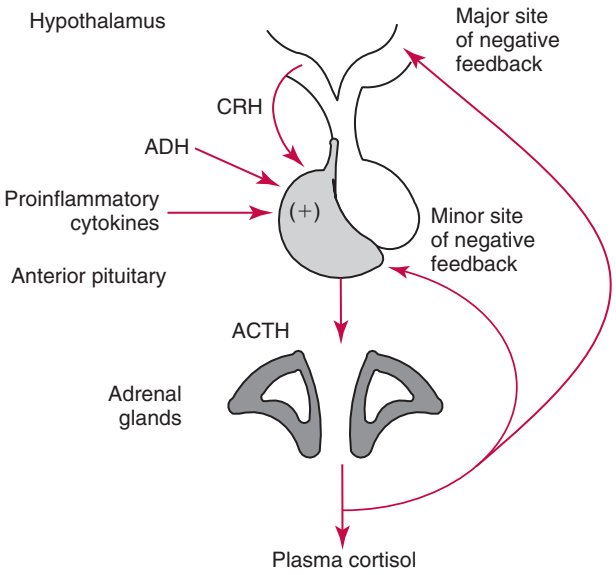

Figure 54-4 Cortisol is controlled through a traditional hypothalamic-pituitary-end organ negative feedback system. Corticotropin-releasing hormone (CRH) is released from the hypothalamus and is delivered to the anterior pituitary via the hypothalamic-pituitary portal system. CRH releases adrenocorticotropic hormone (ACTH) from anterior pituitary corticotrophs. Increased concentrations of antidiuretic hormone (ADH) and proinflammatory cytokines (e.g., IL-1, IL-6, and tumor necrosis factor-alpha) can also stimulate ACTH release. ACTH stimulates the synthesis and release of cortisol from the adrenal cortex. Cortisol feeds back negatively at the pituitary, but the major site of negative feedback is the hypothalamus.

cytokines IL-1, IL-6, and tumor necrosis factor-alpha also release ACTH. There are two CRH receptors (CRH-R1 and CRH-R2) and three splice variants of CRH-2 (CRH-2alpha, CRH-2beta, and CRH-2gamma). CRH mediates its effects on corticotrophs exclusively through CRH-R1. CRH and its receptors are widely distributed throughout the central nervous system (CNS).

ACTH is released from its 32 kDa precursor protein, 266 amino acid pro-opiomelanocortin (POMC; gene: 8 kb; chromosome 2p23), by proteolysis (Figure 54-5).[133,159] In the corticotrophs, subtilisin-like proprotein convertase (PC1/3) cleaves POMC into two fragments: the 22 kDa pro-ACTH fragment and beta-lipotropin (amino acids 42-134), whose function remains poorly understood. Next, PC1/3 releases ACTH (amino acids 1-39) from pro-ACTH. The resulting N-terminal fragment is further cleaved to pro-gamma-melanocyte-stimulating hormone (MSH) and a joining peptide (JP). ACTH is not further cleaved in corticotrophs.

The action of PC2 in the hypothalamus, skin, and melanotrophs of the intermediate lobe is to release gamma-MSH from pro-opiocortin (N-POC); alpha-melanocyte-stimulating hormone (alpha-MSH; amino acids 1-13) and corticotropin-like intermediate lobe peptide (CLIP; amino acids 18-39) from ACTH; and gamma-lipotropin (amino

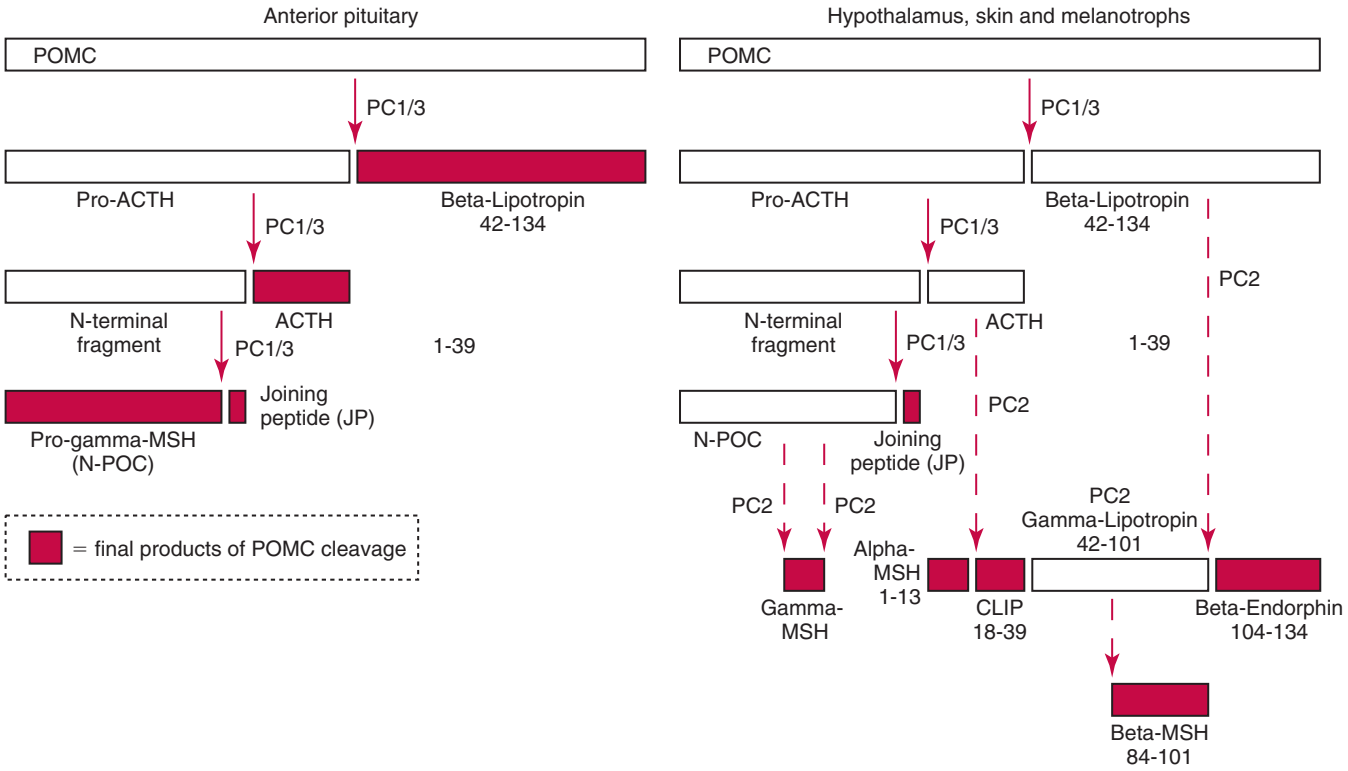

Figure 54-5 Adrenocorticotropic hormone (ACTH) is derived from pro-opiomelanocortin (POMC) by proteolysis. In the corticotrophs through the action of subtilisin-like proprotein convertase PC1/3, POMC is first cleaved into two fragments: the 22 kDa pro-ACTH fragment and beta-lipotropin (amino acids 42-134), whose function remains poorly understood. Next, PC1/3 releases ACTH (amino acids 1-39) from pro-ACTH. The resulting N-terminal fragment is further cleaved to pro-gamma-MSH (a.k.a. N-POC) and a joining peptide (JP). ACTH is not further cleaved in corticotrophs. In the hypothalamus, skin, and melanotrophs, further processing of N-POC, ACTH, and beta-lipotropin occurs. The action of PC2 in the hypothalamus, skin, and melanotrophs of the intermediate lobe of the pituitary is to release gamma-MSH from N-POC; alpha-melanocyte stimulating hormone (alpha-MSH; amino acids 1-13) and corticotropin-like intermediate lobe peptide (CLIP, amino acids 18-39) from ACTH; and gamma-lipotropin (amino acids 42-101) and beta-endorphin (amino acids 104-134) from beta-lipotropin. Last, beta-MSH (amino acids 84-101) is derived from gamma-lipotropin via PC2.

acids 42-101) and beta-endorphin (amino acids 104-134) from beta-lipotropin (see Figure 54-5). Last, beta-MSH (amino acids 84-101) is derived from gamma-lipotropin via PC2.

Hyperpigmentation that occurs with ACTH excess appears to be a direct consequence of the MSH-like activity of ACTH and not ACTH cleavage into alpha-MSH.[349] Whereas (1) a gamma-MSH sequence is contained within the N-terminal fragment, (2) alpha-MSH is contained within ACTH, and (3) beta-MSH is contained within gamma-lipotropin (a fragment of beta-lipotropin), MSH is not released by the human anterior pituitary gland.

ACTH circulates systemically to bind to ACTH receptors located on cells within the adrenal cortex. The ACTH receptor is the G-protein–coupled melanocortin-2 receptor (MC2R; gene location: chromosome 18p11.2).[77] The second messenger system involves adenyl cyclase and the generation of cyclic AMP. The actions of ACTH are then triggered via protein kinase A and protein kinase C, leading to steroidogenesis, increased size and number of adrenocortical cells, and increased size and functional complexity of cellular organelles. Cortisol is then synthesized and released. Cortisol feeds back centrally at the hypothalamus and to a lesser degree feeds back negatively at the pituitary to suppress CRH and ACTH secretion.[158] Other negative feedback loops include ACTH suppression of hypothalamic CRH and an ultra-short feedback loop whereby ACTH suppresses its own release.

Pulses of CRH cause the release of ACTH, which stimulates cortisol secretion. A wide diurnal variation in the secretion of cortisol is noted, with highest concentrations in the early morning (≈2 hours before awakening) and lowest concentrations near midnight (assuming that the individual is asleep overnight).

Adrenal Androgens

The regulation of adrenal androgen synthesis and secretion remains poorly understood. The existence of a pituitary adrenal androgen–stimulating hormone or a cortical androgen–stimulating hormone remains doubtful despite many years of research that sought its existence.[116] The best characterized regulator of androstenedione and DHEA secretion is ACTH. This is not surprising, as CYP17 is regulated by ACTH. A diurnal rhythm in adrenal androgen concentrations parallels cortisol variations. Nevertheless, ACTH regulation of adrenal androgens does not explain the normal prepubertal and pubertal increases in adrenal androgen synthesis that occurs in both boys and girls: ACTH does not increase prior to puberty. Evidence indicates that sympathetic innervation of the zona reticularis may exist and may regulate adrenal androgen secretion. Immune regulation of adrenal androgen secretion has also been proposed.

BIOSYNTHESIS OF ADRENOCORTICAL HORMONES[100]

An overview of steroid biosynthesis is provided in Figure 54-6, and the steroidogenic enzymes are listed in Table 54-6.

Aldosterone

Within the cytoplasm of steroid-producing cells, cholesterol ester is hydrolyzed to free cholesterol and a free fatty acid via the ACTH-responsive steroidogenesis activator protein, which is functionally a cholesterol esterase. Free cholesterol is then transported across the outer mitochondrial membrane by a sterol transfer protein into the mitochondrial intermembranous space. The 30 kDa steroidogenic acute regulatory protein (StAR) next transports cholesterol across the inner membrane into the mitochondria.[205,301] StAR-mediated transport of cholesterol into the mitochondria is a rate-limiting step in steroid hormone synthesis. StAR synthesis is enhanced by rising concentrations of cyclic AMP resulting from ACTH binding to its receptor. In the mitochondria, cholesterol is converted to pregnenolone by the action of CYP11A, which is the cytochrome P450 sidechain cleavage enzyme (P450ssc; gene location: chromosome 15q23-24) that is functionally a 20,22-desmolase that releases isocaproaldehyde. CYP11A therefore initiates the conversion of the C_{27} steroid cholesterol to the other C_{21} steroids (the subscript indicates the number of carbons in the compound).

Pregnenolone moves from the mitochondrion to the lumen of the endoplasmic reticulum. In the zona glomerulosa, CYP17 (P450c17) activity is not expressed; therefore pregnenolone is converted to progesterone via the non-P450 enzyme, 3-beta-hydroxysteroid dehydrogenase type 2 (3 beta-HSD; gene location: chromosome 1p13.1). The conversion of pregnenolone to progesterone also requires delta(5)-ketosteroid isomerase, which "moves" the double bond from the 5 position to the 4 position. Indeed, pregnenolone, 17-hydroxypregnenolone, and DHEA are characterized as delta(5) steroids, whereas progesterone, 17-hydroxyprogesterone, and androstenedione are characterized as delta(4) steroids based on the location of their double bond.

CYP21, a P450 21 alpha-hydroxylase (P450c21; gene location: chromosome 6p21.3) also expressed in the zona fasciculata, converts progesterone to 11-desoxycorticosterone (DOC). DOC migrates back into the mitochondrion, where CYP11B2 (P450 aldo; gene location: 8q24.3) catalyzes the conversion of DOC ultimately to aldosterone. Normally, little CYP11B1 (P450c11; gene location: 8q24.3) activity occurs in the zona glomerulosa.

TABLE 54-6 Major Steroidogenic Enzymes Expressed in Adrenal Cortex

Protein*	P450 Abbreviation	Enzyme Activity(ies)
Major Enzymes Expressed in Zona Glomerulosa		
CYP11A	P450ssc	20,22-Desmolase (20,22-Lyase)
3-Beta HSD (type 2) (gene name: *HSD3B2*)	—	3-Beta hydroxysteroid dehydrogenase
Delta^5-ketosteroid isomerase	—	Delta^5-ketosteroid isomerase
CYP21	P450c21	21-Alpha hydroxylase
CYP11B2	P450 aldo	11-Beta hydroxylase 18-Hydroxylase 18-Oxidase
Major Enzymes Expressed in Zona Fasciculata and Reticularis		
CYP11A	P450ssc	20,22-Desmolase (20,22-Lyase)
3-Beta HSD (type 2) (gene name: *HSD3B2*)	—	3-Beta hydroxysteroid dehydrogenase
Delta^5-ketosteroid isomerase	—	Delta^5-ketosteroid isomerase
CYP17	P450c17	17-Hydroxylase 17,20-Lyase (ZR > ZF)
CYP21	P450c21	21-Alpha hydroxylase
CYP11B1	P450c11	11-Beta hydroxylase

*Usually these terms when italicized refer to the gene name. However, because different sources refer to these enzymes in a variety of ways (gene name vs. enzyme activity), the gene name un-italicized will be used to name the protein. *ZF,* Zona fasciculata; *ZR,* zona reticularis.

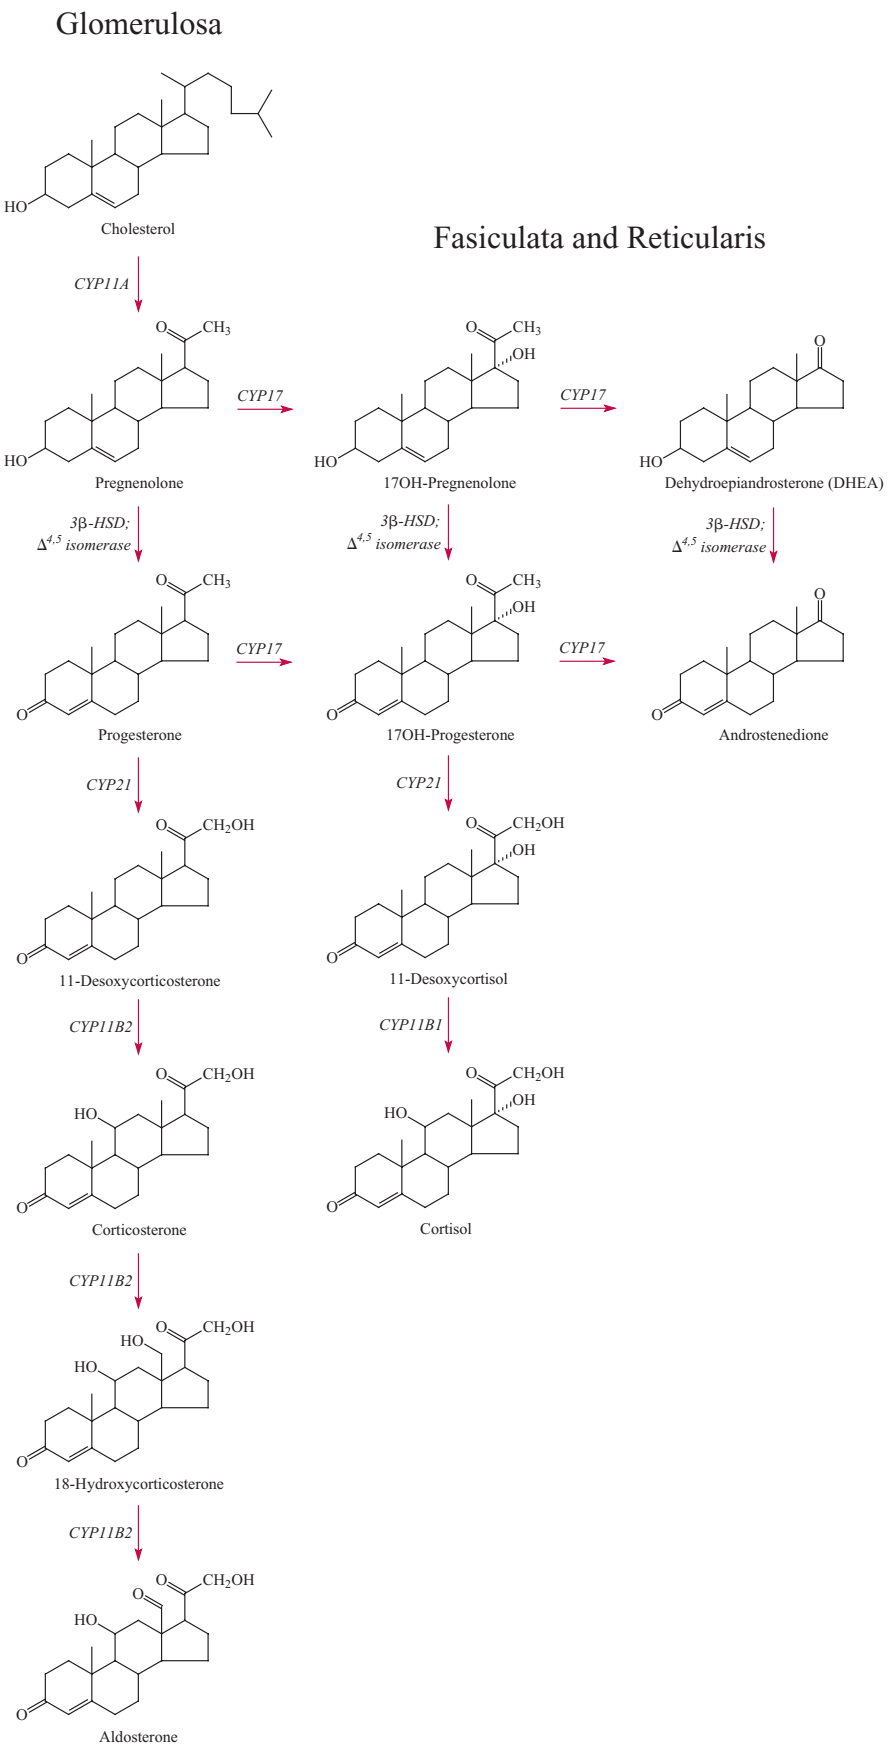

Figure 54-6 **The zona glomerulosa is the site of aldosterone synthesis. CYP11B2 is under the predominant control of angiotensin II, which controls aldosterone synthesis and secretion. In the fasciculata and reticularis layers, cortisol and the adrenal androgens DHEA and androstenedione are produced. CYP11A, 3 beta-HSD, CYP17, CYP21, and CYP11B1 are controlled by ACTH.**

CYP11B2 (aldosterone synthase) encompasses three enzymatic activities: (1) an 11-hydroxylase (DOC → corticosterone), (2) an 18-hydroxylase [corticosterone methyl oxidase I (CMOI); corticosterone → 18-hydroxycorticosterone], and (3) an 18-hydroxydehydrogenase [corticosterone methyl oxidase II (CMOII); 18-hydroxycorticosterone → aldosterone; see Figure 54-6].[234] Aldosterone diffuses out of the mitochondrion into the cytoplasm and across the cell membrane to enter the interstitium and then the circulation. The aldosterone secretion rate per day is 100 to 150 μg, with some estimates varying up to 200 μg. Thus the aldosterone secretion rate is approximately one tenth the secretion rate of cortisol on a weight basis. The half-life of circulating aldosterone is less than 15 minutes.

Whereas CYP11A, CYP17, and CYP11B1 are under ACTH control, CYP11B2 is predominantly controlled by angiotensin II. In this way, control of aldosterone synthesis is mostly independent of the anterior pituitary. Cortisol and adrenal androgens are not formed in the zona glomerulosa because the zona glomerulosa lacks expression of CYP17.

Cortisol

Cortisol production increases within minutes of an increase in circulating ACTH concentrations. In the zona fasciculata, where CYP17 (P450c17; gene location: chromosome 10q24.3) is expressed, CYP17 hydroxylates pregnenolone to 17-hydroxypregnenolone.[206] CYP17 also includes P450 17,20-lyase activity, which is important for the formation of adrenal androgens. 3-Beta-HSD and delta(5)-4-isomerase next catalyze the conversion of 17-hydroxypregnenolone to 17-hydroxyprogesterone. The last step outside of the mitochondrion involves CYP21 that 21-hydroxylates 17-hydroxyprogesterone to 11-desoxycortisol. 11-Desoxycortisol travels back to the mitochondrion, where CYP11B1 (P450c11) catalyzes the conversion of 11-desoxycortisol to cortisol via its 11-beta hydroxylase activity. Little CYP11B2 activity is seen in the zona fasciculata. Similar to aldosterone, cortisol diffuses out of the cell to ultimately enter the circulation. The normal cortisol secretion rate is 6 to 14 mg/m^2 per 24 hours. In adults, this is approximately 10 to 20 mg/d, with some estimates as high as 25 mg/d.

Adrenal Androgens

Debate continues as to the anatomic location of adrenal androgen synthesis.[258] Traditionally, it has been taught that adrenal androgens are synthesized exclusively in the zona reticularis. However, the enzymatic activity of the 17,20-lyase (17,20-desmolase) that converts 17-hydroxypregnenolone to DHEA [a delta(5) steroid] and 17-hydroxyprogesterone to androstenedione [a delta(4) steroid] is included in the CYP17 protein, whose 17-hydroxylase activity was described previously. Therefore, adrenal androgens theoretically could be synthesized within both the zona fasciculata and the zona reticularis. However, a predominance of adrenal androgen synthesis in the zona reticularis may result from high cytochrome 5b expression, which increases the 17,20-lyase activity of CYP17. The 17,20-lyase activity of CYP17 converts C_{21} steroids into C_{19} steroids. Likewise, there is nothing to prevent cortisol synthesis in the zona reticularis. The conversion of DHEA to DHEA-S is catalyzed by DHEA sulfotransferase (SULT2A1; gene location: chromosome 19q13.3). Based on the model presented so far of enzymes partitioned into the mitochondrion or the endoplasmic reticulum, adrenal androgen synthesis is completed within the endoplasmic reticulum because this synthesis does not require CYP21, CYP11B1, or CYP11B2, which are located in the mitochondrion.

A small amount of testosterone is produced by the adrenal cortex. DHEA is converted to androstenediol by 17-ketosteroid reductase (17 beta-hydroxysteroid dehydrogenase, 17 beta-OHSD); this is followed by conversion of androstenediol to testosterone via the actions of 3-beta HSD and delta(4)-5-isomerase. The peripheral conversion of adrenal androgens to testosterone involves the conversion of DHEA to androstenedione and the conversion of androstenedione to testosterone via 17-ketosteroid reductase. Finally, testosterone is activated to dihydrotestosterone by 5-alpha reductase in target tissues (penis, scrotum, and beard). Peripheral aromatization of androstenedione yields estrone, whereas peripheral aromatization of testosterone yields estradiol.

Adrenal androgens are the major product of the adrenal cortex, whose total synthesis exceeds 20 to 25 mg/d. The adult adrenal secretes approximately 6 to 8 mg/d of DHEA, 8 to 16 mg/d of DHEA-S, 1.5 mg/d of androstenedione, and 0.05 mg/d of testosterone. Only small amounts of the estrogens estradiol and estrone and insignificant amounts of progesterone and other precursor steroids are produced.

Adrenal Steroid Synthesis in the Fetus

The fetal adrenal lacks adult concentrations of 3-beta-HSD expression with resulting elevated production of DHEA, DHEA-S, and 16-hydroxy DHEA-S (from hydroxylation of DHEA-S in the fetal liver). In utero, pregnenolone and 17-hydroxypregnenolone from the fetal adrenal enter the fetal circulation to be converted in the placenta, respectively, into progesterone and 17-hydroxyprogesterone via placental 3-beta-HSD. Progesterone and 17-hydroxyprogesterone then return to the adrenal (via the circulation), where they serve as substrates for aldosterone and cortisol, respectively.[225]

Summary of ACTH Activity

The biochemical actions of ACTH on the adrenal cortex is summarized as follows: (1) immediate ACTH effects via steroidogenesis activator protein and StAR; (2) increased cholesterol esterase activity; (3) decreased cholesterol ester synthesis; (4) increased cholesterol transport into the mitochondrion; (5) increased CYP11A binding of cholesterol; and (6) increased synthesis of pregnenolone. Through the action of transcription factors (SF-1), expression of CYP11A, CYP17, CYP11B1 (but not CYP11B2), and the LDL receptor is increased. CYP11B2 is controlled by angiotensin II, separating control of the zona glomerulosa from the zona fasciculata (CYP11B2 is controlled by ACTH). In addition, ACTH and other factors yet not discovered control adrenal androgen synthesis.

ADRENOCORTICAL HORMONES IN THE CIRCULATION

Steroid hormones are 90 to 98% bound to specific carrier proteins or albumin. Steroids that are sulfated or glucuronidated circulate unbound in the plasma. Aldosterone is carried primarily by albumin as cortisol, corticosterone, and 17-hydroxyprogesterone occupy most of the binding sites on corticosteroid-binding globulin (CBG; transcortin), a 58 kDa, 383 amino acid alpha-1 globulin.[111,266] Normal concentrations of total cortisol exceed the normal concentrations of aldosterone by many-fold, explaining why little aldosterone is carried on CBG. CBG is a member of the serine protease inhibitor superfamily, specifically, SERPINA6 (clade A—alpha-1 antiprotease, antitrypsin—member 6; gene location: chromosome 14q3).[168]

Between 80 and 90% of cortisol is carried by CBG, 7% of cortisol is loosely bound to albumin, and 2 to 3% is unbound (free). When total cortisol rises in Cushing syndrome (see later), the increased proportion of plasma free cortisol readily spills into the urine, increasing the urinary free cortisol (UFC) excretion.[176] Typically, only 0.25 to 0.5% of total cortisol is excreted in the urine.

Because more cortisol than aldosterone is bound to CBG, the half-life of cortisol is longer (60 to 80 minutes) than the half-life of aldosterone (20 to 30 minutes).[61] In addition to cortisol, progestins are carried by CBG. *Progestin* is a generic term for any substance that produces some or all of the biological effects of progesterone.

CBG concentrations rise in response to estrogens. In pregnancy, CBG may rise two- to threefold. Some patients with chronic active hepatitis may display increased CBG concentrations. Alternatively, CBG concentrations are reduced in (1) nephrosis (as a result of CBG loss in the urine), (2) cirrhosis (because of decreased production), and (3) hyperthyroidism (as caused by increased metabolism), and with glucocorticoid treatment (probably as a result of catabolism). Even with changes in total cortisol due to changes in CBG, the concentration of free cortisol remains stable if the hypothalamic-pituitary-adrenal axis is functioning normally.

DHEA and its sulfated form, DHEA-S, and estradiol are predominantly carried by albumin. In contrast, testosterone and dihydrotestosterone (DHT) are carried by sex hormone–binding globulin (SHBG), an ≈100 kDa homodimer (each monomer is ≈50 kDa; 373 amino acids; gene location: chromosome 17p1).[254] Estrogens and thyroid hormone increase SHBG concentrations, whereas insulin, growth hormone, glucocorticoids, androgens, and progestins lower SHBG concentrations. SHBG concentrations are higher in children than in adults.

METABOLISM OF ADRENAL STEROIDS[7]

The liver is the major site of steroid metabolism via P450 enzyme systems, with the kidney playing less of a metabolic role but an important excretory role. Clearance of steroid hormones involves (1) hydroxylation, (2) dehydrogenation, (3) reduction of double bonds, and (4) conjugation to sulfates or glucuronides. The reduction in steroid concentrations increases their solubility and provides functional sites (such as hydroxyl groups) for their conjugation to sulfate or glucuronic acid; this increases their solubility in urine, promoting their excretion. Approximately 90% of conjugated steroids are excreted by the kidney.

Aldosterone[20]

Aldosterone is reduced to tetrahydroaldosterone. Glucuronidation produces tetrahydroaldosterone 3-glucuronide, which can be excreted by the kidney. Aldosterone is 3 alpha- and 5 alpha-reduced, or 3 alpha- and 5 beta-reduced (Figure 54-7). Only ≈0.5% of aldosterone is excreted unchanged in the urine. Aldosterone is glucuronidated at the carbon 18 position. Cirrhosis, severe congestive heart failure, and ascites impair hepatic aldosterone clearance.

Cortisol[311]

Cortisone is formed from cortisol via 11 beta-hydroxysteroid dehydrogenase type 2 (see Figure 54-7). In this reaction, the 11-hydroxyl group is converted to an 11-oxo group by removal of two hydrogens. Cortisone lacks glucocorticoid activity. [*Note:* When cortisone is used as a drug, it can be activated back to cortisol in the liver via 11-beta hydroxysteroid dehydrogenase type 1, an nicotinamide adenine dinucleotide phosphate (NADPH)-dependent oxo-reductase.] Reduction of the double bonds at carbons 4-5 via delta(4)-5-beta reductase or delta(4)-5-alpha reductase yields dihydrocortisol and dihydrocortisone (DHE). Metabolism with reduction of the ketone groups at carbon 3 results in tetrahydrocortisol (THF) and tetrahydrocortisone (THE), which account for the major portion of cortisol clearance (≈50%). The only difference in the outcome of delta(4)-5-beta reductase versus delta(4)-5-alpha reductase activity is the alpha or beta orientation of the hydrogen (5 beta-THF or 5-alpha-THF). Normally, the beta metabolite predominates (5-beta THF:5-alpha-THF ratio = 2:1).

Further metabolism of THF and THE via 20-alpha-hydroxysteroid dehydrogenase or 20-beta-hydroxysteroid dehydrogenase produces alpha and beta cortol and cortolone (the cortoic acids), which account for ≈30% of cortisol excretion. Opening the carbon 17-20 bond creates a ketone and gives rise to 11 beta-hydroxyetiocholanolone and 11-ketoetiocholanolone, representing ≈10% of cortisol excretion. Only about 1% of cortisol is normally excreted as free cortisol or cortisone. Minor cortisol metabolites include (1) 20 alpha-hydroxycortisol and 20 beta-hydroxycortisol, which result from reduction of the carbon 20 ketone, and (2) 6 beta-hydroxycortisol, which results from hydroxylation of carbon 6. Oxidation of carbon 17 in THF and THE yields oxo or hydroxy metabolites (Figure 54-8). Minor cortisone metabolites are shown in Figure 54-8.

Of the many cortisol metabolites, more than 95% are conjugated at carbon 3 to glucuronic acid, or sulfated at the C-21 position. Proportionately, the glucuronide metabolites predominate over sulfated metabolites.

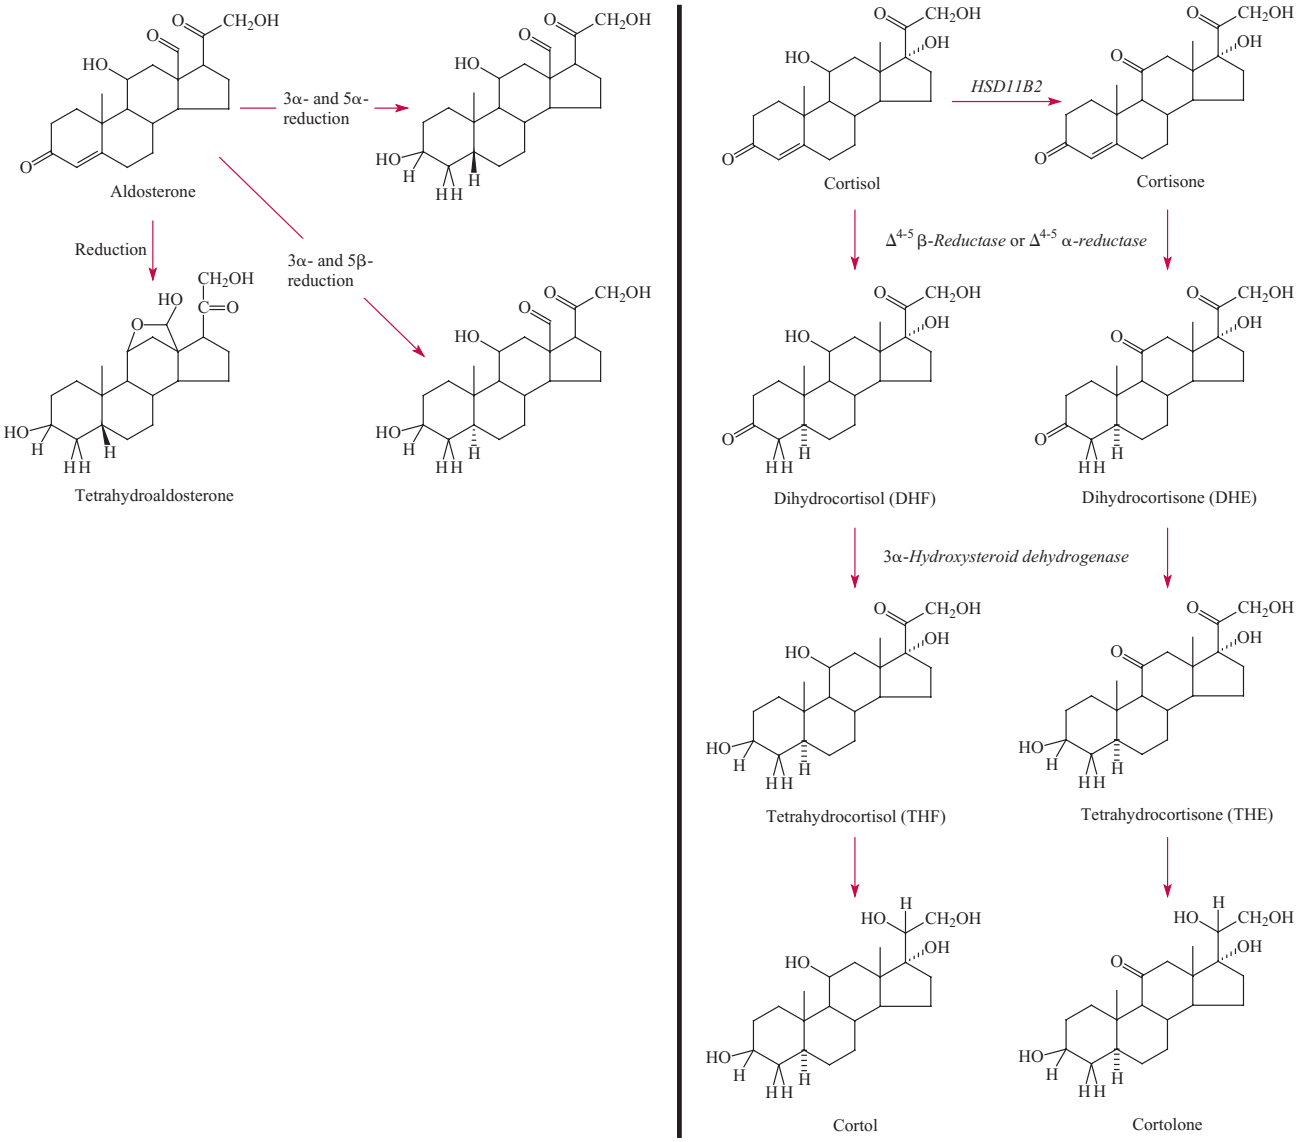

Figure 54-7 ***Left panel:*** **Aldosterone metabolism: Aldosterone is reduced to tetrahydroaldosterone. Aldosterone can be 3 alpha- and 5 alpha-reduced or 3 alpha- and 5 beta-reduced.** ***Right panel:*** **Cortisol metabolism: Cortisone is formed from cortisol via 11-beta hydroxysteroid dehydrogenase-2 (HSD11B2). Reduction of the double bonds at carbons 4-5 via delta(4)-5 beta reductase or delta(4)-5 alpha reductase yields dihydrocortisol (DHF) and dihydrocortisone (DHE). Metabolism with reduction of the ketone groups at carbon 3 results in tetrahydrocortisol (THF) and tetrahydrocortisone (THE), which account for the major portion of cortisol clearance (≈50%). Further metabolism of THF and THE via 20-alpha hydroxysteroid dehydrogenase or 20-beta hydroxysteroid dehydrogenase produces alpha and beta cortol and cortolone (the cortoic acids), which account for ≈30% of cortisol excretion.**

Adrenal Androgens[100]

Regarding the metabolism of the adrenal androgens, DHEA is sulfated to DHEA-S (Figure 54-9). These compounds are 7 alpha-hydroxylated or 16-alpha-hydroxylated. Alternatively, 17-ketosteroid reductase reduces the ketone at carbon 17 to a hydroxyl group, yielding androstenediol from DHEA and androstenediol sulfate from DHEA-S. Androstenedione is converted to androsterone via 3-alpha- and 5-alpha-reduction, whereas 3-alpha- and 5-beta-reduction yields etiocholanolone (see Figure 54-9). Similar to metabolites of cortisol, metabolites of the adrenal androgens are glucuronidated or sulfated for urinary excretion.

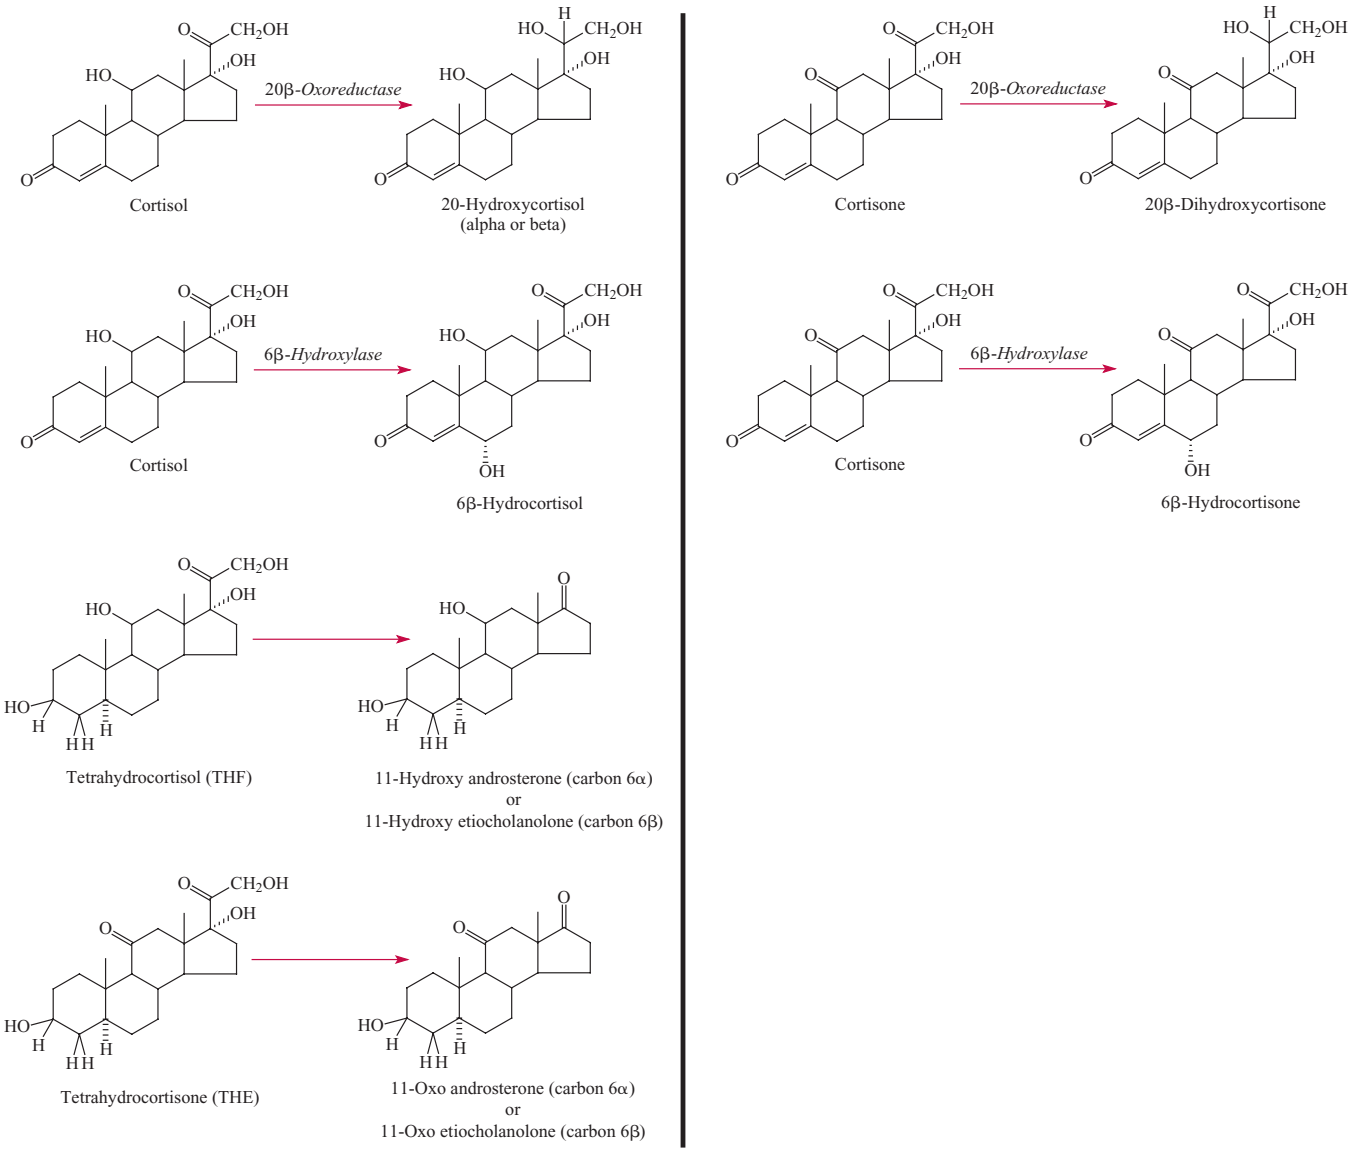

Figure 54-8 ***Left panel:*** **Minor cortisol metabolites include (1) 20-alpha-hydroxycortisol and 20-beta-hydroxycortisol, which result from reduction of the carbon 20 ketone, and (2) 6-beta-hydroxycortisol, which results from hydroxylation of carbon 6. Oxidation of carbon 17 in THF and THE yields oxo or hydroxy metabolites, as listed in the Figure.** ***Right panel:*** **Minor cortisone metabolites include 20 beta-dihydrocortisone and 6 beta-hydrocortisone.**

Urinary Metabolites

Whereas measurement of biliary excretion of adrenal steroids is not clinically useful, measurement of the urinary excretion of these compounds is common in the laboratory assessment of adrenal disease. Immunoassays for the major circulating steroid hormones are widely available.

Biochemically17-hydroxyprogesterone is reduced to pregnanetriol, which is measured in urine. The reduction converts keto groups at the 3-position and the 20-position to hydroxyl groups, giving the molecule three hydroxyl groups (hence the term *triol*). Hydroxylation helps solubilize the compound for renal excretion. Before the development of immunoassays for 17-hydroxyprogesterone, a 24 hour urine was collected for measurement of pregnanetriol excretion in cases of congenital adrenal hyperplasia (CAH) due to CYP21 or CYP11B1 deficiency. If these forms of CAH were managed appropriately, ideally the pregnanetriol excretion would return to within it's reference interval.

The urinary metabolites of 11-desoxycortisol and cortisol are classified as 17-hydroxycorticosteroids (17-OHCS). Analytically, 17-OHCS are photometrically determined by the reaction of 17,21-dihydroxy-20-oxosteroids with a phenylhydrazine-ethanol-sulfuric acid reagent, producing yellow phenylhydrazones that are termed *Porter-Silber*

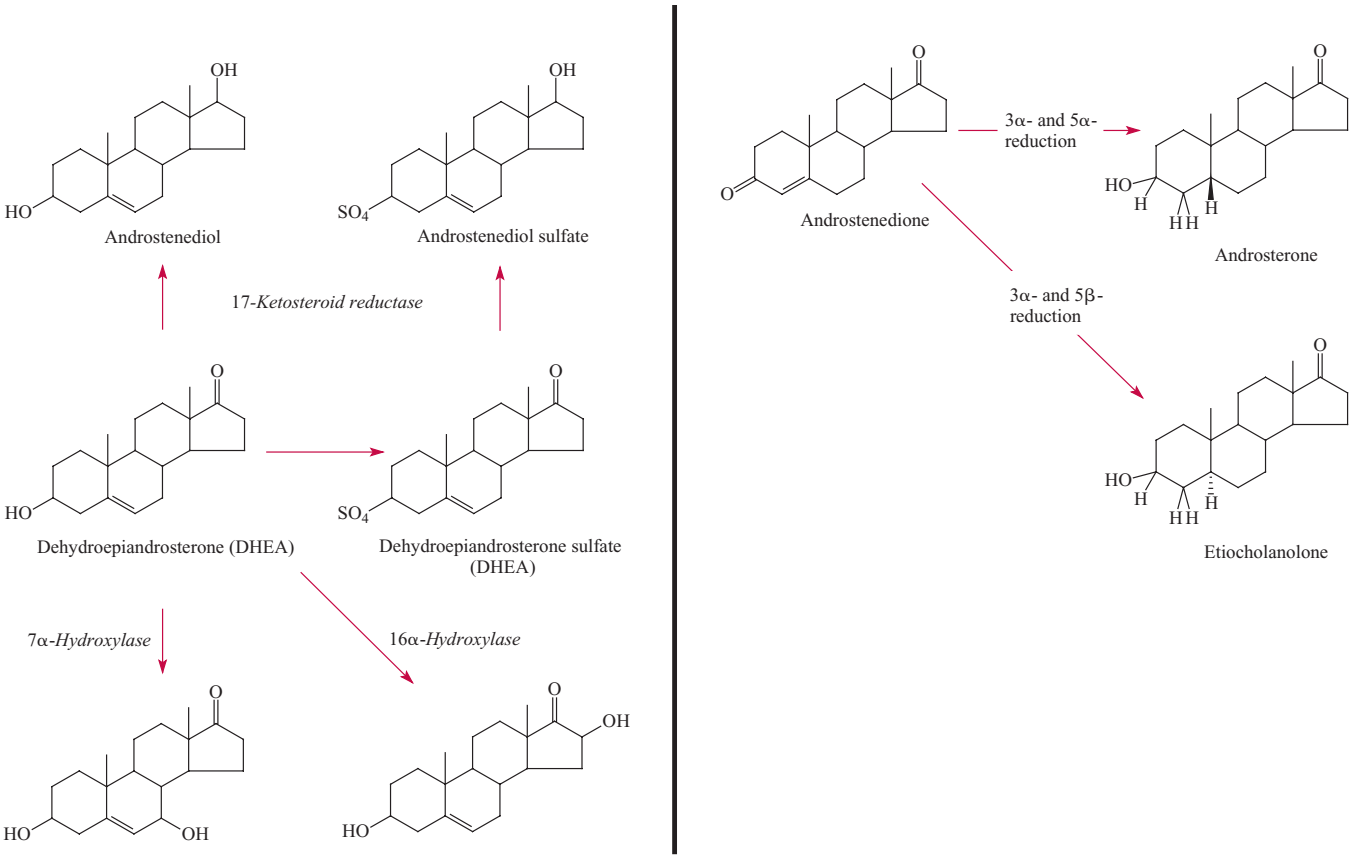

Figure 54-9 ***Left panel:*** **DHEA metabolism: DHEA can be 7 alpha-hydroxylated or 16 alpha-hydroxylated. Alternatively, conversion of the carbon 17 ketone group of DHEA and DHEA-S to a hydroxyl can be accomplished by 17-ketosteroid reductase, yielding androstenediol from DHEA and androstenediol sulfate from DHEA-S.** ***Right panel:*** **Androstenedione metabolism: Androstenedione is converted to androsterone via 3-alpha- and 5-alpha-reduction, whereas 3-alpha- and 5-beta-reduction yields etiocholanolone.**

chromogens. Measurements of 17-OHCS have been used to differentiate CYP21 deficiency from CYP11B1 deficiency. In CYP21 deficiency, 17-OHCS would not be elevated because both 11-desoxycortisol and cortisol are low. However, because CYP11B1 deficiency increases 11-desoxycortisol (the metabolic block is between 11-desoxycortisol and cortisol), 17-OHCS would be elevated in untreated or undertreated CYP11B1 deficiency. Also, CYP11B1 deficiency and CYP21 deficiency are differentiated by the greatly elevated plasma 11-desoxycortisol concentrations in the former.

The urinary metabolites of 17-hydroxyprogesterone, 11-desoxycortisol, and cortisol are 17-ketogenic steroids (17-KGS) because oxidation of these compounds yields a keto group at the 17 position. Ketogenic steroids have been measured using the Zimmermann reaction, in which an alkaline solution of meta-dinitrobenzene reacts with methylene groups at carbon-16 of the 17-ketosteroids. In CYP17 deficiency, 17-KGS would not be elevated. However, in both CYP21 and CYP11B1 deficiencies, when untreated or undertreated, 17-KGS are elevated.

DHEA and androstenedione metabolites are measured in the same way as 17-ketosteroids because both have keto groups in the C-17 position. Because testosterone has a hydroxyl group at the C-17 position, it is not a 17-ketosteroid. DHEA and androstenedione are elevated in untreated and undertreated CYP21 and CYP11B1 deficiencies. Figure 54-10 summarizes these urine steroid measurements.

Factors Affecting Adrenal Steroid Metabolism

Cortisol clearance (or metabolism) affects cortisol concentrations. If the clearance of cortisol is reduced, plasma cortisol concentrations can increase, whereas enhanced clearance of cortisol decreases its concentration. Rifampin-induced Addisonian crisis from increased cortisol metabolism has been reported. However, in most cases, cortisol, free cortisol, and ACTH are normal in these conditions, presumably because alterations in the free cortisol concentration will be sensed by the hypothalamus, which will respond by secreting CRH to ultimately return the free cortisol concentration to within it's

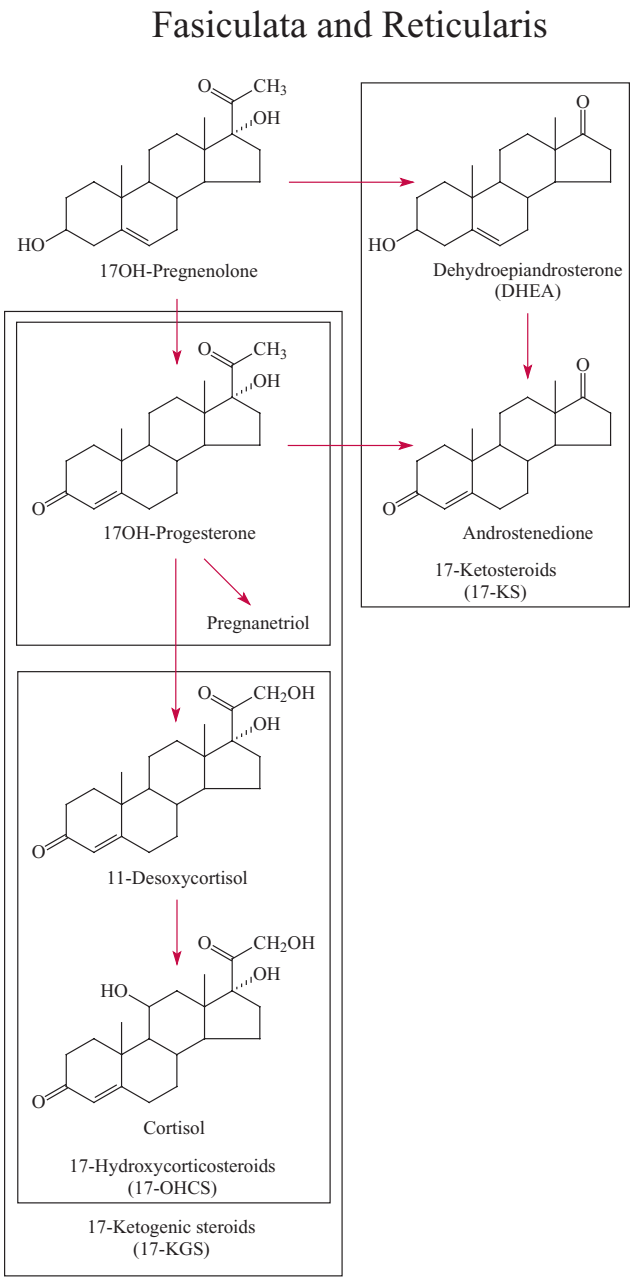

Figure 54-10 This figure summarizes the urinary metabolites generated from steroids involved in cortisol and adrenal androgen synthesis.

reference interval. Table 54-7 lists a number of conditions that affect cortisol concentrations.

DYNAMIC TESTS OF ADRENAL FUNCTION

Several strategies are used to assess adrenal function. These tests are typically designed to differentiate between primary and secondary causes of disease, or to detect abnormalities that may not be apparent in the results of static, baseline laboratory measurements. For example, provocative stimulation tests are useful in documenting hyposecretion of adrenocortical hormones.[226] A specific stimulus is applied, and the release of a given hormone over a specific time frame is measured. Also, suppression tests are used to document hypersecretion of the adrenocortical hormones.[76]

ACTH Stimulation (Cosyntropin) Test

ACTH stimulation tests, sometimes referred to as the *cosyntropin tests,* are designed to document the functional capacity of the adrenal glands to synthesize cortisol (Boxes 54-1 and 54-2). Cosyntropin (Cortrosyn) is a synthetic polypeptide that is the N-terminal 24 amino acid sequence of ACTH, which contains the biologically active domain. Another name for cosyntropin is *tetracosactrin* (Synacthen). Cosyntropin, a potent stimulator of cortisol secretion, has a very brief half-life and minimal antigenicity. The protocols for 1 hour and multiple-day ACTH stimulation tests are shown in Box 54-1.

Investigators have sought to determine whether a lower dose of cosyntropin (1 µg vs. 250 µg) in the 1 hour stimulation test might be more sensitive for the detection of adrenal insufficiency from ACTH deficiency or primary adrenal failure.[143] Some patients have normal responses to 250 µg of ACTH yet inadequate responses to 1 µg of ACTH. This remains a point of controversy, and the 1 µg ACTH dose has not been universally accepted as superior to the 250 µg dose in detecting glucocorticoid deficiency.[89,218,317]

BOX 54-1 Protocol for the 1 Hour (Rapid) Cosyntropin Stimulation Test

Rationale

Administration of ACTH to normal subjects results in a rapid rise in the serum cortisol concentration. Patients with adrenal destruction (e.g., Addison disease) show no change or an inadequate change in serum cortisol concentration after ACTH injection. Patients with atrophy of the adrenal cortex caused by exogenous glucocorticoid treatment or dysfunction of the pituitary gland or hypothalamus may show a slight rise in serum cortisol concentration, but not one of normal magnitude.

Procedure

A baseline blood sample is drawn for determination of serum cortisol concentration; then 250 µg of cosyntropin is given intramuscularly or intravenously. Additional samples for serum cortisol determination are drawn 30 and 60 minutes after injection.

Interpretation

A peak serum cortisol concentration of 18 to 20 µg/dL or greater is a normal response. The expected change in cortisol concentration is 7 to 10 µg/dL (the delta cortisol). The peak cortisol value is more important than the incremental change. The incremental change may not be seen in patients who are tested at times of stress, when their adrenal output of cortisol is already maximally stimulated by endogenous ACTH.

TABLE 54-7 Conditions That Affect Cortisol Clearance

Endocrinopathy	Cortisol Clearance	Mechanism
Hyperthyroidism	Incr	Inhibition of hepatic 11-beta HSDI and stimulation of 5-alpha reductase and 5-beta reductase
Hypothyroidism	Decr	Stimulation of hepatic 11-beta HSDI and inhibition of 5-alpha reductase and 5-beta reductase
Acromegaly	Incr	Inhibition of hepatic 11-beta HSDI
Cushing syndrome	Incr	Induction of 6 beta-hydroxylase
Solid Organ Dysfunction		
Chronic liver disease (disease including alcoholic cirrhosis)	Decr	Decreased cortisol metabolism
Renal disease	Decr	Reduced renal conversion: cortisol → cortisone
Drugs/Toxins		
Acute alcohol ingestion	Decr	—
Rifampin	Incr	Induction of 6 beta-hydroxylase
Phenytoin	Incr	Induction of 6 beta-hydroxylase
Phenobarbital	Incr	Induction of hepatic mixed-function oxidases
Other		
Aging	Decr	*Note:* Decreased clearance is balanced by decreased synthesis; therefore cortisol concentrations and responses to ACTH are normal.
Starvation	Decr	Balanced by decreased production
Anorexia nervosa	Decr	—

—, Not defined; *decr,* decreased; *incr,* increased.

CRH Stimulation Test

A direct and selective test of pituitary gland function is the CRH stimulation test (Box 54-3).[119,179] Injection of ovine CRH stimulates ACTH secretion in normal subjects within 60 to 180 minutes; glucocorticoids inhibit this effect (as in cases of Cushing syndrome resulting from an adrenal adenoma or ectopic ACTH secretion by a tumor). However, in Cushing disease, the corticotropinoma can respond to exogenous CRH with a normal or exaggerated response. This test may be used in the differential diagnosis of adrenocortical hyperfunction and hypofunction. CRH stimulation is also used in the differential diagnosis of endogenous Cushing syndrome and in distinguishing secondary from tertiary ACTH deficiency.

A variation of the CRH stimulation test measures ACTH in blood samples drawn from the two inferior petrosal venous sinuses (IPSs) to differentiate pituitary-dependent Cushing disease from ectopic ACTH syndrome.[237,305] Blood samples are collected from both right and left IPS veins and from a peripheral vein (e.g., the inferior vena cava) at −30, 0, +2, +5, +10, and +30 minutes after intravenous administration of ovine CRH (1 µg/kg body weight) over 20 to 60 seconds. The ratio of the IPS concentration to the peripheral venous concentration of plasma ACTH is used to predict the location of excess ACTH secretion. An IPS-to-peripheral vein ratio greater than 2.0 is consistent with a pituitary lesion (Cushing disease) as the cause of Cushing syndrome, whereas a ratio less than 1.4 to 1.7 supports the diagnosis of an ectopic ACTH syndrome. Some endocrinologists claim that IPS sampling is the best test for distinguishing ACTH-dependent forms of Cushing syndrome (ectopic ACTH syndrome vs. Cushing disease) when performed in the setting of long-standing hypercortisolism. ACTH concentrations are suppressed in patients with primary adrenal tumors compared with patients with Cushing syndrome or the ectopic ACTH syndrome.[138,312] Imaging studies cannot yet replace laboratory testing for Cushing disease.[9] Even when ectopic ACTH syndrome is diagnosed, localization of the source tumor can be very difficult.[107,297]

Insulin-Induced Hypoglycemia Stimulation Test

To test the integrity of the hypothalamic-pituitary-adrenal axis, other indirect tests of ACTH secretion rely on the adrenal response to maneuvers that stimulate endogenous ACTH release. In the insulin-induced hypoglycemia stimulation test, insulin is given to stimulate the release of CRH through hypoglycemia, and plasma ACTH or cortisol concentrations are measured.[79] This test involves the risk of hypoglycemia (obtundation, seizure, coma, and death) and should be performed only with an experienced physician in

BOX 54-2 Protocol for the Multiple-Day Adrenocorticotropic Hormone (ACTH) Stimulation Test

Rationale
Multiple-day ACTH stimulation testing for assessment of adrenal cortex function is required occasionally to evaluate adrenal cortisol responsiveness. A common situation is the diagnosis of adrenal insufficiency, which is treated with glucocorticosteroids before a cause has been established. Prolonged ACTH stimulation is used to distinguish primary from secondary and/or tertiary (central) causes of adrenal insufficiency.

Procedure
A total of 250 μg of cosyntropin is injected daily for 3 days. This is followed by an 8 hour infusion of 250 μg of cosyntropin. Urinary free cortisol and serum cortisol are measured daily.

Interpretation
Serum cortisol values of 18 to 20 μg/dL or greater exclude primary adrenal insufficiency. Glucocorticoid withdrawal would be required before assessment of secondary or tertiary adrenal insufficiency in such cases. Little or no increase in cortisol secretion is seen in primary adrenal failure even over successive days. A progressive staircase rise is seen over 2 to 3 days in adrenal insufficiency caused by pituitary or hypothalamic disease or steroid concentration suppression. Little or no response is seen in congenital adrenal hyperplasia (CAH) caused by 21- and 17-hydroxylase deficiencies. The 2 day and 5 day variations of this test have been employed in clinical practice.

BOX 54-3 Protocol for the Corticotropin-Releasing Hormone (CRH) Stimulation Test

Rationale
Exogenous CRH stimulates the secretion of ACTH from the anterior pituitary gland in normal subjects. The subsequent cortisol concentration is an indicator of the ACTH response.

Procedure
Synthetic ovine CRH (corticorelin ovine triflutate), 1 μg/kg body weight, is administered intravenously in bolus form at 0900 or 2000 hours. Blood samples for cortisol and ACTH assays are collected 15 minutes and immediately before and 5, 15, 30, 60, 120, and 180 minutes after CRH injection.

Interpretation
In normal subjects, plasma ACTH concentrations peak 30 minutes after CRH injection (80 ± 7 pg/mL at 0930 h; 29 ± 2.6 pg/mL at 2030 h), and serum cortisol peaks at 60 minutes (13 ± 1 μg/dL at 1000 h; 17 ± 0.7 μg/dL at 2100 h). Patients with pituitary ACTH deficiency (secondary adrenal insufficiency) have decreased ACTH and cortisol responses. Patients with hypothalamic disease have prolonged ACTH responses and subnormal cortisol responses. Most patients with Cushing syndrome caused by adrenal tumors or nonendocrine ACTH-producing tumors do not respond to CRH injection. Most patients with Cushing disease respond with a normal or excessive increase in ACTH. Responses usually are normal in patients with depression.

attendance. It is contraindicated in patients with a seizure disorder or coronary artery disease. Venous access must be maintained during the procedure to ensure a ready avenue for the rapid administration of glucose should hypoglycemia not spontaneously resolve or a hypoglycemia-induced seizure occur requiring immediate administration of intravenous glucose.

Metyrapone Stimulation Test

A less risky indirect test of hypothalamic-pituitary-adrenal axis function involves the administration of metyrapone, an inhibitor of the 11 beta-hydroxylase enzyme that converts 11-desoxycortisol to cortisol.[24] Several protocols have been designed for metyrapone stimulation testing; one that is simple and relatively safe for outpatient testing is described in Box 54-4.

Dexamethasone Suppression Test

In normal individuals, an elevation in the blood concentration of cortisol inhibits ACTH release from the pituitary gland. This results in decreased production of cortisol and other ACTH-dependent adrenal steroids from the adrenal cortex. The integrity of this feedback mechanism has been tested by administering a potent glucocorticoid, such as

BOX 54-4 Protocol for the Overnight Single-Dose Metyrapone Stimulation Test

Rationale
Metyrapone inhibits 11-beta-hydroxylase (CYP11B1), the enzyme that catalyzes the step immediately preceding cortisol synthesis. As the blood concentration of cortisol falls, the negative feedback effect is diminished, causing the release of ACTH from the pituitary gland. The stimulatory effect of ACTH on the adrenal cortex leads to a rise in 11-deoxycortisol, the compound immediately preceding cortisol in the biosynthetic pathway.

Procedure
Metyrapone (30 mg/kg body weight) is given orally at midnight with milk or a snack (to delay absorption). At 0800 hours the following morning, blood is drawn for determination of 11-deoxycortisol, cortisol, and ACTH concentrations.

Interpretation
In normal subjects, 11-desoxycortisol increases from less than 1 μg/dL to greater than 7 μg/dL after metyrapone stimulation, and ACTH values exceed 150 pg/mL. No response or an impaired response may be seen in pituitary or hypothalamic disease combined with inadequate enzyme blockade (plasma cortisol >3 μg/dL) or with Cushing syndrome caused by adrenal tumors or nonendocrine ACTH-secreting tumors. Exaggerated responses may be seen in pituitary Cushing syndrome.

Note: This test is not recommended in cases of suspected Addison disease for fear that suppression of cortisol production might precipitate an Addisonian crisis. That being said, patients with Addison disease have an inadequate rise in 11-desoxycortisol in response to metyrapone.

BOX 54-5 Protocol for the Overnight Low-Dose Dexamethasone Suppression Test

Rationale
In low doses, dexamethasone, a synthetic glucocorticoid and cortisol analog, suppresses ACTH and cortisol production in normal subjects, but not in patients with Cushing syndrome.

Procedure
One milligram of dexamethasone is given orally between 2200 and 2400. Blood is drawn for determination of serum cortisol at 0800 hours the next morning.

Interpretation
In normal subjects, the serum cortisol concentration is suppressed to 2 µg/dL or less after administration of 1 mg of dexamethasone. A postdexamethasone 0800 hours cortisol cutoff of less than 5 µg/dL is more sensitive for the detection of Cushing syndrome but is less specific. Most patients with Cushing syndrome do not show adequate suppression, and 0800 hours cortisol concentrations are usually 10 µg/dL or greater. Serum cortisol greater than 2 µg/dL may be seen in cases of stress, obesity, infection, acute or chronic illness, alcohol abuse, severe depression, oral contraceptive use, pregnancy, estrogen therapy, failure to take dexamethasone, or treatment with phenytoin or phenobarbital (which can enhance dexamethasone metabolism).

BOX 54-6 Protocol for the Classic Low-Dose/High-Dose Dexamethasone Suppression Test

Rationale
Normal subjects show a decline in urinary free cortisol concentrations under conditions of low-dose dexamethasone suppression. However, patients with excess cortisol production, regardless of the cause, do not suppress on low-dose dexamethasone. Patients with Cushing syndrome caused by an ACTH-producing pituitary adenoma (e.g., Cushing disease from a corticotropinoma) may show suppression of cortisol excretion with high-dose dexamethasone. Patients with Cushing syndrome from other causes (adrenocortical adenoma or carcinoma, or ectopic production of ACTH or CRH) usually do not demonstrate cortisol suppression with high-dose dexamethasone treatment.

Procedure
Twenty-four hour urine samples are collected daily for 6 consecutive days. Free cortisol and creatinine are measured in each 24 hour urine sample. Urinary free cortisol (UFC) is regarded as a more specific measure of cortisol secretion than 17-hydroxycorticosteroids. The first 2 days provide baseline measurements of the excretion of cortisol. Dexamethasone 0.5 mg ("low-dose dexamethasone") is given orally every 6 hours starting at 0800 hours on day 3 (for a total of eight doses: days 3 and 4). Dexamethasone 2.0 mg ("high-dose dexamethasone") is then given orally every 6 hours starting at 0800 hours on day 5 (for a total of eight doses: days 5 and 6).

Interpretation
On the first 2 days, urinary excretion of cortisol (i.e., the baseline measurements) should be elevated in cases of Cushing syndrome. In cases of true endogenous Cushing syndrome, baseline UFC is usually at least two to three times higher than the upper limit of the reference interval. In normal individuals, baseline UFC excretion should be within the reference interval. Should a normal individual be stressed, psychologically or physiologically, and the baseline UFC is elevated, UFC on days 3 and 4 should be suppressed to less than 50% of the baseline level (e.g., "UFC suppression was achieved"). All subjects with true endogenous hypercortisolism should not suppress on day 3 or 4. If suppression of UFC excretion occurs on days 5 and 6 or on day 6, Cushing disease is diagnosed. However, not all cases of Cushing disease suppress on high-dose dexamethasone. Therefore failure to suppress on high-dose dexamethasone leaves three diagnostic possibilities: Cushing disease, adrenal adenoma (or, less commonly, adrenal carcinoma), and ectopic ACTH or CRH syndrome. Those patients taking phenytoin or phenobarbital, or both, may metabolize dexamethasone more rapidly than normal subjects and may not show appropriate suppression.

dexamethasone, and judging suppression of ACTH secretion by measuring serum or urine cortisol concentrations. Several dexamethasone suppression tests are available for clinical use (Boxes 54-5 through 54-7). Dexamethasone is chosen for suppression testing because it does not significantly cross-react in cortisol immunoassays. Therefore the secreted endogenous glucocorticoid, cortisol, can be distinguished from the exogenous glucocorticoid, dexamethasone.

A low dose of dexamethasone (1 mg in adults, 0.3 mg/m^2 in children) is used initially to document true hypersecretion of cortisol (see Box 54-5).[345] Patients with Cushing syndrome of any cause will fail to suppress their morning cortisol concentration to less than 5 µg/dL with a low dose of dexamethasone.[98] It should be emphasized that this is a screening test, and confirmation of Cushing syndrome requires repeat testing or measurement of urinary cortisol on at least two separate days or some other combination of tests (e.g., midnight cortisol <5 µg/dL, salivary cortisol <0.112 µg/dL).[151,166] A 0.5 mg dose variant of the overnight dexamethasone suppression test has been described and validated.[235] On the other hand, a 2 mg dexamethasone dose has been used to exclude Cushing syndrome in obese individuals.[274]

Higher doses of dexamethasone given over 48 hours are used to resolve the differential diagnosis of an ACTH-secreting pituitary adenoma (a corticotropinoma causing Cushing disease) versus an ectopic ACTH source. Suppression of basal urinary cortisol excretion by less than 50% is a response consistent with Cushing disease, but not ectopic ACTH syndrome or primary adrenal pathology for hypercortisolism, in which ACTH is not suppressed by high doses of dexamethasone.

The classic (or "formal") low dose-high dose dexamethasone suppression test is detailed in Box 54-6. On high-dose dexamethasone, suppression will occur in about 60% of patients with Cushing disease. Thus, the high-dose stage may

BOX 54-7 Protocol for the High-Dose Overnight Dexamethasone Suppression Test

Rationale
The rationale for this test is similar to the rationale for the multiple high-dose dexamethasone suppression test.

Procedure
Dexamethasone 4 mg is given orally at 2300 and 2400 hours. Blood is drawn for determination of plasma cortisol at 0700 hours or 0800 hours the next morning, or 8 to 9 hours after dexamethasone is given.

Interpretation
Most patients with Cushing syndrome show suppression of baseline cortisol concentration of at least 50%. If suppression is not greater than 50%, the test should be repeated with 8 to 24 mg of dexamethasone.

allow identification of Cushing disease. However, failure of suppression on high-dose dexamethasone does not distinguish Cushing disease from the other causes of Cushing syndrome, and other diagnostic approaches must be pursued, such as IPS sampling.

Failure of cortisol suppression by dexamethasone has been observed in patients with (1) depression, (2) severe stress, (3) uncontrolled diabetes mellitus, (4) anorexia nervosa with estrogen administration; and (5) in subjects receiving medications (such as phenytoin) that induce the hepatic cytochrome P450 enzymes that metabolize dexamethasone.[325] If noncompliance or hypermetabolism of dexamethasone is a clinical consideration in patients who do not suppress their cortisol during the dexamethasone suppression test, dexamethasone can be measured in reference laboratories.

Mineralocorticoid Stimulation Tests

The renin-angiotensin-aldosterone system responds to electrolyte balance (and imbalance).[104] Sodium excretion and extracellular fluid volume are inversely correlated with plasma renin and aldosterone concentrations. The sodium (Na)-to-creatinine (Cr) ratio in a urine specimen is used as a marker for sodium volume status. As well, the fractional excretion of sodium (FENa) provides insights into the patient's sodium status. The equation for the fractional excretion of sodium is given below:

$$FENa = \frac{[U_{Na^+}][S_{Cr}]}{[S_{Na^+}][U_{Cr}]} \times 100$$

Percent sodium excreted is the unit reported. FENa is typically less than 1%. The FENa has been observed to exceed 1% with tubular disease or injury with sodium wasting. The calculation of the FENa is not valid when patients are treated with diuretics. Procedures for stimulating the renin-angiotensin system are based on volume depletion maneuvers, such as sodium restriction, upright posture, or diuretic administration.

BOX 54-8 Protocol for the Furosemide Stimulation Test

Rationale
Plasma renin activity (PRA) varies with the patient's state of hydration and sodium intake. Administration of furosemide, a potent diuretic, provides a stimulus to increase plasma renin secretion.

Procedure
Furosemide (Lasix; Hoechst-Roussel Pharmaceuticals, Somerville, NJ) 40 to 80 mg is given orally after an overnight fast. The subject is maintained in an upright posture (sitting, standing, or walking) throughout the test. Blood is drawn for determination of PRA before and 4 hours after furosemide administration.

Interpretation
Responses must be defined for the assay technique used. Patients with renin-dependent forms of hypertension (e.g., renovascular hypertension) show values that are approximately five times normal. Increased PRA following furosemide is seen in patients with high-renin essential hypertension, pheochromocytoma, and Bartter syndrome. Patients with hypertension from mineralocorticoid excess (e.g., primary hyperaldosteronism) usually display PRA below the lower limit of detection for the PRA assay. Patients with hyporeninemic hypoaldosteronism usually have low concentrations of plasma renin and low aldosterone concentrations.

In the furosemide stimulation test, oral or intravenous furosemide (40 to 80 mg) is administered, followed by 4 hours of upright posture (Box 54-8). This test does not require hospitalization or special diets, although it is recommended that the patient maintain a diet with a normal salt intake.[23] The typical response to this diuretic is a twofold to threefold rise in plasma renin. Another simple and convenient stimulation test consists of sodium restriction and upright posture. Dietary sodium is restricted to less than 20 mmol/d for 3 to 5 days; urine is collected for creatinine and sodium measurements until equilibrium with the new diet is established. Then, plasma renin activity is obtained after 2 hours of standing. A typical response is a twofold to threefold increase in plasma renin.

Mineralocorticoid Suppression Tests

Mineralocorticoid suppression tests have been designed that are based on salt loading. For example, (1) saline infusion, (2) oral salt loading, or (3) mineralocorticoid administration has been used to suppress the secretion of aldosterone by the adrenal gland. In healthy individuals, acute expansion of plasma volume with salt increases renal perfusion, suppresses renin release, and decreases aldosterone secretion.

The protocol for the saline suppression test is shown in Box 54-9. This test should not be performed in the setting of severe hypertension or heart failure. Administration of fludrocortisone, a synthetic mineralocorticoid, normally produces comparable suppression of aldosterone secretion (see

BOX 54-9 Protocol for the Saline Suppression Test

Rationale
Rapid volume expansion with intravenous saline should suppress plasma aldosterone in normal subjects, but not in patients with primary hyperaldosteronism.

Procedure
Care must be taken to ensure that the subject is not hypokalemic before beginning the test. The subject is awakened at 0600 hours and is kept in an upright posture for 2 hours. Blood is drawn for determination of plasma aldosterone at 0800 hours. The subject then assumes a supine position, and 2 L of isotonic saline 0.9 g/dL is infused over a 4 hour period. Blood is drawn for plasma aldosterone determination at noon.

Interpretation
Normal subjects show a plasma aldosterone concentration of 5 ng/dL (140 pmol/L) or less after saline infusion. Concentrations greater than 10 ng/dL are usually seen in patients with autonomously functioning aldosterone-secreting tumors.

BOX 54-10 Protocol for the Fludrocortisone Suppression Test

Rationale
Fludrocortisone, a potent mineralocorticoid, suppresses aldosterone production in normal subjects, but not in subjects with primary hyperaldosteronism.

Procedure
Hypokalemia must be corrected before starting this test, and serum potassium must be monitored during the test. Fludrocortisone 0.1 mg every 6 hours is given for 3 days. Plasma is collected for aldosterone determination after a standing position has been maintained for 2 hours (for baseline measurement) and at the end of fludrocortisone administration. Twenty-four hour urine collections for measurement of aldosterone are obtained 1 day before fludrocortisone administration is started and on day 3 of the test course.

Interpretation
Normal subjects show suppression of plasma aldosterone to less than 4 ng/dL (111 pmol/L); urine aldosterone is 20 µg/d or greater on day 3.

fludocortisone suppression test; Box 54-10). Fludrocortisone should be administered with caution in patients with hypokalemia and heart or renal failure. An alternate suppression test uses the ACE inhibitor captopril.[182] This test is recommended when risks from volume overload (e.g., the development of pulmonary edema or hypertension) preclude the use of other procedures. Captopril inhibits the conversion of angiotensin I to angiotensin II, removing the angiotensin II stimulus for aldosterone secretion.

Adrenal Androgen Stimulation Tests

The response of adrenal androgen secretion to ACTH stimulation is variable. Plasma DHEA and androstenedione are increased threefold to fourfold after 90 minutes of stimulation with ACTH (10 µg/m^2). DHEA-S, on the other hand, is increased by 30 to 50% with ACTH administration. ACTH stimulation studies are not considered useful in evaluating hypoandrogenic disorders.[246]

Adrenal Androgen Suppression Tests

Overnight suppression using dexamethasone produces small changes in adrenal androgen concentration compared with those of cortisol. Dexamethasone, 0.75 mg, administered at midnight for several days reliably suppresses adrenal androgen concentrations measured in blood. Tissue stores of these androgens may account in part for the delay in response.[201]

DISORDERS OF THE ADRENAL CORTEX

Thomas Addison first reported hypofunction of the adrenal cortex in 1855.[248] However, only over the past 65 years have many of the diseases associated with abnormal adrenal function been discovered and studied.[217] In general, diseases of this organ are classified as resulting from hypofunction or hyperfunction of the adrenal cortex.[321] Nonfunctional adrenal tumors are diagnosed histologically.

Although circulating concentrations of adrenal androgens decline with advancing age, it is unclear whether this simply reflects physiologic changes associated with aging, or if it is a pathologic condition that should be treated.[33] Most experts believe the former and do not prescribe adrenal androgens as "treatment" for aging.[209] Adrenal androgen deficiency does occur as part of primary adrenal failure, but it has no clear pathologic consequences.[4] Excess prenatal adrenal androgens have been known to produce ambiguous genitalia in females. Excess postnatal adrenal androgens can lead to precocious pseudopuberty in boys and hirsutism or virilization in girls. *Pseudopuberty* involves pubertal changes that result from autonomous gonadal or adrenal hypersecretion of sex steroids, independent of the CNS. In central precocious puberty, gonadotropins drive early sexual development.

Adrenal Insufficiency (Addison Disease)[156]

Adrenal insufficiency causing combined mineralocorticoid and glucocorticoid deficiency is a rare disorder with a prevalence of only 4 to 11 cases per 100,000.[80] If untreated, adrenal insufficiency can be fatal.[74] Cortisol deficiency is classified as (1) primary, (2) secondary, or (3) tertiary.[333]

Primary adrenal insufficiency, also known as Addison disease, results from progressive destruction or dysfunction of the adrenal glands by (1) an autoimmune process, (2) some systemic disorder, (3) an inborn error of metabolism (endogenous causes), or (4) by an exogenous cause such as infection (Table 54-8).[130] Worldwide, infectious disease is the most common cause of primary adrenal insufficiency and may include tuberculosis, fungal infection (histoplasmosis, cryptococcosis, North and South American blastomycosis,

TABLE 54-8 Causes of Primary Adrenal Insufficiency or Failure of Aldosterone Production

Endogenous Causes	
Autoimmune disease	Sporadic
	Autoimmune polyglandular syndrome type 1 (Addison's disease, candidiasis, hypoparathyroidism, and primary gonadal failure)
	Autoimmune polyglandular syndrome type 2 (Addison's disease, primary hypothyroidism, primary hypogonadism, diabetes, and pernicious anemia)
Inborn errors	Congenital adrenal hyperplasia
	Congenital adrenal hypoplasia (*DAX-1* mutation)
	Demyelinating disorders: adrenoleukodystrophies
	Childhood X-linked recessive adrenoleukodystrophy (Brown-Schilder disease)
	Neonatal autosomal recessive adrenoleukodystrophy
	X-linked recessive adrenomyeloneuropathy (sudanophilic leukodystrophy)
	Familial (isolated) glucocorticoid deficiency (degeneration of fasciculata-reticularis layers)
	Wolman disease (lysosomal acid lipase deficiency)
	Steroidogenic factor-1 (SF-1) mutations
	Mitochondrial forms of Addison disease (Kearns-Sayre syndrome)
	Smith-Lemli-Opitz syndrome (sterol delta-7-reductase mutations)
	ACTH resistance syndromes
Vascular disorders	Intra-adrenal hemorrhage (Waterhouse-Friderichsen syndrome): infection (caused by *Neisseria meningitidis, Pseudomonas aeruginosa, Haemophilus influenzae, Streptococcus pyogenes, Streptococcus pneumoniae*) or anticoagulants
Glandular infiltration	Neoplastic
	Leukemia, lymphoma, carcinoma of the lung, carcinoma of the breast
	Non-neoplastic
	Amyloid
	Hemochromatosis
Exogenous Causes	
Infection	Granulomatous disease
	Tuberculosis, sarcoidosis, histoplasmosis, cryptococcosis, blastomycosis (North and South American), sporotrichosis, and coccidiomycosis
	Other infections
	Cytomegalovirus, HIV
Drugs	Blockers of steroid synthesis: mitotane, aminoglutethimide, trilostane, ketoconazole, metyrapone
	Glucocorticoid receptor blockers: RU-486
Abdominal Irradiation	
Bilateral adrenalectomy	Intra-adrenal thrombosis: renal vein thrombosis in neonates, heparin-induced thrombocytopenia, the antiphospholipid syndrome
Causes of Deficient Mineralocorticoid Activity	
Failure of Aldosterone Production (Decreased Aldosterone)	
Hyperreninemia hypoaldosteronism (synthetic deficiency)	Primary adrenal insufficiency (see Table 54-10)
	Selective aldosterone deficiency
	Inborn errors (e.g., *CYP11B2* mutations)
	Drug-induced aldosterone suppression
	Heparin (direct inhibition of aldosterone secretion)
	Angiotensin-converting enzyme (ACE) inhibitors
	Angiotensin receptor blockers (ARBs)
	Hypoaldosteronism in critical illness/hypotension (e.g., selective zona glomerulosa injury)
Hyporeninemia hypoaldosteronism (deficient aldosterone stimulation)	Renin deficiency (e.g., diabetes, renal failure)

Continued

sporotrichosis, and coccidiomycosis), and cytomegalovirus infection. Syphilis can produce a syphilitic gumma (a fibrotic and granulomatous lesion) that destroys the adrenal gland. Human immunodeficiency virus (HIV) infection increases the risk of adrenalitis.[93] Autoimmune adrenalitis accounts for more than 70% of cases reported in the Western world, with adrenal autoantibodies measurable in more than 75% of cases.[193] The adrenal glands are atrophic, with loss of cortical cells but an intact medulla. Patients with autoimmune adrenalitis can also have pluriglandular autoimmune deficiency syndromes, as described in detail later.

The most common inborn steroidogenic defects involve the synthesis of cortisol with or without concurrent aldosterone deficiency, producing congenital adrenal hyperplasia.[230] Because such disorders commonly lead to excessive adrenal androgen overproduction, they are discussed in a later section concerning hyperfunction of the adrenal cortex, although such patients present a mixed picture of cortisol deficiency and possible aldosterone deficiency plus adrenal androgen overproduction.

Because the entire adrenal cortex is affected in primary adrenal insufficiency, all classes of adrenal steroids are deficient. The onset of clinical manifestations is usually gradual, and the degree and severity of symptoms depend on the extent of adrenal failure.[64] In early or mild expressions of primary adrenal insufficiency, hypofunction may not be evident unless the patient is under stress (e.g., following trauma or surgery). Complete glucocorticoid deficiency can manifest in a variety of ways, including fatigue, weakness, weight loss, gastrointestinal disturbance, and fasting hypoglycemia. Mineralocorticoid deficiency leads to dehydration with hypotension, acidosis, hyponatremia, and hyperkalemia. Excessive pituitary release of ACTH, unchecked by the negative feedback system, may cause hyperpigmentation of the skin and mucous membranes.[228]

Measurement of basal ACTH and cortisol concentrations along with ACTH stimulation testing (see Box 54-1) is recommended if primary adrenal insufficiency is suspected from the patient's clinical history and symptoms.[39] Basal plasma ACTH concentrations greater than 150 pg/mL, along with serum cortisol concentrations less than 5 µg/dL, are diagnostic of adrenal insufficiency (Figure 54-11). A subnormal cortisol response in the cosyntropin stimulation test supports the diagnosis of primary adrenal insufficiency (Figure 54-12). A normal cortisol response to cosyntropin stimulation establishes that the adrenal cortex is capable of releasing cortisol in a normal fashion and excludes primary adrenal failure. A

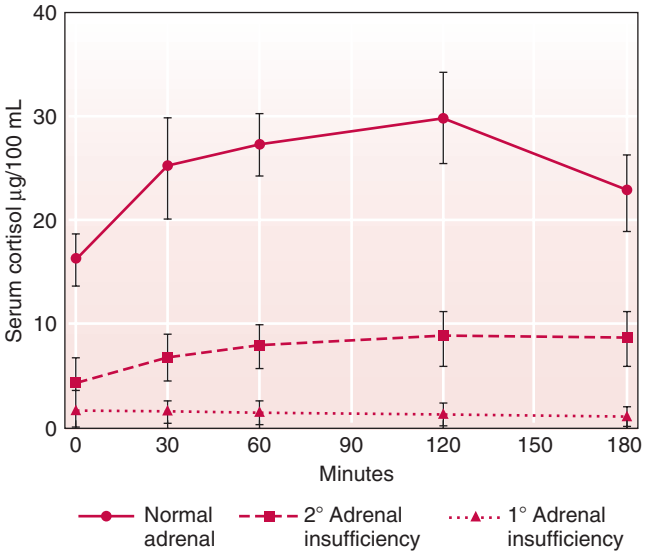

Figure 54-11 Serum cortisol response to 0.25 mg of cosyntropin (ACTH) in nine normal individuals (normal adrenal), eight patients with hypopituitarism (secondary adrenal insufficiency), and seven patients with Addison's disease (primary adrenal insufficiency).

subnormal response to cosyntropin stimulation suggests the diagnosis of primary, secondary, or tertiary adrenal failure. The clinical presentation usually assists in the differentiation of primary (hyperpigmentation and hypotension) from secondary or tertiary hypoadrenalism (other trophic hormone deficiencies may be present, such as growth hormone or thyroid-stimulating hormone, but hyperpigmentation and hyperkalemia are absent). If needed, a plasma ACTH concentration can help differentiate primary from secondary and tertiary hypoadrenalism.

It is important to note that both mineralocortioid and glucocorticoid deficiency may occur in cases of primary adrenal insufficiency. In contrast, when ACTH deficiency (secondary or tertiary) is the cause of adrenal hypofunction, mineralocorticoid secretion is essentially normal.[8] A rare cause of isolated glucocorticoid deficiency of adrenal origin is familial glucocorticoid deficiency. In this autosomal recessive disorder, resistance to the effects of ACTH is caused by mutations in *MCR2* or melanocortin 2 receptor accessory protein (MRAP), although some cases are currently unexplained.[54]

In secondary and tertiary adrenal insufficiency, inadequate cortisol production may be due to destructive processes in

tahir99-VRG & vip.persianss.ir

Disorders of the hypothalamic-pituitary portal system	Trauma Destruction via compression (e.g., tumor)
Pituitary causes of ACTH deficiency	Tumors (e.g., destructive adenoma, craniopharyngioma) Infiltrative disease (e.g., amyloidosis) Inflammation (e.g., autoimmunity: hypophysitis; granuloma) Status post infection Trauma (including surgery) Bleeding Irradiation Infarction (pituitary apoplexy, e.g., Sheehan syndrome) Metabolic (e.g., hemochromatosis) Malformations: transcription factor mutations (e.g., *Pit-1, PROP-1*)

the hypothalamus and/or pituitary that result in a decreased ability to secrete CRH (tertiary) or ACTH (secondary) (Table 54-9).[350] However, the most common cause of tertiary insufficiency is long-term pharmacologic administration of glucocorticoids that suppress CRH. This leads to a decrease in both ACTH release and cortisol secretion. Clinical features of secondary and tertiary adrenal insufficiency are similar to those of primary insufficiency, except that hyperpigmentation is not present and hypotension is less severe. Mineralocorticoid deficiency, hyperkalemia, and ACTH excess are not seen in secondary or tertiary adrenal insufficiency.

The cosyntropin stimulation test (see Box 54-1) may be used to demonstrate adrenal insufficiency in patients with secondary and tertiary adrenal insufficiency. When results of this test are abnormal, however, the cosyntropin stimulation test does not identify the cause of adrenal failure. Mild to moderate dysfunction of ACTH secretion may go undetected. Some patients with partial ACTH deficiency maintain sufficient ACTH to prevent adrenal atrophy, but are unable to augment ACTH secretion in response to stress or hypoglycemia. In these cases, pituitary ACTH reserve can be investigated with a metyrapone test (see Box 54-4) or an insulin-induced hypoglycemia test. Neither test, however, should be performed if primary adrenal insufficiency is suspected, because of the danger of precipitating Addisonian crisis. Subnormal responses to these tests suggest that pituitary ACTH release is inadequate, thus supporting a diagnosis of secondary or tertiary adrenal insufficiency.

ACTH and cortisol concentrations often are not useful for establishing the diagnosis of secondary adrenal insufficiency. Episodic secretion and circadian variation result in ACTH and cortisol concentrations that overlap between normal subjects and individuals with secondary or tertiary adrenal

tahir99-VRG & vip.persianss.ir

insufficiency. Elevated basal plasma ACTH in a patient with an abnormal response to acute ACTH stimulation suggests primary adrenal failure, whereas low ACTH and subnormal response to the cosyntropin stimulation test suggest a hypothalamic or pituitary disorder.

The multiple-day cosyntropin stimulation test is used to distinguish primary and central (i.e., secondary or tertiary) causes of adrenal insufficiency (see Box 54-2). It is particularly useful when patients have been receiving glucocorticoid therapy. In primary adrenal insufficiency, the damaged adrenal glands do not respond to exogenous cosyntropin administration even with several days of repeated cosyntropin stimulation. Patients with secondary or tertiary adrenal insufficiency usually have an inadequate or absent cortisol response at first because the adrenal glands have been unstimulated for some time and steroidogenesis requires the trophic priming of ACTH. Eventually, a delayed or staircase response is seen, indicating reactivation of the normal steroidogenic pathways, as the adrenal gland benefits from the trophic actions of ACTH. This test, however, is not used as frequently in this situation because of the availability of better and sensitive ACTH immunoassays that more accurately determine ACTH concentrations at baseline. In primary adrenal insufficiency, the ACTH concentration is disproportionately elevated compared with the decreased plasma cortisol concentration.

The CRH stimulation test (see Box 54-3) is used to differentiate tertiary from secondary adrenal insufficiency.[237] Those individuals with tertiary disease show an elevation in ACTH following CRH administration, whereas individuals with secondary disease show only minimal changes in ACTH concentration.

Although subnormal basal plasma concentrations of DHEA-S occur in primary, secondary, and tertiary forms of adrenal insufficiency, DHEA-S measurements are of little value in the diagnosis of adrenal insufficiency; low concentrations of adrenal androgens are normally observed in young children (before ages 7 to 9) and in the elderly. Patients with HIV infection have been shown to have reduced concentrations of DHEA-S.[200] DHEA-S concentrations are usually determined in the management of women with hirsutism or patients suspected of having adrenal tumors, or sometimes in the adrenogenital syndrome (e.g., congenital adrenal hyperplasia).[341]

Measurement of adrenal autoantibodies has been shown to be useful in evaluating patients suspected of adrenal insufficiency.[131] Antibodies against the adrenal cytoplasm or the 21 alpha-hydroxylase enzyme have been used in this regard and are diagnostic for autoimmune adrenal destruction in the setting of primary adrenal insufficiency.[279]

The first assay for adrenal autoantibodies utilized indirect immunofluorescence with human adrenal gland as substrate. Fluorescence of the cortex indicates the presence of adrenal cytoplasmic autoantibodies (ACAs) in the serum.[264] Usually all layers of the adrenal cortex fluoresce, whereas the medulla rarely fluoresces, because the adrenal cortical cytoplasmic autoantigens are localized to the microsomes of adrenal cortical cells.[41,72]

Among new-onset patients with Addison disease, 60 to 70% will express ACA. Studies in the 1990s established that target adrenal autoantigens were enzymes whose expression was limited to steroid-producing endocrine glands: 17-hydroxylase and 21-alpha-hydroxylase.[21,22,160,214] Autoantibodies to 21-alpha-hydroxylase (P450c21, CYP21) and 17-hydroxylase (P450c17, CYP17) has been detected by immunoprecipitation or enzyme-linked immunosorbent assay (ELISA) techniques. At least one vendor has developed commercial assays for the detection of autoantibodies to 21-alpha-hydroxylase. In many comparison studies, the ACA and 21-alpha-hydroxylase autoantibody immunoassays performed similarly in identifying humoral adrenal autoimmunity in patients with Addison disease. Once the diagnosis of Addison disease has been established, testing for adrenal antibodies can be undertaken to resolve the underlying cause. In the absence of adrenal autoantibodies, testing for the presence of very long-chain free fatty acids (VLCFAs) is now performed in search of adrenoleukodystrophy (ALD). In the absence of abnormalities of VLCFA, other diagnoses must be considered.[343]

In otherwise asymptomatic individuals, the detection of ACAs or of 21-alpha-hydroxylase autoantibodies predicts the development of Addison disease.[27] The evolution of Addison disease passes through various sequential stages: (1) normal to low aldosterone and elevated renin concentrations, (2) a deficient cortisol response to ACTH injection, (3) increased basal ACTH concentrations, and (4) deficient basal cortisol and aldosterone secretion.[29] Autoantibodies directed against the adrenal cortical cytoplasm or steroidogenic enzymes precede the initial appearance of clinical manifestations of Addison disease[28,55]; however, their predictive power is more evident in children than in adults.[30,31] Autoantibodies of higher titer are also more predictive of progression to clinical disease.[32,167] Approaches to the diagnosis of Addison disease are provided in Figures 54-13 and 54-14.

Hypoaldosteronism

Deficient aldosterone production occurs in conditions other than Addison disease (see Table 54-8).[323] Isolated aldosterone deficiency accompanied by normal cortisol production is seen in patients with (1) inadequate production of renin by the kidney, which leads to secondary aldosterone deficiency (hyporeninemic hypoaldosteronism); (2) inherited enzyme defects in aldosterone biosynthesis (e.g., CYP11B2 deficiency; CYP11B2 = P450 aldo); and (3) acquired forms of primary aldosterone deficiency (heparin therapy and post surgery).[324] The resulting metabolic changes are hyperkalemia and hyponatremia, often with hypochloremic acidosis. Mild or moderate volume depletion, often with postural or unprovoked hypotension, may also occur. Hyporeninemic hypoaldosteronism can be established by demonstrating failure of both plasma renin and aldosterone to increase in response to furosemide stimulation or upright posture (see Box 54-8). This

tahir99-VRG & vip.persianss.ir

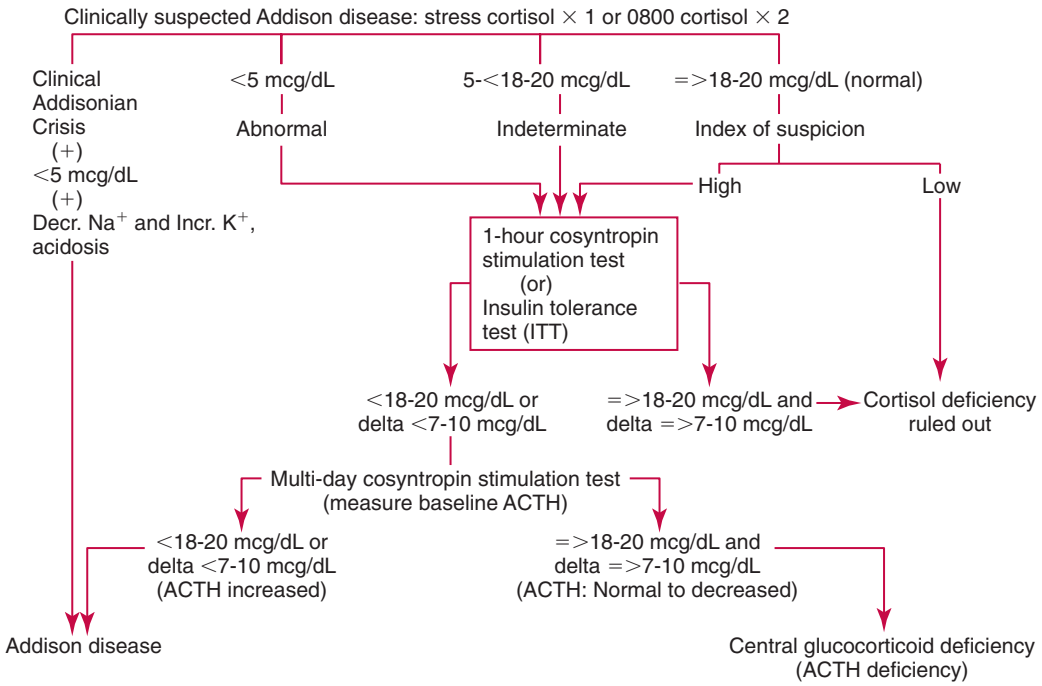

Figure 54-13 **In cases of clinically suspected Addison disease, at the time of an Addisonian crisis with compatible hyponatremia, hyperkalemia, and acidosis, cortisol concentrations less than 5 μg/dL are diagnostic for Addison disease. Otherwise, further testing guided by the cortisol concentration is required (either the "stress" cortisol concentration or the average of two 0800 cortisol levels). Further testing can include the 1 hour cosyntropin stimulation test or an insulin tolerance test (ITT). If the "stress" or average AM cortisol is 18 to 20 μg/dL or greater, and the index of suspicion for Addison disease is low, no further testing is required. However, if the index of suspicion for Addison disease is high despite a "stress" or average AM cortisol of 18 to 20 μg/dL or greater, further testing should be considered. As depicted, results of the 1 hour cosyntropin stimulation test or the ITT determine whether cortisol deficiency is excluded or, alternatively, a multiple-day cosyntropin stimulation test is indicated. Failure to demonstrate increased cortisol production in response to multiple-day cosyntropin stimulation supports the diagnosis of Addison disease (primary adrenal insufficiency). Not shown, but of importance: an elevated ACTH in the setting of proven cortisol deficiency also supports the diagnosis of Addison disease. If cortisol rises in response to prolonged cosyntropin stimulation, ACTH deficiency is evident (e.g., central ACTH deficiency).**

disorder is more common in older patients and in individuals with diabetes mellitus and nephropathy. These patients have a hyperkalemic acidosis with low renin and aldosterone concentrations and may have hypertension.

Patients with primary adrenal insufficiency almost always suffer from aldosterone deficiency, in addition to cortisol deficiency.[3] Most endocrinologists, however, do not ordinarily conduct tests to confirm aldosterone deficiency in such patients, because coexistent electrolyte abormalities (e.g., hyperkalemia) and hypotension support the diagnosis of primary adrenal insufficiency in the setting of cortisol deficiency, an elevated ACTH, and hyperpigmentation.

Hyperfunction of the adrenal cortex produces clinical syndromes of mineralocorticoid excess, glucocorticoid excess, and androgen excess.

Glucocorticoid Excess (Cushing Syndrome)[56]

Endogenous Cushing syndrome is the result of autonomous excessive production of cortisol, leading to the classic symptoms that are characteristic of this disorder (Table 54-10). The clinical picture includes (1) truncal obesity, (2) moon face, (3) a "buffalo" hump on the upper back below the neck, (4) supraclavicular fat pads, (5) purple striae, (6) myopathy, (7) hypertension, (8) hirsutism, (9) hypokalemic alkalosis, (10) carbohydrate intolerance, (11) disturbed reproductive function, and (12) neuropsychiatric symptoms.[37] Exogenous Cushing syndrome is caused by excessive oral or parenteral glucocorticoid therapy.

Endogenous disorders that cause hypersecretion of cortisol and Cushing syndrome may be classified as ACTH dependent or ACTH independent (Table 54-11 and Figure

tahir99-VRG & vip.persianss.ir

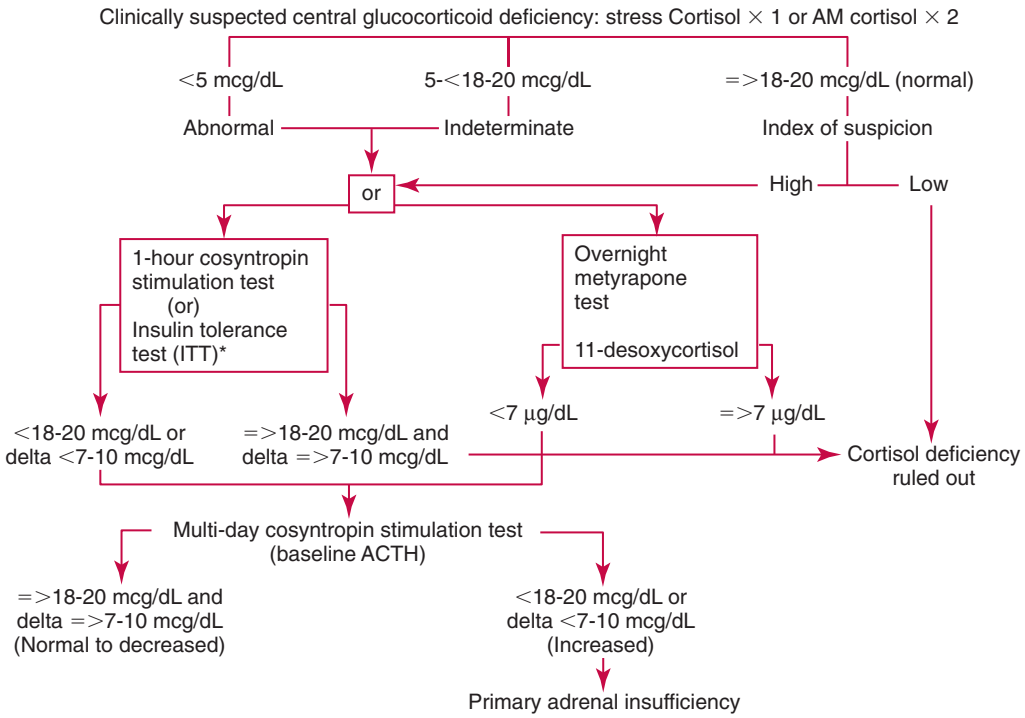

Figure 54-14 **In cases of clinically suspected ACTH deficiency (e.g., central glucocorticoid deficiency), unless the 0800 cortisol is 18 to 20 µg/dL or greater, and the index of suspicion for ACTH deficiency is low, the 1 hour cosyntropin stimulation test, an insulin tolerance test (ITT), or an overnight metyrapone test is performed. (*Note:* Metyrapone is not currently available in the United States.) Normal responses to such tests rule out cortisol deficiency. An abnormal response to such testing triggers testing via the multiple-day cosyntropin stimulation test. If cortisol rises in response to prolonged cosyntropin stimulation, ACTH deficiency is evident. Failure to respond to prolonged cosyntropin stimulation indicates primary adrenal failure, and concurrent mineralocorticoid deficiency should be investigated.**

54-15).[282] Cushing disease is the pituitary-dependent form of Cushing syndrome.[313A] In Cushing disease, hypersecretion of ACTH by a pituitary microadenoma is the primary defect that leads to bilateral adrenal hyperplasia and cortisol overproduction.[26] In the ectopic ACTH syndrome, nonendocrine tumors develop the ability to secrete ACTH, resulting in bilateral adrenal hyperplasia, unregulated cortisol secretion, and suppression of pituitary ACTH release.[229] Rarely, ectopic secretion of CRH occurs. In ectopic ACTH syndrome, the patient's clinical presentation is usually dominated by the presence of cancer, and the patient may not display classic clinical findings of Cushing syndrome such as centripetal obesity.

tahir99-VRG & vip.persianss.ir

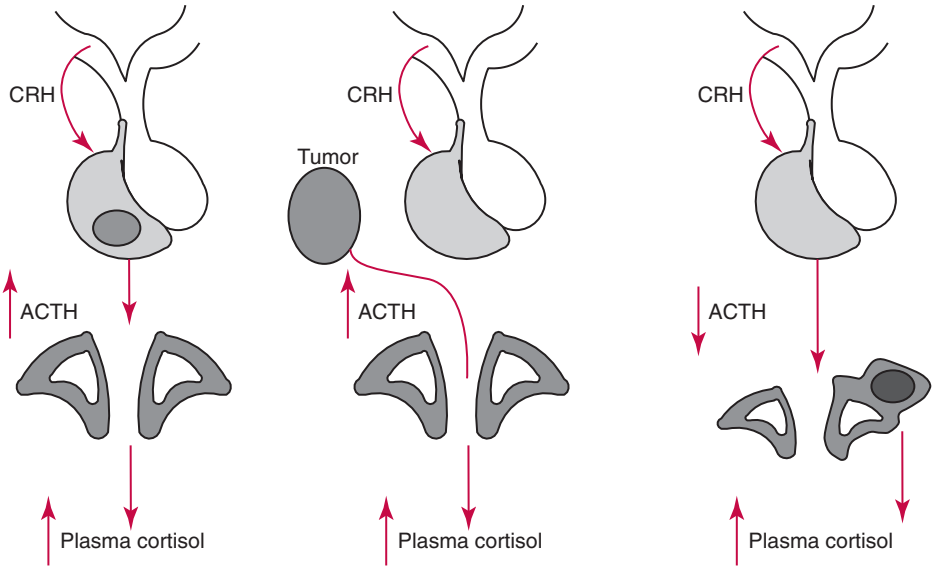

Figure 54-15 Endogenous Cushing syndrome can be classified as Cushing disease *(left panel)*, ectopic ACTH syndrome *(middle panel)*, or adrenal Cushing syndrome *(right panel)*. ACTH is elevated in cases of Cushing disease and ectopic ACTH syndrome. ACTH is suppressed in cases of adrenal Cushing syndrome.

Multiple endocrine neoplasia type 1 (MEN1) can cause Cushing syndrome through (1) hypersecretion of ACTH from a pituitary microadenoma, (2) an ectopic ACTH-secreting tumor of the pancreas, or (3) medullary thyroid carcinoma.[5] Cushing syndrome caused by primary adrenal disease suppresses both CRH and ACTH, resulting in atrophy of the nontumorous adrenal zona fasciculata and zona reticularis.[109]

Glucocorticoid-producing adenomas are usually unilateral, circumscribed, brown-yellow in color, and homogeneous in consistency, and weigh less than 30 g.[126] Histologically, the cells appear normal. Glucocorticoid-producing carcinomas are usually irregular in shape and histologically display (1) hemorrhage, (2) necrosis, (3) nuclear pleomorphism, (4) mitotic figures, and (5) capsular and blood vessel invasion. The clinical history is more acute (4 to 6 months) than in cases of functional adenoma. Adrenal carcinomas have been known to exceed 100 g and may be palpable, and metastases can produce hepatomegaly. Adrenal carcinoma also occur in the Li-Fraumeni syndrome (*p53* loss-of-function mutations),[318] along with sarcoma, brain tumor, leukemia, lymphoma, and early-onset breast cancer.

Less common than adenomas, adrenal hyperplasia can cause cortisol excess.[303] In bilateral micronodular hyperplasia (also called *primary nodular hyperplasia* or *adrenocortical dysplasia*), nodules of 0.1 to 0.3 cm diameter are observed that may be pigmented. The clinical outcome is similar to that of adrenal adenoma. Bilateral micronodular hyperplasia can be observed in the Carney complex, which includes (1) growth hormone–producing anterior pituitary adenoma, (2) Sertoli cell tumor, (3) atrial or ventricular myxoma, (4) mammary fibroadenoma, and (5) cutaneous myxoma.[36,304] Affected patients can display a spotty skin pigmentation pattern. In bilateral macronodular hyperplasia (also called *massive macronodular hyperplasia* or *macronodular adrenal dysplasia*), large nodules of 0.2 to larger than 4 cm diameter are evident. Adrenal weight can exceed 100 g. Because of aberrant expression of a receptor for gastric-inhibitory polypeptide on the surface of tumor cells, hypercortisolism may follow meals. Activating mutations of the G_s protein postreceptor signaling molecule have also been reported.

Screening Tests for Cushing Syndrome

Cushing syndrome is an uncommon disorder, but many of the usual signs and symptoms of this syndrome are seen in patients with normal adrenal function.[276] The initial diagnosis of Cushing syndrome, particularly in mild or early disease, rests on laboratory evidence of excessive and autonomous cortisol production.[251,294] Three simple screening tests are available for detecting Cushing syndrome. One test is the measurement of 24 hour urinary free cortisol. Under normal circumstances, less than 2% of secreted cortisol appears in urine as free cortisol. In general, a 24 hour urinary free cortisol concentration less than 50 µg/d excludes the diagnosis of Cushing syndrome (Figure 54-16). Diagnostic accuracy is greater than 90% when the test is properly performed.[60] An elevated rate of excretion documents overproduction of cortisol. However, (1) improper timing of the urine specimen (e.g., collection over more than 24 hours), (2) concomitant use of a diuretic, (3) high salt intake, (4) depression, and (5) stress have been observed to cause false-positive (abnormal) test results. Any single test that exhibits cortisol excess should not, in itself, be used to definitively diagnose Cushing syndrome, so that the patient will not

tahir99-VRG & vip.persianss.ir

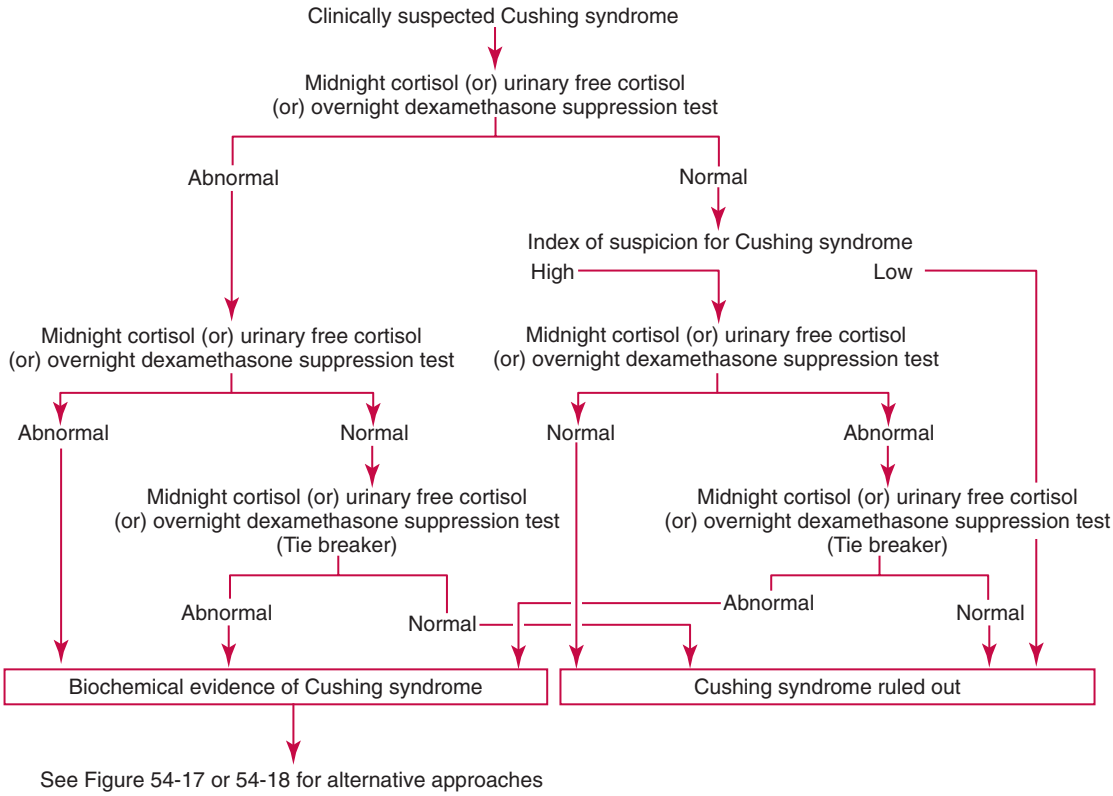

Figure 54-16 The first challenge in diagnosing Cushing syndrome is establishing whether hypercortisolism truly exists. Three screening tests are commonly applied: the overnight dexamethasone suppression test, measurement of the 24 hour urinary free cortisol excretion, and a midnight cortisol measurement (plasma or salivary cortisol). Hypercortisolism is present when two out of two, or two out of three, of any combination of these tests are abnormal.

have to undergo highly invasive therapy (e.g., transsphenoidal neurosurgery for a suspected pituitary adenoma) without proper evaluation.[249]

Another reliable and convenient screening test for Cushing syndrome is the overnight low-dose dexamethasone suppression test, wherein 1 mg of dexamethasone is taken orally between 2200 and 2400 (see Box 54-5). Cortisol concentrations at 0800 suppressed to below 5 μg/dL (<140 nmol/L) are normal and make the diagnosis of Cushing syndrome less likely. A cortisol concentration less than 2 μg/dL essentially rules out Cushing syndrome. Cortisol values greater than 10 μg/dL significantly favor the diagnosis of hypercortisolism and require further evaluation.

A multiple low-dose test may also be used (see Box 54-6 regarding low-dose dexamethasone suppression). Following low-dose dexamethasone (0.5 mg every 6 hours for 48 hours), plasma cortisol is usually suppressed to less than 2.2 μg/dL and urine free cortisol is suppressed to less than 25 μg/d. Diagnostic accuracy of 90% has been achieved with the simultaneous measurement of cortisol and dexamethasone (with assurance that dexamethasone was taken and taken in proper dose), although this approach is rarely used. Incorrect dosing and alterations in the clearance of dexamethasone are detected by measuring dexamethasone; thus both false-negative and false-positive suppression test results can be identified.

Examination of the circadian rhythm of cortisol secretion has been used in the past to screen for Cushing syndrome, although this is considerably less helpful than measurement of urinary cortisol, measurement of the morning cortisol concentration following dexamethasone, or cortisol measurements taken at 2400 (serum or salivary). Elevations in the night cortisol (e.g., concentrations >9 μg/dL) suggest loss of diurnal variation. The later in the night that cortisol can be measured, the more helpful the test will be. Some patients with Cushing syndrome do not exhibit loss of diurnal variation even with elevations in both morning and night and cortisol concentrations. Therefore loss of diurnal variation is not a consistent finding in Cushing syndrome. In general, measuring cortisol at 0800 as a screening test for Cushing syndrome is not recommended. If a single cortisol measurement is to be taken, this should be done near 2400.[227] Salivary cortisol can also be measured at 2400. Because of the ease of obtaining saliva, some endocrinologists favor this screening approach. However, analysis in a reference laboratory is usually required because salivary cortisol concentration is much lower than plasma cortisol concentration.

tahir99-VRG & vip.persianss.ir

Differential Diagnosis of Cushing Syndrome

When findings are abnormal, the screening tests discussed support the diagnosis of endogenous Cushing syndrome by revealing hypercortisolism. More definitive testing should then be performed to determine the source of the overproduction of cortisol (Table 54-12 and Figures 54-17 and 54-18). Plasma ACTH concentrations are low in patients with adrenal tumor (<10 pg/mL) and are normal or moderately elevated in patients with Cushing disease (generally >50 pg/mL). Plasma concentrations of ACTH are very often markedly elevated in patients with nonendocrine ACTH-secreting tumors (ectopic ACTH syndrome), because the tumor source of the ACTH does not respond to negative feedback from cortisol. On the other hand, we can consider the ACTH-secreting pituitary adenoma of Cushing disease as having an elevated set point for negative feedback; if the cortisol (or other glucocorticoid) concentration is elevated high enough, some measure of negative feedback will occur (e.g., 60% of patients with Cushing disease achieve ACTH and urinary free cortisol suppression when treated with high-dose dexamethasone). Plasma ACTH concentrations greater than 300 pg/mL are usually suggestive of a nonendocrine ACTH-secreting tumor (ectopic ACTH syndrome).

High-dose dexamethasone suppression testing (overnight high dose or multiple-day high dose; see Boxes 54-6 and 54-7) is useful in differentiating Cushing syndrome caused by adrenal tumor and nonendocrine ACTH-secreting tumor from pituitary Cushing disease.

Some patients with Cushing disease may fail to suppress cortisol (plasma or urinary) on high-dose dexamethasone, as would be expected in cases of Cushing disease. Such test results can be assessed by administering 1.0 mg (low dose) or 8 mg (high dose) of dexamethasone at midnight (overnight dexamethasone suppression test). Serum is collected at 0800 hours for the measurement of cortisol. In the overnight dexamethasone suppression test, 1 mg of dexamethasone should not suppress cortisol in any form of Cushing syndrome. In patients with adrenal tumor and, with a few exceptions, in those patients with nonendocrine ACTH-secreting tumor, suppression does not occur after the high-dose 8 mg dexamethasone administration. Furthermore, with high-dose dexamethasone testing, less than 10% of patients with Cushing disease fail to show some degree of suppression, although most patients show only 50 to 60% suppression. Failure to suppress in response to high-dose dexamethasone has occurred in patients with accelerated clearance of dexamethasone in response to hepatic cytochrome P450–inducing drugs, such as phenytoin and rifampicin. In these patients, measurements of plasma dexamethasone can be useful in gauging the effective blood concentration.

The CRH stimulation test (see Box 54-3) produces exaggerated ACTH or cortisol response, or both, in about 90% of patients with Cushing disease. Usually plasma cortisol increases by 20% and plasma ACTH increases by 50% following CRH (1.0 μg/kg). Poor responses occur in patients with adrenal tumor and in most patients with nonendocrine ACTH-secreting tumor (usually those having elevated basal concentrations of plasma ACTH). Patients with depression and anorexia nervosa usually do not exhibit an exaggerated ACTH response to CRH injection.

If the cause of Cushing syndrome is uncertain, measurement of ACTH from inferior petrosal venous sinus specimens before and after CRH stimulation can be helpful.[237] When ACTH concentrations in inferior petrosal venous sinus specimens are similar to those of simultaneously obtained peripheral vein plasma specimens (e.g., from the inferior vena cava), the diagnosis of a nonpituitary source of ACTH is evident. In virtually all patients with ectopic production of ACTH, the ratio of ACTH concentrations between the inferior petrosal venous sinus and a peripheral venous specimen is less than 1.4:1. In contrast, patients with Cushing disease have a ratio greater than 2.0, and an average ratio near 15.[180] Inferior petrosal venous sinus sampling is not useful in delineating the side of the lesion because venous drainage can cross over.[305,353] Table 54-13 provides examples of ACTH

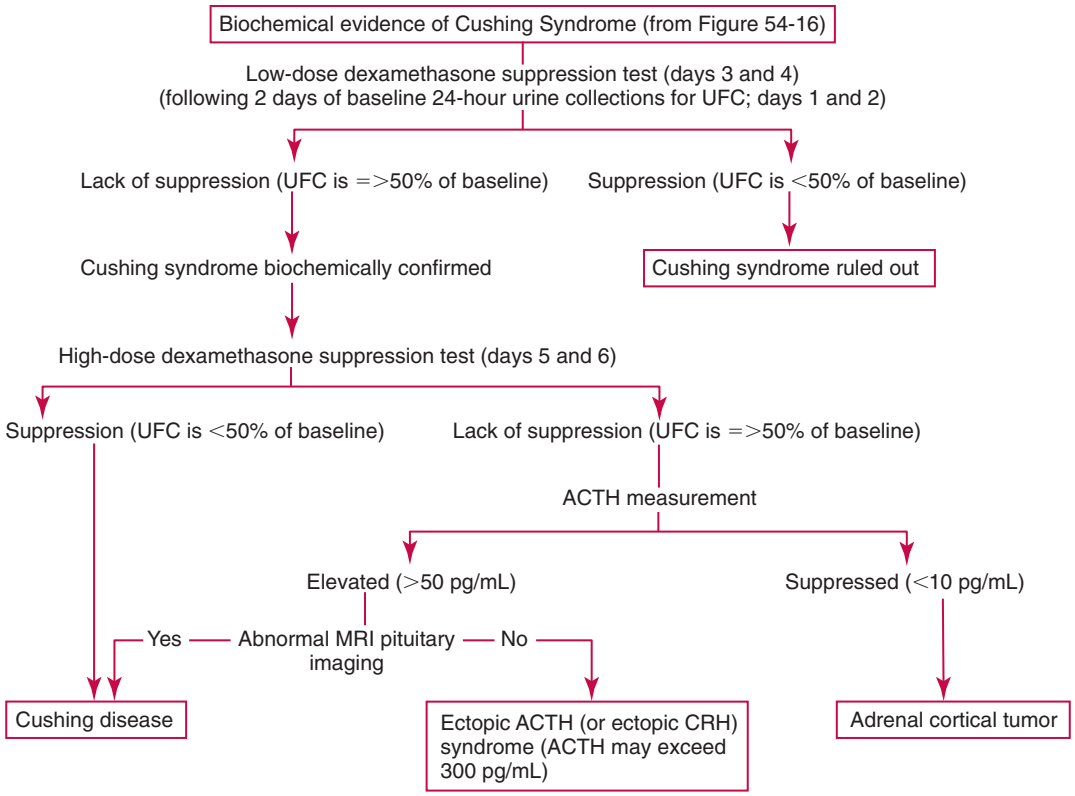

Figure 54-17 **Once the diagnosis of hypercortisolism is established, low-dose/high-dose dexamethasone suppression testing can be carried out. Suppression of urinary free cortisol (UFC) on low-dose dexamethasone excludes cortisol excess. Suppression on high-dose dexamethasone establishes the diagnosis of Cushing disease, but not all patients with Cushing disease are suppressed on high-dose dexamethasone. Lack of suppression on high-dose dexamethasone triggers the measurement of ACTH. Suppressed ACTH establishes the diagnosis of adrenal Cushing syndrome (e.g., a cortisol-secreting adrenal cortical tumor). If ACTH is elevated, the pituitary is studied radiologically (and via inferior petrosal venous sinus sampling) to distinguish Cushing disease from ectopic ACTH (or ectopic CRH) syndrome. ACTH levels are usually higher in ectopic ACTH syndrome than in Cushing disease.**

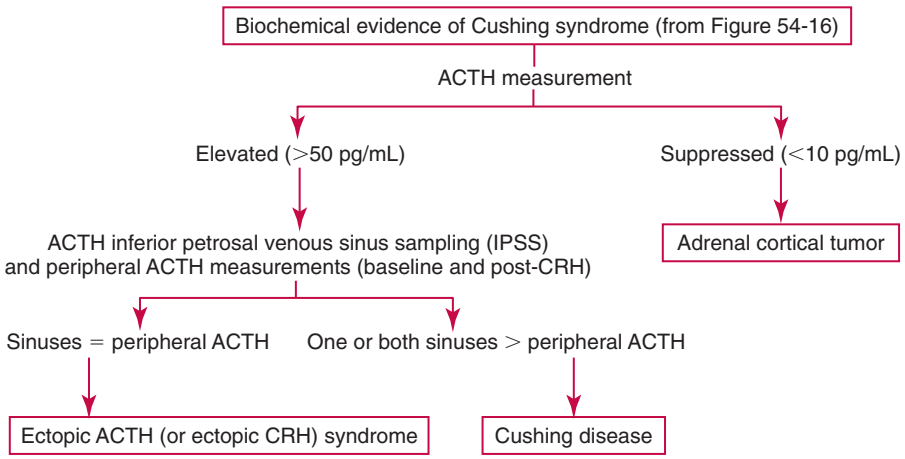

Figure 54-18 **In an alternative diagnostic approach, once hypercortisolism is confirmed, ACTH is measured. A suppressed ACTH establishes the diagnosis of adrenal Cushing syndrome (i.e., a cortisol-secreting adrenal cortical tumor). If ACTH is elevated, the pituitary is examined via inferior petrosal venous sinus sampling (and MRI scanning) to resolve Cushing disease versus ectopic ACTH syndrome.**

concentrations from IPS testing in a patient proven to have Cushing disease.

Adrenal androgens and plasma DHEA-S are measured in the differential diagnosis of hirsutism without Cushing syndrome.[92] In patients with Cushing syndrome, plasma DHEA-S concentrations are usually normal or moderately elevated (plasma DHEA-S ≈5 µg/mL). Patients with an adrenal adenoma usually have low age-adjusted concentrations of DHEA-S. The concentrations for plasma DHEA-S in patients with nonendocrine ACTH-secreting tumors range from normal to elevated. In patients with congenital adrenal hyperplasia (CAH), adrenal androgens are suppressed normally with administration of 0.75 mg of dexamethasone for 2 to 3 weeks, but suppression does not occur in patients with adrenal tumors and nonendocrine ACTH-secreting tumors.

CRH stimulation of ACTH after dexamethasone suppression has been used for the detection of hypercortisolism. The concept is that a normal individual were exposed to dexamethasone, would secrete reduced amounts of ACTH in response to CRH compared with a patient with Cushing syndrome. In a 2007 paper it was reported that a post-CRH ACTH concentration of 28 pg/mL or greater yielded clinical sensitivity of 95% and specificity of 97% for the recognition of Cushing syndrome, and a 15 minute cortisol of 2.6 µg/dL or greater was 90% sensitive and 90% specific.[81] Such combined testing (i.e., dexamethasone suppressed, post-CRH ACTH measurements) is being used in a variety of psychiatric evaluations.[289]

In addition to suppression and stimulation testing, methods of tumor localization should be used to document the cause of Cushing syndrome. Computed tomography (CT) of the adrenal glands has been helpful in localizing adrenal tumors, macronodular hyperplasia, and bilateral hyperplasia of the adrenal glands.[106] CT in combination with magnetic resonance imaging (MRI) of the pituitary gland can help to detect pituitary microadenomas.[273] However as mentioned elsewhere, anatomic abnormalities are not always related to functional abnormalities. For this reason, when an adrenal source of excess cortisol is suggested by CT scanning or MRI, it is prudent that the patient undergo venography with measurement of cortisol in each adrenal vein. In the case of a cortisol-secreting adrenal adenoma, the cortisol should be significantly higher (e.g., 50% higher) in one adrenal vein compared with the other adrenal vein. In the case of bilateral hyperplasia causing hypercortisolism, no significant difference (<50%) between sides should be noted. The search for ectopic sources of ACTH can require conventional radiography, ultrasonography, and CT scanning or MRI for the detection of suspected neoplasms.

Especially challenging are cases of episodic Cushing syndrome, wherein hypercortisolism is not always present. Some rare cortisol-secreting adrenal tumors have been reported that express incretin receptors.[25] In these cases, hypercortisolism occurs only with meals.

Conditions That Mimic Cushing Syndrome

Alcohol abuse has been known to induce a "pseudo-Cushing syndrome" that mimics the clinical and biochemical features of the actual disease. The abnormalities are all reversible when alcohol abuse by the patient is stopped. The clinician therefore must use considerable judgment in detecting the cause of Cushing syndrome before therapy is initiated.[85,332] HIV, anorexia nervosa, and depression are associated with elevated serum cortisol concentrations, and patients with these disorders may have abnormal low-dose, overnight dexamethasone suppression tests (morning cortisol ≥5 µg/dL). Cortisol measurements at 2400 may help exclude Cushing syndrome in these circumstances.[245] However, the clinical features of patients with HIV and anorexia nervosa are not typical of patients with Cushing syndrome. Measurement of urinary free cortisol and plasma cortisol with the dexamethasone suppression test improves the predictive value in the diagnosis of both Cushing syndrome and depression.[199] In patients with depression, it is best to repeat testing after the depression has been treated.

Obese patients have also presented with clinical features that mimic true Cushing syndrome.[19] Truncal obesity,

tahir99-VRG & vip.persianss.ir

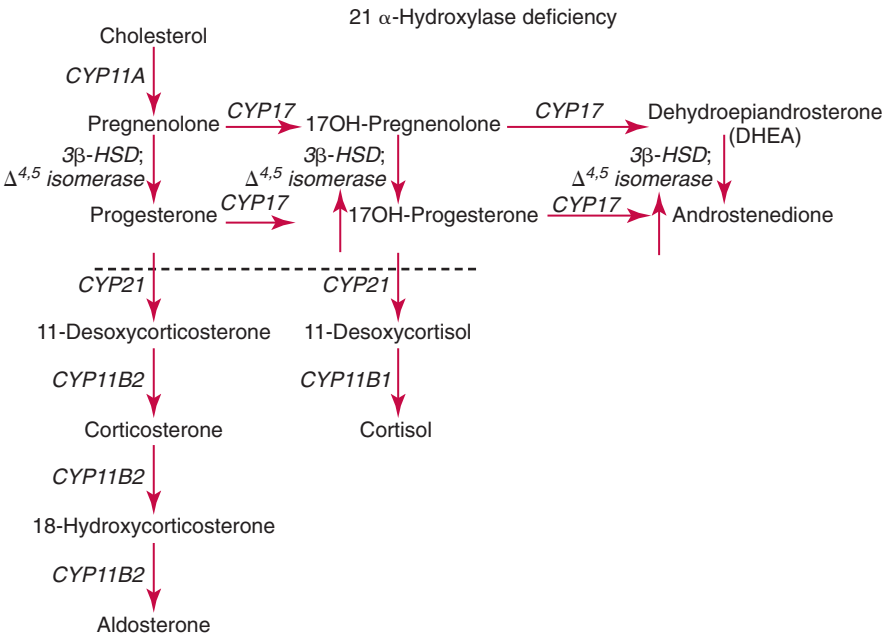

Figure 54-19 In 21 alpha-hydroxylase deficiency (CYP21; *dashed line*), cortisol deficiency and possibly aldosterone deficiency are present. Elevations in 17-hydroxyprogesterone and androstenedione are observed. The normal major pathway of cortisol synthesis is noted by the *bold arrows*.

striae, and excretion of elevated concentrations of 17-hydroxycorticosteroids are features of Cushing syndrome that occur in normal, obese subjects. Urinary free cortisol, however, is normal in the obese individual and can effectively differentiate normal subjects from those with true Cushing syndrome.[255] Likewise, 48 hours of low-dose dexamethasone (0.5 mg orally every 6 hours) should suppress urinary free cortisol excretion by more than 50% in obese subjects.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is the most common cause of adrenocortical insufficiency in newborns.[337] However, CAH is discussed under adrenal hormone overproduction syndromes because CAH commonly leads to overproduction of adrenal androgens. Thus, as noted previously, CAH presents a mixed picture of cortisol deficiency (hypofunction) and adrenal androgen overproduction (hyperfunction).

CAH results from loss-of-function mutations in specific adrenocortical enzymes that are responsible for the synthesis of cortisol.[10] These disorders are inherited as autosomal recessive traits. Rarely, traumatic adrenal hemorrhage or adrenal hemorrhage from sepsis causes adrenal failure in newborns. Six enzymes are necessary for the conversion of cholesterol into cortisol: CYP11A (a 20,22-desmolase; sometimes called a 20 alpha-hydroxylase), CYP17 (a 17-hydroxylase), 3 beta-hydroxysteroid dehydrogenase, delta(4)-5-isomerase, CYP21 (a 21-alpha-hydroxylase), and CYP11B1 (an 11-beta-hydroxylase).

With insufficient cortisol production, ACTH concentrations increase and anatomically stimulate the adrenal hyperplasia in utero for which CAH is named.[102,223,224] 21-Alpha-hydroxylase deficiency (CYP21 deficiency; Figure 54-19) and 11-beta-hydroxylase deficiency (CYP11B1 deficiency); are the two most common causes of CAH (Figure 54-20). A total of 95% of CAH cases result from 21-alpha-hydroxylase deficiency, and 11-beta-hydroxylase deficiency accounts for most of the remaining CAH cases. Other causes of CAH are rare. The incidence of 21-alpha-hydroxylase CAH in Western societies varies from 1 in 5000 to 15,000 live births.[1]

Screening for 21-alpha-hydroxylase–deficient and 11-beta-hydroxylase–deficient CAH in newborns by measuring 17-alpha-hydroxyprogesterone (17-OHP) is standard practice in the United States and many other countries.[123,299,300,320] The application of methods based on tandem mass spectrometry for steroid analysis may decrease false-positive 17-alpha-hydroxyprogesterone CAH screens.[163,192]

The metabolic block in cortisol biosynthesis leads to an accumulation of precursors including adrenal androgens.[203] Therefore, measurements of the precursor steroids in blood are useful for identifying the specific enzyme defect and for monitoring response to cortisol replacement therapy. A partial block may cause marked or subtle clinical manifestations, whereas a complete enzyme block can be incompatible with life. The closer the enzyme block is to the final cortisol product, the less life threatening are the symptoms.

Because CAH produces elevations of adrenal androgens (DHEA and androstenedione) in utero, virilization of the external genitalia of the female fetus occurs, producing sexual ambiguity (ambiguous genitalia). Only rarely does CAH lead to inadequate male sexual development (see 3-beta-hydroxysteroid reductase deficiency, later).

tahir99-VRG & vip.persianss.ir

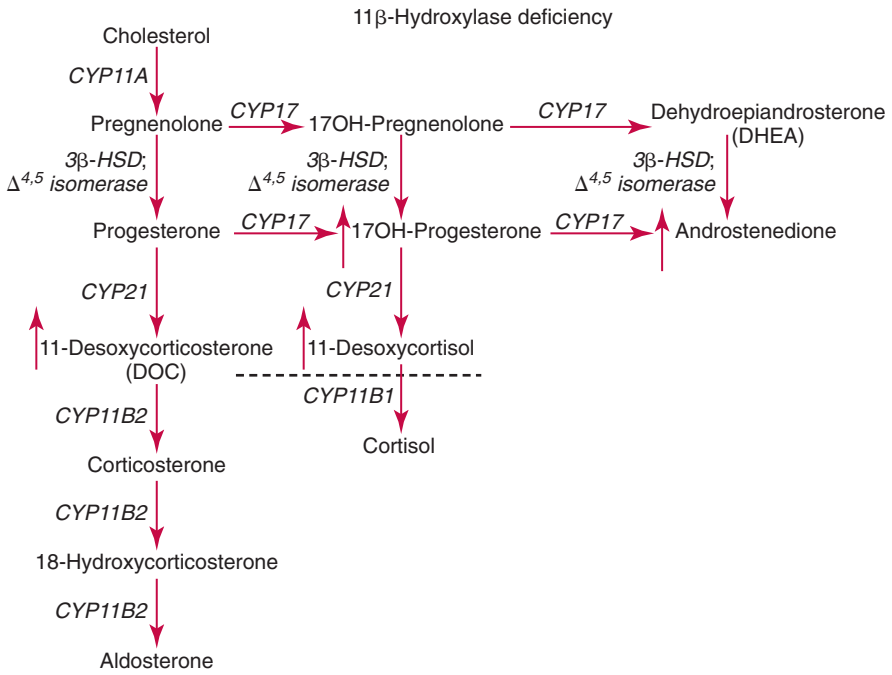

Figure 54-20 In 11 beta-hydroxylase deficiency (CYP11B1) *(dashed line)*, cortisol production is deficient. Elevations in 11-desoxycortisol, 17-hydroxyprogesterone, androstenedione, and 11-desoxycorticosterone concentrations are observed. The normal major pathway of cortisol synthesis is noted by the *bold arrows*.

Cortisol deficiency in affected individuals leads to (1) malaise, (2) failure to thrive, (3) hypoglycemia, and (4) vascular instability. In approximately one half of infants afflicted with 21-alpha-hydroxylase–deficient CAH, in addition to inadequate cortisol production, insufficient aldosterone production can cause (1) hyponatremia, (2) hyperkalemia, (3) acidosis, (4) dehydration, and (5) hypotension. In its most severe form, this type of "salt-losing" 21-alpha-hydroxylase–deficient CAH clinically presents at 10 to 14 days of age with Addisonian crisis. Untreated, mortality is very high in salt-losing 21-alpha-hydroxylase deficiency. The non–salt-losing form of this disease is customarily referred to as *simple virilizing* 21 alpha-hydroxylase–deficient CAH.

Before newborn screening for CAH with 17-alpha-hydroxyprogesterone measurements was available, the diagnosis of CAH was more common in girls than in boys.[247] The lower number of males diagnosed with CAH appeared to be the result of deaths of undiagnosed males afflicted with salt-losing CAH. The cause of death could have been erroneously ascribed to sepsis or idiopathic dehydration and not to Addisonian crisis. Presently, with newborn CAH screening, the male and female incidences of CAH are approximately equal, which is characteristic of an autosomal recessive condition.

In 21-alpha-hydroxylase deficiency and 11-beta-hydroxylase deficiency, the excess of ACTH and the metabolic block in cortisol biosynthesis result in overproduction of the adrenal androgens DHEA, DHEA-S, and androstenedione.[202] In females, overproduction of the adrenal androgens induces virilization of the external genitalia in utero, producing ambiguous genitalia [intersex or a disorder of sexual development (DSD)]. Virilization in females varies from mild fusion of the labia, to marked labial fusion with clitoromegaly, to complete masculinization with apparent male external genitalia. (*Note:* Such newborns can be incorrectly categorized as males with bilaterally undescended testes.) Untreated, postnatal females who survive will continue to virilize. Because salt-losing 21-alpha-hydroxylase deficiency is a more severe expression of the inborn error than is non–salt-losing 21-alpha-hydroxylase deficiency, the salt-losing form of CAH is associated with more severe degrees of virilization in females.

In males, adrenal androgen overproduction produces precocious pseudopuberty and some degree of hyperpigmentation of the male external genitalia. Untreated, postnatal males will experience early-onset puberty with advanced secondary sex characteristics, and, despite an early acceleration in their growth rate and tall stature, they may ultimately suffer from short stature because of premature closure of their epiphyses.[129] The more profound the defect in cortisol biosynthesis, the greater is the degree of precocious pseudopuberty in males. True precocious puberty is driven by the pituitary gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH), as evidenced in testicular enlargement. In contrast, CAH-induced pseudopuberty does not produce testicular enlargement until true puberty occurs (which likely will be early because of the boys' advanced biological age). If adrenal rests are adherent to the testes, they can enlarge with untreated or undertreated CAH (a *rest* is a

group of cells that has become displaced and lies embedded in another tissue).

In summary, females with 21-alpha-hydroxylase deficiency CAH can present with ambiguous genitalia and postnatal virilization, and may display neonatal salt-losing Addisonian crisis. Males present with precocious pseudopuberty during infancy or childhood, or present in the neonatal period with salt-losing crisis.

In the case of 11-beta-hydroxylase deficiency CAH from *CYP11B1* mutations, mineralocorticoid deficiency does not occur.[145] This is expected because the conversion of DOC to corticosterone in the zona glomerulosa is predominantly catalyzed by CYP11B2 (aldosterone synthase, P450 aldo) which is not affected in 11-beta-hydroxylase (CYP11B1) deficiency CAH. Also, elevated ACTH may have some effect in stimulating DOC production, and DOC is reported to be elevated in CYP11B1 11-beta-hydroxylase deficiency CAH.[231] Because 11-beta-hydroxylase activity of CYP11B2 is normal in CYP11B1 11-beta-hydroxylase deficiency CAH, DOC may be elevated by the small amount of 11-beta-hydroxylase activity of CYP11B1 that is normally present in the zona glomerulosa.

Whereas girls with CYP11B1 11-beta-hydroxylase deficiency present with ambiguous genitalia and boys display precocious pseudopuberty, salt loss does not occur in CYP11B1 11-beta-hydroxylase deficiency. Thus, electrolyte disturbances and acidosis do not occur, nor does Addisonian crisis develop, in the newborn period or later. However, later in childhood, hypertension, with or without hypokalemia, can develop. The incidence of CYP11B1 11-beta hydroxylase CAH is approximately 1 in 100,000.

The diagnosis of 21-alpha-hydroxylase deficiency and CYP-11B1 11-beta-hydroxylase deficiency is dependent on finding elevated concentrations of 17-OHP in plasma or serum (see Figures 54-19 and 54-20). These two conditions are differentiated by several findings: patients with CYP-11B1 11-beta-hydroxylase deficiency do not exhibit hypotension and may develop hypokalemic hypertension during childhood (Table 54-14). Biochemically, 17-OHCS are elevated in CYP11B1 11-beta-hydroxylase deficiency (i.e., 11-desoxycortisol is elevated and contributes to 17-OHCS), whereas 17-OHCS are low in 21-hydroxylase deficiency (both 11-desoxycortisol and cortisol are low). 11-Desoxycortisol and its urinary metabolite tetrahydrodesoxycortisol (THS) will be elevated in CYP-11B1 11-beta-hydroxylase deficiency, as will the ratio of plasma 11-desoxycortisol to plasma cortisol and the ratio of their urinary metabolites, THS to tetrahydrocortisol (THF). In 21-alpha-hydroxylase deficiency the synthesis of both 11-desoxyocortisol and cortisol is impaired and the ratio of urinary THS to THF is not elevated.

Once a proband child in a family is diagnosed with CAH, fetal DNA testing in subsequent pregnancies allows prenatal diagnosis of CAH.[247] The importance of prenatal diagnosis is that maternal treatment with high-dose dexamethasone can suppress excess fetal adrenal androgen production. This prevents ambiguous genitalia in females, as well as the androgenizing effects of excess fetal adrenal androgens on the fetal brain.[189,232]

A "late-onset" or "attenuated" (nonclassical) form of 21-alpha-hydroxylase deficiency can present in female adolescents as hirsutism or virilization associated with (1) menstrual irregularities, (2) oligomenorrhea, (3) amenorrhea, and (4) a polycystic ovary–like syndrome.[52,162] Thus, late-onset 21-alpha-hydroxylase deficiency CAH is much milder than the classical ("virilizing") form of 21-alpha-hydroxylase deficiency of prenatal onset. Whereas baseline and post-ACTH 17-OHP concentrations in attenuated 21-alpha-hydroxylase–deficient CAH are higher than in controls, the values are not

as high as those seen in classical 21-alpha-hydroxylase deficiency CAH. Nomograms are available in the literature that allow basal 17-OHP to be plotted against post-ACTH 17-OHP in diagnosing CAH gene carriers versus attenuated 21-alpha-hydroxylase deficiency versus classical 21-alpha-hydroxylase deficiency. Gene carriers (individuals heterozygous for a wild-type allele and a mutant allele) usually have normal basal concentrations of 17-OHP but excessive 17-OHP responses to a cosyntropin challenge.

Measurements of early morning 17-OHP or random androstenedione are used to assess the CAH patient's response to glucocorticoid replacement.[10] With adequate glucocorticoid replacement, 17-OHP or androstenedione should not be elevated above the upper limit of the reference interval for age and sex. Insufficient glucocorticoid replacement permits excess adrenal production of androgens. Alternatively, overtreatment with glucocorticoids can suppress growth through the induction of a mild state of iatrogenic Cushing syndrome. Some investigators have questioned whether patients with CAH should undergo adrenalectomy to "ablate" adrenal hyperandrogenism. However, this would be fraught with danger, as it would produce frank Addison disease.

In patients with 21-alpha-hydroxylase deficiency CAH, aldosterone is replaced with oral fludrocortisone (Fluorinef). Adequacy of mineralocorticoid replacement is assessed by measuring the patient's blood pressure and renin. Inadequate replacement may result in hypertension from elevated renin that increases angiotensin II, causing vasoconstriction despite possible volume depletion. However, mineralocorticoid overdosage can also induce hypertension through excess sodium retention. Hypokalemia and alkalosis are possible consequences of over-replacement with fludrocortisone. The effectiveness of treatment is judged on the basis of the presence or absence of normal linear growth, normal sexual development, and suppression of 17-OHP and/or adrenal androgen concentrations into the reference intervals.

Medically, 17-Alpha-hydroxylase deficiency (CYP17, P450c17) is a rare cause of CAH (Figure 54-21).[15] Normally, 17-alpha-hydroxylase converts pregnenolone to 17-hydroxypregnenelone and progesterone to 17-alpha-hydroxyprogesterone in the zona glomerulosa and the zona reticularis. In the absence of 17-alpha-hydroxylase activity, there exists an obstruction to cortisol biosynthesis. *CYP17* mutations will also influence sex steroid production in males in utero and in females at the time of puberty, as this gene provides zona reticularis and gonadal 17,20-desmolase (lyase) activity. 17,20-Desmolase converts 17-hydroxypregnenelone to DHEA and 17-hydroxyprogesterone to androstenedione. In turn, in the gonad, the adrenal androgen DHEA is the precursor of androstenediol, which is the immediate precursor of testosterone. Thus, in addition to interference in cortisol biosynthesis, *CYP17* mutations preclude sex steroid production of both androgens and estrogens. In contrast, the aldosterone pathway remains intact and salt-wasting does not

occur with elevated DOC, causing hypertension in later childhood. Because both *CYP17* and *CYP11B1* mutations can cause hypertension, these conditions are compared in Table 54-14.

Similar to 21-alpha-hydroxylase deficiency and CYP11B1 11-beta-hydroxylase deficiency, ACTH concentrations increase because of cortisol deficiency in 17-alpha-hydroxylase deficiency. Elevated ACTH elicits mineralocorticoid overproduction in the zona glomerulosa. Salt and water retention can then suppress aldosterone synthesis and secretion. Because of excess mineralocorticoid activity, salt-wasting is not present in 17-alpha-hydroxylase deficiency; in fact, excessive salt and water retention from excessive mineralocorticoid activity frequently produces hypertension in childhood. Because sex steroids are not produced, genetic males will appear as sexually ambiguous or phenotypic females with delayed puberty. The uterus, the fallopian tubes, and the upper one third of the vagina are absent because of Müllerian inhibiting hormone (MIH, or anti-Müllerian hormone, AMH) that is elaborated by the Sertoli cells of the testes. Virilization of the external genitalia is reduced or absent in males in utero because of the block in testosterone biosynthesis. In genetic females, the genitalia are not ambiguous; however, puberty and menses will not occur spontaneously because estrogens will not be produced.

Another rare form of CAH causing cortisol deficiency is 3-beta-hydroxysteroid dehydrogenase deficiency (see Figure 54-21).[293] This non-P450 enzyme converts ^{5}delta to ^{4}delta steroids such as pregnenolone to progesterone, 17-hydroxypregnenolone to 17-OHP, and DHEA to androstenedione. Because the gonads share these pathways with the adrenal glands, male fetuses are undervirilized as the result of deficient testosterone production, and female fetuses are overvirilized because of excessive adrenal androgen production (overproduction of DHEA). In 3-beta-hydroxysteroid dehydrogenase deficiency, the ratios of (1) pregnenolone to progesterone, (2) 17-hydroxypregnenolone to 17-OHP, and (3) DHEA to androstenedione are elevated. A late-onset form has been described in patients with premature pubarche with hirsutism, acne, and menstrual irregularities. Biochemically, 17-ketosteroid reductase deficiency affects sex steroid synthesis in the gonads, but it does not affect aldosterone or cortisol biosynthesis.[243] Therefore, 17-ketosteroid reductase deficiency causes in utero testosterone deficiency with sexual ambiguity in males, and primary amenorrhea and failure to enter puberty in girls.

The least common (but most severe) form of CAH is not an enzyme deficiency but a disorder involving steroidogenic acute regulatory protein (StAR).[187] StAR mediates the transport of cholesterol across the inner mitochondrial membrane. A deficiency of StAR is potentially lethal and causes congenital lipoid adrenal hyperplasia when the adrenal glands are packed with cholesterol and cholesterol esters that are not further metabolized because of the inborn error. In this disorder, deficiencies of all steroid hormones are present. Failure of androgen production in males is expressed as ambiguous genitalia.

Functioning Adrenocortical Tumors[298]

Plasma DHEA-S, DHEA, androstenedione, and testosterone concentrations are elevated in patients with virilizing adrenal adenomas and Cushing syndrome. The plasma concentrations of DHEA may also be elevated in women with virilizing ovarian tumors. CT scans along with MRI are useful in differentiating the sites of the tumors.[287] Aldosterone-producing adenomas, referred to as *Conn syndrome,* are typically small microadenomas found in the zona glomerulosa that hypersecrete aldosterone, producing the syndrome characterized by low renin hypertension.[174]

Adrenal carcinomas are rare, with an incidence of only 1 per million population; they usually are larger than 4 cm, and they may cause only virilization, and not the typical features of Cushing syndrome.[329] Adrenal carcinomas occur more commonly in women than in men, by a 2.5:1 ratio. Most adrenal carcinomas are functional, producing glucocorticoids alone or glucocorticoids and androgens. Plasma DHEA-S, DHEA, and androstenedione concentrations are markedly elevated in patients with functional adrenal carcinomas. The peripheral conversion of adrenal androgens to testosterone results in hirsutism and virilization. Concentrations of DHEA-S can often exceed 10 µg/mL in patients with adrenal carcinoma and usually are diagnostic for this malignancy. High-dose glucocorticoids do not suppress the elevated androgen concentrations.

Feminizing adrenocortical carcinomas are also rare.[210,288] These tumors result in elevations of plasma DHEA-S, DHEA, androstenedione, estrone, and estradiol concentrations. Gynecomastia and sexual dysfunction occur in males, and precocious pseudopuberty occurs in females. Steroid hormone production fails to decrease normally after treatment with dexamethasone.

Nonfunctioning Adrenocortical Tumors

Approximately 2% of the population has an adrenal tumor; most of these tumors are nonfunctioning and benign and are called *incidentalomas* (or *incidentomas*) when found by accident.[6,57] The tumors usually are found when CT or MRI scans of the abdomen are performed that easily detect tumors 1 cm in diameter or 5 g in weight. No virilizing tumors smaller than 1 cm in diameter have been reported. Carcinomas usually weigh more than 30 g.

The challenge occurs when CT or MRI of the abdomen reveals an adrenal mass in a patient lacking clinical evidence of adrenal hyperfunction.[307] The CT or MRI might have been ordered for evaluation of undiagnosed "chronic abdominal pain," for example. Upon finding an unexpected adrenal mass, the clinician generally is obliged to exclude subclinical adrenal disease by screening for (1) Cushing syndrome, (2) hypermineralocorticoidism, and (3) pheochromocytoma. Screening for Cushing syndrome is as described earlier with a 24 hour urinary free cortisol measurement, an overnight 1 mg dexamethasone suppression test, or a midnight plasma or salivary cortisol measurement. Diagnostically challenging cases with possibly mild hypercortisolism may be revealed.[308] Screening for hypermineralocorticoidism could

be accomplished by measuring the patient's blood pressure and serum potassium (assuming that the patient has not previously been diagnosed with hypertension, and the patient is not on potassium-wasting diuretics). Because adrenal androgen- or estrogen-secreting tumors are very rare, it is argued that these may be detected solely by taking a history and performing a physical examination with attention to evidence of androgen or estrogen excess. Screening for pheochromocytoma involves measuring plasma free metanephrine or 24 hour urinary metanephrines and/or catecholamines.

Mineralocorticoid Excess (Hyperaldosteronism)

Primary hyperaldosteronism, commonly referred to as *Conn syndrome,* is a syndrome of hypersecretion of the aldosterone.[198] In primary hyperaldosteronism, excessive aldosterone production originates within the adrenal gland; in secondary hyperaldosteronism, a stimulus outside the adrenal gland activates the renin-angiotensin system. (*Note:* The term *aldosteronism* is often used synonymously with *hyperaldosteronism.*) The interaction of renin, angiotensin, and aldosterone is important in the regulation of extracellular fluid volume and blood pressure, and in the balance of sodium and potassium ions as well as acid-base balance.

Control of renin release from the kidney is influenced by (1) the specialized distal convoluted tubule, where chemoreceptor macula densa cells monitor the sodium concentration of fluid in the distal tubules; (2) the pressure-transducer juxtaglomerular cells, which monitor renal perfusion pressure; (3) the sympathetic nervous system, which supplies the kidney and controls catecholamine release; and (4) humoral factors such as potassium, atrial natriuretic peptides, and angiotensin II. Secondary events that disturb the normal equilibrium of renin release are much more common than primary abnormalities of renin secretion (Table 54-15). For example, a decrease in effective plasma volume or mean arterial pressure from sudden blood loss leads to release of renin from the juxtaglomerular cells of the kidneys; more angiotensin I and angiotensin II are formed, and production of aldosterone by the adrenal glands is increased. Angiotensin II also causes increased sodium reabsorption in the proximal convoluted tubule, increased thirst, increased release of ADH, and release of catecholamines. These events result in retention of sodium and water, an increase in extracellular volume, hydrogen ion wasting, and a decrease in the serum potassium ion concentration as renal potassium excretion increases. This state of secondary hyperaldosteronism is commonly present in patients with (1) congestive heart failure, (2) nephrotic syndrome, (3) cirrhosis of the liver, (4) other hypoproteinemic states, or (5) conditions of chronic depletion of plasma volume.

Secondary hyperaldosteronism is suspected in patients with volume depletion, edema, and hypokalemic alkalosis. Whereas hypertension is present in primary hyperaldosteronism, it is usually absent in secondary hyperaldosteronism, unless the patient has a reninoma or renal artery stenosis. Measurements of renin and aldosterone concentrations are seldom needed in cases of secondary hyperaldosteronism, because precipitating circumstances that explain the patient's hypokalemia and alkalosis (e.g., secondary hyperaldosteronism is expected in congestive heart failure) are apparent. Renin and aldosterone measurements are invaluable, however, in the investigation of primary disturbances in the renin-angiotensin-aldosterone system, in the assessment of renal artery stenosis, and in the genesis and maintenance of arterial hypertension.

TABLE 54-15 Causes of Functional Hypermineralocorticoidism

Hyperaldosteronism	Primary (hyporeninemic) • Aldosterone-producing adenoma • Aldosterone-producing carcinoma • Idiopathic adrenal hyperplasia • Unilaternal adrenocortical hyperplasia • Glucocorticoid remediable hypertension Secondary (hyperreninemic) • Renin-secreting tumors • Renovascular hypertension • Compensatory (nephrosis, cirrhosis, CHF) • Bartter syndrome • Gitelman syndrome
Desoxycorticosterone (DOC) excess	DOC-secreting adrenal adenoma 11 Beta-hydroxylase (CYP11B1) deficiency 17-Hydroxylase (CYP17) deficiency
Glucocorticoid excess	Cushing syndrome Cortisol resistance
Increased mineralocorticoid action without circulating mineralocorticoid excess	Apparent mineralocorticoid excess (HSD11B2 deficiency) Acquired HSD11B2 inhibition (glycyrrhizic acid induced) • Liddle syndrome (type 1 pseudohyperaldosteronism) • MR gain-of-function mutation (type 2 pseudohyperaldosteronism)

CHF, Congestive heart failure; *MR,* mineralocorticoid receptor.

Primary Hyperaldosteronism

Primary hyperaldosteronism, which was first described by Conn in 1955, is characterized by an elevated plasma concentration of aldosterone and a suppressed renin concentration, along with hypertension and hypokalemic alkalosis. Historically, it has been taught that no more than 1% of hypertensive patients have primary hyperaldosteronism. However, results

from a 2007 study identified primary hyperaldosteronism in 10% or more of cases of otherwise defined "essential" hypertension.[269]

Clinical indications for a formal evaluation of hyperaldosteronism (measurement of the aldosterone-to-renin ratio)[268] include hypokalemia that is unprovoked by diuretics and the patient's lack of response to conventional antihypertensive drug treatment.[262] However, not all patients with primary hyperaldosteronism are hypokalemic.

Overproduction of aldosterone may be due to autonomous and inappropriate secretion of aldosterone by (1) an adenoma of one adrenal gland [aldosterone-producing adrenal adenoma (APA), or Conn syndrome], (2) hyperplasia of aldosterone-producing cells in both glands [bilateral idiopathic adrenal hyperplasia (IAH)], (3) an aldosterone-producing adrenal carcinoma, or (4) a rare familial condition known as *glucocorticoid-suppressible hyperaldosteronism* (familial hyperaldosteronism type 1).[215,238] Familial hyperaldosteronism type 2 is the rare occurrence of familial APA, familial hyperaldosteronism from IAH, or combined familial APA and hyperplasia. A rare cause of hyperaldosteronism is unilateral adrenocortical zona glomerulosa hyperplasia, which can be micronodular or macronodular. Very rarely, does primary hyperaldosteronism result from ectopic aldosterone secretion from the ovary or kidney.

Clinical features of primary hyperaldosteronism generally are related to the consequences of aldosterone overproduction. Increased retention of sodium through the effects of aldosterone on the renal tubular handling of sodium (increased ENaC activity), expansion of extracellular fluid volume, and increased tubular secretion of potassium and hydrogen ions constitute the cardinal manifestations of primary hyperaldosteronism. Hypokalemic alkalosis is a consequence of progressive renal depletion of body potassium and hydrogen ions. As a consequence of sodium retention, a modest expansion of extracellular fluid volume occurs, along with an increase in arterial blood pressure.

Diagnosis and Treatment of Primary Hyperaldosteronism

Hypokalemia is the principal clue that primary hyperaldosteronism may be present in a patient with diastolic hypertension. To confirm the diagnosis, it is necessary to demonstrate (1) hyposecretion of renin, which is not appropriately elevated during volume depletion, and (2) hypersecretion of aldosterone, which fails to suppress appropriately during volume expansion.[38] Figure 54-22 shows a suggested scheme for evaluating patients with suspected excessive mineralocorticoid action causing hypertension.

Most patients with autonomous aldosterone overproduction are hypokalemic, but most patients with hypokalemia do not have primary hyperaldosteronism. Because not all patients with primary hyperaldosteronism are hypokalemic, primary hyperaldosteronism as a cause of hypertension may be under-recognized. In hyperaldosteronism, urinary potassium excretion is inappropriately high, and a random urine potassium greater than 30 mmol/L is usually indicative of primary hyperaldosteronism, or some form of mineralocorticoid excess. If hypokalemia can be shown to be due to nonrenal potassium loss, the diagnosis of hyperaldosteronism does not need to be considered further.

In primary hyperaldosteronism, low renin activity and elevated aldosterone concentration are expected.[101,283] Many other factors, however, influence the secretion of renin and aldosterone, and these factors must be considered before testing.[164] Because drugs such as ACE inhibitors, beta blockers, and spironolactone alter renin release, patients should be withdrawn from these medications for several weeks before the plasma aldosterone-to-renin ratio is determined. When patients with suspected primary hyperaldosteronism are evaluated, it is helpful, for example, (1) to compare ambulatory PRA activity versus the patient's urinary sodium excretion, or (2) to stimulate renin production with a potent diuretic such as furosemide. An elevated plasma renin activity could be due to secondary hyperaldosteronism (e.g., renovascular hypertension, pheochromocytoma). Low renin activity, on the other hand, suggests primary hyperaldosteronism or low-renin hypertension. The latter may be caused by exogenous or endogenous mineralocorticoids that mimic the action of aldosterone, producing expanded plasma volume, hypertension, and hypokalemia.

The ACE inhibitor captopril has been used for the diagnosis of primary hyperaldosteronism.[348] In individuals who are normotensive or have essential hypertension, acute inhibition of ACE decreases angiotensin-mediated aldosterone production to less than 15 ng/dL, whereas autonomous aldosterone production from an aldosterone-producing adenoma is unaffected by the ACE inhibitor. The determination of plasma renin responsiveness, however, is not sufficient in diagnosing primary aldosteronism because suppressed renin activity also occurs in about 25% of patients with essential hypertension. Recently, losartan (an angiotensin II receptor antagonist drug marketed under the name Cozaar) suppression of aldosterone was found to be superior to captopril suppression in the diagnosis of primary hyperaldosteronism.[347]

Primary hyperaldosteronism is differentiated from other hypermineralocorticoid states on the basis of inappropriate secretion of aldosterone.[97] Demonstration of an elevated concentration of aldosterone in blood or urine in a patient with an unequivocally suppressed renin concentration (a plasma aldosterone-to-renin ratio >25 to 30) is presumptive evidence of primary hyperaldosteronism.[233,283] Because hypokalemia has a suppressive effect on aldosterone secretion, the potassium deficit should be replaced before aldosterone measurements are performed. To establish aldosterone autonomy, aldosterone production may be suppressed with rapid volume expansion using the saline suppression test (see Box 54-9)[146] with a potent mineralocorticoid such as fludrocortisone (see Box 54-10)[35] or pharmacologically with captopril. Failure of aldosterone to be suppressed by these maneuvers confirms the diagnosis of primary hyperaldosteronism.

Once the diagnosis of primary hyperaldosteronism is established, it is necessary to distinguish between APA and bilateral IAH. This differentiation is vital because most

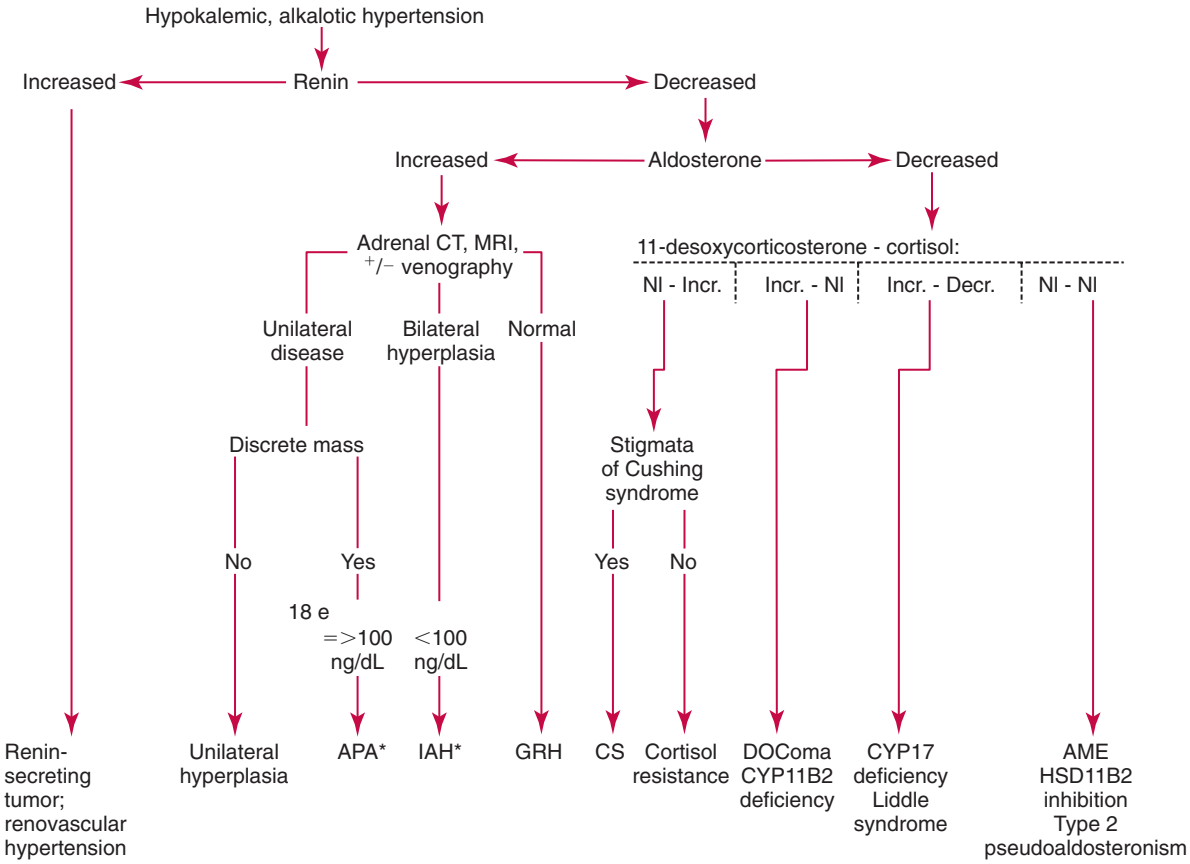

Figure 54-22 This figure provides a reasonable approach to the differential diagnosis of hypokalemic, alkalotic hypertension. If the concentration of renin is elevated, diagnostic considerations include a juxtaglomerular renin-secreting tumor (a reninoma) and renovascular hypertension (assuming that intrinsic renal disease has been ruled out, which can cause elevated renin and aldosterone, leading to hypertension). If renin is suppressed and aldosterone is elevated (an aldosterone-to-renin ratio >20 to 25), imaging and venography can help separate unilateral disease without a discrete mass (rare unilateral adrenal hyperplasia), unilateral disease with a discrete mass (aldosteronoma), bilateral idiopathic adrenal hyperplasia (IAH), or the rare condition of glucocorticoid-remediable hyperaldosteronism, with no masses or hyperplasia (see text for details). If aldosterone is not elevated, 11-desoxycorticosterone (DOC) and cortisol should be assayed, allowing the discrimination of several entities: Cushing syndrome or cortisol resistance (normal DOC and elevated cortisol), DOComa (DOC-secreting adrenal adenoma) or CYP11B2 (aldosterone synthase) deficiency (increased DOC and normal cortisol), deficiency of CYP17 (17-hydroxylase deficiency) (increased DOC and decreased cortisol), and end-organ disorders (normal DOC and cortisol).* In familial hyperaldosteronism type 2, aldosterone-producing adrenal adenoma (APA), IAH, or combined disease can be observed. *AME,* Apparent mineralocorticoid excess; *decr,* decrease; *incr,* increase; *Nl,* normal.

patients with adrenal adenoma respond favorably to surgical removal of the tumor, whereas those with adrenal hyperplasia do not respond favorably and are managed medically.[177] Localization using imaging techniques[144] [spiral CT scans,[124,287] ultrasonography, and adrenal scanning with NP-59 (^{125}I-6-iodomethyl-19-norcholesterol)] can be helpful, and adrenal venography with or without selective adrenal venous sampling for aldosterone measurements is used to determine whether the right or left adrenal is hypersecreting aldosterone. This is valuable when tumors are too small to be detected by imaging techniques. However, when CT or MRI findings are equated with a functional APA, mistakes can be made (e.g., the visualized mass was an incidentaloma and was not the APA).[147] This was discovered when surgery did not cure the patient's hypertension and hyperaldosteronism. Therefore, it has been argued that venography with aldosterone measurements should always be completed before adrenal surgery for a suspected APA, to confirm the laterality suggested by CT or MRI. Also if venography is performed, it is prudent to consider measuring cortisol in the adrenal

veins and inferior vena cava (in addition to aldosterone) to confirm the anatomic identification of the vein, in case one of the adrenal veins is not truly cannulated. The usual ratio of cortisol in the adrenal veins to the inferior vena cava is 10 to 1. Adrenal carcinomas are rare causes of primary hyperaldosteronism.[334]

Numerous biochemical clues help in the differential diagnosis of APA versus bilateral IAH. Aldosterone hypersecretion and plasma renin suppression are usually greater with adrenal adenoma. After sodium depletion, or after 2 to 4 hours of upright posture, patients with APA usually show no change or a paradoxical fall in plasma aldosterone, whereas patients with IAH typically show a rise in plasma aldosterone (presumably because the hyperplastic glands are sensitive to increases in the PRA, and adenomas are insensitive to increases in the PRA).[117] Elevated plasma concentrations of 18-hydroxycorticosterone (>100 ng/dL) are observed in most patients with APA, but not in patients with IAH (see Figure 54-22).

Adrenal vein catheterization is considered the gold standard for differentiation of an aldosteronoma versus IAH. To correct for variations in cortisol and aldosterone concentrations induced by the stress of venography, a cosyntropin intravenous infusion of 50 μg/h can be provided during the procedure. When the aldosterone-to-cortisol ratio of one side versus the aldosterone-to-cortisol ratio of the other side is studied, aldosteronomas display a mean side-to-side ratio of 18, whereas the ratio in patients with IAH averages 1.8. The consensus is that side-to-side aldosterone-to-cortisol ratios of 4 or greater are consistent with aldosteronoma, whereas side-to-side ratios of 3 or less are consistent with IAH. Ratios greater than 3 and less than 4 fall into a gray zone, and other techniques must be relied upon to differentiate aldosteronoma and IAH.

A small percentage of patients with hypermineralocorticoidism respond to dexamethasone treatment (e.g., rare glucocorticoid-remediable hyperaldosteronism, also called *dexamethasone-suppressible hypertension*) with normalization of their blood pressure and correction of their biochemical abnormalities.[96,175,263] Dexamethasone treatment should be attempted before surgery, particularly in young patients, or when the normal fall in plasma aldosterone concentration after salt depletion and standing does not occur and no unilateral lesion is seen on CT/MRI. Also, a trial treatment of spironolactone, an aldosterone antagonist, usually normalizes blood pressure in patients who are likely to have a good response to surgery. In glucocorticoid-remediable hyperaldosteronism, concentrations of 18-oxocortisol and 18-hydroxycortisol are increased as a result of the gene fusion between CYP11B1, the 11-beta-hydroxylase (P450c11) of the zona fasciculata/reticularis, and CYP11B2 (aldosterone synthase, P450 aldo).

Adrenocortical carcinomas have been found to produce excess mineralocorticoid and cause hypertension with hypokalemia.[286] Aldosterone or DOC, or both, may be produced in excess.[219,313,327] Mineralocorticoid concentrations do not respond to glucocorticoid therapy or alterations in salt status. CT scans are helpful; adrenal carcinomas are usually large tumors that weigh more than 30 g, whereas aldosterone-producing adenomas are usually much smaller. Carcinomas are similar to adenomas in that furosemide stimulation or upright posture should not elevate renin or aldosterone concentrations.

Other Causes of Excessive Mineralocorticoid Action

Unusual conditions that suggest aldosterone excess but do not involve disorders of renin, angiotensin II, or aldosterone[285] include (1) apparent mineralocorticoid excess, (2) type 1 pseudohyperaldosteronism (Liddle syndrome), (3) type 2 pseudohyperaldosteronism, and (4) cortisol resistance.[190]

Apparent mineralocorticoid excess (AME) results from 11-beta-hydroxysteroid dehydrogenase-2 (HSD11B2) deficiency or inhibition.[292] Normally, HSD11B2 protects the MR from cortisol by converting cortisol to cortisone in tissues expressing the MR. Cortisone does not bind to the MR. Impaired conversion of cortisol to cortisone allows cortisol to bind to the MR, producing a mineralocorticoid effect in the absence of elevations in aldosterone or DOC. Therefore, 11-beta-hydroxysteroid dehydrogenase-2 (HSD11B2) deficiency is described as an "apparent" excess of mineralocorticoid because patients can manifest hypertension, hypokalemia, and alkalosis without elevation of aldosterone nor DOC.

Apparent mineralocorticoid excess is inherited as an autosomal recessive trait and presents in childhood. Spironolactone is used to treat hypertension because spironolactone blocks the MR. Through feedback inhibition of ACTH to suppress cortisol production, dexamethasone sometimes corrects hypokalemia; however, this treatment does not consistently lower the patient's blood pressure.[204] Glycyrrhetinic acid, which is found in black licorice, inhibits 11-beta-hydroxysteroid dehydrogenase-2, causing an acquired form of apparent mineralocorticoid excess.[339] Apparent mineralocorticoid excess is diagnosed by an increased ratio of cortisol to cortisone and an increased ratio of urinary tetrahydrocortisol to urinary tetrahydrocorticosterone.[240]

Liddle syndrome (type 1 pseudohyperaldosteronism) results from gain-of-function mutations in the beta or gamma subunit of the amiloride-sensitive ENaC.[112,241,291] Consequences include (1) excessive sodium reabsorption, (2) expanded blood volume, (3) hypertension, (4) hypokalemia, and (5) alkalosis. Because the activity of ENaC is autonomous, both renin and aldosterone are suppressed. This disorder responds to triamterene but not to spironolactone (which blocks the MR). Triamterene is believed to inhibit ENaC through a mechanism similar to the action of amiloride. Type 2 pseudohyperaldosteronism is a gain-of-function mutation in the MR.

Loss-of-function mutations in the GR cause cortisol resistance.[272] In response to decreased cortisol action, CRH and ACTH concentrations rise, increasing the circulating cortisol to a sufficient concentration that functional cortisol deficiency is not present. However, the protective action of

TABLE 54-16 Renal Tubule Disorders Characterized by Loss of Sodium Chloride That Lead to Secondary Hyperaldosteronism*

Subtype	Channel/Transporter	Site of Expression	Gene	Gene Location

ALH, Ascending loop of Henle; *DCT,* distal convoluted tubule.

HSD11B2 in converting cortisol to cortisone is overwhelmed, resulting in increased binding of cortisol to the MR and excessive mineralocorticoid effects. This is treated with a mineralocorticoid receptor blocker such as spironolactone or dexamethasone, which suppresses ACTH.

Non–Mineralocorticoid-Deficient Causes of Urinary Sodium Loss

Bartter syndrome is a consequence of sodium loss from dysfunction of the ascending, thick loop of Henle or the distal convoluted tubule.[336] Loss of sodium evokes a compensatory secondary hyperaldosteronism (with increased renin and aldosterone), producing hypokalemia and alkalosis. Although affected adults may be asymptomatic, infants can display (1) failure to thrive, (2) salt craving, (3) polyuria, and (4) polydipsia. Potassium depletion elicits prostaglandin-induced vasodilatation that can further worsen the attempted compensatory hyperaldosteronism. A variety of gene mutations cause urinary sodium loss that leads to secondary hyperaldosteronism with hypokalemia and alkalosis (Table 54-16).

In pseudohypoaldosteronism (resistance to aldosterone), the clinical view of hypoaldosteronism is seen (acidosis, hyperkalemia, possible hypotension) concurrent with elevated concentrations of aldosterone. Pseudohypoaldosteronism (PHA) may be classified as (1) renal type 1 PHA, (2) multiple target organ defects type 1 PHA, (3) early childhood hyperkalemia type 1 PHA, (4) Spitzer-Weinstein syndrome (adolescent hyperkalemic syndrome, (5) subtype 3 RTA [renal tubular acidosis] IV type 2 PHA), and (6) Gordon syndrome (mineralocorticoid-resistant hyperkalemia, chloride shunt syndrome type 2 PHA).

Renal type 1 PHA results from reduced numbers or function of the renal MR. This occurs as an autosomal dominant or sporadic disorder, and usually the child is asymptomatic by age 2. In multiple target organ defects type 1 PHA (an autosomal recessive disorder), a loss-of-function mutation in ENaC affects the sweat glands, salivary glands, and colon, in addition to the kidney, throughout the patient's life. Early childhood hyperkalemia type 1 PHA is milder than renal type 1 PHA, and its cause is unknown. The child usually has "outgrown" this disorder by age 5.

Whereas renin and aldosterone are elevated in PHA type 1, in PHA type 2 renin and aldosterone are normal to low. Type 2 PHA results from a defect in the distal nephron consequent to absent WNK1 or WNK4 kinase function. Some researchers have speculated that Gordon syndrome is caused by increased generalized activity of the bumetanide-sensitive Na^+-K^+-$2Cl^-$ cotransporter, but this requires formal study.

Plasma Renin in Renovascular Hypertension

When used as a screening test, elevated plasma renin after furosemide stimulation, or when correlated with urinary sodium excretion, suggests renal artery stenosis as the cause of hypertension.[165,340] If arteriographic evidence indicates the presence of renal artery stenosis, measurement of plasma renin in specimens obtained from selective renal vein catheterization is helpful in predicting the response to surgical correction of the renal vascular lesion or nephrectomy.[103] Lateralization of renin in the renal vein to the radiographically involved side, especially after sodium depletion, is predictive of a good response to surgery in 90% of cases (Box 54-11).[197] Comparison of renin activity in the renal artery with that in the renal vein can allow a further distinction.[322]

LABORATORY EVALUATION OF ADRENOCORTICAL FUNCTION

Laboratory evaluation of adrenal cortex function centers on measurement of (1) cortisol, the primary corticosteroid; (2) aldosterone, the primary mineralocorticoid; and (3) sex hormones, of which the adrenal cortex is a secondary source. Chromaffin cells in the adrenal medulla are a source of catecholamines, which are discussed in Chapter 30. Underproduction or overproduction of cortisol and aldosterone gives rise to characteristic clinical syndromes, and genetic defects in steroid hormone biosynthesis produce abnormalities in

BOX 54-11 Protocol for the Differential Renal Vein Renin Test

Rationale
In renovascular hypertension, plasma renin activity (PRA) is significantly higher in the renal vein on the involved side.

Procedure
The patient should be on a low-sodium, high-potassium diet and receiving a diuretic for 3 days before the procedure. Under fluoroscopic guidance, percutaneous catheterization is performed, and blood samples are obtained from both renal veins and the inferior vena cava for determination of PRA.

Interpretation
Various criteria have been suggested for interpretation. A ratio of PRA (affected side to unaffected side) that is greater than 1.5 suggests functionally significant renovascular disease.

sex hormone concentrations that are associated with clinical symptoms as well. Therefore, measurement of steroid hormones produced in the adrenal cortex is essential to the clinical diagnosis of a variety of endocrine disorders.

Steroid hormones such as those produced in the adrenal cortex share considerable structural similarity based on their terpenoid sterane core, which is modified by functional groups at various locations on the tetracyclic backbone. In general, steroids are lipophilic compounds, but they require additional modification—esterification to fatty acids—to facilitate their transport across cellular membranes. Transport in the bloodstream typically involves carrier proteins (e.g., transcortin, SHBG). These properties influence the choice of analytical methods for measuring steroid hormone concentrations; most procedures begin with enzymatic or chemical hydrolysis of steroid esters and displacement of the steroid from carrier proteins through addition of a protein-binding agent such as 8-anilino-1-naphthalene-sulfonic acid (ANS) or salicylate. Photometric and fluorometric measurements of steroids lack specificity unless extraction and purification procedures are used. Immunoassays are practical for the measurement of steroid hormones and are widely available on a variety of automated instrumental platforms, but cross-reactivity with structurally similar hormones often results in bias between various immunochemical methods. Endogenous interferences also occur, for example, near the time of birth, when placental steroid concentrations are very high. Steroids can be extracted into organic solvents and analyzed, however, chromatographic methods coupled with mass spectrometric detection provide sensitive and specific quantitative results for these compounds. In contrast to peptide hormones, most of which exhibit considerable heterogeneity as the result of post-translational modifications, steroid hormones constitute a relatively homogenous group of compounds that are calibrated against gravimetrically validated synthetic calibrators.

Episodic secretion and circadian variation limit the clinical diagnostic accuracy of basal serum cortisol concentrations.[67] Serum cortisol concentrations are highest in the early morning hours and vary between 7 and 25 μg/dL at between 0400 and 1200 hours. Late afternoon concentrations are about half the morning concentrations and frequently are less than 5 μg/dL at between 2200 and 0200 hours. A midnight cortisol less than 5 μg/dL is considered normal. Serum cortisol combined with plasma ACTH improves the diagnostic accuracy of basal values, although ACTH concentrations display even greater variation throughout the day than cortisol concentrations.

Choice of Specimen

Steroid hormones have been measured in urine, blood, saliva, and recently, hair.[309] The choice of specimen depends on the application. For clinical assessment of adrenal function, blood (plasma) measurements are convenient, but conditions that cause the binding protein concentration to increase have been known to produce clinically irrelevant elevations in the total cortisol concentration. Urinary concentrations are helpful in determining time-integrated hormone production and provide useful estimates of free hormone concentrations in blood, if an appropriately timed urine specimen collection is available. Measurement of steroid hormones in saliva has been proposed as an alternative to urinary hormone assays to estimate free hormone concentrations in blood, the principal advantage being ease of collection. Hair analysis may be useful for assessing adrenal hormone production over an extended time, but currently hair testing is not in widespread use.

Urine

Urinary excretion of a hormone, or its metabolites, provides an approximation of the amount secreted over the time the urine is collected, typically 24 hours. Thus, urinary hormone or metabolite measurements are useful when the hormone has a very short biological half-life and/or its secretion is pulsatile or varies in predictable cycles. Timed urine collections suffer variability associated with factors such as completeness of collection and impaired renal function. Urinary metabolites may reflect only a fraction of the active steroid hormones; these metabolites, in turn, may be affected by metabolic disease, as well as diet and medications. Even with these limitations, urinary free cortisol and measurement of urinary free estradiol, estrone, and testosterone are useful for estimating the rates at which these steroids are produced, and are not affected by variations in the concentrations of proteins that bind hormones, such as corticosteroid-binding globulin (CBG) and albumin. Use of the term *urinary free cortisol,* or *UFC,* is common, although it is somewhat redundant; only the uncomplexed fraction of blood cortisol is filtered in the glomerulus, so urinary cortisol is, by definition, the free hormone.

UFC obtained from a 24 hour urine collection, an integrated measure of plasma free cortisol, eliminates the circadian influence on cortisol secretion.[46] With increases in

total cortisol and stable concentrations of CBG, the serum free cortisol fraction rises substantially and is cleared into the urine. UFC measurements therefore are considered a superior screening test for cortisol excess. In Cushing syndrome, UFC is two to three times the upper limit of the reference interval. The UFC excretion rate in normal subjects is less than 50 μg/d when assayed by high-performance liquid chromatography (HPLC).

Blood

Circulating concentrations of steroids in the blood provide the most direct measure of endocrine activity mediated by these hormones. Immunoassays and chromatographic methods have been developed for measuring most of the clinically relevant steroids in blood. Provocative testing (stimulation and suppression tests, discussed earlier) may require blood samples because of the rapid changes that occur in hormone activity when stimulus or suppression is applied. Many of the steroid hormones are released in a pulsatile or rhythmic fashion, so their concentrations in an isolated blood specimen should take into account these variables.

Mineralocorticoid and adrenal androgen secretion is circadian and episodic in nature, but the dynamic swings in concentration are not as pronounced as with cortisol. It is usually recommended, however, that blood samples for adrenal steroids should be collected in the 0700 to 1000 hour time frame for consistency in interpreting the results.

Steroid hormone concentrations in serum and plasma are nearly the same. It has been suggested that steroid hormone concentrations may change in unseparated blood specimens as the result of 17β-hydroxysteroid dehydrogenase activity in red blood cells and macrophages, but stability studies of estradiol, cortisol, testosterone, progesterone, 17α-hydroxyprogesterone, androstenedione, and DHEA-S have failed to reveal any clinically significant changes in these hormones in whole blood specimens stored at room temperature for up to 1 week.[69]

Saliva

Most steroids of clinical interest have been measured in saliva, and for some steroids, such as cortisol, estriol, and progesterone, salivary concentrations appear to correlate with the free hormone concentration in plasma.[326] For other steroids (e.g., testosterone, 17α-hydroxyprogesterone, estradiol, aldosterone), the clinical usefulness of salivary measurements has not been established.

Measurement of steroids in saliva is attractive because specimens are simple to collect; this consideration is particularly important in pediatric patients. Several saliva collection devices using absorbent materials have been designed to collect a sufficient volume of saliva for steroid analysis. However, recovery of cortisol from these devices has been questioned. Using cotton swabs, cotton ropes, and hydrocellulose microsponges, Harmon and colleagues demonstrated that recovery of both the volume of saliva specimen and the cortisol concentration was variable, relative to a directly collected ("passive drool") saliva specimen.[114]

Hair

Hair grows at an average rate of 1 cm per month; therefore it can reveal historical blood concentrations of substances that are deposited in the forming hair matrix. Also it has been used as an alternative to urine specimens for the detection of illicit drug use, because a number drugs are detectable in urine for only a few days following exposure.[95] Several reports describe methods for measuring steroid hormones in hair.[53,152,309,351] These methods have shown potential as diagnostic tools but will require additional validation studies before they can be applied generally.

Basal Peptide and Steroid Hormone Concentrations

Concentrations of adrenal mineralocorticoids and elements of the renin-angiotensin system are routinely measured in body fluids by various immunoassay and mass spectrometric methods.[270,271] As with cortisol, aldosterone is secreted episodically, with the highest circulating concentrations near the time of awakening, and the lowest concentrations shortly after sleep onset. Aldosterone concentrations, however, are only modestly stimulated by ACTH secretion. In healthy subjects, consuming a low-sodium diet, maintaining an upright posture, and using diuretics all increase plasma aldosterone concentrations, whereas consuming a high-sodium diet and lying in the supine position decrease aldosterone secretion. Standardized procedures for obtaining blood and urine specimens are required for proper interpretation of test results. It is useful to interpret aldosterone concentrations together with urinary sodium excretion, because salt intake can profoundly influence the aldosterone concentration. Normally, the aldosterone concentration is inversely proportional to the urinary sodium concentration.

Because it has enzymatic activity, renin is measured by its activity or its mass, and both methods are available. Plasma renin activity (PRA) is determined by the generation of angiotensin I, which is measured using immunoassay techniques.[13] The relative merits of activity and mass assays of renin are discussed in the following paragraphs.

Renin release is controlled by many physiologic factors. Consuming low-sodium diets, maintaining an upright posture, and using diuretic medications increase renin release (causing a rise in aldosterone) and should be controlled or eliminated before testing of the renin-angiotensin-aldosterone axis is begun. Because plasma renin varies with sodium balance, it is helpful to interpret ambulatory renin measurements together with urinary sodium excretion. An inverse relationship exists (similar to aldosterone), allowing the identification of low-, normal-, and high-plasma renin groups from a standard nomogram.

Age, estrogen therapy, and diabetes mellitus without renal failure affect plasma renin results.[1] Patients older than 55 years and those with diabetes have PRA results that are about 50% of normal. Estrogen causes an increase in the hepatic synthesis of angiotensinogen, thereby increasing the endogenous substrate concentration for the renin enzyme. This causes inappropriately elevated renin activity for the urinary

sodium concentration. Several medications may affect plasma renin activities. Angiotensin-converting enzyme (ACE) inhibitors and spironolactone raise renin concentrations, whereas beta blockers and nonsteroidal anti-inflammatory agents block renin release.

Even when time of sampling, posture, drug intake, and diet are controlled, it is often difficult to identify disorders of mineralocorticoid secretion on the basis of basal hormone concentrations alone.[43] A variety of dynamic tests have been developed to assess hypersecretion or hyposecretion of aldosterone and renin.

The diagnosis of adrenal insufficiency in the setting of critical illness has become highly controversial.[11,40,153,191,257] On one hand, if the diagnosis of cortisol deficiency or combined cortisol and aldosterone deficiencies is missed and replacement medication is not administered, the patient can die from Addisonian crisis, as might occur in Waterhouse-Friderichsen syndrome. However, inappropriate administration of cortisol in the setting of sepsis could produce immunosuppression that may be fatal. Some investigators believe that free cortisol measurements would be of diagnostic help because CBG concentrations frequently decline from liver disease or acute malnutrition that could lead to overdiagnosis of cortisol deficiency. In equivocal cases of adrenal insufficiency, some authors caution that a single low cortisol concentration should not be used to make the diagnosis of cortisol deficiency.[257] Just as free testosterone can be estimated from total testosterone and SHBG concentrations, a free cortisol index has been described as the simple ratio of total cortisol to CBG.[169]

Free Versus Bound Steroids

Many hormones circulate in the blood bound to carrier proteins. Hormone-binding proteins serve two functions: (1) they solubilize lipophilic compounds such as steroid hormones to facilitate their transport in the primarily aqueous circulatory environment, and (2) they buffer the concentration of free, active hormone in tissue. Protein-bound hormones are not ordinarily active, but the protein-bound reservoir provides a relatively constant, buffered concentration of the free hormone for activity at tissue receptors. However, for hormones that are highly protein bound, the concentration of the binding protein is the principal determinant of the total concentration of hormone. Therefore, total hormone concentration vary significantly, while the free, active hormone concentration remains within physiologically appropriate limits. Measurement of free (unbound) hormone concentrations provides the best indicator of hormone activity, but analytical methods that isolate free hormone concentrations without disrupting the free/bound equilibrium are sometimes difficult to design. Antibodies that recognize steroid hormones may have binding affinities that compete with binding proteins and detect portions, if not all, of the bound fraction. Preanalytical methods to separate bound and free fractions often disrupt the physiologic equilibrium between bound and free hormone. Urinary and salivary steroid hormone measurements have been widely used to estimate free hormone concentrations; specific applications are discussed later.

Analytical Methods

In contrast to peptide hormones, which may exhibit considerable structural heterogeneity, steroids present less of a challenge in the design of specific analytical methods because these compounds, for the most part, are homogeneous. Sensitive immunometric methods for measuring steroid hormones have been available for decades, and methodological approaches include most, if not all, of the common labels (radioisotope, enzyme, fluorescent, chemiluminescent) and immunoassay designs (heterogeneous, homogeneous, competitive, noncompetitive). Currently, a participant survey from a 2009 College of American Pathologists proficiency challenge revealed that, among participating clinical laboratories reporting cortisol results, a vast majority use heterogeneous chemiluminescent or electrochemiluminescent immunoassays.

Measurement of Cortisol

Approximately 90% of circulating cortisol is bound to plasma proteins, primarily to CBG (corticosteroid binding globulin, or transcortin). Cortisol also binds weakly to albumin. The concentration of CBG in the plasma rises in hyperestrogenic states, including pregnancy and oral contraceptive use; therefore total cortisol in serum is increased in these conditions, although free cortisol remains normal. Analytical methods involving organic solvent extraction or protein precipitation estimate both free and protein-bound cortisol in the circulation, but immunoassays for direct measurement of cortisol have mostly replaced extraction/chromatographic methods for routine cortisol determinations.

Historical methods for the quantitative estimation of total cortisol in blood include the Porter-Silber color reaction,[222,253] in which dihydroxyacetone groups at carbons 19, 20, and 21 of 17-hydroxycorticosteroids react with phenylhydrazine to produce a yellow adduct and sulfuric acid–induced fluorescence.[150,196] However, immunoassays and chromatographic assays are now used in most clinical laboratories for the quantitative determination of cortisol in serum or urine. Methods for measuring cortisol in clinical laboratories have been reviewed.[99]

Chromatographic Methods

Gas chromatography (GC),[142,346] thin-layer chromatography (TLC),[83] and HPLC[135,176,194,213,236] have been used to measure cortisol. GC and HPLC coupled to mass spectrophotometric detectors (GC/MS, LC/MS, and LC/MS-MS) provide the most specific methods for measuring corticosteroids.[70,290] Cortisol methods based on capillary electrophoresis are also available.[157,281] All of these methods demonstrate high specificity for cortisol but have relatively low throughput and require sample preparation steps before analysis. For example, most HPLC methods require preanalytical extraction of cortisol with solid-phase extraction columns[319] or liquid-liquid extraction[181] prior to separation and detection by

reversed- or normal-phase HPLC and a fluorescence or ultraviolet absorption detector.[113] A reference method for serum cortisol using isotope dilution GC/MS has been proposed.[142] GC/MS methods for cortisol typically require extraction of the hormone from plasma and conversion to the methoxime-trimethylsilyl derivative prior to analysis. Deuterated cortisol is available for use as the internal standard.

Although GC/MS has long been considered the standard for reference methods measuring organic compounds, liquid chromatography-tandem mass spectrometry (LC/MS-MS) methods are becoming increasingly common. Liquid chromatography has the advantage of not requiring volatile derivatives, so specimen preparation can be vastly simplified. LC/MS-MS methods have been developed that measure cortisol,[195,331] cortisol and corticosterone,[90] and multiple corticosteroids.[49,108,259,260] LC/MS-MS appears poised to become the method of choice for corticosteroid profiling.

Immunoassay

In routine laboratory practice, immunoassays are the most common methods used for measuring cortisol in serum and urine, and are widely available on various automated immunoassay platforms. Most cortisol immunoassays in routine use are heterogeneous, competitive-binding assays that require no initial extraction of steroids from the specimen. Cortisol is displaced from CBG and other endogenous binding proteins by (1) protein-binding agents such as ANS or salicylate, (2) low pH, or (3) heat treatment. The efficiency of cortisol displacement from proteins by agents such as ANS may be influenced by the concentration of binding proteins in the specimen. For example, the amount of ANS that is adequate for plasma obtained from healthy men and nonpregnant women may be insufficient to displace cortisol from CBG in pregnancy, when CBG concentrations are elevated.

Isotopic Methods

Radioimmunoassays (RIAs) for cortisol are predominantly of historical interest, having been widely replaced by nonisotopic assays. The tracer most commonly used in RIAs for total cortisol was iodine-125 (^{125}I). A variety of formats have been used in cortisol RIAs, including both solid- and liquid-phase capture antibodies, and a variety of methods for immobilizing antibodies (e.g., coated tube, glass beads, paramagnetic particles). Some commercial RIA kits for serum cortisol use liquid-phase double-antibody separations or solid-phase antibody suspensions. In double-antibody systems, a second antibody is used to precipitate the primary antibody after incubation with specimen and labeled antigen. Solid-phase suspension systems use antibodies bound to small particles that remain suspended in the reaction medium. After incubation, the suspended particles are separated by centrifugation and the radioactivity in the precipitate is measured.

Almost all commercial RIA methods for serum cortisol demonstrate some cross-reactivity with prednisolone, which is a metabolic product of prednisone. Therefore, these methods should be used with caution to measure cortisol in patients on prednisone therapy. The degree of cross-reactivity with 11-desoxycorticosterone, corticosterone, and prednisone varies from 1 to 5%, depending on the particular assay.[127] In patients with high plasma concentrations of 11-desoxycorticosterone (such as in 11α-hydroxylase deficiency or after administration of metyrapone), extraction with carbon tetrachloride to remove this steroid may be necessary to avoid significant interference.

Nonisotopic Methods

Most contemporary automated cortisol immunoassays use nonisotopic labels. Enzyme labels used in these immunoassays include horseradish peroxidase, alkaline phosphatase, or β-galactosidase, and enzyme activity has been measured using photometric,[136,161,172] fluorescent,[171] or chemiluminescent substrates.[354] Nonenzymatic approaches involve fluorescent and chemiluminescent[335] labels; these are the most common methods currently in use.[265] Both heterogeneous and homogeneous designs have been developed. Most current heterogeneous immunoassays for cortisol involve chemiluminescent labels and magnetic separation. Homogeneous immunoassays for cortisol include fluorescence polarization immunoassay (FPIA), enzyme-multiplied immunoassay technique (EMIT),[335] and the cloned enzyme donor immunoassay (CEDIA).[59] These assays do not require separation of bound and free fractions. Most immunoassay methods for cortisol are available on fully automated immunoassay systems.[265]

Other Methods

A highly sensitive method for measuring salivary cortisol using a biosensor based on nanolinking and surface plasmon resonance detection has been described.[207] This method had a detection limit of 49 pg/mL in human saliva, and the technology eventually may give rise to point-of-care instruments that measure salivary cortisol.

Specimen Collection and Storage[338]

Cortisol can be measured in serum, heparinized plasma, or ethylenediaminetetraacetic acid (EDTA) plasma, although some methods recommend against using EDTA plasma because of assay interference. In serum or plasma specimens, cortisol is stable for 7 days at room temperature or refrigerated, and is stable for 3 months frozen at −20 °C.

Comments

Blood cortisol concentrations parallel ACTH concentrations, with episodic and diurnal minima and maxima observed throughout the day. The cortisol concentration in the evening is normally less than 50% of the morning cortisol concentration. Increased cortisol is associated with (1) stress, (2) glucocorticoid therapy, (3) pregnancy, (4) depression, (5) hypoglycemia, and (6) hyperthyroidism. No significant difference in cortisol concentrations has been noted between men and women, and reference intervals for cortisol are not age dependent. The half-life of cortisol in the circulation is approximately 60 minutes,[338] so concentrations of this hormone in blood can change rapidly. In newborns, a

transient rise in cortisol occurs immediately after delivery, but after 12 to 48 hours, cortisol declines to concentrations below umbilical cord blood concentrations; it then increases to a stable reference interval by about 1 week of age. Renal failure does not directly affect serum cortisol, but metabolites that are not cleared in the urine have the potential to cross-react with immunoassays, causing overestimation of blood cortisol concentrations. Extraction of cortisol into an organic solvent may eliminate interference from hydrophilic metabolites. Celite chromatography has been used to "clear" the sample of possible interference before immunoassay measurements are carried out in patients with renal failure.

Measurement of Free Cortisol

Free or unbound cortisol is the biologically active form of the circulating hormone; its concentration is buffered by the large reservoir bound to its transport proteins, CBG and albumin. Various methods have been developed to measure the free fraction of cortisol in serum, including ultrafiltration, equilibrium dialysis, and gel filtration, but these assays are technically demanding and expensive, and are not in general use.[99] Algorithms have been suggested for estimating the free cortisol concentration on the basis of CBG and albumin concentrations.[18,58,71]

Measurement of urinary cortisol provides an estimate of the free hormone concentration and for many years has been considered the gold standard screening test for Cushing disease,[37] although salivary cortisol has been recommended as the first-line diagnostic test.[227] Approximately 2% of total cortisol is excreted into the urine, and urinary cortisol may be used as a screening test for cortisol hypersecretion. However, β-hydroxycortisol also appears in the urine and may interfere with some immunoassays used to measure cortisol in urine.[170]

Measurement of cortisol in saliva (or oral fluid) is a practical and convenient way to assess the free hormone.[14,256] Salivary cortisol reflects the concentration of free cortisol in blood because CBG and albumin, the primary cortisol-binding proteins, do not appear in saliva. Most immunoassay kits for total serum cortisol can be used for the measurement of cortisol in saliva[221]; extraction is not required because saliva contains virtually no cortisol-binding proteins or other cortisol metabolites. The glycoproteins in saliva is precipitated by freezing and thawing followed by centrifugation, producing a clear fluid that is free of protein interference. At this point, the challenge in measuring salivary cortisol involves achieving an adequate lower limit of detection, because the concentration of cortisol in saliva is less than in serum or plasmal.

Immunoassays designed to measure total serum cortisol can be used to measure urinary (free) cortisol if cortisol metabolites and conjugates that cross-react with the anticortisol antibodies are removed. Because most interfering substances are more soluble in the aqueous urine matrix than cortisol, it can be partitioned into an organic solvent such as dichloromethane or ethyl acetate. Typically, the urine specimen is thoroughly mixed with the organic solvent; the two phases separate, and the organic layer containing the cortisol is removed. The organic solvent is evaporated to dryness, and the residue is resuspended in a buffer before analysis is begun. Extraction efficiency can be assessed by adding known amounts of cortisol (the method of standard additions) prior to extraction. Radiolabeled cortisol can be used to assess recovery of cortisol during the extraction procedure.

Unextracted urine may be assayed for cortisol if the antibody has sufficient selectivity, although reference values may differ from those seen in methods that include an extraction step.[208] Even with solvent extraction, most commercial assays for cortisol in urine are subject to interference and imprecision. Chromatographic procedures (such as HPLC) are more specific than immunoassays for measuring urinary cortisol; LC/MS-MS is emerging as the preferred method.[49,90,331]

Specimen Collection and Storage

A 24 hour urine specimen should be collected with 10 g of boric acid to maintain the urine pH below 7.5, and the urine should be refrigerated. After the total volume is measured, a thoroughly mixed aliquot may be stored at −20 °C prior to analysis. Care should be taken to ensure an appropriately timed, complete 24 hour collection because an incorrectly timed sample is the largest source of error with this method. Cortisol measurements on randomly collected urines are not useful. A 2009 report described falsely elevated urinary cortisol results attributed to interference from carbamazepine.[310] The drug interfered with the liquid chromatography method used for measuring urinary cortisol. It was also speculated that CYP3A4 induction by carbamazepine affected the results of the low-dose dexamethasone suppression test through enhanced metabolism of dexamethasone.

Cortisol is stable in saliva for 1 week at 4 °C and for 4 months when stored frozen. Freezing of specimens is recommended because it leads to precipitation of salivary glycoproteins and produces a nonviscous liquid supernatant that makes volumetric transfer by pipette more reliable.[208]

Measurement of urinary creatinine sometimes is used to assess the completeness of the collection, or to adjust concentrations of urinary constituents in spot urine collections for changes in urine specific gravity related to water intake. Diurnal variations in cortisol production, however, place greater importance on the integrity of the 24 hour urine specimen, in that daily cortisol excretion is what correlates with the functional adrenal status of the patient. Salivary cortisol measurements serve as a practical and convenient method to assess cortisol secretion in many patients. Morning salivary cortisol concentration is decreased in adrenal insufficiency; evening values are increased in Cushing syndrome.

Measurement of Aldosterone

Measurement of aldosterone is technically challenging, because the concentration of this hormone in blood is very low, nearly one thousandth that of the cortisol concentration. Immunoassays for measuring aldosterone in blood and urine are available. Radioimmunoassay methods for measuring aldosterone ordinarily use antibodies generated against an

aldosterone-3-mono-oxime-bovine serum albumin (BSA) conjugate, an ^{125}I-labeled ligand, and ANS at pH 3.6 to displace aldosterone from binding proteins (primarily albumin). Although RIA methods for measuring aldosterone remain relatively common, nonisotopic immunoassays are becoming increasingly available.[302]

The cross-reactivity of antialdosterone antibodies with other adrenal steroids (e.g., DOC, corticosterone) is relatively low (<0.01%). Nevertheless, the concentration of potentially cross-reacting steroids sometimes is very high, requiring some purification of aldosterone before measurement. Unconjugated plasma aldosterone will extract into an organic solvent and can be purified by chromatography. The addition of tritiated aldosterone as an internal standard corrects for incomplete extraction. In urine, unconjugated steroids first are extracted into an organic solvent such as ethyl acetate or methylene chloride after acid hydrolysis of the conjugates. The solvent is evaporated, and the dried extract is reconstituted in a buffer before analysis. Whether the specimen requires purification depends on the diagnostic kit being used and the type of patient being evaluated. For example, specificity is not a significant concern in hypertensive adults without adrenal disease, whereas greater specificity may be needed for newborns and young infants, patients with adrenal disease, and pregnant women, in whom high concentrations of potentially interfering steroids are likely.

An automated heterogeneous immunoassay for aldosterone involving a monoclonal antialdosterone antibody and a chemiluminescent tracer has been validated against three RIA methods.[280] This method displays minimal (<0.05) cross-reactivity with corticosterone, cortisol, 11-desoxycorticosterone, 18-hydroxycorticosterone, and dexamethasone, and a linear range of 15 to 1200 ng/L. A time-resolved fluorescence immunoassay for measuring aldosterone in saliva was described in 2010.[188] LC/MS-MS has also been applied to aldosterone measurements[306]; these results were in close agreement with RIA measurements. The LC/MS-MS method has a detection limit of 69 pmol/L and a linearity up to 5.5 nmol/L.

Specimen Collection and Storage[338,355]

If possible, the patient should be in an upright position (standing or seated) for at least 2 hours before collection. Plasma (heparin or EDTA) or serum is suitable for aldosterone measurement, although EDTA plasma is preferred. The aldosterone concentration in specimens stored at room temperature begins to decline after 24 hours, although little change in aldosterone was observed in unseparated blood specimens stored at 32 °C for 24 hours. The aldosterone concentration in refrigerated or frozen specimens is stable for at least 4 days. For urine assays, a 24 hour urine specimen should be collected with boric acid as a preservative.

Measurement of 17-Hydroxyprogesterone

The most common cause of congenital adrenal hyperplasia (CAH) is a deficiency in the 21α-hydroxylase enzyme (CYP21), which converts 17-hydroxyprogesterone (17-OHP) to 11-desoxycortisol. 17-OHP is also elevated in CYP11B1-11-beta-hydroxylase deficiency CAH. Therefore, measurement of serum or plasma 17-OHP can be used to diagnose almost all cases of CAH. In 21α-hydroxylase deficiency, 17-OHP concentrations may reach several hundred times the upper limit of normal.

Radioimmunoassays for 17-OHP that use antibodies against 17-hydroxyprogesterone-3-carboxymethyloxime-BSA are available; these methods can be used with serum, plasma, saliva, and even amniotic fluid. Monoclonal antibody–based methods have also been described.[50] In addition to radioiodinated tracers,[73,123,328] nonisotopic labels used in 17-OHP immunoassays include enzymes with photometric, fluorescent, or chemiluminescent substrates,[50,51,184,314] and fluorescence-based immunoassays using fluorescein or streptavidin-europium labels,[75] and chemiluminescent labels.[12] Despite the use of highly specific antisera, most immunoassays are susceptible to interference by other corticosteroids that may be present in neonatal and infant plasma specimens.[186,344]

Methods for measuring 17-OHP in serum by gas chromatography/mass spectrometry[185] and LC/MS-MS[82,261,316] have been described. For chromatographic analysis, 17-OHP is typically extracted using a liquid-liquid (diethylether/diethylacetate,[316] methyl-tert-butyl-ether[267]), solid-phase,[82] or on-line[108,261] extraction procedure; these methods have detection limits below 1 nmol/L. LC/MS-MS methods for measuring 17-OHP in dried blood spots obtained from neonates[121,137] and in urine[49] are also available.

Specimen Collection and Storage

Most reports of analytical methods for measuring 17-OHP use serum, although plasma has also been used. Specimens have been stored at 4 °C for up to 4 days or at −20 °C for up to 1 month. 17-OHP was stable in unseparated blood at room temperature for 1 week.[69]

Screening newborns for 21α-hydroxylase deficiency has been possible since the introduction of 17-OHP immunoassays in 1977.[242] Neonatal specimens can be obtained by heel puncture and collected in capillary tubes or on filter paper. Dried blood specimens are stable and easily transported and are widely used to screen newborns for metabolic defects. It has been reported that the presence of EDTA in dried blood specimens may interfere with 17-OHP results measured by immunometric methods based on lanthanide fluorescence.[125] The utility of salivary 17-OHP measurements has been reviewed,[220] and the principal advantage is ease of collection.[105]

Measurement of 11-Desoxycortisol

Serum or plasma 11-desoxycortisol (compound S) measurements are used to detect 11β-hydroxylase (or C-11 hydroxylase) deficiency or as part of the metyrapone stimulation test. Metyrapone inhibits the 11β-hydroxylase enzyme, and a 40- to 80-fold increase in plasma 11-desoxycortisol is observed after metyrapone stimulation in patients with normal pituitary-adrenal reserve. As a consequence,

analytical methods for 11-desoxycortisol in metyrapone stimulation tests do not require particularly high sensitivity.

Radioimmunoassay methods for the direct determination of plasma 11-desoxycortisol are available.[250] Antiserum raised against 11-desoxycortisol-3-carboxymethyloxime-BSA has provided appropriate specificity with minimal cross-reactivity against other adrenal steroids. Some radioimmunoassay methods include an extraction step or column chromatography, or both.[66,84] Nonisotopic methods for measuring 11-desoxycortisol in serum have been described, including enzyme immunoassays,[155,173] fluorometric methods,[88,330] and fluorescence polarization.[2] One method[132] for measurement of 11-desoxycortisol involves the "open-sandwich enzyme immunoassay" technique, which is based on the reassociation of two cloned antibody variable regions) by a bridging antigen.

Liquid chromatography/tandem mass spectrometry methods for measuring 11-desoxycortisol have been described, mostly as part of corticosteroid profiles.[49,108,259,260,267] These methods typically involve liquid-liquid extraction into an organic solvent, although solid-phase extraction has been used as well.[49]

Specimen Collection and Storage

Most of the methods used for measuring 11-desoxycortisol have used serum, although use of plasma and urine are also used. Data in the literature on the stability of 11-desoxycortisol in stored specimens are lacking.

Measurement of Renin

Methods for measuring renin have been the subject of two reviews,[45,277] upon which most of the following discussion is based.

Circulating concentrations of prorenin may be as many as 100-fold greater than the concentration of renin (although a 10:1 ratio of prorenin to renin is more common); therefore even minimal cross-reactivity of prorenin with antirenin antibodies used in immunoassays to measure renin can be problematic. Assays exist to measure plasma renin activity (by monitoring the production of angiotensin I) or the mass of renin by immunoassay. Each approach has advantages and disadvantages.

Measuring Renin Activity

Measuring renin activity (traditionally called "plasma renin activity," or PRA) provides an indication of the biologically active fraction of renin in the specimen, because it measures the primary function of the enzyme, which is the conversion of angiotensinogen to angiotensin I. Renin activity measurements, however, are difficult to standardize, and two general approaches are used to measure renin activity. In the classic PRA method, first described in 1975,[94] inhibitors of angiotensinase and angiotensin-converting enzyme (ACE) are added to prevent the conversion of angiotensin I to angiotensin II (some methods "trap" angiotensin I with an antibody to prevent its conversion to angiotensin II), the specimen is incubated at 37 °C, and production of angiotensin I is measured. The rate of the reaction is influenced by pH, incubation time, and, most important, the endogenous angiotensinogen concentration in the specimen (which can be increased in pregnancy, glucocorticoid excess, and estrogen administration). Because the angiotensinogen concentration in blood does not ordinarily exceed the K_m for the renin-angiotensinogen complex, its concentration is rate limiting. Therefore, the classic PRA method produces results that vary significantly, depending on the endogenous concentration of angiotensinogen. An ELISA method has been described to measure angiotensinogen.[141] PRA procedures are also susceptible to variability associated with storage conditions.[42]

Although several variations of the classic PRA method exist, a typical approach involves the preparation of two aliquots of plasma. One of the aliquots is incubated at 37 °C for 3 hours, and the other is kept at 4 °C (renin is not active at cold temperature). Following the incubation period, angiotensin I is measured by RIA in both aliquots, and the difference between the two reflects the renin activity, expressed as pg of angiotensin I per mL of plasma. The specificity of the PRA assay can be validated using plasma from anephric patients or deangiotensinized plasma.[68]

A second approach to measuring renin activity uses exogenous angiotensinogen as substrate and thereby avoids the variability associated with endogenous angiotensinogen concentrations. This approach is sometimes called *plasma renin concentration assay,*[45,277] which is a confusing term in that the assay still involves the measurement of activity, rather than concentration. Furthermore, the term is not consistently applied; *plasma renin concentration* has been used in reference to immunoassays that measure the renin concentration, rather than activity.[16,42]

These renin activity methods use angiotensinogen derived from plasma collected from nephrectomized sheep; it is added at a concentration that is several times the K_m for the renin-angiotensinogen complex, ensuring that the reaction rate is limited by renin activity alone. The advantage of using a consistent source of angiotensinogen is that the activity assays can be calibrated against renin reference materials; an International Reference Preparation of human renin (68/356), validated by bioassay, has been available since 1975.[17]

Prorenin exists in two forms, depending on whether the 46 amino acid "pro" segment is in an "open" or "closed" conformation. The open conformation of prorenin has the active site of the enzyme exposed, so this form is enzymatically active. In the blood, approximately 2% of prorenin is in the open conformation, but assay conditions such as cooling and low pH can cause the closed conformation of prorenin to open, which results in an overestimate of physiologic renin activity. Incubation of plasma at 22 °C for 24 hours reversibly activates (unfolds) approximately 5% of prorenin,[65] although incubation at 37 °C promotes refolding of the "pro" segment to its closed form.[252] In some assays, the closed prorenin is deliberately opened by acidification (pH 3.3) or incubation with trypsin, which removes the "pro" segment from prorenin altogether. These assays measure total renin and

prorenin by activating all of the prorenin and following with a standard renin activity assay.[284]

Care must be taken when measuring and interpreting renin activity in patients who are taking renin inhibitors, a relatively new class of drugs used to treat essential hypertension. Aliskiren was the first member of this class of drugs to be approved by the U.S. Food and Drug Administration (FDA). Renin activity will be suppressed in these patients, although renin and prorenin concentrations will be high.[45,277]

Measuring Angiotensin I and II

All renin activity assays rely on angiotensin I as a direct measure of renin activity and a surrogate marker for angiotensin II, which is the active form of the hormone. Angiotensin II has a very short half-life (1 to 2 minutes), and is difficult to measure.[48] Monoclonal antibodies with high affinity and specificity have been produced against angiotensin II. These have been used to develop a direct radioimmunoassay; as little as 0.8 fmol of angiotensin II in 2 mL of plasma has been detected without interference from angiotensin I.[296] When angiotensinogen and ACE are in sufficient supply, however, the concentration of the prohormone angiotensin I is a reliable estimate of renin activity and angiotensin II concentration in blood.[45] Most angiotensin I methods involve radioimmunoassay, but enzyme immunoassays,[128,278] HPLC,[154] and fluorescence polarization methods[183] have also been described. A 2009 report described a homogeneous immunoassay for angiotensin I that is based on luminescent oxygen channeling, a technology involving chemiluminescence stimulated by photoexcited singlet oxygen.[47]

Angiotensin I and angiotensin II have poor immunogenicity because of their small molecular size. They must be conjugated to proteins such as albumin, hemocyanin, or succinylated polylysine to be sufficiently immunogenic to elicit antibodies. Polyclonal antisera usually lack sufficient specificity to distinguish between the decapeptide, heptapeptide, and hexapeptide angiotensins. Problems associated with immunoassay of angiotensins have been reviewed.[284] Angiotensins are labile oligopeptides in plasma and can be generated in vitro even in frozen plasma. Therefore great care must be taken in the collection and storage of specimens for angiotensin assays.[118]

With continued improvement and availability of nonisotopic immunometric assays for direct measurement of the concentration of renin, activity assays may soon be replaced by direct mass assays for routine assessment of plasma renin. However, because physicians are so familiar with PRA testing results, renin mass assays will require realignment of physician practices.

Measuring Renin Concentration

As an alternative to the PRA assay, the concentration of renin can be measured by immunoassay (these methods are sometimes called *direct renin assays* or *mass assays*). As discussed previously, immunoassays for renin cross-react with prorenin in both closed and open conformations, and assays based on monoclonal antibodies are likely to have the highest specificity for renin. A variety of monoclonal immunoradiometric assays (IRMAs) for renin have been developed, some of which measure renin and prorenin in the open configuration, and others that measure all forms of renin and prorenin.[45] An example of a two-site IRMA was described by Simon and coworkers.[295] This assay uses two monoclonal antibodies, and the specificity of the assay was verified by immunoprecipitation of prorenin with a monoclonal antibody directed to the "pro" sequence. The method had a limit of detection of 3.5 ng/L and is linear from 7 to 270 ng/L. Immunochemiluminometric (ICL) methods for renin are also available, and the results of these assays have been correlated with IRMA results. One such assay[62] involves a biotinylated capture antibody (which recognizes both renin and prorenin) immobilized to streptavidin-coated magnetic particles, and an acridinium ester–labeled signal antibody that recognizes only renin.[120] The chemiluminescent assay had a limit of detection of less than 0.1 mU/L and a functional sensitivity (CV <20%) of 2.6 mU/L.

Direct renin immunoassays (both IRMA and ICL) have been compared with renin activity assays.[115] With direct renin results expressed in mIU/L, and PRA results expressed in ng • mL^{-1} • h^{-1}, the overall correlation coefficient was 0.98, and the standard error of the residuals was 11.8 mU/L. Better interlaboratory agreement with direct renin assay results compared with PRA has been reported.[212]

The aldosterone-to-renin ratio (ARR), based on aldosterone concentration and PRA, was proposed[122] in 1981 as a sensitive screening test for primary hyperaldosteronism in normokalemic patients. The screening thresholds for ARR have been re-established using measurements of renin concentration, rather than activity.[87]

Specimen Collection and Storage

EDTA plasma is typically used for PRA assays. After centrifugation, plasma should be removed and frozen at −20 °C or lower, although the renin concentration is stable in unseparated blood at room temperature for up to 6 hours. Plasma for PRA can be stored frozen up to 1 month before assay, but freeze-thaw cycles should be avoided because of the possible activation of prorenin. At the time of collection, blood should not be chilled or placed on ice because irreversible cryoactivation of prorenin can occur, leading to falsely high estimates of PRA. Serum or plasma collected in another anticoagulant can also be used as long as EDTA is added (3 mmol/L) before incubation, because it inhibits ACE. Cryoactivation of prorenin, however, is more likely in serum than in plasma. Hemolyzed specimens should not be used because red blood cells contain angiotensinases.

The patient should be ambulatory for 2 hours before blood collection. A 24 hour urine specimen for sodium is often collected on the day before the renin test to reference the result to salt intake. Specimens with high renin activity can generate considerable amounts of angiotensin I before and during storage even at −20 °C. This will not affect results, however, because angiotensin I is determined with and without the incubation step.
