CHAPTER 55

The Thyroid: Pathophysiology and Thyroid Function Testing

*William E. Winter, M.D., Desmond Schatz, M.D., and Roger L. Bertholf, Ph.D.**

The thyroid is a butterfly-shaped gland located in the front of the neck, just above the trachea. The fully developed thyroid gland in a human is composed of two lobes connected by a thin band of tissue, the isthmus, which gives the gland the appearance of a butterfly. The gland is closely attached to the trachea in the anterior aspect of the neck. Anatomically and embryologically, the thyroid gland is two glands in one: the thyroid follicular cells produce thyroid hormones and the parafollicular (or C) cells secrete calcitonin.[21]

THYROID GLAND: STRUCTURAL AND FUNCTIONAL ONTOGENY

Embryologically at day 24, the thyroid gland develops from an anterior outpouching of the foregut. From this thyroid diverticulum, the thyroid gland descends, and the process is usually complete at 7 weeks. Failure of descent can produce (1) a lingual thyroid gland (located at the base of the tongue), (2) an ectopic gland, or (3) a hypoplastic or aplastic gland. Coincident with thyroid development, the parafollicular (C cells) cells (producing calcitonin) develop.

The fetus is dependent on the transplacental passage of maternal thyroid hormone for the first half of gestation.[26,29,65,225] Although only minute amounts of maternal thyroid hormone cross the placenta, maternal hypothyroidism in the first 20 weeks of gestation may adversely impact fetal central nervous system (CNS) development, leading to neuropsychologic impairment in infants and children.[178] Worldwide, the most common cause of hypothyroidism during pregnancy is iodine deficiency. Conversely, in developed countries, where iodine fortification is widespread, the most common cause of primary hypothyroidism is Hashimoto thyroiditis (chronic autoimmune thyroiditis/inflammation of the thyroid gland).

Hypothalamic thyrotropin-releasing hormone (TRH) stimulates thyrotropin [thyroid-stimulating hormone (TSH)], which in turn stimulates thyroid hormone synthesis. By 10 weeks, fetal thyroid follicles and thyroxine synthesis are demonstrable. By the mid second trimester, maturation of the hypothalamic-pituitary-thyroid axis occurs, so that by 20 weeks, the fetus is becoming responsible for its own production of thyroid hormone. Thyroxine-binding globulin (TBG) and thyroxine are first detectable in fetal serum at 8 to 10 weeks' gestation and increase thereafter until they plateau at 35 to 37 weeks (Figure 55-1). Thyroxine [tetraiodothyronine (T_4); see Table 55-1 for nomenclature and abbreviations) and TSH rise until birth, with T_4 near ≈10 μg/dL and TSH reaching a concentration of 7 to 10 mIU/L. Beginning at ≈30 weeks, T_4 is converted to triiodothyronine (T_3) by increased activity of the type 1 deiodinase (D1), so that T_3 concentrations rise, while reverse T_3 (rT_3) concentrations decline. At 30 weeks, T_3 is less than 15 ng/dL; at term, T_3 is ≈50 ng/dL.

Within hours of birth, TSH, T_4, and T_3 rise rapidly (Figure 55-2).[52] Cold stress is believed to be responsible for the massive TSH surge to concentrations of 70 to 100 mIU/L. By 2 to 3 days, the TSH concentration falls in most cases to less than 20 mIU/L. Total T_4 peaks near ≈17 μg/dL. T_4 then falls to adult concentrations by 1 to 2 months of age. The postbirth rise in T_3 results from increased thyroid gland release in response to the rising TSH concentration and increased conversion of T_4 to T_3 due to maturation of the type 1 deiodinase enzyme (D1).

The authors gratefully acknowledge the previous contributions of L. M. Demers and C. Spencer, on which portions of this chapter are based.

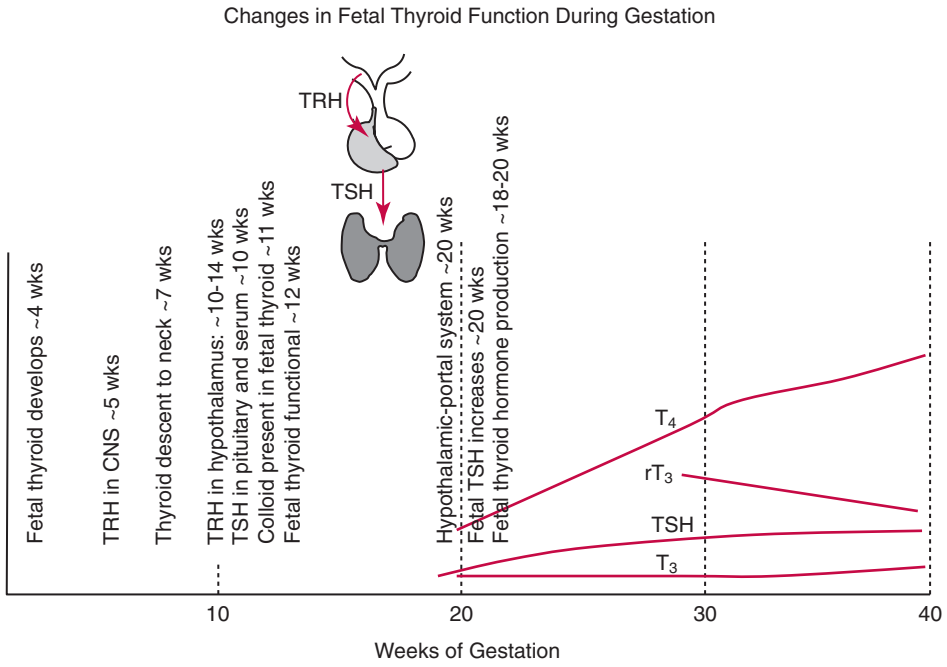

Figure 55-1 Changes in fetal thyroid function during gestation. During the first half of gestation, the fetus is dependent on transplacental passage of thyroid hormone. After mid gestation, the fetus produces its own thyroid hormone.

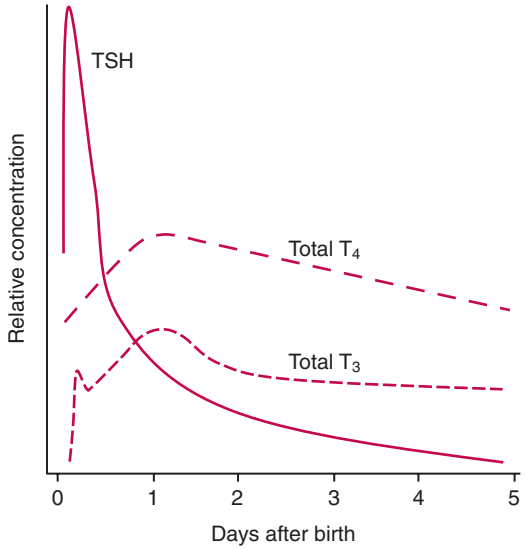

Figure 55-2 Concentrations of thyroid hormones for 5 days after birth. After birth, an immediate TSH surge peaks at ≈30 minutes. T_3 and T_4 rapidly rise, peaking at ≈24 hours after delivery. The greater initial rise in T_3 as compared with T_4 in the first 24 hours of life likely represents acutely increased conversion of T_4 to T_3. Following their peak concentrations, T_4 and T_3 decline to stable concentrations.

THYROID GLAND ANATOMY

The adult thyroid gland weighs between 15 and 20 g. However, in disease states, the gland can attain a weight of several hundred grams. The thyroid gland is normally bilobed, with the right lobe somewhat larger than the left lobe. In adults, the lobes are ≈2.0 to 2.5 cm thick by ≈2.0 to 2.5 cm wide by ≈4 cm high. The lobes are connected by the isthmus, which is ≈0.5 cm thick by ≈2.0 cm wide by ≈1 to 2 cm high.

Microscopically, the thyroid gland is composed of follicles or acini (Figure 55-3, *A*). The outside of the follicular unit/acinus is enveloped by a basement membrane. Along the inside of the basement membrane are squamous or cuboidal epithelial follicular cells. The height of the follicular cells reflects their biochemical activity: the greater their height, the more thyroid hormone synthetic activity is occurring. The basal pole of the follicular cell is oriented toward the basement membrane, and the apical pole is oriented toward the center of the follicle (Figure 55-3, *B*). In the center of the follicle, lined by the apical aspects of the follicular cells, is the lacuna, which contains colloid composed predominantly of thyroglobulin.

On average, follicles are ≈200 microns wide (compared with a normal red blood cell diameter of 7 microns). The parafollicular cells usually are located below the basement membrane but are not adjacent to the lumen (lacuna) of the follicle. Without immunohistochemical staining for calcitonin, the parafollicular cells are very difficult to identify.

Branches of the common carotid artery (the superior thyroid arteries) and the subclavian arteries (the inferior thyroid arteries) supply the thyroid. It is surprising to note that on a per gram basis, the thyroid gland receives more blood than the kidney: 4 to 6 mL/min/g of thyroid tissue versus 3 mL/min/g of kidney. In cases of hyperthyroidism, blood flow to the entire thyroid gland can exceed 1000 mL/min, which is ≈20% of the normal cardiac output of an adult.

TABLE 55-1 Nomenclature and Abbreviations for Thyroid Tests

Name	Abbreviation
Hormones	
Total thyroxine	T_4
Total triiodothyronine (3,5,3′-triiodothyronine)	T_3
Free thyroxine	FT_4
Free triiodothyronine	FT_3
Thyrotropin (thyroid-stimulating hormone)	TSH
Reverse T_3 (3,3′,5′-triiodothyronine)	rT_3
Serum-Binding Proteins	
Thyroxine-binding globulin	TBG
Thyroxine-binding prealbumin (transthyretin)	TBPA
Thyroxine-binding proteins	TBP
Tests for Autoimmune Thyroid Disease	
Thyroglobulin autoantibodies	TGA
Thyroid microsomal autoantibodies	TMA
Thyroperoxidase autoantibodies	TPOA
TSH receptor autoantibodies	TRA
Thyroid-stimulating immunoglobulins	TSI
Thyrotropin-binding inhibitory immunoglobulin	TBII
Other Hormones, Thyroid-Related Proteins, and Conditions	
Thyrotropin-releasing hormone	TRH
Thyroglobulin	Tg
Thyroid hormone receptor	TR
Thyroperoxidase	TPO
TSH receptor autoantibodies	TRA
Thyroid hormone receptor-alpha	THRA
Thyroid hormone receptor-beta	THRB
Autoimmune thyroid disease	AITD
Calcitonin	CT

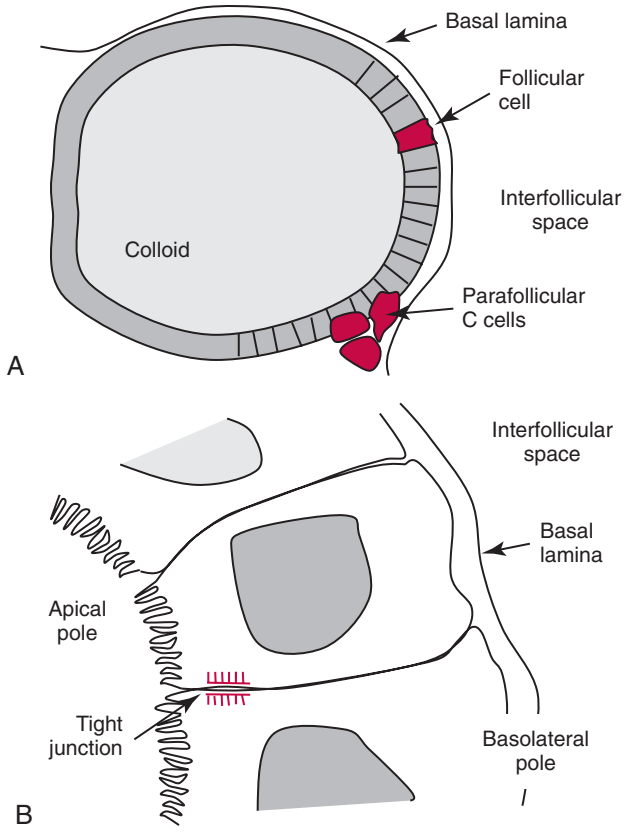

Figure 55-3 A, Basic unit of the thyroid gland. The follicle is the basic unit of the thyroid gland. It is composed of thyroid follicular cells surrounding the colloid. Outside the follicular cells is a basal lamina. B, Apical and basolateral poles of the follicular cells and tight junctions between the follicular cells. Parafollicular (C cells) that secrete calcitonin can be found beneath or outside the basal lamina. Not pictured between the follicles are capillaries and fibroblasts.

BIOLOGICAL FUNCTION

Thyroid hormones (T_4 and T_3) bind to intranuclear receptors that function as transcription factors and thereby regulate gene expression. Thyroid hormones have ubiquitous effects on growth and development in the fetus, child, and adolescent, and they regulate calorigenesis and metabolic rate throughout life. At a molecular level, thyroid hormones (1) increase oxygen consumption within tissues via increased membrane transport (cycling of sodium/potassium ATPase with increased synthesis and consumption of adenosine triphosphate), (2) enhance mitochondrial metabolism (stimulation of mitochondrial respiration and oxidative phosphorylation), (3) increase sensitivity to catecholamines with increased heart rate and myocardial contractility, (4) stimulate protein synthesis and carbohydrate metabolism, (5) increase synthesis and degradation of cholesterol and triglycerides (e.g., regulation of low density lipoprotein receptor expression by the liver), (6) increase vitamin requirements, and (7) regulate calcium and phosphorous metabolism.

Thyroid hormones maintains the basal metabolic rate and thus regulates the metabolism of endogenous and exogenous substances. Hypothyroidism impairs the excretion of many drugs, with hyperthyroidism accelerating their clearance.

BIOCHEMISTRY

Thyroid hormone is derived from the amino acid tyrosine. Thyronine is produced by substitution of a second phenol moiety for the phenolic hydrogen on tyrosine, producing a diphenyl ether having two phenol rings attached to one another through an ether linkage (Figure 55-4).

There are four possible sites for iodine attachment to thyronine at the meta positions on both phenyl rings, designated the 3, 5, 3′, and 5′ positions. The 3 and 5 positions are on

the alpha (inner) ring, and the 3′ and 5′ positions are on the beta (outer) ring. The biologically important thyroid hormones are 3,5,3′,5′-tetraiodothyronine [thyroxine (T_4)] and 3,5,3′-triiodothyronine (T_3). Debate continues over whether T_4 has any intrinsic biological activity, or whether it is a prohormone.

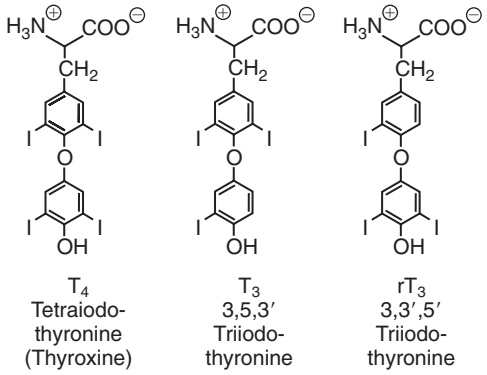

Figure 55-4 Chemical structures of T_4, T_3, and rT_3.

Iodination of tyrosine to ultimately produce T_4 and T_3 involves the tyrosine residues on thyroglobulin.[86] An isomer of T_3 is reverse T_3 (rT_3), in which the alpha ring is monoiodinated and the beta ring is di-iodinated, producing 3,3′,5′-L-triiodothyronine. Reverse T_3 is not biologically active. Almost all rT_3 is formed by the extrathyroidal conversion of T_4 to rT_3, and approximately 80% of T_3 is formed by extrathyroidal monodeiodination of T_4 to T_3.

Thyroid hormone biosynthesis begins with the active transport of iodide (I^-) into the thyroid gland via the Na^+/I^- (sodium-iodide) symporter (NIS, SLC5A; SLC = solute carrier; chromosome 19p12-13.2; Figure 55-5).[20] Iodide transport is inhibited by lithium, which competes with sodium, but the NIS transports other anions besides iodide. In the follicular cells, the iodine concentration is 30- to 40-fold greater than the circulating concentration. When the thyroid gland is stimulated by TSH, even larger iodide concentration gradients can result. Antithyroid drugs such as propylthiouracil and methimazole inhibit iodination and coupling; this can lead to an 800-fold difference in the concentration of iodide in the thyroid gland versus the plasma.

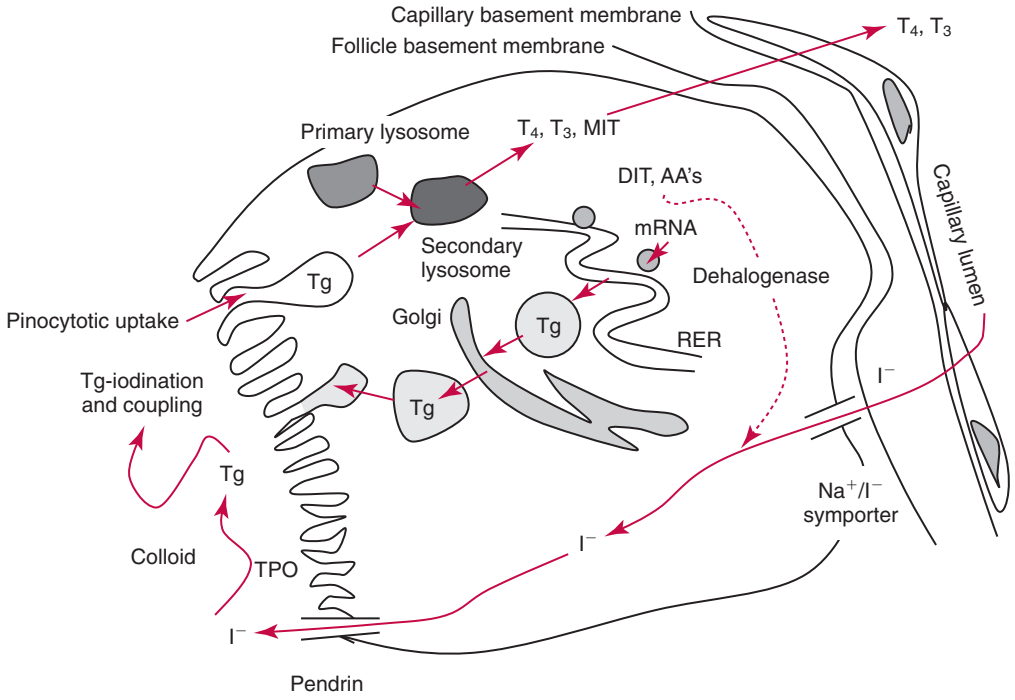

Figure 55-5 Synthesis of thyroid hormones begins with absorption of iodide by the thyroid follicular cell and the Na^+/I^- symporter (NIS). From the cytoplasm, iodide moves into the lacunae via pendrin. Within the lacunae, thyroperoxidase (TPO) and the dual oxidases [DUOX (not depicted)] convert iodide to iodine, leading to iodination of tyrosine residues on thyroglobulin (Tg). Tg is synthesized in the cell and exported to the lacunae. TPO is responsible for the coupling of monoiodotyrosine (MIT) and di-iodotyrosine (DIT) to form T_3, and di-iodotyrosine and di-iodotyrosine to form T_4. Upon uptake of iodinated Tg (containing T_4 and T_3) and fusion of this phagosome-like vesicle with a primary lysosome, Tg is degraded in a secondary lysosome, releasing T_4 and T_3 into the circulation and MIT and DIT undergo deiodination via a dehalogenase to recycle the iodine for new thyroid hormone synthesis.

Once in the thyroid follicular cells, cytoplasmic iodide moves into the lacuna (colloid) via pendrin (*SLC26A4* gene on chromosome 7q21-34) (see Figure 55-5).[88] Pendrin is a passive iodide-transporting glycoprotein identified during studies of patients with Pendred syndrome. Pendred syndrome is an autosomal recessive disorder of dyshormonogenesis that is characterized by goiter and sensorineural deafness.

Thyroglobulin (Tg) is necessary for thyroid hormone synthesis. Similar to other proteins, Tg is synthesized in follicular epithelial cells by ribosomes located on the endoplasmic reticulum (see Figure 55-5). Tg may represent up to 50% of protein synthesis in the thyroid gland and may account for 75% of glandular total protein.

The 42-exon gene encoding Tg is located on chromosome 8q24 and spans 250 kilobases. Tg is a glycoprotein homodimer of 660 kDa. A total of 134 tyrosine residues are found in the homodimer, and 25 to 30 of these residues are iodinated. However, T_4 is formed only at residues 5, 1290, and 2553, and T_3 is formed only at residue 2746. The Tg sedimentation coefficient of 19S is similar to that of circulating pentameric IgM, reflecting the large size of Tg. TSH is the principal stimulator of Tg synthesis. Thyroid transcription factor 1 (TTF1) interacts with the Tg promoter to stimulate Tg mRNA synthesis.

Although most Tg is secreted into the follicular lumen, a small amount of Tg is released from the follicular cells without transport into the colloid, and this Tg is not iodinated. Of consequence in autoimmune thyroid disease, iodination increases the immunogenicity of Tg. Increased dietary iodine exposure is associated with the development or expression of Hashimoto thyroiditis.[112]

Once in the lacuna, iodide is oxidized ("organified") to an iodine radical by the thyroperoxidase (TPO) enzyme. Hydrogen peroxide (H_2O_2) serves as the terminal electron acceptor, forming $H_2O_2^-$.[185] Hydrogen peroxide is generated at the apical membrane by the action of DUOX1 and DUOX2 (DUOX was previously known as THOX, or thyroid oxidase). DUOX is a dual oxidase that has domains analogous to the domains found in nicotinamide adenine dinucleotide phosphate (NADPH) oxidoreductases. Hypothyroidism due to *DUOX* mutations has been reported.[130]

TPO catalyzes the monoiodination of Tg tyrosines to monoiodotyrosine (MIT) (Figure 55-6). Di-iodination of tyrosine forms di-iodotyrosine (DIT) (Figure 55-6). After Tg is iodinated to form MIT and DIT, TPO catalyzes the coupling reaction to produce T_4 (Figure 55-7) and T_3 (Figure 55-8). In the coupling reaction, T_3 (bound to Tg) is formed from one DIT and one MIT residue with the transfer of one monoiodinated phenolic group to a DIT residue. T_4 (bound to Tg) is formed from two DIT residues with the transfer of one di-iodinated phenolic group to another DIT residue.

Tg, along with its T_3 and T_4 residues, remains in the colloid, providing a reservoir of thyroid hormone. With TSH stimulation, the apical pole of the follicular cell releases colloid into a vesicle by pinocytosis (see Figure 55-5). The follicular cell digests the intravesicular colloid containing Tg after fusion of the phagosome body with a primary lysosome. Fusion of the endocytosed Tg with the primary lysosome forms a secondary lysosome, in which digestion of Tg occurs, releasing T_4, T_3, MIT, DIT, and amino acids. By diffusion, the lipophilic T_4 and T_3 molecules exit the lysosome and cross the follicular cell plasma membrane to be captured in thyroid capillaries, where the vast majority of thyroid hormone is protein bound. Only 0.03% of total T_4 is free (unbound and bioactive), and only 0.3% of total T_3 is unbound and bioactive.

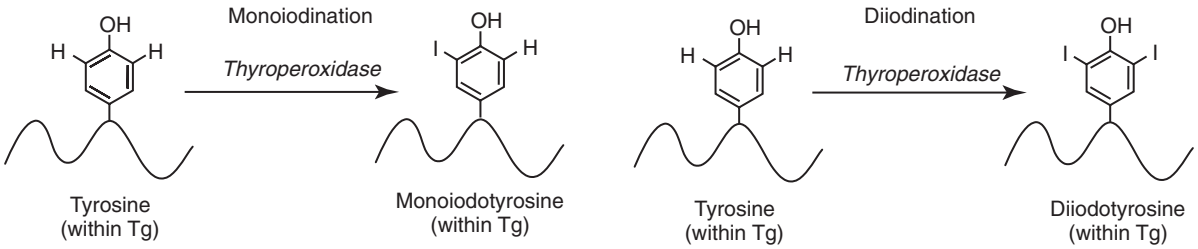

Figure 55-6 Monoiodination and di-iodination of tyrosine.

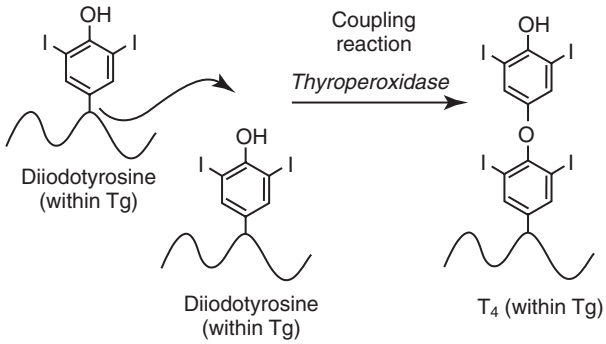

Figure 55-7 Chemical coupling of two molecules of di-iodotyrosine to produce a molecule of T_4 (thyroxine). The reaction is catalyzed by thyroperoxidase.

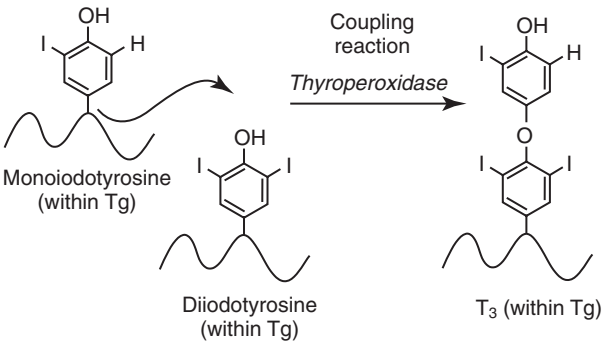

Figure 55-8 Chemical coupling of one molecule of monoiodotyrosine and one molecule of di-iodotyrosine to produce one molecule of T_3. The reaction is catalyzed by thyroperoxidase.

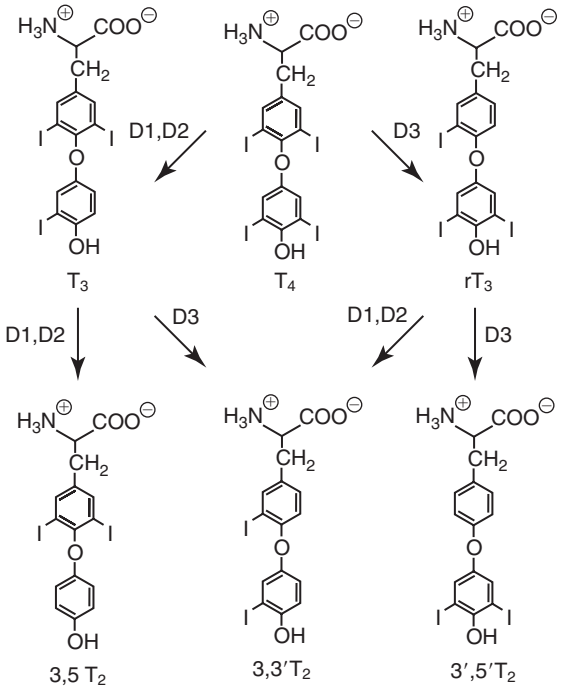

Figure 55-9 Metabolic pathways of T_4. Type 1 deiodinase (D1) converts T_4 to T_3 or rT_3. D1 then converts T_3 to 3,3′-T_2, while D1 converts rT_3 to 3,3′-T_2. Type 2 deiodinase (D2) converts T_4 to T_3 and rT_3 to 3,3′-T_2. Type 3 deiodinase (D3) converts T_4 to rT_3 and T_3 to 3,3′-T_2.

Within the cytoplasm of the follicular cell, the released MIT and DIT are stripped of iodine by dehalogenase (Dhal) to produce free iodide ions, which can be recycled immediately for the synthesis of new thyroid hormone.[64] Two dehalogenase genes have been described: *Dhal1* and *Dhal1b*. Normally, only negligible amounts of MIT and DIT are released from the thyroid gland into the circulation. However, loss-of-function mutations in the dehalogenase enzyme potentially lead to iodine loss in the urine and increased concentrations of DIT and MIT in the circulation.

The peripheral metabolism of thyroid hormones is very complex.[191] Three homodimeric deiodinases are present: type 1 (D1), with inner and outer ring deiodinase activities found in liver, kidney, thyroid, and possibly the anterior pituitary gland (Figure 55-9); type 2 (D2), with outer ring deiodinase activity expressed in the CNS, anterior pituitary, brown fat, placenta, heart, skeletal muscle, and thyroid; and type 3 (D3), with inner ring deiodinase activity identified in CNS, liver, endometrium, and placenta. Approximately 40% of T_4 is deiodinated to T_3 by D1 or D2, and ≈45% is deiodinated to rT_3 by D1 or D3. About 80% of circulating T_3 comes from 5′-deiodination of T_4; only ≈20% of T_3 is released directly from the thyroid gland (Figure 55-9). Almost all circulating rT_3 results from 5-deiodination of T_4. By regulating the conversion of T_4 to T_3, the body, in part, regulates the metabolic rate.

D1 converts T_4 to rT_3 (via 5-deiodination) and T_4 to T_3 (via 5′-deiodination) (Figure 55-10). The preferred substrates for D1 are sulfated T_3 (converted to 3,3′-T_2 via 5-deiodination) and rT_3 (converted to 3,3′-T_2 via 5′-deiodination). D1 activity is stimulated by thyroid hormone through increased gene

transcription. Thus, increased D1 activity promotes peripheral conversion of T_4 to T_3 in hyperthyroidism. Therapeutically, D1 is inhibited by propylthiouracil, which is used to treat hyperthyroidism. In contrast to the effect of thyroid hormone on D1, D2 expression is suppressed by thyroid hormone. The K_m for the D1-T4 complex is approximately 1000-fold greater than the corresponding K_m for D2 or D3. Regulation of the $T_4 \rightarrow T_3$ and $T_4 \rightarrow rT_3$ conversions is dependent on the tissue distribution of D1, D2, and D3. The free T_3 (FT_3)-to-T_4 (FT_4) ratio is affected by a genetic polymorphism in the D1 gene (*DIO1;* the single-nucleotide polymorphism rs2235544).[143]

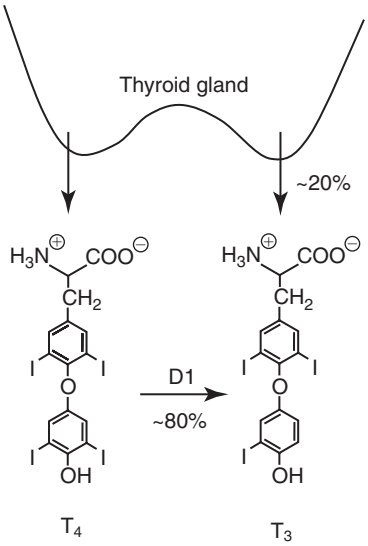

Figure 55-10 Metabolic sources of T_4 and T_3. The only source of T_4 is the thyroid gland. However, most T_3 (≈80%) comes from peripheral monodeiodination of T_4 to T_3 [catalyzed by type 1 deiodinase (D1) and type 2 deiodinase (D2)] with only a minority of T_3 (≈20%) coming directly from the thyroid gland.

Each of the deiodinase enzymes has a single transmembrane domain. The deiodinases are attached to the inner plasma membrane (D1 and D3) or endoplasmic reticulum (D2), and the active site of the enzyme is on the cytoplasmic domain. Therefore, thyroid hormone must enter the cytoplasm of cells to be metabolized. In addition to thyroid hormone metabolism via deiodination, small amounts of T_4 are glucuronidated or sulfated and excreted in the bile. Intestinal cleavage of glucuronidated T_4 releases T_4 that can then be reabsorbed from the intestine back into the circulation.

Until recently it was believed that both T_4 and T_3 entered cells by passive diffusion across the plasma membrane. However, evidence has shown that thyroid hormones cross plasma membranes using specific transporters.[74] One important thyroid hormone transporter is monocarboxylate transporter 8 (MCT8).[118] The solute carrier family of monocarboxylate transporters has 14 members (MCT1 through MCT14); examples of other monocarboxylates transported by these carriers are lactate and pyruvate.

It has been shown that MCT10 (*SLC16A10;* chromosome 6q) transports iodothyronines and aromatic amino acids across membranes, and MCT10 is likely more preferential than MCT8 in transporting T_3 over T_4 across plasma membranes. Organic anion transporting polypeptide 1C1 (OATP1C1) also has high affinity for thyroid hormone and may be an important component of the transport of T_3 and T_4.

Transport of thyroid hormone into neurons is especially critical for normal CNS development and function (Figure 55-11). OATP1C1 may be responsible for thyroid hormone uptake and release by astrocytes, although this has not yet

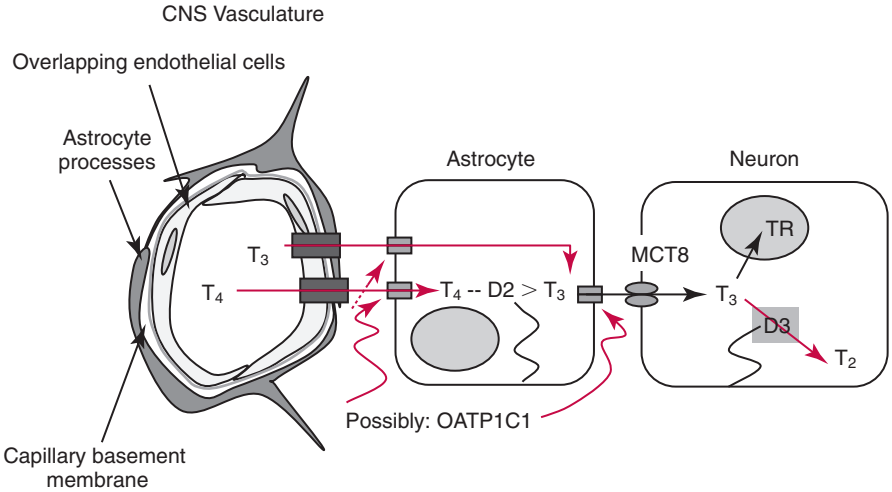

Figure 55-11 Transport of thyroid hormones to neurons. Before thyroid hormones are transported to neurons, T_4 and T_3 pass through endothelial cells and astrocytes. Organic anion–transporting polypeptide 1C1 (OATP1C1) may allow astrocyte uptake of T_4 and T_3. Within the astrocyte, T_4 may be converted to T_3 via type 2 deiodinase (D2). T_3 then may leave the astrocyte via OATP1C1 to enter neurons via monocarboxylate transporter 8 (MCT8). Within the neuron, T_3 can interact with a thyroid hormone receptor (TR) or can be converted to 3,3′-T_2 via type 3 deiodinase (D3).

been definitively demonstrated. Within the astrocyte, T_4 is converted to T_3 via D2 attached to the astrocyte membrane. T_3 may exit the astrocyte via OATP1C1 to be taken up by neurons via MCT8. Within the neuron, T_3 can interact with the intranuclear thyroid hormone receptor (TR), or can be converted to 3,3′-T_2 via membrane-attached D3.

Although T_4 is converted to T_3 outside of target organs (the liver converts T_4 to T_3 and then releases T_3 back into the circulation), target organs can also deiodinate T_4 to T_3 so that T_3 can bind to TRs. The liver, kidney, brain, brown fat, anterior pituitary, pineal, heart, skeletal muscle, and placenta all express a 5′-deiodinase capable of deriving T_3 from T_4.

T_3 binds to specific intranuclear TRs to exert its hormonal effects. In humans (and various animals), thyroid hormone upregulates the expression of growth hormone,[110] myelin basic protein, the alpha-myosin heavy chain, and a sarcoplasmic reticulum calcium ATPase, while downregulating the expression of the TSH beta chain and the beta-myosin heavy chain. In part, suppression of TSH beta chain synthesis contributes to negative feedback.

TRs are members of the steroid hormone supergene family and serve as transcription factors that include domains for DNA binding, T_3 binding, and transactivation. T_3 binds to the TRs with 15-fold greater affinity than T_4. The TRs form heterodimers with the retinoid X receptor (RXR) to interact with the thyroid response elements (TREs) in DNA. Monomers and homodimers of TRs can also bind to the TREs. TRs have zinc-finger structures that form alpha helices for interaction with the response elements.

Two types of TRs are known: TRα and TRβ (Table 55-2).[218] TRα is encoded by the thyroid hormone receptor-alpha *(THRA)* gene on chromosome 17q11.2. Of its two expressed isoforms (TRα1 and TRα2), only TRα1 binds thyroid hormone. A TRα3 isoform produced by alternative splicing has also been reported. TRα1 is expressed throughout the body, but its mRNA is in highest concentrations in the heart, brain, liver, and kidneys.

TRβ is encoded by 11 exons on the thyroid hormone receptor-beta *(THRB)* gene on chromosome 3p24.3. Three isoforms of TRβ exist: TRβ1, TRβ2, and TRβ3. The highest concentrations of TRβ1 are found in heart, kidney, liver, and brain. Expression of TRβ2 has been identified in the anterior pituitary, hypothalamus, retina, cochlea of the inner ear, and developing brain. Defects in TRβ1 can produce resistance to thyroid hormone; defects in TRα have not been reported.

Within most cells, ≈90% of T_3 is cytosolic and ≈10% is intranuclear. An exception is seen in the pituitary gland, where T_3 is distributed approximately equally between the cytoplasm and the nucleus. A T_3-binding protein (CTBP, or C-T_3BP) has been identified that may influence the intracellular distribution of thyroid hormone; however, this protein does not exhibit receptor activity.

It is important to consider the comparative biological activity of circulating T_4 and T_3. On a molar basis, there is ≈100 times as much circulating T_4 as T_3. Typical reference intervals for T_4 and T_3 are 60 to 135 nmol/Land 1 to 3.5, nmol/L, respectively. The difference in T_4 and T_3 concentrations narrows, however, to a 10-fold excess of free (active) T_4, compared with unbound T_3, in the circulation. Because T_3 is 4 to 15 times as biologically active as T_4, the difference in effectiveness narrows further. It is debated whether the effects of T_4 exceed those of T_3, or whether they equally influence the tissues. Within the cells of the anterior pituitary, large intracellular amounts of T_3 are derived from monodeiodination of T_4, so circulating FT_4 appears to be the major regulator of pituitary TSH secretion. This is an important concept that explains why TSH remains normal in the early stages of the sick euthyroid syndrome, when FT_4 is normal, preventing a rise in TSH, yet the T_3 is decreased.

In the pituitary, most T_3 is derived from intrapituitary conversion of T_4 to T_3. Within target tissues, if more T_3 comes from T_4 (via target cell 5′-deiodination) than from the circulation itself, T_4 has a major effect on tissues. Nevertheless because most T_3 is derived from T_4, within the circulation or within a target cell, T_4 is often considered to be a prohormone in the generation of T_3.

Compared with the kidney, liver, and cerebral cortex, much higher concentrations of TRs are found in the anterior pituitary gland and brown adipose tissue. In both of the latter tissues, two thirds to three quarters of the receptors are occupied by T_3, with slightly more than half of the T_3 derived from intracellular conversion of T_4 to T_3 via D2, versus T_3 taken up from the circulation (derived from T_4 outside the target tissue by D1 and D2). Most of the hepatic and renal T_3 comes from circulating hormone. On the other hand, the vast majority of T_3 in the cerebral cortex is derived intracellularly from T_4 by monodeiodination of T_4 to T_3.

TABLE 55-2 Thyroid Hormone Receptor (TR) Sizes

	Amino Acids	kDa
TRα1	410	47
TRα2	490*	55
TRβ1	461	53
TRβ2	514†	58

*Extended C-terminal region (does not bind T_3).

PHYSIOLOGY

Thyroid Hormone Negative Feedback Control of TRH and TSH

Thyroid hormone synthesis and secretion are controlled by a negative feedback system involving the hypothalamus, the pituitary, and the thyroid follicular cells (Figure 55-12).[30] In contrast to other hypothalamic-anterior pituitary target organ systems that utilize a negative feedback system, however, the major site of thyroid hormone feedback is at the level of the anterior pituitary thyrotrophs—not at the level of the hypothalamus.

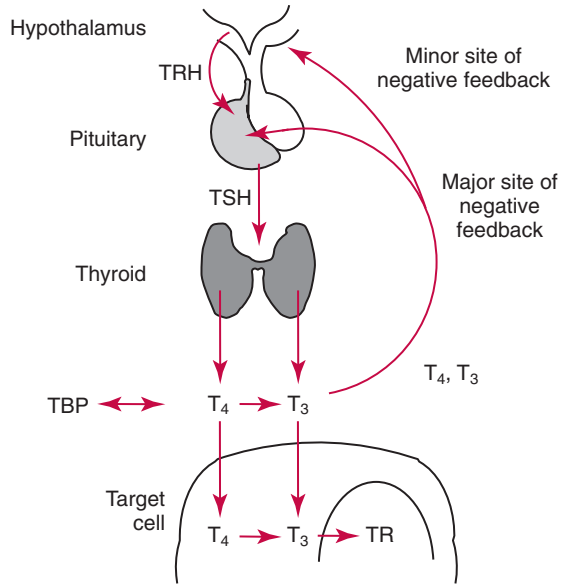

Figure 55-12 Metabolic control of thyroid hormones. Thyrotropin-releasing hormone (TRH) from the hypothalamus enters the hypothalamic-pituitary portal system to release thyroid-stimulating hormone (TSH; thyrotropin) from anterior pituitary thyrotrophs. TSH stimulates the release of T_4 and T_3 from the thyroid gland, although most T_3 comes from peripheral monodeiodination of T_4 to T_3. More than 99% of T_4 and T_3 is bound to various thyroid hormone–binding proteins. T_4 and T_3 negatively feed back on the hypothalamus and, more powerfully, the pituitary. T_4 and T_3 enter into target tissues, where T_4 is converted to T_3 with T_3 binding to the thyroid hormone receptor (TR).

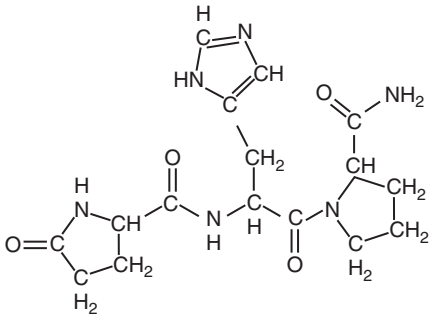

Figure 55-13 Chemical structure of thyrotropin-releasing hormone (TRH). Note that TRH is a tripeptide (L-pyroglutamyl-L-histidyl-L-prolinamide).

Hypothalamic Physiology

Thyrotropin-releasing hormone (TRH; thyrotropin-releasing factor, thyroliberin, or protirelin) is encoded on chromosome 3, and the modified tripeptide L-pyroglutamyl-L-histidyl-L-prolinamide is secreted by the paraventricular nuclei (PVN) in the hypothalamus (Figure 55-13). Cyclization of the glutamate terminus is required for TRH bioactivity. The PVN are located in the anterior hypothalamus, rostral to the optic chiasm. TRH concentrations rise in thyroid hormone deficiency with TRH declining when thyroid hormone is in excess. TRH is delivered to the anterior pituitary gland via the hypothalamic-pituitary portal system.

Anterior Pituitary Thyrotroph Physiology

Thyrotrophs, the anterior pituitary cells that secrete thyroid-stimulating hormone (TSH; thyrotropin), express TRH receptors, which are G-protein–coupled receptors with seven transmembrane domains. When TRH binds to its receptor, the thyrotroph depolarizes, triggering calcium influx. Consequently, increased free cytosolic calcium activates the Ca^{2+}-phosphatidylinositol cascade, effecting TSH release, synthesis, and glycosylation of alpha and beta TSH subunits. In relative terms, TRH has a greater effect on TSH glycosylation than hormone release.[165] However, glycosylation of TSH is necessary for normal TSH bioactivity. When TRH is deficient, TSH may lack potency as the result of insufficient glycosylation, yet nonglycosylated TSH may retain much of its immunoreactivity. Therefore, immunoassays for TSH may not reflect the activity of the hormone when injury or disease results in a TRH deficiency.

TRH modifies the sensitivity of the thyrotroph to thyroid hormone negative feedback; increased TRH makes the thyrotroph less sensitive to inhibition with decreasing TRH makes the thyrotroph more sensitive to negative feedback. The mechanism for TRH control involves reduced expression of TRs in the thyrotroph following TRH stimulation. When the thyrotroph is less sensitive to negative feedback from thyroid hormone, TSH release is potentiated. Therefore, TSH secretion rises in thyroid hormone deficiency and declines in thyroid hormone excess. An inverse logarithmic relationship exists between TSH and FT_4 concentrations (Figure 55-14); a 50% decline in FT_4 concentration results in a 100-fold increase in TSH.

TSH is a 30 kDa heterodimeric glycoprotein that shares a subunit with luteinizing hormone (LH), follicular stimulating hormone (FSH), and human chorionic gonadotropin (hCG).[174] All four hormones contain a 14.7 kDa alpha subunit (gene location: chromosome 6q21.1-q23). Each of these hormones has a unique beta subunit that is responsible for the specific activity of the hormone. The 15.6 kDa TSH beta chain is encoded by a three-exon gene located on chromosome 1p. The alpha chain contains two oligosaccharides, and the TSH beta subunit contains one oligosaccharide modification.

Thyroid Follicular Cell Physiology

The effects of TSH on the thyroid follicular cell are mediated through TSH receptor (TSHR)–G-protein–adenyl cyclase–coupled synthesis of intracellular cyclic adenosine monophosphate (cAMP).[197] At supraphysiologic concentrations (100× normal), TSH will signal through the inositol-phosphate diacylglycerol cascade, activating phospholipase C (PLC) and raising intracellular calcium concentrations, with

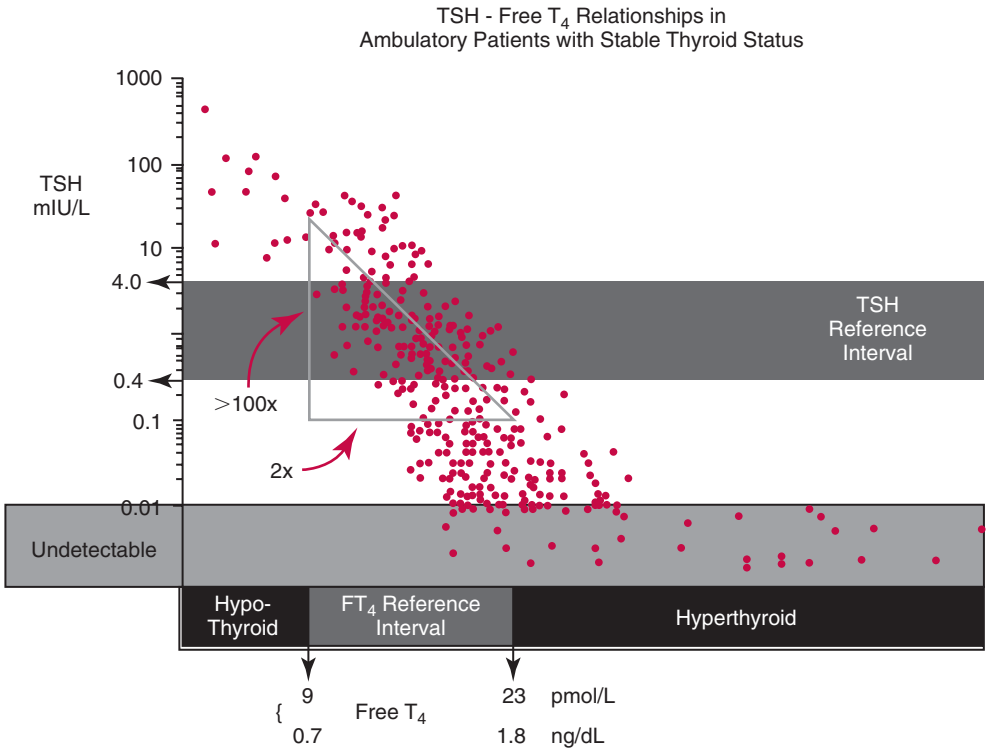

Figure 55-14 The log-linear relationship between thyroid-stimulating hormone (TSH) and FT_4. A twofold change in TSH is associated with an approximate 100-fold change in circulating FT_4 concentrations. *(Modified from Spencer CA, LoPresti JS, Patel A, Guttler RB, Eigen A, Shen D, et al. Applications of a new chemiluminometric thyrotropin assay to subnormal measurement. J Clin Endocrinol Metab 1990;70:453-60. Copyright © 1990, The Endocrine Society.)*

subsequent stimulation of H_2O_2 generation and iodide efflux into the follicular lumen.

The TSHR is a 743 amino acid, 84.5 kDa protein generated after cleavage of a 21 amino acid pre- (or leader) sequence. After post-translational glycosylation, the TSHR is ≈100 kDa. The first nine exons encode the 398 amino acid N-terminal extracellular domain. The extracellular domain contains six N-glycosylation sites that make up the TSH-binding domain. The TSHR may be in either of two conformations: the "on" conformation, with active signaling, or the "off" conformation, where signaling does not occur. TSH binding to the TSHR puts it in the "on" conformation, leading to stimulation of the thyroid gland.

Within the TSH-stimulated thyroid follicular cell, the activity of the sodium-iodine symporter increases; increased synthesis of thyroglobulin (Tg) and TPO, increased generation of hydrogen peroxide and NADPH, and pinocytosis of colloid with consequent degradation and release of T_4 and T_3 from Tg are also noted. Replication of thyroid follicular cells is stimulated by cAMP, phospholipase C, insulin-like growth factor-I (IGF-I), and a fibroblastic growth factor (FGF)-mediated kinase. TSH stimulation increases the size and number of thyroid follicular cells. Likewise, follicular cellular hyperplasia is seen in Graves' disease, when an agonistic autoantibody stimulates the TSH receptor.

THYROID HORMONES IN THE CIRCULATION

Both T_4 and T_3 are highly bound to plasma proteins in circulation. Protein-bound T_4 and T_3 serve as thyroid hormone reservoirs within plasma. In the thyroid gland, Tg serves as a reservoir. The unbound fraction of circulating thyroid hormone is the biologically active form, so FT_4 concentrations correlate more closely with the clinical status of the patient than do total T_4 concentrations.[15,142] However, elevations in FT_3 usually correlate with the clinical status of the patient, low FT_3 concentrations do not always equate with clinical hypothyroidism, as evidenced in the sick euthyroid syndrome (see later). Similarly, elevated free concentrations of T_4 or T_3 do not always correlate with hyperthyroidism because of the possibility of peripheral thyroid hormone resistance syndromes and rare MCT8 loss-of-function mutations. Alterations in the concentrations of thyroid hormone–binding proteins can profoundly affect the total concentrations of T_4 and T_3 without significant changes in the free hormone concentrations.

T_4 binds to thyroxine-binding globulin (TBG; a 54 kDa α_1-globulin), thyroxine-binding prealbumin (TBPA, or transthyretin; 54 kDa), and albumin. T_3 binds almost exclusively to TBG and albumin; TBPA binds only negligible amounts of T_3 (Table 55-3).[176] On serum protein electrophoresis, TBPA

migrates in the prealbumin region (hence, its name). TBG (chromosome Xq11-23) is a 395 amino acid acidic glycoprotein with one iodothyronine-binding site. TBG has 4 heterosaccharide sidechains with 5 to 9 sialic acid moieties. As the degree of sialylation increases (an effect of estrogen), the half-life of TBG increases, thus raising TBG concentrations.

Increased concentrations of TBG raise total T_4, yet FT_4 remains within the euthyroid interval as the result of negative feedback (see Figure 55-12). Similarly, decreased TBG concentrations lower total T_4 while maintaining normal FT_4.

Causes of elevations and depressions in thyroid hormone–binding protein (TBP) are shown in Box 55-1. In congenital TBG excess (an X-linked dominant condition), male hemizygotes display threefold to fivefold elevations in TBG concentration, while female heterozygotes typically have twofold to threefold elevations in TBG. Abnormal forms of albumin (familial dysalbuminemic hyperthyroxinemia) and TBPA (familial euthyroid thyroid excess) alter the concentrations of total T_4, yet do not affect FT_4, total T_3, or FT_3. These conditions are discussed later, along with antithyroid hormone autoantibodies that raise total thyroid hormone concentrations. Isolated euthyroid hypertriiodothyroninemia (with all other thyroid parameters normal) caused by a rare form of dysalbuminemia has been reported.

TABLE 55-3 Thyroid Hormone Transport in Plasma

TBP	TBG	TTR	Albumin
Concentration	4-5.4 mg/dL	10-20 mg/dL	3.5-5 g/dL
Affinity for T_4	High	Modest	Low
T_4 capacity, mcg/dL	22	120	1000
Distribution			
T_4	67%	20%	13%
T_3	53%	1%	46%

BOX 55-1 Alterations in the Concentration or Affinity of Thyroid Hormone–Binding Proteins

Increases in
- A. Thyroxine-binding globulin (TBG) concentration (or affinity)
  - 1. Genetic (inherited) causes
  - 2. Nonthyroidal illness (HIV infection, infectious and chronic active hepatitis, estrogen-producing tumors, acute intermittent porphyria)
  - 3. Normal physiology (pregnancy, newborn)
  - 4. Drug use (oral contraceptives, estrogens, tamoxifen, methadone)
- B. Prealbumin binding (familial euthyroid thyroxine excess)
- C. Albumin binding (familial dysalbuminemic hyperthyroxinemia)
- D. T_4 binding by antibodies (autoimmune thyroid disease, hepatocellular carcinoma)

Decreases in
- A. TBG concentration
  - 1. Genetic (inherited) determination
  - 2. Nonthyroidal illness (major illness or surgical stress, chronic liver disease, protein-losing enteropathy, nephrotic syndrome)
  - 3. Drug use (androgens, anabolic steroids, large doses of glucocorticoids)
- B. TBG-binding capacity (drugs bound to TBG such as salicylates and phenytoin)
- C. Prealbumin concentration

RADIOGRAPHIC THYROID TESTING

Thyroid gland location, anatomy, and function is also assessed radiographically. For example, thyroidal uptake of radioactive iodine (I-123 or I-131) or technetium pertechnetate (^{99m}Tc-pertechnetate; TcO_4^-) is assessed over time as an index of thyroid function.[116]

The degree of uptake of an exogenously administered radioactive tracer versus time reflects the activity of the thyroid gland (Figure 55-15). Radioactive iodine or technetium pertechnetate can be used. The radioactive iodine uptake (RAIU) is typically expressed as the counts measured (via scanning of the thyroid gland) divided by the total counts administered. The reference interval for the RAIU is usually 5 to 25%, which means that 5 to 25% of administered radioactive tracers are present in the thyroid gland at the time of the scan (usually at 24 hours).

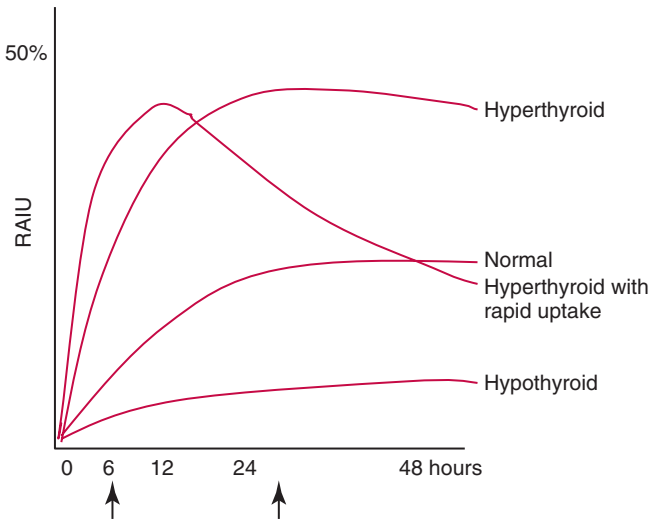

Figure 55-15 Radioactive iodine uptake (RAIU) as a function of time. RAIU is dependent on the activity of the thyroid gland. In hyperthyroidism, excessive uptake of radioactive iodine occurs. In hypothyroidism, uptake of radioactive iodine is deficient. In cases of severe hyperthyroidism, RAIU may peak before 24 hours and a 6 hour measurement is necessary to detect an elevated uptake.

In most endogenous hyperthyroid states, the RAIU is increased; in hypothyroid states, the RAIU is decreased. In thyrotoxicosis, measurement of the RAIU at 6 hours may be helpful because a hyperactive thyroid gland takes up the radioiodine at a very rapid rate and may have released some of the tracer by 24 hours. Otherwise, scanning at 24 hours alone might reveal a falsely lower measurement of the RAIU. As iodine has become more plentiful in the diet, the reference interval for the RAIU has declined.

Thyroid Scans

Administration of radioactive iodine or technetium pertechnetate allows visualization of thyroid tissue in the neck and throughout the body. In such studies, the scanner provides an image of the thyroid gland that can reveal low uptake, high uptake, and anatomic disorders such as (1) hemithyroid, a toxic (hyperactive) nodule; (2) a cold nodule (a nodule that fails to take up the radioactive tracer); or (3) ectopic thyroid tissue. Thyroid scans have been used after thyroidectomy to detect residual thyroid tissue at the surgical site, as well as differentiated thyroid cancer metastases.

Perchlorate Discharge

Normally, iodide is rapidly transported into the thyroid gland via the NIS. Within minutes of entry into the thyroid gland, intracellular iodide is transported into the lacunae via pendrin and undergoes oxidation, leading to iodination of tyrosine residues on thyroglobulin. DUOX and thyroperoxidase are responsible for the formation of organified iodine, and thyroperoxidase is responsible for the iodination of tyrosine. TPO couples MIT and DIT to produce T_3, and DIT and DIT to produce T_4. The NIS also concentrates other anions within the thyroid gland, such as thiocyanate (SCN^-), pertechnetate (TcO_4^-), and perchlorate (ClO_4^-).

The *perchlorate discharge test* is used to detect defects in thyroid gland iodide oxidation or iodination of Tg. Radioactive iodine is administered prior to perchlorate, and any radioiodine still in the follicular cells that has not yet been incorporated into colloidal Tg is released.[227] Perchlorate does not block iodination of Tg. If the NIS has transported radioiodide into the thyroid gland, but the iodide is not yet incorporated into Tg after perchlorate administration, a supranormal amount of radioiodine is released from the thyroid gland (an increase in the perchlorate discharge of radioiodine occurs).

Causes of increased radioiodide discharge after perchlorate administration include defects in pendrin, thyroperoxidase, and DUOX. Alternatively, if an inborn error is present in the NIS (e.g., a loss-of-function mutation), release of radioiodide is not increased after perchlorate because radioiodide was not initially taken up by the thyroid gland.

CLINICAL CONDITIONS

Because the signs and symptoms of thyroid dysfunction are extremely variable, thyroid function studies are often measured in clinical practice.[36,41] An enlarged thyroid gland (goiter) is typically evaluated by measurement of TSH and thyroid hormones, and on the basis of (1) history, (2) physical examination, and (3) laboratory results; patients may be classified as (1) euthyroid, (2) hypothyroid, or (3) hyperthyroid.[95,125,153]

Patients presenting with a thyroid mass are typically euthyroid. Suspicious masses are typically followed by ultrasound-guided fine-needle aspiration of the mass with cytologic examination. A thorough discussion of all forms of thyroid cancer is beyond the scope of this chapter, although the role of Tg measurements will be examined as a tumor marker for differentiated thyroid cancers.[67]

If clinical findings do not suggest an abnormality in the hypothalamic-pituitary thyroid axis, laboratory evaluation is begun with measurement of TSH (Figure 55-16).[4,95A] If TSH is within the reference interval, thyroid dysfunction generally can be excluded. If TSH is below the reference interval, measurement of FT_4 is indicated. If TSH is depressed and FT_4 is elevated, the biochemical diagnosis of primary hyperthyroidism is established. Although total T_3 can be measured at this point (and is expected to be greatly elevated), this value should not change the diagnosis or the initial therapy. If TSH is depressed and FT_4 is within the reference interval, T_3 should be measured in search of T_3 toxicosis. The authors favor total T_3 measurements over FT_3 measurements because total T_3 measurements are both more accurate and less expensive than FT_3 measurements. If TSH is depressed and both FT_4 and T_3 are normal on more than one occasion, subclinical hyperthyroidism is diagnosed. This assumes that causes of TSH suppression such as high-dose glucocorticoids and dopamine have been excluded. If TSH is depressed, FT_4 is normal, and T_3 is elevated, the diagnosis of T_3 toxicosis is established.[50]

If TSH is above the reference interval, FT_4 should be measured. If FT_4 is depressed, the biochemical diagnosis of primary hypothyroidism is established. Measurement of T_3 (or FT_3) provides no essential or additional information when hypothyroidism is a clinical consideration. Furthermore, in primary hypothyroidism, T_3 declines later than T_4 because elevated TSH concentrations in primary hypothyroidism stimulate T_3 production more than T_4 production. Whether this is due to limited availability of iodine during an attempt at increased thyroid hormone production or the increased "speed" of synthesis (T_3 synthesis requires only one iodination versus two for T_4 synthesis) is unknown.

If TSH is elevated and FT_4 is within the reference interval on more than one occasion in an asymptomatic patient, subclinical hypothyroidism is diagnosed (assuming that heterophilic antibodies have been excluded as a cause of TSH elevation).[8,145] Elevated TSH and FT_4 raise the possibility of central hyperthyroidism or thyroid hormone resistance. These disorders are differentiated clinically: patients with thyroid hormone resistance usually are euthyroid or, at worst, mildly hypothyroid, however, those with true hyperthyroidism clinically manifest thyrotoxicosis (see later). Because of the log-linear relationship of TSH to FT_4, FT_4 usually is normal as long as TSH is between 0.5 and 10 mcIU/mL.

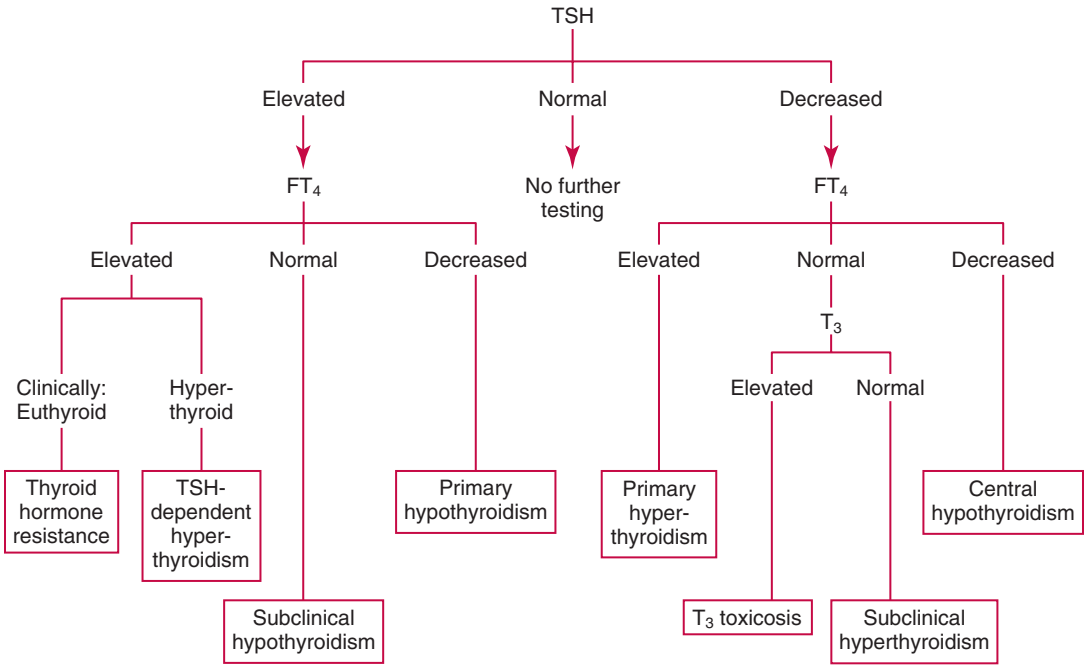

Figure 55-16 Suggested algorithm for the laboratory evaluation of thyroid function.

If hypothalamic or pituitary disease is suspected, initial testing requires measurement of both TSH and FT_4 (with FT_4 being more important). FT_4 is used to establish the presence of the biochemical euthyroid state, hypothyroidism, or hyperthyroidism. When FT_4 is low and TSH is low or normal, central hypothyroidism may be present. If FT_4 is low with only a mild elevation in TSH, central hypothyroidism is still possible because of discordance in the ratio of immunoreactivity to bioactivity, with a decrement in bioactivity from abnormal TSH glycosylation from pituitary disease or TRH deficiency. In the setting of clinical hyperthyroidism, central hyperthyroidism is diagnosed with an elevated FT_4 and normal or elevated TSH.

HYPOTHYROIDISM

Hypothyroidism is defined as a deficiency in thyroid hormone secretion and action that produces a variety of clinical signs and symptoms of hypometabolism.[73,84,198] This common disorder occurs in 2 to 15% of the population, more commonly in women than in men. The risk of developing hypothyroidism increases with age.[39]

Clinical symptoms suggesting hypothyroidism include (1) mental dullness (including mental retardation in children with untreated or undertreated congenital hypothyroidism), (2) somnolence, (3) increased sleeping, (4) lethargy, (5) easy fatigability, (6) hoarseness or deepening of the voice, (7) hair loss, (8) weight gain, (9) cold intolerance, (10) menstrual irregularities, (11) infertility, (12) growth failure, (13) delayed puberty in adolescents, (14) constipation, (15) muscle weakness or cramps, and (16) depressed affect or frank clinical depression.[171] Physical signs compatible with hypothyroidism include (1) bradycardia, (2) decreased pulse pressure, (3) cool and/or dry skin, (4) puffy eyes, (5) loss of the outer lateral eyebrows, (6) delayed relaxation phase of reflexes ("hung-up" reflexes), (7) myopathy, (8) carotenemia, (9) occasional galactorrhea, and (10) radiologic evidence of delayed bone age in children. In cases of severe hypothyroidism, congestive heart failure or coma may develop.[90] In children with untreated congenital hypothyroidism, severe growth failure and mental retardation ensue. The development of biological and biochemical processes is delayed in cases of congenital hypothyroidism. For example, affected infants often have prolonged jaundice as the result of immaturity of UDP-glucuronyl transferase.

A rare (and controversial) manifestation of Hashimoto thyroiditis is encephalopathy.[216] However, no definitive clinical test is available to diagnose encephalopathy resulting from Hashimoto thyroiditis. The diagnosis is considered when encephalopathy of unknown origin is associated with autoantibodies against the thyroid gland.

Laboratory evidence compatible with hypothyroidism encompasses hyponatremia, a normocytic or macrocytic anemia, elevated creatine kinase (from myopathy), and hypercholesterolemia and/or hypertriglyceridemia [from decreased lipoprotein-lipase activity and decreased low-density lipoprotein (LDL) receptor expression]. Anatomically, stimulation of the TSH receptor can cause follicular cell hyperplasia and goiter. Goiter can also be caused by glandular infiltration (e.g., Hashimoto thyroiditis, in which the gland is heavily infiltrated by lymphocytes).

Based on TSH and FT_4, the causes of hypothyroidism are classified as primary thyroid gland failure (low FT_4 and increased TSH; primary hypothyroidism) or central hypothyroidism (low FT_4 and usually a normal or low TSH concentration). Central hypothyroidism results from pituitary

BOX 55-2 Causes of Primary Hypothyroidism

Endogenous Disorders
Autoimmune thyroid disease
- Hashimoto thyroiditis
- Atrophic thyroiditis
- Late-stage Graves' disease
- Postpartum thyroiditis

Inborn errors in thyroid hormone biosynthesis (dyshormonogenesis)
- Na^+/iodide pump dysfunction
- Inadequate organification/iodination—thyroperoxidase dysfunction
- Defective thyroglobulin
- Deiodinase deficiency
- Pendred syndrome—hypothyroidism and deafness

Developmental disorders involving the thyroid gland
- Congenital hypothyroidism: aplasia, hypoplasia
- Ectopic thyroid: lingual thyroid, thyroglossal duct cyst

Consumptive hypothyroidism

Exogenous Disorders
Iodine excess/deficiency
Drugs
Thionamides
Lithium
Nitroprusside
Amiodarone
Biologicals (e.g., interferon, interleukin-2)
Dietary goitrogens
Radiation-induced hypothyroidism
Surgical removal of the thyroid gland
Viral or bacterial thyroiditis

disease (secondary hypothyroidism from TSH deficiency) or hypothalamic disease (tertiary hypothyroidism from TRH deficiency).

Primary Hypothyroidism

The causes of primary hypothyroidism are classified as endogenous or exogenous (Box 55-2).[38] Endogenous disorders are conditions that develop within the patient such as autoimmune thyroid gland dysfunction, inborn errors, and developmental abnormalities. Exogenous disorders are conditions that originate outside the patient such as iodine deficiency or excess, goitrogen or drug effects, and postsurgical hypothyroidism or hypothyroidism following radioactive iodine treatment.

Autoimmune Hypothyroidism

Excluding the newborn period, autoimmune thyroid disease (AITD) is the most common cause of thyroid disease and primary hypothyroidism.[111,148,203] Hashimoto thyroiditis (chronic lymphocytic thyroiditis) leads to destruction of the thyroid follicular cells through a cell-mediated autoimmune process.[102] Histologically, the gland is infiltrated with lymphocytes and plasma cells to the extent that secondary lymphoid follicles develop within the thyroid gland that are similar to the secondary follicles observed in normal lymph nodes. Initially, the gland is usually enlarged. Over time, with destruction of the gland, the gland can atrophy or become firm. In the rare condition of Riedel thyroiditis (Riedel disease or struma, ligneous struma, ligneous thyroiditis, chronic fibrous thyroiditis), the thyroid gland becomes fibrotic with possible attachment to adjacent structures that can produce, for example, tracheal compression.[144] Subacute (viral) thyroiditis may also cause Riedel thyroiditis.[31] Not all cases of Riedel thyroiditis are presaged by Hashimoto thyroiditis.

Although atrophy may occur in Hashimoto thyroiditis, atrophic thyroiditis may also occur when autoantibodies against the TSH receptor bind to the receptor and block the action of endogenous TSH. TSH receptor blocking autoantibodies can cross the placenta during pregnancy, causing transient hyperthyrotropinemia in infants (elevated TSH with a normal T_4) or even transient congenital hypothyroidism. Therefore atrophic thyroiditis falls under the rubric of AITD.

The diagnosis of Hashimoto thyroiditis is supported by recognition of autoantibodies against TPO or Tg.[113] Ninety percent of patients with chronic lymphocytic thyroiditis (the histologic description of Hashimoto thyroiditis) have antithyroperoxidase autoantibodies (TPOA), antithyroid microsomal autoantibodies (TMA), and/or antithyroglobulin autoantibodies (TgA), making these autoantibodies excellent markers for Hashimoto thyroiditis.[182] TPOA testing was initially pursued by testing for TMA (see section on thyroid autoantibody testing). TMA testing is being replaced by specific testing for TPOA using TPO as the antigen in the immunoassay. TPOA/TMA positivity is more common at the time of diagnosis than TgA positivity with TgA usually appearing later in the disease process. TgA overall are less common than TMA or TPOA. Ultrasound has limited value and is not routinely used to detect Hashimoto thyroiditis.

In many families, AITD appears to be inherited in an autosomal dominant pattern although some family members develop Hashimoto thyroiditis and other family members develop Graves' disease. Several genetic loci have been associated with susceptibility to Hashimoto thyroiditis (or AITD): HLA-DR, CTLA-4, CD40, FCRL3, Tg, the TSH receptor, PTPN22, and the IL-2 receptor. However, no single Mendelian locus explains the apparent autosomal dominant pattern of inheritance of AITD.[66] It is most appropriate to describe AITD as polygenic and multifactorial, indicating that both environment and multiple genes provide susceptibility to these very common disorders.

Nonendocrine and endocrine autoimmune disorders can occur with increased frequency in people with AITD. Chronic lymphocytic gastritis causing pernicious anemia may accompany AITD, particularly in older patients. AITD also occurs commonly in association with type 1 diabetes and pernicious anemia.[61,91,104] Another, less common, association is AITD and Addison disease.[82]

AITD can occur as part of autoimmune polyglandular syndrome type 2 (APS 2) and, more rarely, APS 1.[161,175] APS 2 affects women more often than men with onset in childhood or early adulthood and is diagnosed when Addison

disease (or adrenal autoantibodies) occurs together with AITD and/or type 1 diabetes. In contrast to the polygenic nature of APS 2, mutations in AIRE (the autoimmune regulator gene that is a transcription factor; gene location: chromosome 21q22.3) produce autoimmune polyglandular syndrome type 1 (APS 1), which is inherited in an autosomal recessive pattern, thus affecting males and females equally.[18,93]

Another variant of AITD is postpartum thyroiditis (PPT).[192] PPT develops presumably as a consequence of a decline in the natural immunosuppression of pregnancy following delivery. PPT follows ≈5% of all pregnancies and ≈10% of pregnancies in women with type 1 diabetes. The clinical phenotype of PPT is transient hypothyroidism, hyperthyroidism, or both (one following the other) with a return to the euthyroid state by approximately 1 year postpartum. Women with thyroid autoantibodies are at highest risk for PPT. Later in life, permanent clinical evidence of AITD can develop in women afflicted with PPT. Thyroid autoimmunity, even in the absence of hypothyroidism, may impair fertility in women and increase the risk of spontaneous abortion in those women who do become pregnant.[154] Therefore an indication for thyroid autoantibody testing in the absence of hypothyroidism would be female infertility or recurrent miscarriage. Convincing data suggest that T_4 treatment of pregnant women who are positive for thyroid autoantibodies (especially TPOA) leads to a higher frequency of miscarriage (13.8%) than is seen in pregnant women who lack TPOA (2.4% rate of miscarriage), and that T_4 treatment of the TPOA-positive group reduces the rate of miscarriage to approximately 3.5%.[136]

Inborn Errors in Thyroid Hormone Biosynthesis

Inborn errors in thyroid hormone biosynthesis (dyshormonogenesis) are rare causes of primary hypothyroidism. These defects usually present early in life and can appear in newborns as a goiter. In very rare cases, asphyxia from tracheal compression has been reported.[213] Biochemical defects include iodine transport defects from loss-of-function mutations in the NIS (no increase in the perchlorate discharge); defects in thyroperoxidase, DUOX2,[130] and pendrin (with increased perchlorate discharge); thyroglobulin deficiency; and iodotyrosine dehalogenase mutations (potentially causing iodine deficiency through loss of MIT, DIT, and iodine in the urine).[129]

Developmental Hypothyroidism Disorders

Developmental causes of primary hypothyroidism involve aplasia or hypoplasia of the thyroid gland and ectopic and lingual thyroid glands.[202] These disorders account for ≈75% of cases of congenital hypothyroidism. Other causes of congenital hypothyroidism include thyroid dyshormonogenesis (10% of cases; see earlier), hypothalamic or pituitary abnormalities (5% of cases). Ten percent of cases of congenital hypothyroidism are transient.

Rare causes of congenital hypothyroidism involve loss-of-function mutations in the pituitary TRH receptor,[23] the TSH beta chain,[128] and the TSH receptor.[19,58] Mutations in anterior pituitary transcription factors (HESX1, LHX3, LHX4, PROP1, PIT1) can lead to TSH deficiency. Causes of transient congenital hypothyroidism include (1) severe maternal iodine deficiency, (2) acute iodine exposure, (3) transplacental passage of thionamides taken for treatment of maternal hyperthyroidism, (4) transplacental transfer of TSH receptor blocking antibodies, (5) hypothyroxinemia of prematurity, and (6) heterozygosity for a DUOX2 mutation.

Dried blood spot (DBS) screening for congenital hypothyroidism in North America reveals a general population frequency of congenital hypothyroidism of ≈1 in 4000. Congenital hypothyroidism is more common in Hispanic infants, less common in Caucasian infants, and least common in African American infants. The male-to-female ratio is 1:2. A higher frequency of congenital hypothyroidism is seen in infants with Down syndrome (≈1 in 140).

Clinically, fewer than 1 in 20 hypothyroid babies are recognized in the newborn nursery by physicians. This emphasizes the critical need for newborn biochemical screening. Early intervention improves clinical outcomes in these cases. However, some studies report that even with rapid treatment after birth, the IQ of affected children may be ≈10 points below that of their unaffected siblings. An increased frequency of neuropsychologic deficits has been reported in children with appropriately treated congenital hypothyroidism.

In North America, screening for congenital hypothyroidism is carried out predominantly by measuring total T_4 on DBSs. A common practice is to measure TSH in babies who have the lowest 10% of T_4's measured on the day of testing. Usually if the TSH is 60 mcIU/mL or greater (after the first 24 to 48 hours of life), a presumptive diagnosis of primary hypothyroidism is made, and the infant is transferred to a referral center emergently to be evaluated and started on thyroxine replacement therapy (e.g., 10 to 15 μg/kg/d). If the TSH is between 20 and 59 mIU/L, the infant is clinically evaluated and repeat thyroid function testing is performed before thyroid hormone replacement is started. If the TSH is less than 20 mIU/L, primary hypothyroidism is excluded. Screening with "T_4 only testing" will lead to missed rare cases of central hypothyroidism (1/100,000) and cases of hypothyroidism wherein TSH is elevated but T_4 is not yet depressed. In Europe, many screening programs use a TSH-first strategy. Although TSH screening will detect subclinical hypothyroidism (see later), cases of central hypothyroidism will be missed. Transcription factor mutations involving *TTF-1* and *Pax8* have been recognized in some children with congenital hypothyroidism. It is not clear whether molecular testing will prove useful in future screening programs for congenital hypothyroidism.

Hypothyroidism Caused by Iodine Deficiency or Excess

Worldwide, the most common cause of goiter is iodine deficiency. In iodine-deficient areas, especially mountainous areas, iodine deficiency produces "endemic" goiter. Frank hypothyroidism, however, is far less common because with

iodine deficiency, more T_3 is synthesized than T_4, and within the thyroid gland, more T_4 is converted to T_3 to maintain the euthyroid state overall. Endemic goiters can develop nodularity (with or without hemorrhage into the nodule); in such cases, neoplasia must be excluded. Large goiters can produce dysphagia, obstruction of the trachea, or compression of the recurrent laryngeal nerves. A rare cause of iodine deficiency is nephrotic syndrome, with increased urinary loss of iodine often in the form of thyroid hormone.[53,114]

A significant danger of iodine deficiency is maternal hypothyroidism leading to an insufficient supply of thyroid hormone to the fetus in the first half of gestation, when the fetus is entirely dependent on maternal thyroid hormone. Thus maternal hypothyroidism can produce a reduction in the IQ of the affected child. Maternal iodine deficiency will produce fetal iodine deficiency.

Although it is logical that iodine deficiency would produce hypothyroidism because iodine is a necessary component in the synthesis of thyroid hormone, it is ironic that excess iodine can interfere with normal thyroid gland function.[106] However, excessive iodine does suppress thyroid gland function. High doses of iodine [super-saturated potassium iodide (SSKI) or Lugol's solution] are routinely used before planned surgical thyroidectomy for Graves' disease, to inhibit further thyroid hormone release and decrease the vascularity of the gland to reduce surgical blood loss.

Excess iodine reduces thyroid hormone release and inhibits organification of iodine and iodination of Tg (the *Wolff-Chaikoff effect*). The Wolff-Chaikoff effect can speculatively be interpreted as an autoregulatory response of the thyroid gland to avoid excessive production of thyroid hormone when exposed to high doses of exogenous iodine. Nondietary sources of excess iodine include amiodarone (an antiarrhythmic drug), povidone-iodine (used to disinfect the skin before surgery), and radiologic contrast agents that contain iodine. Excess iodine does not usually cause permanent thyroid dysfunction because the gland normally recovers ("escapes") from suppression after approximately 10 days of high-dose iodine administration. However, if the patient has underlying disease that may involve the thyroid (e.g., Hashimoto thyroiditis, Graves' disease), escape from the Wolff-Chaikoff effect is less likely and permanent hypothyroidism can develop.

Drug-Induced Hypothyroidism

Various drugs affect thyroid gland function (Table 55-4).[63] Collectively known as thionamides or thioureas, propylthiouracil (PTU), methimazole, and carbimazole inhibit the oxidation of iodide and the subsequent binding of iodine to tyrosine residues in Tg. Other drugs with thionamide-like activity include ethionamide, aminoglutethimide, phenylbutazone, and para-aminosalicylic acid. Evidence suggests an immunosuppressive effect of thionamides on thyroid autoimmunity.

PTU, methimazole, and carbimazole are commonly used to treat hyperthyroidism. (*Note:* Carbimazole is not available in the United States.) When large doses of PTU are used, the

TABLE 55-4 Effects of Some Drugs on Tests of Thyroid Function

Cause	Drug	Effect
Inhibit TSH secretion	Dopamine L-dopa Glucocorticoids Somatostatin	↓ T_4; ↓ T_3; ↓ TSH
Inhibit thyroid hormone synthesis or release	Iodine Lithium	↓ T_4; ↓ T_3; ↑ TSH
Inhibit conversion of T_4 to T_3	Amiodarone Glucocorticoids Propranolol Propylthiouracil Radiographic contrast agents	↓ T_3; ↑ rT_3; ↓, ⇌, ↑ T_4 and FT_4; ⇌, ↑ TSH
Inhibit binding of T_4/T_3 to serum proteins	Salicylates Phenytoin Carbamazepine Furosemide Nonsteroidal anti-inflammatory agents Heparin (in vitro effect)	↓ T_4; ↓ T_3; ↓ FT_4E, ⇌, ↑ FT_4; ⇌ TSH
Stimulate metabolism of iodothyronines	Phenobarbital Phenytoin Carbamazepine Rifampicin	↓ T_4; ↓ FT_4; ⇌ TSH
Inhibit absorption of ingested T_4	Aluminum hydroxide Ferrous sulfate Cholestyramine Colestipol Iron sucralfate Soybean preparations Kayexalate	↓ T_4; ↓ FT_4; ↑ TSH
Increase in concentration of T_4-binding proteins	Estrogen Clofibrate Opiates (heroin, methadone) 5-Fluorouracil Perphenazine	↑ T_4; ↑ T_3; ⇌ FT_4; ⇌ TSH
Decrease in concentration of T_4-binding proteins	Androgens Glucocorticoids	↓ T_4; ↓ T_3; ⇌ FT_4; ⇌ TSH

Data from Smallridge RD. Chapter 33. Thyroid function tests. In: Becker KL, ed. Principles and practice of endocrinology and metabolism, 7th edition. Philadelphia, Pa: JB Lippincott, 1995:299-306; Stockigt JR. Thyroid hormone changes in critical illness: the sick euthyroid "syndrome." Diagn Endo Metab 1997;15:39-46.

↓, Reduced serum concentration; ↑, increased serum concentration; ⇌, no change.

drug decreases peripheral conversion of T_4 to T_3 through inhibition of the D1 deiodinase. Because of this effect (in addition to the direct suppressive effect of PTU on the thyroid gland), some endocrinologists argue that PTU should be chosen over methimazole for the treatment of hyperthyroidism. However, recognition of serious or even fatal liver disease in a small (but significant) number of children treated with PTU is increasing.[100] Therefore, many pediatric endocrinologists discourage the routine use of PTU for the treatment of hyperthyroidism in children. Reduced granulocyte counts and subsequent infections are serious but uncommon side effects of thionamides. Therefore the white blood cell count and the differential count should be monitored during such therapy.

A potential advantage of methimazole over PTU is its longer half-life (PTU $t_{1/2}$ = 1.5 hours and methimazole $t_{1/2}$ = 6 hours). Both PTU and methimazole cross the placenta, can interfere with fetal thyroid function, and can cause goiter. Additionally, methimazole has been associated with aplasia cutis and choanal atresia. Therefore during pregnancy, PTU is the preferred drug in the treatment of maternal hyperthyroidism.

A variety of other drugs have been known to cause hypothyroidism. For example, lithium, which is used in the treatment of bipolar disorder (manic-depressive illness), can induce hypothyroidism.[85] The action of lithium appears similar to that of high-dose iodine, inhibiting thyroid hormone release and organification of iodine. Prolonged use of nitroprusside, a drug used to treat acute-onset, severe hypertension or severe heart failure by inducing preload and afterload reduction, may lead to hypothyroidism. Cyanide (CN^-) released from nitroprusside is metabolically converted to thiocyanate (SCN^-), which inhibits iodide uptake by the thyroid gland. Fortunately, nitroprusside only rarely causes hypothyroidism. Amiodarone is an antiarrhythmic drug that contains two iodine atoms per molecule and can induce hypothyroidism or hyperthyroidism.[22,204] Various recombinant DNA-derived biologicals (e.g., interferon-alpha, interleukin-2) used to treat chronic viral hepatitis or cancer have been found to cause thyroid dysfunction (hypothyroidism or hyperthyroidism).[124]

Surgical and Radiation-Induced Hypothyroidism

Surgical removal of the thyroid gland will produce hypothyroidism. External irradiation of the thyroid gland (e.g., treatment of lymphoma or Hodgkin disease) or ingestion of radioactive iodine can ablate the gland, causing hypothyroidism.[123] Administration of radioactive iodine to pregnant women can lead to ablation of the fetal thyroid gland, causing congenital hypothyroidism.

Viral or Bacterial Thyroiditis

Only rarely do viral or bacterial infections of the thyroid gland occur. Even more rarely do these entities damage the thyroid gland sufficiently to produce hypothyroidism. Viral infection of the thyroid gland is termed *subacute thyroiditis* (de Quervain, granulomatous, or giant cell thyroiditis) and can produce generalized thyroid gland tenderness. Bacterial infection of the thyroid gland is termed *acute thyroiditis* and can produce a thyroid abscess.[3]

Central Hypothyroidism

In a patient with clinical evidence of hypothyroidism, supported by laboratory findings of a low FT_4, if TSH is not elevated to the extent predicted (by FT_4), or if TSH is within or below the reference interval, central hypothyroidism should be considered.[92,229] Isolated pituitary TSH deficiency is rare, as most patients with secondary hypothyroidism also have other anterior pituitary hormone deficiencies (panhypopituitarism). Causes of central hypothyroidism (hypothalamic or pituitary disease) include (1) tumor, (2) hemorrhage, (3) trauma, (4) malformation, (5) postinfectious damage, and (6) postsurgical damage. Also, several rare autosomal recessive or dominant hereditary disorders involving transcription factor mutations can cause hypopituitarism and TSH deficiency: examples include paired-like homeodomain transcription factor-1 (Pit-1) and PROphet of Pit-1 *(PROP1)* mutations.[131]

Subclinical Hypothyroidism

Subclinical hypothyroidism is defined by a persistent elevation in TSH (6 to 12 weeks or longer) in the setting of FT_4 concentrations that are repeatedly found within the reference interval.[49] Other conditions wherein TSH is elevated but FT_4 is normal encompass recent reinstitution of thyroid hormone replacement therapy (FT_4 returns to normal before TSH declines), poor compliance with treatment in primary hypothyroidism, recovery from nonthyroidal illness, positively interfering heterophilic antibodies [e.g., human antimouse antibodies (HAMA)] in double-antibody immunoassays, and thyroid hormone resistance.

Subclinical hypothyroidism is very common, affecting 3 to 8% of the general population. By the sixth decade of life, 10% of the population exhibits laboratory findings consistent with subclinical hypothyroidism. Consequences of subclinical hypothyroidism include a high risk of progression to clinical hypothyroidism, dyslipidemia, vascular endothelial dysfunction, increased risk of cardiovascular disease and death, and possible neurocognitive deficits. The general consensus is that if TSH is repeatedly 10 mIU/L or greater, thyroid hormone replacement therapy is warranted. It is controversial whether thyroid hormone therapy is beneficial when TSH is less than 10 mIU/L, except during pregnancy, wherein any persistent TSH elevation requires treatment.

Controversy is ongoing over the appropriate upper limit of the reference interval for TSH. Basing the TSH reference interval on the central 95% of the general, healthy population results in an upper limit of normal between 4.0 and 5.0 mIU/L for many TSH assays. If patients with thyroid autoantibodies such as TPOA, a family history of thyroid disease, or an abnormal thyroid gland ultrasound are excluded from the reference population, the upper limit of the reference interval declines to approximately 2.5 to 3.0 mIU/L. Therefore, an upper limit of 2.5 to 3.0 mIU/L for TSH may be a truer

definition of normal, because the reference population mostly excludes individuals with endogenous thyroid disease or propensity to develop thyroid disease. However, it is unclear how patients with TSH concentrations between 2.5/3.0 mIU/L and 4.0/5.0 mIU/L should be managed. It has been argued that lowering the upper limit of the reference interval will provide no clear patient benefit and inevitably will lead to confusion and possible overtreatment of subclinical hypothyroidism. Overtreatment carries the risk of predisposing the patient to osteoporosis and atrial fibrillation. As noted previously, the value of treatment when TSH is between 4.0/5.0 and 9.9 mIU/L is currently debated. Another component of the TSH reference interval debate is that according to National Health and Nutrition Examination Survey (NHANES) data,[9,134A,209] TSH rises as populations age. For example, in healthy adults age 80 and older, the upper limit of the reference interval for TSH is 7.5 mIU/L.

Thyroid Hormone Monitoring During Replacement Therapy

The thyroid hormone replacement of choice is Na^+-L-thyroxine (levothyroxine; T_4). Several brands of T_4 are available, including Synthroid (Abbott, North Chicago, Ill), Levothroid (Forest, St Louis, Mo) and Levoxyl (King, Bristol, Tenn). USP (United States Pharmacopeia) Thyroid or mixtures of T_4 and T_3 should not be used for thyroid hormone replacement. USP Thyroid is a desiccated extract of whole animal thyroid containing variable proportions of T_3 and T_4. Because its exact formulation is highly variable and is not standardized, USP Thyroid will not produce stable concentrations of thyroid hormone over the long term, leading to periods of excess or deficient thyroid hormone replacement. Despite many trials, fixed mixtures of T_3 plus T_4—examples include Naturethroid (RLC, Tempe, Ariz) and Thyrolar (Forest)—have not been shown to be clinically superior to T_4 replacement alone. Administering T_4 alone allows the body to regulate the production of T_3. Recall that normally 80% of T_3 comes from peripheral monodeiodination of T_4 to T_3. The sodium salt of T_3 (liothyronine) is available in tablet (Cytomel, King) and injectable (Triostat, King) forms. Considerable controversy surrounds whether generic preparations of T_4 are as effective as brand name preparations because of variable consistency and/or absorption from the gastrointestinal tract. Anecdotal reports have suggested that brand name preparations are clinically superior to generics.

Thyroxine should be taken at the same time of day for clinical consistency. The timing of FT_4 measurements should also be standardized because FT_4 may rise abruptly within hours of oral thyroxine ingestion. Thyroxine is best absorbed without food. A 2009 study demonstrated that TSH was lowest when thyroxine was taken in the fasting state (mean TSH, 1.06 mIU/L) versus when taken with breakfast (2.93 mIU/L) or at bedtime (2.19 mIU/L).[12] Many reasons have been put forth for variations in TSH measurements over time,[52] including intraindividual variation of 15 to 35%.[6] The 2003 National Academy of Clinical Biochemistry Laboratory Practice Management Guideline on thyroid function testing reported intraindividual coefficients of variation for TSH of 19.3% for 1 week, 20.6% for 6 weeks, and 22.4% for 1 year.[13] A significant source of biological variation in TSH is the pulsatile pattern of secretion and the fairly short half-life of TSH (approximately 1 to 2 hours).[80] In one study, TSH was released in approximately 18 pulses over the course of a day, and TSH half-life was 60 to 90 minutes. The half-life of TSH may vary between individuals, depending on interindividual differences in the degree of sialylation and sulfation of TSH.[47,149]

FT_4 and TSH are usually measured approximately 6 weeks after the beginning of thyroxine treatment for hypothyroidism. The dose of thyroxine should be titrated upward until FT_4 is in the upper half of the reference interval. TSH returns to the reference interval more slowly than the rise of FT_4 into the reference interval occurs in response to therapy. Ideally during treatment, TSH should be maintained within the reference interval. As the dose of thyroxine is increased during the initial months of therapy, some endocrinologists will allow TSH to be slightly suppressed (but >0.02 to 0.04 mIU/L) if the patient feels substantially better. It can be argued that, particularly in women, it is prudent to measure bone mineral density by dual-energy x-ray absorptiometry (DEXA) scan at least once a year to screen for bone loss that could result from overtreatment with thyroxine. Overtreatment of hypothyroidism is not uncommon.[7]

HYPERTHYROIDISM

Hyperthyroidism, also known as thyrotoxicosis, is the clinical syndrome that results from elevated concentrations of free thyroid hormone in the plasma, associated with clinical evidence of hypermetabolism.[135,139,178A] Symptoms of thyrotoxicosis include (1) nervousness, (2) erratic behavior, (3) emotional lability, (4) restlessness, 5) sleeplessness, (6) difficulty concentrating, (7) smooth and/or shiny hair and/or skin, (8) weight loss, (9) excessive sweating, (10) heat intolerance, (11) menstrual irregularities, and (12) diarrhea or frequent bowel movements. Physical signs compatible with hyperthyroidism include tachycardia, atrial arrhythmias, systolic murmurs, increased pulse pressure, a bounding pulse, warm and/or damp skin, softened texture of the skin, tremor, increased reflexes, eyelid retraction (and other signs of ophthalmopathy in Graves' disease), and hypocholesterolemia.

Based on TSH and FT_4, the causes of hyperthyroidism may be classified as primary (elevated FT_4 and decreased TSH) or central (elevated FT_4 and normal to elevated TSH). Central hyperthyroidism can be further parsed into pituitary (secondary hyperthyroidism from TSH excess) and hypothalamic (tertiary hyperthyroidism from TRH excess) causes. In primary hyperthyroidism, TSH is typically less than 0.05 mIU/L. With current assays, a TSH concentration within the reference interval nearly always excludes the diagnosis of primary hyperthyroidism.

Causes of Hyperthyroidism

The causes of hyperthyroidism are listed in Box 55-3. Endogenous disorders causing hyperthyroidism include intrinsic thyroid disease (primary hyperthyroidism), ectopic thyroid tissue (struma ovarii),[166] and disorders of the hypothalamus or pituitary causing excess TSH secretion (secondary hyperthyroidism). Exogenous causes of hyperthyroidism (disease related to external factors) encompass infectious origins (thyroid gland inflammation and destruction), iodine-induced hyperthyroidism, and thyroid hormone ingestion (thyrotoxicosis factitia).

The first line of treatment for primary hyperthyroidism is controversial. Administration of radioactive iodine is the first choice in many adults and older children with Graves' disease. When medical therapy is chosen, thionamides are used to suppress thyroid gland hyperactivity.[195] In the immediate period following the start of thionamide therapy, TSH measurements may poorly reflect the patient's thyroid status because TSH can remain suppressed for months even after the patient becomes clinically euthyroid. This is similar to the treatment of hypothyroidism, where 6 weeks or more can elapse before TSH returns to normal even with adequate thyroxine replacement.

After 1 to 2 years of thionamide therapy, if disease remission has not occurred, radioactive iodine is usually advised.[71] An alternative therapy is thyroidectomy, particularly in specialized centers with extensive surgical experience. However, with radioactive iodine ablation of the gland, there is no surgical risk of inadvertent parathyroidectomy or recurrent laryngeal nerve injury. As a consequence of radioactive iodine treatment or thyroidectomy, primary hypothyroidism can subsequently develop, necessitating surveillance for hypothyroidism with yearly TSH measurements.

BOX 55-3 Causes of Hyperthyroidism

Endogenous Thyroid Disorders
- Autoimmune thyroid disease
  - Graves' disease
  - Hashitoxicosis
  - Postpartum thyroiditis
  - Gain-of-function mutation in the TSH receptor
  - Toxic nodule
- Toxic multinodular goiter
  - Toxic adenoma
  - Familial
  - Struma ovarii
  - hCG-induced hyperthyroidism
- Gestational transient thyrotoxicosis
- TSH receptor sensitivity to hCG
- hCG-secreting tumors
  - Secondary hyperthyroidism (e.g., central hyperthyroidism)

Exogenous Disorders
- Thyroid destruction from viral or bacterial thyroiditis
- Iodine-induced hyperthyroidism
- Thyroid hormone ingestion (thyrotoxicosis factitia)

T_3 Toxicosis

T_3 toxicosis is defined by the presence of clinical hyperthyroidism in a patient with suppressed TSH, normal FT_4, and elevated T_3 (or FT_3).[50] FT_4 may be normal in early hyperthyroidism when a very mild excess of thyroid hormone is causing increased thyroidal and peripheral deiodination of T_4 to T_3, raising the latter but not the former. Recall that D1 conversion of T_4 to T_3 is enhanced in hyperthyroidism. T_3 toxicosis is also possible when hyperthyroidism occurs in the presence of mild iodine deficiency, when iodine is sufficient to synthesize excessive amounts of T_3 but not T_4. Last, it is known that stimulation of the TSHR enhances the production of T_3 more than T_4. T_3 toxicosis is not a unique or individual disease, but rather can be considered a phase in the natural progression of primary hyperthyroidism that may or may not be recognized by the clinician.

Graves' Disease

Graves' disease affects approximately 0.4% of the U.S. population and results from agonistic autoantibodies that bind to, and activate, the TSH receptor, producing excess release of thyroid hormone and subsequent clinical hyperthyroidism.[24] Women are more frequently affected by Graves' disease than men, by a 5:1 ratio.

The classical clinical triad observed in patients with Graves' disease consists of (1) goiter and biochemical hyperthyroidism, (2) exophthalmos, and (3) nonpitting pretibial myxedema.[220] The presence of exophthalmos strongly suggests Graves' disease in a hyperthyroid patient. Exophthalmos appears to have an autoimmune cause. Retro-orbital tissues may express TSH receptors, and consequent to stimulatory TSH receptor autoantibodies, retro-orbital tissue hyperplasia occurs, producing exophthalmos.[17] Myxedema is the accumulation of mucopolysaccharides in subcutaneous tissue that cause visible and palpable swelling. The potential finding of myxedema in both Graves' disease and Hashimoto thyroiditis (with hypothyroidism) is not readily explained.

Similar to Hashimoto thyroiditis, genetic susceptibility to Graves' disease is polygenic.[66] In practice, Hashimoto thyroiditis is often associated with HLA-DR5 while Graves' disease is associated with HLA-DR3.

TPOA (including TMA) and TgA are seen in both Hashimoto thyroiditis and Graves' disease but usually are found in higher concentrations in Hashimoto thyroiditis. However, these autoantibodies do not distinguish between the two conditions. Testing for TSH receptor autoantibodies should be reserved for cases where the diagnosis of Graves' disease is in doubt. TSH receptor autoantibody (TRA) testing is available for stimulatory autoantibodies [TSH receptor stimulatory autoantibodies (TSI)] and receptor-binding autoantibodies [thyrotropin-binding inhibitory immunoglobulins (TBII)]. Usually, both TSI and TBII tests are positive in patients with Graves' disease.

Hashitoxicosis and Postpartum Thyroiditis

During the clinical course of Hashimoto thyroiditis, if a period of accelerated destruction of thyroid follicular cells occurs, subsequent release of thyroid hormone can produce a transient interval of hyperthyroidism, termed *Hashitoxicosis*.[133] Hashitoxicosis should be differentiated from Graves' disease because the treatments for these two conditions are different. Hashitoxicosis is self-limited, and if any treatment is required, β-blockers (such as propranolol) are used to suppress the effects of excess catecholamines, such as tachycardia. TRA are usually positive in patients with Graves' disease and negative in Hashitoxicosis. In addition, the RAIU is elevated in Graves' disease but is not elevated in Hashitoxicosis. Patients with postpartum thyroiditis can experience a period of transient, usually self-limited, hyperthyroidism from accelerated breakdown of thyroid tissue. Subacute or acute thyroiditis can produce a period of transient hyperthyroidism.

Toxic Nodular or Multinodular Goiter

A subset of patients with nodular or multinodular goiter can develop hyperthyroidism.[35,155,181] When hyperthyroidism is caused by these lesions, the term *toxic* has been used *(toxic multinodular goiter)*. In the older literature, toxic multinodular goiter is referred to as Plummer disease.

The cause of nodular or multinodular goiter is not well characterized. One theory is that these disorders arise from colloid goiters.[37] A colloid goiter itself is a disorder of unknown origin, in which the thyroid gland enlarges because of increased size of the follicular lacunae.[5] Microscopically, the enlarged lacunae display wide variation in size. However, colloid goiters do not display the follicular cell hyperplasia typical of Graves' disease. Patients with colloid goiter lack thyroid autoantibodies, and no evidence suggests a defect in thyroid hormone biosynthesis. Over many years, some regions of colloid goiters undergo further hypertrophy, while other areas atrophy, producing nodules that may become palpable. TRA are negative in toxic multinodular goiter.[214]

In some cases of nodular or multinodular goiter, the hyperactive tissue can display a somatic gain-of-function mutation in the TSH receptor or G_s protein, so that the receptor is perpetually in the "on" confirmation or functions as though it is in the "on" position, in the absence of TSH binding to the receptor.[201] This mutation occurs in at least 60% of cases of nodular or multinodular goiter with hyperthyroidism. However, in the other 40% of cases, the cause of the hyperthyroidism is unknown. Somatically acquired gain-of-function mutations in the G_s alpha subunit produce many of the symptoms of McClune-Albright syndrome, including thyrotoxicosis.

Sometimes follicular adenomas are autonomously hyperactive, producing hyperthyroidism (toxic adenomas).[87] Other than elevated FT_4 and depressed TSH from hyperthyroidism, no specific laboratory tests can diagnose nodular or multinodular goiter, or a toxic adenoma. Toxic (hyperactive, or "hot") nodules are very rarely carcinomas. Cold nodules (nodules that do not synthesize thyroid hormone and do not take up radioactive iodine or technetium) may result from TSH receptor loss-of-function mutations. Any nodule that is not "hot" may be cancerous, and fine-needle aspiration biopsy should be strongly considered.

Gain-of-Function Mutations in the TSH Receptor

A familial, autosomal dominant form of non–Graves' disease hyperthyroidism that is due to gain-of-function mutations in the TSH receptor has been described.[89] The gain-of-function mutation places the TSH receptor in the "on" position in the absence of ligand (TSH) binding. In infants homozygous for such mutations, neonatal thyrotoxicosis, even requiring emergency thyroidectomy, has been observed. Certain heterozygous mutations have caused infantile hyperthyroidism.[217]

Central Hyperthyroidism

TSH-secreting anterior pituitary adenomas are very rare.[103] This diagnosis is suggested by (1) clinical hyperthyroidism, (2) elevated FT_4, (3) normal to elevated TSH concentration, and (4) evidence of a pituitary mass on computed tomography (CT) scan or magnetic resonance imaging (MRI). Incidentalomas of the pituitary are found in approximately 5% of the general population; therefore a CT or MRI anomaly is not pathognomonic for a pituitary adenoma. A thyrotropinoma can produce a mass displacement effect, resulting in deficiencies of other anterior pituitary hormones caused by compression of pituitary tissue.[96]

Rarely, selective pituitary resistance to the effects of thyroid hormone is present, yet peripheral sensitivity is normal.[226] This condition produces clinical hyperthyroidism because only elevated concentrations of thyroid hormones suppress TSH. The subsequent rise in TSH promotes thyroid hormone synthesis and release from the thyroid gland, producing clinical hyperthyroidism because the peripheral tissues have normal responsiveness to thyroid hormone. Selective pituitary resistance to thyroid hormone feedback is suggested when the pituitary CT scan or MRI is normal. Unique mutations in TRβ causing selective pituitary resistance have been described.[169]

Hyperthyroidism Due to Human Chorionic Gonadotropin

Human chorionic gonadotropin (hCG)–induced hyperthyroidism is observed in gestational transient thyrotoxicosis, TSH receptor sensitivity to appropriate hCG concentrations during pregnancy, and hCG-secreting tumors.[94,97,163] Gestational transient thyrotoxicosis occurs in 2 to 3% of all pregnancies, and results from activation of TSH receptors by hCG, which is greatly elevated during pregnancy. The degree of hyperthyroidism is typically mild, and treatment is not usually required. In contrast to Graves' disease, thyroid autoantibodies are negative. If PTU or methimazole is used, fetal monitoring for thyroid dysfunction is important, because these drugs cross the placenta, potentially causing fetal hypothyroidism and goiter.

Fetal thyroid gland suppression by thionamides is a concern when any pregnant woman with hyperthyroidism is treated. The size of the fetal thyroid gland can be monitored

by ultrasound. TSH and T_4 can be measured in fetal blood obtained by cordocentesis (a high-risk procedure) or in the amniotic fluid.[34] Besides the analytical challenge of measuring the very low concentrations of these hormones in nonplasma body fluids, finding an appropriate reference interval can be difficult. Also, it is unlikely that many laboratories have validated measurements of thyroid hormone or TSH in amniotic fluid. Hyperemesis gravidarum (severe vomiting during pregnancy) has been associated with gestational transient thyrotoxicosis and may be related to very high hCG concentrations.[147]

Tumors that secrete hCG, such as choriocarcinoma, hydatidiform mole, or metastatic embryonal carcinoma, have caused hyperthyroidism through hCG stimulation of the TSH receptor.[212]

Iodine-Induced Hyperthyroidism

In a patient with iodine deficiency and underlying Graves' disease or nodular/multinodular goiter, iodine administration may lead to hyperthyroidism.[132] Before iodine replenishment is provided, hyperthyroidism is likely to be kept in check by iodine deficiency.[193] The phenomenon of iodine-induced hyperthyroidism is termed the *Jod-Basedow syndrome* (or phenomenon). Distinct from these two disorders (iodine-induced hyperthyroidism in iodine-deficient Graves' disease and nodular/multinodular goiter) are rare patients without underlying thyroid disease who paradoxically develop hyperthyroidism with iodine treatment.[10,101]

Sources of iodine besides the diet include administered iodinated radiocontrast dyes, Lugol's solution, topical antiseptics, iodine-containing expectorants, and amiodarone.[152] The typical intake of iodine in the United States is 150 to 200 μg/d, one 200 mg tablet of amiodarone contains 75 mg of iodine, of which 6 mg is liberated (corresponding to at least 30 times the usual daily intake!).

Other Exogenous Causes of Hyperthyroidism

Thyroid gland destruction from any cause, including nonautoimmune thyroiditis from viral (subacute) or bacterial (acute) causes, can release excessive amounts of thyroid hormone, producing hyperthyroidism.[179,180] Intentional or unintentional ingestion of excess thyroid hormone can also produce hyperthyroidism.[76] In one interesting report, hyperthyroidism developed in people who ate hamburger meat that included bovine thyroid glands added during the grinding process.[146]

When thyroid hormone is ingested or released from an inflamed or damaged thyroid gland, subsequent suppression of TSH reduces thyroidal iodine uptake, which is reflected in a reduction in the RAIU test. Likewise, glandular suppression will lower circulating Tg concentrations. If T_3 is ingested (e.g., Cytomel), hyperthyroidism can ensue, producing an unusual set of biochemical abnormalities: suppressed TSH, suppressed FT_4 (and total T_4, because of TSH suppression), and elevated total T_3 (and FT_3).

Maternal Graves' disease can cause fetal (and transient neonatal) hyperthyroidism from the transplacental passage of TSI.[89] In these cases, neonatal hyperthyroidism, although potentially serious and possibly fatal if not recognized and appropriately treated, is usually self-limited.

Thyroid Storm and Apathic Hyperthyroidism

Thyroid storm (also, *thyrotoxic crisis*) is an uncommon syndrome of severe and accelerating hyperthyroidism potentially manifested in (1) tachycardia, (2) restlessness, (3) high-output congestive heart failure, (4) fever greater than 41 °C, (5) extreme irritability, (6) delirium or coma, (7) hypotension, and (8) vomiting or diarrhea.[134] Although laboratory tests reveal suppressed TSH and elevated FT_4 and T_3 concentrations, thyroid storm remains a clinical diagnosis. Thyroid storm cannot be diagnosed on the basis of the magnitude of FT_4 or T_3 concentrations, or of changes observed in these hormones compared with previous measurements.

In older individuals, an unusual variant of hyperthyroidism is termed *apathetic hyperthyroidism*.[127] In this disorder, biochemical evidence of thyroid hormone excess is observed in the absence of any clinical evidence of hyperthyroidism. Alternatively, only a single organ system may be affected.

Subclinical Hyperthyroidism

A persistent depression in TSH when FT_4 and T_3 concentrations are normal identifies subclinical hyperthyroidism.[55] Patients with subclinical hyperthyroidism have increased frequencies of atrial fibrillation and osteoporosis. In the absence of a clinically compatible cardiac arrhythmia or significantly reduced bone mineral density, there is little justification for placing a patient with subclinical hyperthyroidism on thionamide therapy. The treatment of patients with asymptomatic hyperthyroidism is much more controversial than the treatment of those with asymptomatic hypothyroidism.

Nonthyroidal Illness (Sick Euthyroid Syndrome)

Any type of significant nutritional deprivation, acute severe illness, or chronic illness can result in thyroid function changes characterized as *nonthyroidal illness* (NTI; "sick euthyroid syndrome"; low T_3 syndrome; Table 55-5).[1] Suppressed peripheral conversion of T_4 to T_3 by D1 and D2 leads to decreased circulating T_3 (and FT_3), while diminished degradation of rT_3 by D1 raises circulating rT_3 concentrations (Figure 55-17). In experimental systems, interleukin (IL)-1 and IL-6 have been shown to impair D1 activity. T_3 can decline by as much as 50% with a twofold to threefold increase in rT_3. Poorly controlled diabetes mellitus and drugs such as glucocorticoids and β-blockers can also inhibit the conversion of T_4 to T_3. As mentioned previously, one effect of propylthiouracil is to block D1, inhibiting the conversion of T_4 to T_3.

Decreased T_3 reduces oxygen and nutritional demands and is considered to be an adaptive and beneficial response to illness. The recognition that NTI does not represent hypothyroidism is important because thyroid hormone replacement therapy of patients affected with NTI does not improve clinical outcome and may be detrimental.[48,79,207]

Because FT_4 concentrations are usually normal in NTI (at least in the early stages), and D2 activity is sustained in the

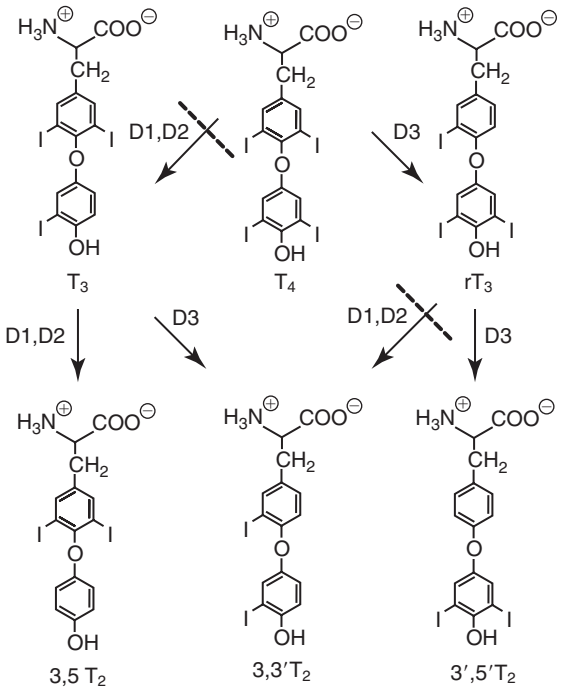

Figure 55-17 Effects of altered deiodination. In states of nonthyroidal illness (e.g., the sick euthyroid syndrome), thyroid hormone deiodination patterns are altered, with reduced T_3 concentrations and elevated concentrations of rT_3.

TABLE 55-5 Nonthyroidal Illness

	Initial	Mid Course	Prolonged	Resolution
TSH	Nl	Nl, Decr	Decr	Incr
T_4	Nl	Variable	Decr	Decr
T_3	Decr (–)	Decr (– –)	Decr (– – –)	Decr (–)
rT_3	Incr (+)	Incr (+ +)	Incr (+)	Incr (+)

Note: The severity of decreased T_3 is proportional to the number of (–) signs. The degree of increase in rT_3 is proportional to the number of (+) signs.

pituitary, the pituitary is exposed to adequate concentrations of T_3 from intrapituitary conversion of T_4 to T_3. Therefore, although plasma T_3 may decline in NTI, TSH concentrations do not rise (at least not before the recovery stage of NTI). The pulsatility of TSH is attenuated, yet TSH typically remains within the reference interval. Occasionally, paradoxical increases in FT_4 result from T_4 displacement from thyroxine-binding proteins caused by elevated free fatty acid concentrations, as well as other uncharacterized substances that rise in concentration in NTI.

With prolonged NTI, disordered hypothalamic-pituitary function causes a decline in TSH concentration, which results in a concurrent decline in FT_4. During recovery, TSH can rise above the reference interval and remain elevated until FT_4 and T_3 return to normal, usually after 1 to 2 months. The sequential stages in NTI are illustrated in Table 55-5.

Because of NTI, it can be very difficult to interpret thyroid function abnormalities in hospitalized patients. Thus, thyroid function testing in inpatients should be carried out only when there is the legitimate suspicion that thyroid dysfunction is contributing to the patient's acute need for hospitalization (such as cardiovascular disease, heart failure, or coma).

In a hospitalized patient, thyroid replacement therapy should be considered only if the TSH is significantly elevated (≥20 mIU/L). When modest elevations in TSH are observed (5 to 19 mIU/L), measurement of rT_3 may be helpful; rT_3 is low in hypothyroidism, but elevated in NTI. However, rT_3 measurements usually are not essential to the diagnosis of NTI. If a long-term hospitalized patient without hypothalamic or pituitary disease has TSH less than 0.05 mIU/L, hyperthyroidism is a possibility. With hospitalized patents, a cooperative dialogue between the clinician and the laboratorian can be helpful in deciding the proper diagnosis and management of the patient.

Thyroid Hormone Resistance

Loss-of-function mutations in the TRβ chain (the intranuclear thyroid hormone receptor, beta chain) lead to the rare syndrome of thyroid hormone resistance.[2] In this autosomal dominant condition, supraphysiologic concentrations of T_3

and T_4 (and FT_3 and FT_4) are required to maintain the euthyroid state. Therefore, in the absence of clinical hyperthyroidism, if the biochemical picture of elevated T_4, FT_4, T_3, and FT_3 is present with TSH in the upper reference interval or mildly elevated, thyroid hormone resistance is likely. Because of TSH stimulation of the thyroid, glandular enlargement may be seen because there is no resistance to TSH. Some affected patients may, in fact, have mild clinical findings of hypothyroidism. If patients with thyroid hormone resistance are incorrectly treated with thyroid-suppressing drugs, clinical hypothyroidism may be induced.

Another form of thyroid hormone resistance results from defective conversion of T_4 to T_3. This condition results from a mutation in the sequence-binding protein 2 (gene name: *SECISBP2*), which influences the synthesis of cellular deiodinases.

Euthyroid Hyperthyroxinemia

Euthyroid hyperthyroxinemia exists when total T_4 is elevated yet the patient is clinically euthyroid.[158,205] Because FT_4 measurements have supplanted total T_4 measurements, euthyroid hyperthyroxinemia is not commonly encountered in modern clinical practice.

Besides TBG elevations and the thyroid hormone resistance syndromes, euthyroid hyperthyroxinemia can also result from acute illness (through a mechanism that is not well understood) or abnormalities in albumin and transthyretin. Familial dysalbuminemic hyperthyroxinemia is an autosomal dominant disorder characterized by an albumin variant that has a greater binding affinity for T_4 (but not T_3).[16,28] Although TSH, FT_4, and total T_3 (and FT_3) are all normal, total T_4 is elevated. Mutations in transthyretin can lead to familial euthyroid thyroxine excess, an autosomal dominant disorder producing abnormal thyroid function tests similar to what is observed in familial dysalbuminemic hyperthyroxinemia.[14] These two disorders can be distinguished from conditions involving overproduction of TBG by measuring TBG concentration.

MCT8 Mutations

Loss-of-function mutations in MCT8, causing a rare form of X-linked mental retardation, have been reported.[74,211] Because MCT8 is important for the transport of thyroid hormone into neurons, there are profound adverse effects on the development of the nervous system in affected males. In addition to mental retardation and hypotonia, an unusual pattern of thyroid function abnormalities occurs, with increased T_3, normal to decreased T_4 (and FT_4), normal to elevated TSH, and low rT_3 concentrations.

Defective cellular uptake of T_3 can, in part, explain elevated T_3 concentrations in the blood. However, evidence indicates that not all tissues display equivalent defects in thyroid hormone uptake, and this may explain the decline in T_4 and rT_3. Increased T_3 concentrations in the liver may also promote T_4 and rT_3 clearance. If the pituitary or hypothalamus is less sensitive to negative feedback from thyroid hormones (because T_3 does not normally enter thyrotrophs or the hypothalamic PVN), theoretically, TSH concentrations would rise. The elevation in TSH may further contribute to elevated T_3 concentrations caused by increased T_3 production by the thyroid gland. The observation that MCT8 mutations exist requires recognition of a new pattern of thyroid function studies. Various patterns of thyroid function tests are shown in Table 55-6.

SCREENING FOR THYROID DYSFUNCTION

Other than newborn screening for congenital hypothyroidism, the value of thyroid function testing in asymptomatic individuals is highly controversial.[72,196,210] Excluding newborn screening for congenital hypothyroidism, so far no compelling data show that screening asymptomatic individuals,

TABLE 55-6 Patterns of Thyroid Dysfunction

	TSH	FT_4	Comments
Primary hypothyroidism	Increased	Decreased	– – – – –
Subclinical primary hypothyroidism	Increased	Normal	– – – – –
Primary hyperthyroidism	Decreased	Increased	T_3: increased
T_3 toxicosis	Decreased	Normal	T_3: increased
Subclinical primary hyperthyroidism	Decreased	Normal	T_3: normal
Thyroid hormone resistance due to defects in the thyroid hormone receptor	Normal to increased	Increased	T_3: increased; rT_3: increased
Thyroid hormone resistance due to defects in thyroid hormone metabolism	Mildly increased	Increased	T_3: decreased; rT_3: increased
Thyroid hormone resistance due to defects in thyroid hormone transport into cells	Normal to increased	Normal to decreased	T_3: increased; rT_3: decreased

including pregnant women or the elderly, improves the clinical outcome of the patient.

DRUG EFFECTS ON THYROID FUNCTION

Various drugs alter thyroid function in a large number of ways.[60,170] For example, dopamine, L-dopa, glucocorticoids, and somatostatin all depress TSH, potentially leading to a fall in thyroid hormone concentrations. As noted previously, iodine (including amiodarone) and lithium impair thyroid hormone synthesis or release, causing primary hypothyroidism.[85]

Many drugs inhibit conversion of T_4 to T_3, including amiodarone, glucocorticoids, β-blockers, propylthiouracil, and radiographic contrast agents. While T_3 declines and rT_3 rises, FT_4 may increase, decrease, or remain unchanged. Other drugs can displace T_4 and T_3 from thyroid hormone–binding proteins; salicylates, phenytoin, carbamazepine, furosemide, nonsteroidal anti-inflammatory agents, and heparin (in vitro effect) lower total T_4 and T_3 by occupying binding sites on proteins, yet FT_4 remains within the reference interval or rises.

Increased metabolism of thyroid hormone lowers T_4 and T_3. Phenobarbital, phenytoin, carbamazepine, and rifampicin can lower T_4 and T_3. Because (1) aluminum hydroxide, (2) ferrous sulfate, (3) cholestyramine, (4) colestipol, (5) iron sucralfate, (6) soybean preparations, and (7) Kayexalate all inhibit thyroid hormone absorption, their effects should be considered in any patient being treated with thyroxine replacement.

THYROGLOBULIN

The biology of Tg was extensively reviewed in the biochemistry section of this chapter. Some Tg normally enters the circulation by direct exocytosis from thyroid follicular cells without being iodinated. Tg is normally detected in the circulation in concentrations between 3 and 40 ng/mL. The highest Tg concentrations are in cord blood and are noted during the first weeks of life. Between 2 and 6 weeks of age, Tg concentrations are between 10 and 250 ng/mL,[51] and they decline until adulthood.[141] Three factors influence the concentration of Tg in the plasma: (1) the degree of thyroid gland stimulation via the TSH receptor, (2) the mass of thyroid tissue present in the individual, and (3) the presence of thyroid disease or damage, which leads to increased release of Tg into the circulation.

When TSH is within the reference interval, each gram of thyroid tissue provides approximately 1 ng/mL of Tg to the circulation. At TSH concentrations less than 0.1 mIU/L, each gram of thyroid tissue releases only about 0.5 ng/dL of Tg into the plasma. Trauma to the thyroid gland, inflammation (such as subacute thyroiditis or amiodarone-induced thyroiditis), surgical removal, or irradiation produces elevated Tg concentrations. Following fine-needle aspiration, Tg can be elevated for up to 3 weeks. Tg is typically decreased in acquired hypothyroidism, congenital hypothyroidism (from thyroid hypoplasia), factitious hyperthyroidism (because of TSH suppression), and following thyroidectomy.

Clinical Utility of Thyroglobulin Measurements

Thyroid cancer is classified according to the cell of origin (follicular vs. parafollicular) and the degree of differentiation (cancers of follicular origin, including differentiated papillary, follicular, or Hürthle cell carcinoma, vs. anaplastic thyroid cancer). Following surgery for differentiated thyroid carcinoma, the completeness of tumor excision can be assessed by measuring serum Tg concentrations.[54,67] If thyroglobulin autoantibodies are present (see later), Tg measurements are unreliable.

Following thyroidectomy and/or radioactive iodine therapy, plasma Tg should be undetectable unless residual thyroid tissue or metastatic lesions are present. To ensure that any remnant thyroid, or metastatic tumor, tissue is stimulated to produce Tg, the patient's TSH must not be suppressed (postoperative thyroid hormone replacement must be discontinued), or, alternatively, exogenous recombinant DNA-produced TSH (thyrogen-alpha; Thyrogen, Genzyme, Cambridge, Mass) may be given.[140] Exogenous TSH administration normally stimulates at least a fivefold increase in Tg if responsive tissue is present. With a local thyroid tumor remnant (following incomplete thyroidectomy) or a well-differentiated thyroid tumor, TSH can stimulate a tenfold increase in Tg concentration.[188] With poorly differentiated tumors, Tg rises less than threefold after TSH. One caveat is that the differentiated thyroid cancer should be shown to produce Tg before surgery is performed, lest the patient be judged to be in remission following surgery but his or her cancer is a rare non–Tg-secreting differentiated thyroid carcinoma.

Tg measurements have other clinical uses. For example, the absence of detectable Tg in the serum of an infant with congenital hypothyroidism supports the diagnosis of thyroid dysgenesis. In cases of congenital hypothyroidism where Tg is undetectable, but thyroid gland tissue is identified by thyroid scan, a Tg gene mutation should be considered. In cases of suspected factitious hyperthyroidism (hyperthyroidism caused by exogenous thyroid hormone ingestion), Tg will be suppressed; in Graves' disease, Tg is measurable.

ANALYTICAL METHODS

The approach to the laboratory assessment of thyroid function has changed considerably over the past 2 decades. This change was driven by two technologic advances: (1) a roughly 100-fold improvement in the lower detection limits of analytical methods to measure TSH, and (2) widespread availability of free (unbound) T_4 assays on automated platforms. An unfortunate consequence of this change, however, was the emergence of a confusing array of terms used to describe the analytical methods that measure thyroid hormones. Terms such as "direct," "indirect," "index," "one-step," and "two-step" are used in nonstandard and often inconsistent ways in reference to FT_4 assays.[120] In addition, the term

"analog" (or "analogue," in the UK) is often used to describe FT_4 immunoassays, as though these methods involve a technology that is unique from other competitive and noncompetitive binding immunoassays that make use of a chemically modified antigen, when the approach basically is the same. Finally, "generational" numbers have been applied to TSH immunoassays to designate the analytical sensitivity. In other analytes (such as troponin T), generational numbers mostly refer to improvements in specificity, and more sensitive assays for analytes such as C-reactive protein are simply designated as "high sensitivity." Except where helpful to establish historical relationships, use of these terms will be avoided in favor of more standard immunoassay terminology.

Measurement of Thyrotropin (TSH)

Human thyrotropin [thyroid-stimulating hormone (TSH)] is a 28 to 30 kDa dimeric glycoprotein consisting of a 92 amino acid alpha subunit (identical to the alpha subunit of human chorionic gonadotropin, follicle-stimulating hormone, and luteinizing hormone) and a 112 to 118 amino acid beta subunit. Functionally important domains are present on both alpha and beta subunits; neither is active alone. Residues 113 to 118 of the beta subunit undergo post-translational proteolytic cleavage without affecting hormonal activity, so the C-terminal end of the beta subunit apparently is not necessary for receptor binding.

Although bioassays are available for measurement of TSH activity, and radioimmunoassay (RIA) has been used as well, nearly all modern TSH methods are two-site "sandwich" heterogeneous immunoassays involving an enzyme or chemiluminescent label. Migration to more sensitive TSH methods about 2 decades ago prompted a change in the strategy for laboratory investigation of thyroid dysfunction, establishing TSH as its foundation. Sensitivity was the essential catalyst of this change because TSH concentrations may be decreased in nonthyroidal illness, and the lower limit of detection was necessary to distinguish between nonthyroidal causes of suppressed TSH and thyrotoxicosis, which is associated with TSH concentrations less than 0.01 mIU/L.

The "generational" classification divides TSH methods by analytical sensitivities separated by roughly one log unit. Thus, first-, second-, and third-generation methods have functional sensitivities of 1.0, 0.1, and 0.01 mIU/L, respectively. Some methods claim a detection limit of 0.001 mIU/L and, following this convention, are called fourth-generation methods. These definitions are not formal but were loosely adopted by manufacturers of TSH assays and are used more for marketing purposes than to express analytical performance by standard criteria.

In 1991, the Nomenclature Committee of the American Thyroid Association recommended that the *functional detection limit* of serum TSH assays should be determined on the basis of low-end interassay precision characteristics.[69] The Committee recommended that precision [coefficient of variation (CV)] at the lower reporting limit should be 10 to 15%, but no worse than 20%. Currently, functional sensitivity is defined as the lowest concentration of TSH at which an interassay CV of 20% or less can be achieved.[168,190] The American Thyroid Association determined that only TSH assays with third-generation (≤0.01 mIU/L) functional sensitivity are sufficient for use as screening tests for hyperthyroidism; their recommendation is consistent with the National Academy of Clinical Biochemistry Laboratory Medicine Practice Guideline[13] for assessment of thyroid function.

An additional complication in defining the analytical performance of TSH assays is that the hormone is subject to structural heterogeneity because of genetic polymorphisms and post-translational modifications affecting the carbohydrate content, as well as proteolytic removal of the six C-terminal beta subunit residues. There was poor agreement between various TSH immunoassays until an International Reference Preparation (IRP) isolated from pituitary tissue was made available in the 1980s. In 1999, a recombinant human TSH IRP was created,[157] but significant differences have been noted between recombinant TSH and isolates from pituitary tissue, primarily as the result of modifications of polysaccharide moieties on TSH, which are highly cell specific. Pituitary-derived TSH contains polysaccharides that are mostly sulfated, however the recombinant hormone is primarily sialylated.[157] These modifications produce epitopic diversity and change the antigenic profile of the protein. Efforts have been made to chemically modify recombinant TSH to more closely resemble the circulating form of the hormone. This approach eventually may result in better agreement between various TSH immunoassays.[40]

Principles of TSH Immunoassays

Modern automated TSH immunoassays typically involve a double-antibody approach [for which the enzyme-linked immunosorbent assay (ELISA) is the prototype], with the capture antibody directed toward the alpha subunit and a signal antibody that recognizes an epitope on the unique beta subunit.

Heterogeneous immunoassays differ in the method used to separate bound and free fractions before application of the signal antibody. The various designs of automated heterogeneous immunoassays are discussed in Chapter 16.

As noted previously, TSH immunoassays are calibrated with a reference preparation of TSH (World Health Organization Second International Reference Preparation, 2nd IRP 80/558) and are expressed as milli-international units of biological activity per liter of serum (mIU/L), a value established by bioassay. In contrast to the inverse dose-response curve produced in radioimmunoassay, immunometric assays generate a proportional dose-response curve, with larger signals corresponding to higher concentrations of analyte. Because the physiologic interval of TSH concentrations is typically three orders of magnitude, high-dose hook effects are rarely encountered with TSH immunoassays. Automated heterogeneous immunoassays for TSH offer improved sensitivity and rapid turnaround time, along with a wider linear measurement range, when compared with traditional competitive immunoassays such as RIA.

A wide variety of TSH methods are now available. Most TSH methods use a detection antibody labeled with a chemiluminescent (or electrochemiluminescent) tracer.[119,156] Some assays use peroxidase, alkaline phosphatase, photometric, and fluorescent[167] labels. Other TSH methods are based on fluorescent labels using europium chelates,[78] chemiluminescent compounds such as acridinium esters or ruthenium, or bioluminescent molecules such as recombinant aequorin.

Chemiluminescence-based immunoassays are available in several configurations.[109] For example, one assay involves a polystyrene tube coated with a monoclonal capture antibody and a polyclonal detection antibody conjugated to an acridinium ester; the acridinium ester emits a photon when reacted with hydrogen peroxide in alkaline solution.[189] Another approach uses an antibody-coated tube, a polyclonal antibody conjugated to alkaline phosphatase, and an adamantyl dioxetane phosphate ester as substrate; on dephosphorylation, the substrate decomposes and emits a sustained glow of light.[25] Cross-reactivity of this TSH assay with luteinizing hormone, follicle-stimulating hormone, human chorionic gonadotropin, or the free beta subunit of glycoprotein hormones is less than 0.001%.

Specimen Collection and Storage

Serum or plasma may be used for TSH measurements. TSH is stable for 5 days at 2 to 8 °C, and for at least 1 month when stored frozen. For newborn screening, whole blood may be collected by heel puncture 48 to 72 hours after birth.

Comments on TSH Measurements

Secretion of TSH is circadian; peak concentrations of TSH occur between 0200 and 0400, and the nadir occurs between 1700 and 1800. Low-amplitude oscillations occur throughout the day. The nocturnal increase in TSH is lost in critical illness and after surgery. TSH surges immediately after birth, reaching a peak of 25 to 160 mIU/L within 30 minutes, and declining back to cord blood concentrations by postpartum day 3. TSH concentrations stabilize to near adult concentrations within the first few weeks of life. In the first trimester of pregnancy, TSH concentrations decline as hCG stimulates the maternal thyroid gland to produce thyroid hormone, sometimes leading to a TSH concentration that is just below the lower limit of the reference interval. Reference intervals for adult TSH concentrations are the same for men and women, and no significant racial influence on concentrations of this hormone has been noted. The distribution of TSH concentrations in healthy populations is log-Gaussian (or log-normal); reference intervals should be determined nonparametrically.

Measurement of Total Thyroxine (T_4)

Thyroxine [3,5,3′,5′-tetraiodothyronine (T_4)] is the principal hormone secreted by the thyroid gland (see Figure 55-4), and its circulating concentration is under the influence of TSH. The hormone is synthesized from tyrosine residues on thyroglobulin in the colloid of the thyroid gland. Circulating T_4 is highly (>99.9%) protein bound, and the fraction that is bound to protein is biologically inactive.

Instrument-Based Methods

Electron capture gas chromatography,[150] high-performance liquid chromatography,[68] and isotope dilution tandem mass spectrometry[126,183,184A] have been used in measuring T_4 in human serum. The latter method has been suggested as a reference method for assay of T_4. With this technique, tritium-labeled T_4 is added as an internal standard before extraction, derivatization, and quantitation of T_4 by combined gas chromatography–mass spectrometry.

Immunoassays

Most clinical laboratories measure total T_4 by using an automated competitive immunoassay. Many T_4 immunoassays use high-affinity polyclonal antibodies produced against an albumin-T_4 conjugate. These polyclonal antibodies are highly specific and display minimal cross-reactivity with T_3. Thyroglobulin sometimes has been used as the immunogen because it contains iodinated tyrosine residues that are the precursors of T_4 and T_3. Monoclonal antibodies against T_4 have also been developed.

Immunoassays of total T_4 measure both free and protein-bound hormone. Accurate measurement of total T_4 therefore requires dissociation of the hormone from serum proteins (thyroxine-binding globulin, albumin, and transthyretin) that bind more than 99.9% of circulating T_4. Dissociation of T_4 from albumin is not a concern because the association constant of T_4 for anti-T_4 antibodies (usually $\geq 10^9$ L/mol) is several orders of magnitude higher than the association constant for albumin-bound T_4 (approximately 1.6×10^6 L/mol). However, association constants for T_4 binding to thyroxine-binding globulin (TBG) and transthyretin are higher: 2×10^{10} L/mol and 2×10^8 L/mol, respectively. T_4 can be dissociated from transthyretin by the addition of barbital, which competitively inhibits T_4 binding to this protein. Various blocking agents have been used to dissociate T_4 from TBG. The most common of these blocking agents is 8-anilino-1-naphthalene-sulfonic acid (ANS), although salicylate, thimerosal, and phenytoin have been used to displace T_4 from TBG. In some assays, proportional bias has been attributed to incomplete release of T_4 from serum-binding proteins.[138]

Considerable effort has been directed toward the development of immunoassays that do not require the use and measurement of radioactivity, and nonisotopic assays for T_4 are widely available for use on various automated immunoassay systems, or adaptable to automated chemistry platforms. In recent College of American Pathologists Ligand Assay Surveys, the number of participants using RIA to measure total T_4 was insufficient to report as a peer group. A variety of different labels have been used in the design of nonisotopic immunoassays. Enzymes such as horseradish peroxidase, alkaline phosphatase, and alpha-D-galactosidase are popular, in addition to fluorescent and chemiluminescent labels.

Heterogeneous enzyme immunoassays for T_4 often involve solid-phase separation systems. Some methods immobilize the anti-T_4 antibodies on a plastic surface (e.g., polystyrene beads, test tubes, microwells) so that bound and free analyte may be separated by decanting and washing. For example, one automated assay uses test tubes that contain polystyrene beads coated with a monoclonal anti-T_4 capture antibody.[11] T_4 in the specimen is liberated from binding proteins by ANS and competes with a T_4–alkaline phosphatase conjugate for binding sites on antibodies attached to the polystyrene beads. After the unbound label is rinsed away, the bound enzyme is measured using a chemiluminescent substrate. This combination of an enzyme label with a chemiluminescent substrate has been applied to other automated T_4 procedures as well. An antibody-coated tube enzyme immunoassay has been devised for measurement of T_4 and includes a peroxidase-T_4 conjugate with a photometric substrate.

Several enzyme immunoassays attach paramagnetic particles to the anti-T_4 antibodies so that free and bound T_4 can be separated magnetically. In one automated scheme, plastic cups contain magnetic beads coated with a T_4 antibody. Endogenous T_4, displaced from its binding proteins by ANS, competes with alkaline phosphatase–labeled T_4 for a limited number of binding sites on the immobilized antibody. The magnetized beads are washed to remove unbound enzyme-labeled T_4 and then are incubated with a fluorogenic substrate. As with all competitive immunoassays, the amount of enzyme-labeled T_4 captured on the magnetic beads is inversely proportional to the T_4 concentration in the specimen.

Homogeneous enzyme immunoassays have been developed for measuring serum T_4 concentration. Chapter 16 discusses several approaches to homogeneous immunoassays. In the enzyme-multiplied immunoassay technique (EMIT) for T_4, glucose-6-phosphate dehydrogenase (G-6-PDH) is covalently linked to T_4 as the enzyme label. When T_4-specific antibodies bind to the enzyme-labeled T_4, enzyme activity is inhibited as the result of steric obstruction of the substrate-binding site. The cloned enzyme donor immunoassay (CEDIA) technique for measuring T_4 is based on the use of cloned fragments of alpha-galactosidase, a tetrameric hydrolase enzyme that converts alpha-galactosides into galactose. The CEDIA approach involves two fragments of the monomeric subunit of alpha-galactosidase, the larger of which is called the *acceptor,* and the smaller of which is called the *donor.* In solution, the two fragments spontaneously associate to form a monomeric subunit, which subsequently associates with three other monomers to form the active enzyme. In the CEDIA method, T_4 is labeled with the donor fragment of alpha-galactosidase monomer, and antibody binding to the labeled T_4 prevents association with the acceptor fragment; hence, enzyme activity is lost.

Fluorescent probes have been used to measure T_4, and both heterogeneous and homogeneous immunoassays based on fluorescent labels are available. An example of the latter is the fluorescence polarization immunoassay (FPIA). In the FPIA, fluorescein-labeled T_4 competes with unlabeled hormone in the patient specimen for binding sites on anti-T_4 antibodies. Polarized excitation light (485 nm) induces fluorescence of the fluorescein tracer. Polarization of the emitted light (525 to 550 nm) requires that the orientation of the tracer remain fixed for the time interval between excitation and fluorescence; this interval is typically nanoseconds. The unbound T_4-fluorescein conjugate has a rotational frequency of femtoseconds^{-1}, so the orientation of the uncomplexed tracer is randomized between excitation and fluorescence, and polarization is lost. However, when fluorescein-labeled T_4 is bound to antibody, the rotational frequency is several orders of magnitude slower, so excitation and fluorescence occur in the same plane, and polarization is maintained.

Heterogeneous fluorescent immunoassays for T_4 based on lanthanide rare earth elements and time-resolved fluorescence are also available. The use of europium chelates as fluorescent probes is particularly attractive because of their wide Stokes shifts and long fluorescence decay times, which improve the specificity of the measurement by limiting interference from scattered excitation light and endogenous fluorophores. In a typical competitive immunoassay design, T_4 in the specimen competes with europium-labeled T_4 for a limited number of binding sites on monoclonal T_4 antibodies. Antibody-bound and free antigen fractions are separated by adsorption of T_4 antibodies to the surface of a microwell coated with antimouse immunoglobulin (Ig)G. After incubation and washing, the europium ions are dissociated from the bound phase, converted into a highly fluorescent chelate, and measured in a fluorometer with time resolution capability. A variation on this technique involves attachment of biotin to a monoclonal T_4 antibody and streptavidin coupled to the europium chelate.

Most contemporary automated immunoassays for measuring total T_4 use chemiluminescent labels. In one design, endogenous T_4 competes with T_4 coupled to paramagnetic particles for binding sites on a mouse monoclonal antibody labeled with acridinium ester. After incubation, the labeled T_4 is captured on a magnetized surface that is subsequently washed to remove the unbound label. The antibody-bound labeled T_4 is quantified in a luminometer after hydrogen peroxide is added to initiate the chemiluminescence reaction.

Electrochemiluminescence has also been applied to total T_4 measurement. In this technology, a ruthenium tris(bipyridyl) [$Ru(bpy)_3^{2+}$] complex is used as the antibody label. In the presence of tripropylamine and an applied electrical potential, the ruthenium complex undergoes a chemiluminescent reaction.

Particle-enhanced immunoassays involving turbidimetric measurements have been developed for measuring T_4 in serum. These homogeneous immunoassays are based on competition between T_4 in the specimen and a T_4-ficoll conjugate for binding sites on a monoclonal antibody coupled to microparticles. The rate of formation of cross-linked complexes is inhibited by competing T_4 and is measured turbidimetrically by the change in absorbance at 600 nm.

Dry-chemistry immunoassay systems, which do not require liquid reagents or sample pretreatment, have also been developed for T_4. One such system uses a thin-film

multilayer test module consisting of three distinct layers mounted on a plastic support. The serum specimen is applied to the top layer of film, which contains phenoxynaphthalene sulfonic acid, to displace T_4 from binding proteins. The released T_4 passes through an iron oxide screen into the detection layer, where the hormone competes with rhodamine-labeled T_4 for binding sites on immobilized T_4 antibodies. Unbound fluorescent-labeled T_4 diffuses into the opaque layers above the screen, where it cannot be detected. The fluorescent signal of the remaining antibody-bound labeled T_4 fraction is measured fluorometrically. This signal is inversely proportional to the concentration of T_4 in the specimen.

Specimen Collection and Storage

Serum is the preferred specimen for the measurement of T_4, but plasma with EDTA or heparin as anticoagulant has also been used. Plasma may form fibrin clots after freezing and thawing, however, and may produce spurious results in methods that are susceptible to changes in specimen viscosity. Gel barrier collection devices do not have any apparent adverse effect on T_4 methods. T_4 is a stable analyte with no appreciable change in concentration for up to 7 days at room temperature, or 30 days when frozen. As with most analytes, repeated freezing and thawing of specimens should be avoided because it can produce concentration gradients that require vigorous mixing to alleviate. Mild to moderate hemolysis and lipemia do not significantly affect most T_4 immunoassays; however, grossly hemolyzed specimens should be avoided because of dilutional effects. Intracellular T_4 concentrations are very low because thyroxine-binding proteins are mostly extracellular. T_4 autoantibodies interfere with some immunoassays and may produce erroneously low or high results, depending on the method.[215]

Heelstick capillary specimens have been used for T_4 measurement, as have dried blood specimens collected on filter paper. Dried blood specimens are stable and easily transported and are widely used in the United States to screen neonates for congenital hypothyroidism.[115] When this collection technique is used, a one eighth inch dot is punched out from the blood-saturated filter paper and T_4 is extracted into a buffer before the assay is performed. The filter paper should not be exposed to extreme heat or light.

Comments on Total T_4 Measurements

Total T_4 concentration alone provides limited clinical information, because it reflects mostly inactive (protein-bound) hormone. In fact, it is reasonable to question whether isolated measurements of total T_4 currently have any value in the assessment of thyroid disease. In conjunction with free hormone measurements, total T_4 may reveal protein-binding abnormalities that influence the ratio of bound to free hormone, and total T_4 should inversely correlate with TSH activity in the absence of protein-binding abnormalities. In patients with normal serum thyroxine-binding capacity (normal albumin, TBG, and transthyretin), total T_4 is proportional to the active free hormone concentration. Methods for measuring free T_4 are widely available and largely supplant the need for total T_4 measurements. As discussed later, free (unbound) T_4 measurements are more useful clinically, except in unusual circumstances.

Cord blood T_4 concentrations are lower in preterm than in full-term neonates, and they correlate positively with birth weight in full-term infants. At birth, serum total T_4 concentrations are higher in neonates because of the maternal estrogen-induced increase in serum TBG; free T_4 concentrations are near adult concentrations. Total T_4 rises abruptly in the first few hours after birth and declines gradually until adolescence. In males, T_4 production declines as they mature sexually, but this phenomenon is not observed in females.

Analytical performance goals have been recommended for thyroid hormone assays.[13] When total T_4 is used to diagnose thyroid disease, the suggested goals for maximum bias and imprecision (coefficient of variation) are 2.9% and 5.7%, respectively. When the T_4 assay is used to monitor changes in an individual over time, bias and imprecision goals are 1.3% and 2.6%, respectively.

Measurement of Triiodothyronine (T_3)

Triiodothyronine [3,5,3′-triiodothyronine (T_3)] is the principal active thyroid hormone, and although a small amount of T_3 is secreted directly by the thyroid gland, most of this hormone is produced by deiodination of T_4 in the peripheral tissues, primarily in the liver. Similar to T_4, T_3 is highly bound to protein, with less than 1% of the total concentration as free active hormone. Total T_3 measurements have limited clinical use in that the T_3 concentration usually reflects its progenitor, T_4. However, clinical conditions are known that affect peripheral conversion of T_4 to T_3 (discussed earlier), resulting in a clinical hypothyroid state in the presence of normal or elevated T_4, with normal (or even elevated) TSH. Compared with T_4, T_3 is less tightly bound to serum proteins by about an order of magnitude, so displacement of bound T_3 from proteins is essentially complete in the presence of conventional blocking agents such as ANS. T_3 does not ordinarily displace T_4 from thyroid hormone–binding proteins.

Radioimmunoassays

Numerous commercial RIA kits have been introduced for measuring total T_3 concentrations in serum. These methods are similar to the RIAs previously described for T_4, except that a ^{125}I-T_3 tracer and T_3-specific antibody are used. Most analytical designs incorporate antibodies bound to a solid phase, such as the wall of a cuvette or paramagnetic particles. As with T_4 methods, ANS can be used to release the hormone from proteins without disturbing T_3 binding to antibody.

Nonisotopic Immunoassays

Nonisotopic immunoassays for T_3 are similar to total T_4 methods. Many of the T_3 methods have been developed for use on automated immunoassay systems, and some are compatible with chemistry platforms. Many commercial methods use enzyme labels, such as peroxidase or alkaline phosphatase, conjugated to T_3 or anti-T_3 antibodies. Enzyme activity

is determined by using a variety of sensitive photometric,[99] fluorescent, or chemiluminescent substrates. Immunoassays for T_3 that use fluorescent and chemiluminescent labels are also available, and as with T_4 assays, chemiluminescence-based methods on automated platforms dominate the present clinical laboratory market. Both heterogeneous and homogeneous immunoassays for T_3 have been described.[81]

Specimen Collection and Storage

Serum is the preferred specimen, but plasma with ethylenediaminetetraacetic acid (EDTA) or heparin as anticoagulant may be used. Serum specimens should be tested within 24 hours of collection, or stored at 2 to 8 °C if tested beyond 24 hours. Frozen specimens are stable for at least 30 days. Repeated freezing and thawing of the specimens should be avoided for reasons described earlier. Turbid samples may require centrifugation before testing.

Comments on Total T_3 Measurements

Significant discrepancies have been observed when the results of different T_3 immunoassays were compared using reference sera. Interlaboratory quality assurance (proficiency testing) results also demonstrate higher analytical variance for T_3 compared with T_4 methods. Among the factors that have been suggested to account for the poorer analytical performance of T_3 immunoassays are the lower concentration of T_3 in serum, the greater antibody cross-reactivity, protein interferences, and the different assay limits of detection. Performance goals for bias and precision have been suggested for T_3.[13] When a total T_3 assay is used for diagnosis, the suggested goals for maximum bias and imprecision are 5.7% and 11.5% (CV), respectively. For therapeutic guidance, bias and imprecision goals are 2.6% and 5.2%, respectively. Total T_3 measurements are useful in the diagnosis and monitoring of hyperthyroid patients with suppressed TSH and normal free T_4 concentrations ("T_3-thyrotoxicosis"); T_3 measurements have only limited value in euthyroid and hypothyroid patients.[83] Thyroid hormone replacement for hypothyroid patients is based on TSH and FT_4 measurements.

Measurement of Reverse Triiodothyronine (rT_3)

Reverse T_3 is produced by monodeiodination of the alpha ring of T_4 to 3,3′,5′-triiodothyronine and is biologically inert. Several radioimmunoassay methods for measuring rT_3 have been developed. Antibodies to rT_3 generally are obtained by immunizing rabbits with rT_3-human serum albumin (HSA) [or bovine serum albumin (BSA)] conjugates.[32] Cross-reactivity of anti-rT_3 antibodies with T_4 varies between 0.01% and 0.15%, and insignificant cross-reactivity of these antibodies with monoiodinated and di-iodinated thyronines is noted.[117] Similar to T_3 and T_4, rT_3 is highly bound to TBG, transthyretin, and albumin in serum but is displaced by ethanol extraction or ANS.

Commercial assays for measurement of rT_3 are available, but none has been adapted to an automated platform because rT_3 measurement has limited diagnostic value.

Specimen Collection and Storage

Specimen requirements for rT_3 are essentially the same as those previously described for T_3.

Comments on rT_3 Measurements

Reverse T_3 in serum is produced almost exclusively from peripheral deiodination of T_4 by 5-deiodinase (D1 or D3) enzymes. Although deiodination of T_4 in the peripheral tissues produces roughly equal amounts of T_3 and rT_3, the serum concentration of rT_3 is typically lower than that of T_3 because it is metabolized and cleared more rapidly. Serum rT_3 concentrations are elevated at birth, but decrease to stable concentrations by about the fifth day of life. Reverse T_3 in amniotic fluid decreases with increasing gestational age. The use of rT_3 to diagnose sick euthyroid syndrome has been questioned because of its poor sensitivity. Renal failure is associated with low rT_3 concentrations.

Measurement of Free Thyroid Hormones

No practical methods are available for measuring the exact concentration of unbound, active thyroid hormones. Bioassays can measure the activity of T_3 and T_4 but are imprecise and are not easily adapted to automated chemistry analyzers. Direct potentiometry measures the activity of various electrolytes, independent of the inactive bound fraction, but electrodes that respond to thyroid hormones have not been developed. Methods that remove unbound T_4 inevitably disrupt the equilibrium between bound and free hormone; therefore at best, FT_4 methods only approximate the true active concentration of the hormone.

In physiologic systems, proteins often act in much the same way as the conjugate acid or base in a pH buffered solution, providing a large reservoir of bound, inactive ligand that protects against precipitous changes in the total concentration of a hormone resulting from variations in glandular output. In principle, the free, active concentration of T_4 or T_3 could be mathematically derived by measuring the total T_4 concentration in a manner analogous to the way blood gas analyzers use the Henderson-Hasselbalch equation to calculate the bicarbonate concentration from measured pH and PCO_2 (from which the undissociated acid is estimated). The cumulative dissociation constant for T_4 from its binding proteins is approximately 10^{-5}, which is similar to the K_a of a weak acid, producing a free T_4 concentration that is approximately 0.03% of the total T_4 concentration. However, this approach is not satisfactory for two reasons: (1) T_4 binds to at least three different proteins, the concentrations of which change in a variety of clinical conditions, and only one (albumin) is routinely measured in clinical laboratories; and (2) the affinities of T_4-binding proteins for the hormone can be altered by competing ligands, as well as by genetic polymorphisms that alter the protein structure and thyroid hormone–binding affinities.

Clinical assessment of thyroid function in symptomatic patients with normal TSH, or asymptomatic patients with low or high TSH, has focused on measuring FT_4, because this can reveal whether TSH activity is consistent with the

concentration of active hormone, regardless of abnormalities in binding protein concentrations or affinities.

Analytical strategies for measuring FT_4 have followed one of two basic paths: (1) separate the bound and free fractions and measure the concentration of T_4 (immunometrically or gravimetrically) in the free fraction; or (2) assay the free fraction using a competitive T_4 analog that does not bind to albumin, TBG, or transthyretin. The former category includes equilibrium dialysis and ultrafiltration (coupled with a variety of immunochemical or mass spectrometric methods for measuring T_4 and T_3 in the free fraction), and the latter comprises an assortment of competitive and noncompetitive immunoassays available on automated systems. The term *direct method* has been used to describe FT_4 methods that measure the concentration of free hormone (i.e., equilibrium dialysis and ultrafiltration). Alternatively, the *indirect method* often refers to an immunoassay that measures quantities of both bound and free fractions, relying on calibration against specimens with FT_4 concentrations verified by "direct" methods. Neither of these terms is consistently used, however, and both approaches, to a greater or lesser degree, only approximate the FT_4 concentration.

The analytical validity and clinical utility of FT_4 methods have been debated for longer than 2 decades.[43-45,121,122,222-224] Special reports from the Nomenclature Committee of the American Thyroid Association of the National Academy of Clinical Biochemistry[69] the Clinical and Laboratory Standards Institute (CLSI) [formerly National Committee for Clinical Laboratory Standards (NCCLS)] review some of the issues and concerns regarding free thyroid hormone measurements.

Direct (Reference) Methods

Direct measurement of FT_4 (and FT_3) in serum is technically challenging because the amount of free hormone in normal serum is exceedingly small—typically less than 100 pmol/L (or ng/L). The most reliable methods for measuring FT_4 and FT_3 in serum involve separation of free and bound hormone fractions by equilibrium dialysis or ultrafiltration, and subsequent measurement of the free concentration by a sensitive analytical method such as immunoassay or mass spectrometry. In equilibrium dialysis, the dialysis buffer dilutes the specimen, so there is some effect on the equilibrium between bound and free hormones, but the effect is minimal. Similarly, ultrafiltration changes the concentration of T_4-binding proteins in the retentate, changing the bound/free equilibrium.

Equilibrium Dialysis

In a equilibrium dialysis method for FT_4 and FT_3 described in 2008,[230] 200 µL aliquots of serum were dialyzed against 200 µL of a HEPES buffer containing physiologic concentrations of sodium, chloride, potassium, magnesium, sulfate, phosphate, calcium, and urea, with sodium azide added as a preservative using a cellulose membrane (5 kDa molecular weight cutoff). Specimens were dialyzed at 37 °C for approximately 20 hours. After the addition of ^{13}C-labeled internal standards, T_3 and T_4 were extracted from the dialysate onto a C5 guard column, and then were eluted into a polar LC column [solid-phase extraction-liquid chromatography (SPE-LC)] before analysis by tandem mass spectrometry. The upper and lower limits of quantitation, using the criterion of ±15% total bias, were 400 and 1.0 ng/L, respectively. FT_4 results using this method correlated well with equilibrium dialysis/RIA. FT_3 results by the SPE-LC-MS/MS method were compared with equilibrium tracer dialysis (see later), and a bias of 38 to 53% was observed. Others have reported similar equilibrium dialysis methods using LC-MS/MS to quantify FT_4.[208]

Ultrafiltration

A second method for separating protein bound and free fractions of T_4 is ultrafiltration, which is significantly less time-consuming than dialysis.[200] In an ultrafiltration method described by Soldin and coworkers,[184] the serum specimen was filtered through a 30 K MW cutoff filter by centrifugation for 1 hour at 25 °C and 2900 rpm in a fixed-angle rotor. T_4 was measured in the ultrafiltrate by isotope dilution LC/MS-MS. Results using this ultrafiltration method correlated closely with equilibrium dialysis and immunoassay. In a 2009 report,[77] performance of this method was assessed in four different patient populations: (1) pediatric, (2) euthyroid adults with thyroid disease (both before and after thyroidectomy), (3) healthy nonpregnant women, and (4) pregnant women. In all of these groups, FT_4 values measured by ultrafiltration and LC-MS/MS correlated inversely with log-transformed TSH concentrations.

Equilibrium Tracer Dialysis

Equilibrium tracer dialysis is a variation of equilibrium dialysis, except that isotopically labeled T_4 or T_3 "tracer" is added to the specimen before dialysis is performed. When equilibrium is established, concentrations of the tracer on both sides of the dialysis membrane are used to calculate the ratio of bound to free hormone, so the FT_4 (or FT_3) concentration can be calculated based on the total T_4 (or T_3) concentration. If the amount of tracer added to the specimen is small in comparison with the endogenous hormone concentration, minimal disruption of free/bound hormone is noted. This method is thought to provide the best estimate of FT_4 concentration, because radioassay methods for measuring T_4 have very low limits of detection, and displacement of hormone from binding proteins in the retentate is not required. However, equilibrium tracer dialysis involves the use of radioactive isotopes, a lengthy dialysis step, and instrumentation for measuring radioactivity. These considerations limit its use for routine measurement of FT_4 and FT_3.

Comments on Free Hormone Measurements Using Separation Techniques

Ultrafiltration provides a faster (an hour or less) means for separating protein-bound and free hormone fractions compared with equilibrium dialysis, which ordinarily requires 24 hours. Mass action, however, suggests that ultrafiltration

disrupts free/bound equilibrium concentrations, as the protein concentration increases in the retentate during filtration. Some ultrafiltration methods are performed at physiologic temperature because of concerns about temperature-related changes in the equilibrium concentration of free hormone, but it is interesting to note that Soldin and associates found that ultrafiltration at 25 °C produced FT_4 results that correlated better with equilibrium dialysis (at 37 °C) than with ultrafiltration at 37 °C.[184]

The reliability of ultrafiltration as a method for quantitatively separating free T_3 and T_4 fractions in serum has been questioned. In a 2007 study, Fritz and colleagues[56] demonstrated poor recovery of isotopically labeled T_4 and T_3 when reference materials prepared in protein-free serum filtrates were passed through four commercially available ultrafiltration devices. Tritiated water was used as the internal standard and was evenly distributed between ultrafiltrate and retentate in all cases. However, large discrepancies between labeled hormone concentrations in the filtrate and retentate were observed. The authors of the study conclude that ultrafiltration "is complex, poorly characterized, and incompletely understood." Whether such anomalies also affect the results of equilibrium dialysis, which is similarly based on the presumption that free hormone equilibrates across a semipermeable membrane, has not been studied.

Free Thyroid Hormone Immunoassays

Many free thyroid hormone assays are commercially available for use on automated chemistry and immunoassay platforms. Before the advent of automated methods for measuring free T_4, strategies emerged to approximate free hormone by measuring the total T_4 concentration and using an indirect method to assess protein-binding capacity. These methods are no longer useful because immunoassays to measure the FT_4 concentration are widely available. Even though FT_4 immunoassays (both one- and two-step) are susceptible to bias when serum proteins that bind the hormone deviate significantly from normal concentrations, or when binding affinity is altered by genetic polymorphisms or competing ligands, in the vast number of patients, these assays provide reliable estimates of FT_4 concentration. Therefore, "index" methods that estimate free hormone concentrations based on protein-binding capacity are mostly obsolete. For more information on index methods, see the previous edition of this textbook.

General Considerations

Immunochemical methods for measuring FT_4 follow two basic strategies: (1) noncompetitive assays involve adsorption of free hormone on immobilized anti-T_4 antibodies, removal of the supernatant, and quantitation of the unoccupied solid-phase binding sites through addition of labeled T_4; the captured amount of labeled T_4 is inversely proportional to the FT_4 concentration; (2) alternatively, competitive immunoassays involve a labeled T_4 derivative (often called "analog," the distinguishing feature of which is significantly reduced affinity for T_4-binding proteins) that is added to serum along with anti-T_4 antibodies, and after isolation of the antibody fraction, the amount of labeled T_4 analog captured by the antibody will be inversely proportional to the endogenous FT_4 concentration. This approach is sometimes called "one-step," because only one separation of bound and free ligand is involved, in contrast to "two-step" methods, which remove the soluble protein fraction before the addition of the labeled ligand. Another approach is to immobilize T_4 analogs on a solid support and measure the amount of labeled antibody adsorbed on the solid support; in this design, captured label will be inversely proportional to the concentration of FT_4, which competes for binding sites on the labeled antibody.

Analog methods measure the distribution of labeled T_4 between endogenous binding proteins (TBP, transthyretin, and albumin) and an anti-T_4 antibody. Therefore, these methods produce only an estimate of the FT_4 concentration, because the introduction of an exogenous binding protein—the T_4 antibody—disrupts the equilibrium between free and bound hormones in the specimen. If the assay is calibrated with calibrators that have similar T_4 protein–binding capacity to the specimen being assayed, and if the calibrators have been validated using a reference method (such as equilibrium dialysis), then the results provide a good estimate of FT_4 concentration. However, biases will be introduced when the concentrations, or affinities, of T_4-binding proteins deviate significantly from expected values, because calibration of these methods assumes a normal serum T_4-binding capacity. The serum protein-binding capacity for thyroid hormones can be affected by physiological variations in protein synthesis (as in pregnancy and infancy), proteinopathies resulting from liver dysfunction (such as hypoalbuminemia), nonthyroidal disease, genetic factors that produce proteins with diminished or enhanced T_4 binding, competing ligands, and the presence of T_4 autoantibodies. With the exceptions of pregnancy and infancy—most notably, prematurity—most of these conditions are relatively rare.

Another source of bias in FT_4 immunoassays that involve a T_4 analog is the binding of analog to serum proteins, which has been demonstrated to occur.[137] Because analog methods are based on the theoretical principle of competition between free analog and free endogenous T_4 for binding sites on the capture antibody, significant binding of the hormone analog to serum proteins invalidates the theoretical model. The extent to which these limitations affect the FT_4 estimates obtained by one-step analog methods has been debated (see earlier).

Two-Step FT_4 Immunoassays

The key feature of the two-step method is that the labeled hormone is added only after serum-binding proteins have been removed, ensuring that no competition exists between antibody and serum proteins for binding of tracer. This does not ensure that the assay is not susceptible to changes in serum protein-binding capacity, because the initial step involves equilibration of labeled FT_4 between the capture antibody and serum hormone-binding proteins. However, results using this approach correlate well with reference

(equilibrium or ultrafiltration) methods across a wide variety of clinical disorders.

The first commercially available two-step immunoassay for FT_4 was introduced in 1979. Subsequently, a number of manual and automated procedures were developed for FT_4 (and FT_3). The earliest methods used radioactive labels and antibody-coated tubes or microbeads, but these have been largely replaced by automated methods involving nonisotopic labels and a variety of solid-phase formats. Automated "one-step" homogeneous FT_4 immunoassays have largely supplanted the use of these methods.

One-Step FT_4 Immunoassays

"One-step" FT_4 immunoassay is a slightly confusing misnomer, because homogeneous immunoassays are typically "one-step," in that no separation is required. However, all "one-step" approaches to immunochemical measurement of FT_4 and FT_3 are competitive, heterogeneous immunoassays, requiring separation of bound and free ligand prior to measurement of signal. These FT_4 methods are, for the most part, variations on the prototypical ELISA described in Chapter 16. Two common approaches consist of one involving labeled ligand, and the other using a labeled antibody.

In the labeled ligand scheme, anti-T_4 antibody may be immobilized to a solid support or bound to a paramagnetic particle, which can be used to capture the antibody-ligand complex. Free T_4 in the specimen and the labeled T_4 analog compete for binding sites on the anti-T_4 antibodies, and the amount of label adsorbed by the antibody is inversely proportional to the endogenous T_4 concentration. Of course, capture of endogenous T_4 will disrupt the equilibrium between protein-bound and free T_4, so the assay really measures the competition between thyroid hormone–binding proteins and the anti-T_4 antibody. Typical assays of this type remove 1 to 2% of the protein-bound T_4 fraction—a quantity that exceeds the true FT_4 concentration by at least two orders of magnitude. Theoretical arguments have been made that removal of such a small amount of the total T_4 causes minimal disruption of the bound/free ratio; therefore a properly calibrated method should produce a close estimate of the actual FT_4 concentration.[33,121,122]

Another analytical strategy for measuring FT_4 is to immobilize a modified T_4 analog to a solid support (or paramagnetic particle), and allow a labeled anti-T_4 antibody to equilibrate between endogenous FT_4 and the immobilized analog. Evidence suggests that immobilized T_4 analog has less affinity for T_4-binding proteins than the labeled free analog described earlier,[231] which makes the labeled antibody methods less susceptible to bias resulting from binding of the T_4 analog to endogenous proteins. In the labeled antibody method, after the unbound fraction is removed, the signal is measured in the solid (or immobilized) phase and will be inversely proportional to the FT_4 concentration. As with labeled ligand methods, substantially more endogenous T_4 is bound to antibody than is contained in the original free fraction as the result of re-equilibration after free T_4 binds to antibody, but the fraction removed from binding proteins is small (1 to 2%) compared with the total T_4 concentration, so the equilibrium bound/free ratio is not significantly affected. These methods are calibrated with reference materials containing normal quantities of T_4-binding proteins, and in which FT_4 (or FT_3) has been measured by a reference method such as equilibrium dialysis or ultrafiltration.

Many commercially available FT_4 and FT_3 assays follow one or the other of the labeled ligand or labeled antibody schemes, differing only in (1) the label, (2) the analog, and (3) the chemical method for immobilizing antibody or analog. Radioactive isotopes, enzymes, fluorophores, and chemiluminescent and electrochemiluminescent labels have been used in FT_4 immunoassays, but most modern methods use one of the latter two. The structure of the analog, which is a modified form of T_4 designed to have limited affinity for thyroxine-binding protein, albumin, and transthyretin, is often proprietary, although T_4 analogs involving protein conjugates have been described in the literature.[231] In these experiments, T_4 was conjugated to rabbit gamma globulin, thyroglobulin, transferrin-1 (and -2), and ferritin. The antibody or analog are immobilized by biotin-avidin (or streptavidin) or paramagnetic particles.

Selection of Tests for Measuring Free Thyroid Hormones

Immunoassays that estimate FT_4 and FT_3 using the approaches just described generally produce reliable results in healthy subjects, hyperthyroid and hypothyroid patients, and patients with mild protein-binding abnormalities. Hence, for most clinical situations, selection of a specific FT_4 or FT_3 method can be based on factors such as (1) technical convenience, (2) turnaround time, (3) commercial availability, and (4) cost. In certain clinical conditions, however, free hormone estimates may produce results with significant bias compared with reference methods. Table 54-4 summarizes the types of bias that have been observed between reference and estimate methods for FT_4 in patients with thyroid hormone–binding protein abnormalities. One study[172] examined the bias between nine commercially available FT_4 immunoassays and equilibrium dialysis in patient specimens with low, normal, and high concentrations of T_4-binding proteins. Relative to specimens with normal concentrations of binding proteins, the low group had a mean TBG concentration 21% lower, and the high group had a mean TBG concentration 167% higher. Although little bias was observed for high-concentration TBG specimens, significant negative bias was observed in low-TBG concentration specimens. A 2009 study[98] compared FT_4 measured by two immunoassays in nonpregnant women and pregnant women subdivided by trimester. Although results were not compared with FT_4 measured by a reference method, a large number (5 to 67%) of pregnant subjects had FT_4 concentrations below the assay manufacturer's lower reference limit, although all specimens had normal total T_4 concentrations.

In addition to pregnancy, other clinical conditions may produce unreliable FT_4 results. In patients with familial dysalbuminemic hyperthyroxinemia (estimated incidence among Caucasians: 1:10,000), a normally minor albumin

variant with a high affinity for T_4 is overexpressed, resulting in a larger fraction of albumin-bound T_4 and elevated total T_4. The affinity of the albumin variant for T_3 is not significantly different from normal albumin. Patients with familial dysalbuminemic hyperthyroxinemia are clinically euthyroid, and free hormone concentrations are normal as measured by reference methods and by most two-step immunoassays. However, one-step immunoassays are likely to produce erroneously high FT_4 estimates as the result of binding of the T_4 analog to the variant albumin. Patients with circulating T_4 autoantibodies, or with increased transthyretin, will produce similarly elevated FT_4 results by these immunoassays, because both conditions result in enhanced T_4-binding capacity in the serum.

FT_4 and FT_3 methods may not be reliable in patients with congenital TBG excess or deficiency, because the immunoassay methods are calibrated with reference materials containing normal amounts of TBG, and most of the circulating hormone is bound to this protein. Patients with these conditions are clinically euthyroid, and their FT_4 and FT_3 are usually within their reference interval when measured by reference methods (and sometimes by two-step immunoassays).

Estimates of FT_4 and FT_3 may be affected by medications that displace hormones from binding sites on serum proteins. The free hormone concentration will rise in the presence of such drugs, and in patients with normal thyroid function, TSH will be suppressed and production of T_4 will decrease, resulting in lower total T_4 with (after delay) normalized FT_4. With methods that use undiluted serum (ultrafiltration and equilibrium dialysis), measurement of FT_4 and FT_3 in the presence of competing drugs should be reliable. However, methods that dilute the specimen diminish the effects of inhibitors, and free hormone concentration may be underestimated.

Measurement of Thyroxine-Binding Globulin (TBG) and Other Thyroid Hormone–Binding Proteins

Thyroxine-binding globulin (TBG) is a 54 kDa protein that binds T_4 and T_3 with high affinity ($K_a \cong 10^{10}$). Although TBG has the lowest concentration of any of the three proteins that bind T_4, and its hormone binding sites are normally only 25% saturated, about 70% of the total T_4 and 80% of the total T_3 is bound to TBG. Therefore, TBG concentration is the primary regulator of total and free T_4 and T_3 concentrations. Estrogen-induced TBG excess and congenital TBG deficiency are the most significant TBG abnormalities that affect the interpretation of thyroid function test results (Box 55-4).

Methods for Measuring TBG

Historical methods measured TBG indirectly by competition between unlabeled and radiolabeled T_4 for binding sites on TBG, while blocking T_4-binding sites on transthyretin and albumin with a barbital buffer. After removal of the unbound hormone, radioactivity retained in the protein fraction was proportional to the TBG concentration. The presence of various drugs that inhibit T_4 binding to TBG, or abnormal transthyretin and albumin concentration or affinity, can interfere with these assays and produce artificially low TBG measurements.

Modern TBG methods measure the protein concentration directly using a variety of immunochemical approaches. One competitive, heterogeneous method measures the competition between endogenous TBG and labeled TBG for binding to an immobilized anti-TBG antibody. After incubation, bound and free fractions are separated by a variety of standard methods, and the concentration of label in the bound fraction is inversely proportional to endogenous TBG concentration. A competitive chemiluminescence enzyme immunoassay for TBG uses peroxidase-labeled TBG and anti-TBG antibody that is captured by a solid-phase second antibody; bound conjugate is measured by chemiluminescence after the addition of luminol and hydrogen peroxide. Another immunoassay for TBG is based on enhanced microparticle turbidimetry, in which the presence of endogenous antigen inhibits the cross-linking of antigen-microparticle complexes by anti-TBG antibody, reducing the turbidity of the reaction mixture.

Specimen Collection and Storage

Serum is the preferred specimen; plasma with EDTA or heparin as anticoagulant may also be used. Serum specimens are best stored at 2 to 8 °C if they will not be tested within 24 hours. If longer periods of storage are necessary, freezing the

BOX 55-4 Alterations in the Concentration or Affinity of Thyroid Hormone–Binding Proteins

Increases in
- A. Thyroxine-binding globulin (TBG) concentration (or affinity)
  - 1. Genetic (inherited) causes
  - 2. Nonthyroidal illness (HIV infection, infectious and chronic active hepatitis, estrogen-producing tumors, acute intermittent porphyria)
  - 3. Normal physiology (pregnancy, newborn)
  - 4. Drug use (oral contraceptives, estrogens, tamoxifen, methadone)
- B. Prealbumin concentration
- C. Albumin binding (familial dysalbuminemic hyperthyroxinemia)
- D. T_4 binding by antibodies (autoimmune thyroid disease, hepatocellular carcinoma)

Decreases in
- A. TBG concentration
  - 1. Genetic (inherited) determination
  - 2. Nonthyroidal illness (major illness or surgical stress, nephrotic syndrome)
  - 3. Drug use (androgens, anabolic steroids, large doses of glucocorticoids)
- B. TBG-binding capacity (drugs bound to TBG such as salicylates and phenytoin)
- C. Prealbumin concentration

specimens is recommended. Frozen specimens are stable for at least 30 days. Repeated freezing and thawing of the specimens should be avoided. Turbid samples should be centrifuged before testing.

Thyroglobulin Measurement

Both competitive and noncompetitive immunoassays have been applied to Tg measurement.[190,228] Present-day competitive immunoassays typically incubate the serum with anti-Tg antibody; this is followed by the addition of ^{125}I-labeled Tg. The Tg–anti-Tg complex is precipitated by a second antibody, separating antibody-bound from free ^{125}I-labeled Tg. Longer incubation generally enhances the sensitivity of the assay.

Noncompetitive (sandwich) immunoassays for Tg have been developed using a variety of labels (radioactive isotope, enzyme, chemiluminescent, and electrochemiluminescent). The capture antibody and the labeled (or signal) antibody recognize different epitopes on Tg that do not sterically interfere with one another. The capture antibody can be attached to a polystyrene bead or a paramagnetic bead to separate bound and free fractions of antigen. Another variation is to attach an antibody to biotin and separate the biotin-antibody-Tg complex using avidin bound to a solid phase.

For most Tg double-antibody assays, the lower limit of detection is near 0.5 to 1 ng/mL, with a coefficient of variation of ≈20%. Day-to-day coefficients of variation are usually less than 6% near the center of the reportable interval but can rise to 15% at very low or very high Tg concentrations.

A Tg reference preparation developed by the European Community Bureau of Reference is used in many present-day immunometric assays. With this reference preparation, interassay variability is ≈30%, which exceeds intraindividual biological variability by a factor of three. Because of such variability between different Tg assays, Tg monitoring requires that the same assay be used longitudinally. Alternatively, if a new Tg assay is introduced, the baseline Tg concentration for the patient should be re-established with the new assay.

Technical challenges in Tg measurement include poor interassay agreement, hook effects, interassay calibration variability, and the need to reduce the lower limits of detection of Tg immunoassays for improved detection of residual thyroid cancer, metastasis, or recurrence.[75] A new generation of Tg assays with enhanced lower limits of detection may eliminate the need to withdraw thyroid hormone replacement or administer rDNA TSH before Tg testing is performed.[62]

Thyroglobulin Assay Interferences

Interference from human antimouse antibodies (HAMA), other heterophile antibodies, or rheumatoid factor can affect almost any immunoassay. Thyroglobulin autoantibodies (TGA) in the patient's blood also interfere with accurate measurement of Tg.[187] Unfortunately, anti-Tg autoantibodies are much more common in thyroid cancer patients than in the general population. TGA are reported in 15 to 35% of thyroid cancer patients.

It is standard practice to search for TGA whenever Tg is measured. The TGA assay should be sensitive to low concentrations of TGA. TGA tend to decrease Tg measurements in noncompetitive assays. Although some laboratories might use polyethylene glycol to precipitate TGA-bound Tg to measure the nonbound Tg fraction, practically speaking, if TGA are detected, the Tg determination is not reliable. Therefore, Tg measurements should not be used as tumor markers in the clinical management of patients with demonstrated TGA.

The interference of TGA with various two-site sandwich immunoassays is unpredictable. TGA increase Tg concentrations in some assays. In other assays, TGA may result in negative bias. Recovery studies generally are not useful for determining whether TGA influences the Tg concentration.[107,186]

When TGA are detected, their concentration may be useful as a secondary marker of the mass of thyroid tissue present in the patient. If TGA concentrations reflect the degree of antigenic stimulation of B cells, higher TGA concentrations should correlate with greater amounts of thyroid tissue in the patient. Therefore, in differentiated thyroid cancers where TGA are positive, higher TGA concentrations suggest more residual thyroid tissue and/or local or distal spread of the tumor. Because of the uncertainty that TGA positivity introduces into the interpretation of any Tg assay, however, clinicians should rely principally on thyroid scans to detect residual thyroid tissue in cases of differentiated thyroid cancer when TGA are present.

Specimen Collection and Storage

The preferred specimen for Tg measurement is serum, but EDTA or heparinized plasma may also be used. If not tested within 24 hours, serum specimens are best stored at 2 to 8 °C. If testing is delayed beyond a few days, the specimen should be frozen until it is analyzed. Frozen specimens are stable for at least 30 days. Repeated freeze-thaw cycles should be avoided. Turbid samples should be centrifuged before testing.

Reference Interval

The reference interval for Tg in euthyroid individuals varies from a lower limit of 0.5 to 2 ng/mL to an upper limit of 20 to 42 ng/mL, depending on the method. One major reference laboratory provides the following reference intervals: 0 to 11 months: 0.6 to 5.5 ng/mL; 1 to 11 years: 0.6 to 40.0 ng/mL; and 12 years and older: 1.3 to 31.8 ng/mL. For patients lacking a thyroid gland who are not receiving T_4 replacement therapy, Tg should not be detectable regardless of the patient's TSH concentration.

Novel Markers of Thyroid Tissue in the Management of Differentiated Thyroid Carcinoma

Another approach to the detection of residual thyroid cancer is the measurement of Tg mRNA in the circulation.[164] This may be helpful when Tg cannot be measured because of TGA.

This procedure involves reverse-transcriptase polymerase chain reaction amplification of mRNA in serum.[159] This nucleic acid approach may be valuable as an early marker of relapse.[160] However, the value of Tg mRNA detection is controversial because of problems with both sensitivity and specificity.[46,57] Thyroperoxidase and TSH receptor mRNAs are alternative markers that are under investigation.[162] In research studies, the detection of minimal residual disease in thyroid cancer has also included polymerase chain reaction detection of cytokeratin 20.[219]

Thyroid Autoantibodies

Multiple autoantigens are targeted in AITD, including thyroperoxidase, thyroglobulin, the TSH receptor, a thyroid colloidal antigen, the NIS, and megalin.[105,177] Autoantibodies that appear to promote thyroid growth have also been described.[206] These antibodies stimulate tritiated thymidine uptake, a measure of cellular proliferation, without increasing cAMP generation—a measure of TSH-like stimulation. Autoantibodies against T_4 and T_3 have also been described; and these may interfere with measurement of these hormones but do not appear to cause clinical disease.[151,173]

Thyroid microsomal autoantibodies (TMAs), thyroperoxidase autoantibodies (TPOAs), and thyroglobulin autoantibodies (TGAs) can be detected by a variety of methods, including (1) indirect immunofluorescence, (2) the agar gel diffusion precipitin technique, (3) agglutination (hemagglutination or latex particle agglutination), (4) radioimmunoassay, (5) complement fixation, (6) ELISA techniques, and (7) chemiluminescence-based immunometric assays.[27,221] Modern assays have reduced the lower limits of detection of these autoantibodies. With the older agglutination techniques, red blood cells denatured with tannic acid treatment were coated with microsomal antigen isolated from human hyperplastic thyroid glands. TMA-positive sera would agglutinate the "tanned" RBCs. Serial dilutions were performed until agglutination was not detected. The last dilution before the disappearance of agglutination represented the "titer." Newer immunoassays are more sensitive and can detect lower concentrations of these autoantibodies. For example, some assays attach TPOs to a solid support, and, with the addition of patient serum, TPOA bind to the immobilized TPOs. A labeled antihuman immunoglobulin antibody is added to detect the TPOAs. Similar assays for TGAs are available. Because of the interference of TGAs with Tg measurements, TGAs assays with excellent low-end sensitivity are very important.

It was initially believed that TGAs developed because thyroglobulin was released into the circulation following thyroid follicular cell damage, thus exposing the immune system to a previously sequestered antigen. However, as discussed previously, sensitive radioimmunoassays demonstrated that Tg was present in normal serum; thus Tg does not appear to be a sequestered antigen.

Two assay formats are commonly used for measuring thyroid receptor autoantibodies (TRAs): measurement of (1) thyroid-stimulating immunoglobulins (TSIs), and (2) thyrotropin-binding inhibitory immunoglobulins (TBIIs). TRAs are detected using bioassays for TSIs and radioreceptor assays for TBII. A report published in 2009 describes an automated assay for TBIIs.[59] In most patients with Graves' disease, TSIs can be detected.[194]

TSIs are measured by adding patient serum to thyroid follicular cells and assessing the release of T_4 or cAMP (the secondary messenger generated by stimulation of the TSH receptor), or by observing colloid mobilization.[199] A variety of sources of thyroid follicular cells have been used, such as thyroid slices or cultured human thyroid cell monolayers (FRTL-5).

TBIIs are measured in a radioreceptor assay format.[70] Patient serum is added to a solution containing TSH receptors. Competition then occurs between ^{125}I-labeled TSH and TRAs in the patient serum for binding to TSH receptors. As the concentration of TRAs rise in a patient's serum, less ^{125}I-labeled TSH will bind to TSH receptors present in the assay. The TBIIs assay does not distinguish agonistic from antagonistic TRAs. Therefore, TBIIs typically are positive in both Graves' disease and atrophic thyroiditis, and negative in Hashimoto thyroiditis. However, TSIs are negative in atrophic thyroiditis. TSIs and TBIIs should be measured in pregnant women with Graves' disease (past or present) to assess the risk of fetal or neonatal thyrotoxicosis from maternal IgG that has crossed the placenta: if TSIs are present in high concentration, the risk for the development of fetal or neonatal thyrotoxicosis is increased. TSIs are detected in 95% of patients with untreated Graves' disease. Several studies have shown that higher TSIs concentrations predict relapse and lower rates of remission. In atrophic thyroiditis in pregnant women, TBIIs can cross the placenta, and this may result in transient congenital hypothyroidism or transient hyperthyrotropinemia.[108] On the other hand, TPOAs/TMAs and TGAs are not associated with congenital hypothyroidism, indicating that these autoantibodies are not pathogenic.[42]

CHAPTER 56

Reproductive Endocrinology and Related Disorders

*T. Scott Isbell, Ph.D., Emily Jungheim, M.D., and Ann M. Gronowski, Ph.D.**

Reproductive endocrinology encompasses the hormones of the hypothalamic-pituitary-gonadal axis, as well as the adrenal glands (see Chapter 54). These hormones are crucial for reproductive function and include gonadotropin-releasing hormone (GnRH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), and a multitude of sex steroids. The sex steroids are synthesized by the ovaries, testes, and adrenal glands and are responsible for the manifestation of primary and secondary sex characteristics. This chapter is divided into four sections: Male Reproductive Biology, Female Reproductive Biology, Infertility, and Methods.

MALE REPRODUCTIVE BIOLOGY

The mature testes synthesize both sperm and androgens. The testes contain a structured network of tightly packed seminiferous tubules. The lumina of the seminiferous tubules are lined by maturing germ cells and Sertoli cells. Sertoli cells play a crucial role in sperm maturation and secrete *inhibin,* a glycoprotein that inhibits the pituitary secretion of FSH. Surrounding the seminiferous tubules are the interstitial Leydig cells, the primary site of androgen production. The principal androgen in man is testosterone, which serves a central role in reproductive physiology. Testosterone is required for sexual differentiation, spermatogenesis, and promotion and maintenance of sexual maturity at puberty. At the cellular level, these effects are mediated by binding of testosterone or its more potent metabolite dihydrotestosterone (DHT) to the androgen receptor or via aromatization to estradiol and subsequent binding to the estrogen receptor. Testicular function is under the control of the hypothalamic-pituitary-gonadal axis.

Hypothalamic-Pituitary-Gonadal Axis

Gonadotropin-releasing hormone (GnRH) is a decapeptide synthesized in the hypothalamus and transported to the anterior pituitary gland, where it stimulates the release of both FSH and LH (see also Chapter 53).

In adult men, GnRH and thus LH and FSH are secreted in pulsatile patterns. A circadian rhythm is present, with higher concentrations found in the early morning hours and lower concentrations in the late evening.[302] LH acts on Leydig cells to stimulate the conversion of cholesterol to pregnenolone. FSH acts on Sertoli cells and spermatocytes and is central to the initiation (in puberty) and maintenance (in adulthood) of spermatogenesis.[297] Sex steroids and inhibin (a 32 kDa protein secreted by the Sertoli cells) provide negative feedback control of LH and FSH secretion, respectively. LH secretion is inhibited by testosterone and by its metabolites, estradiol and DHT. FSH may be elevated in disorders in which Sertoli cell numbers (and hence inhibin concentrations) are reduced. Likewise, a reduction in the number of Leydig cells (and hence testosterone secretion) leads to increased LH concentrations.

Androgens

Androgens are a group of C-19 steroids (Figure 56-1) responsible for masculinization of the genital tract and development and maintenance of male secondary sex characteristics. Testosterone is the principle androgen secreted in men.

Biosynthesis of Testosterone

Testosterone is synthesized primarily by the Leydig cells of the testes (95%) and, to a lesser extent (≈5%) via peripheral conversion from the precursors dehydroepiandrosterone (DHEA) and androstenedione (which are synthesized in the

zona reticularis of the adrenal glands). Synthesis of androgens begins with mobilization of cholesterol derived from lipoprotein cholesterol or by de novo synthesis.[84,124] Cholesterol released from the lipid droplets migrates to the inner mitochondrial membrane, where pregnenolone formation is catalyzed by the cholesterol sidechain cleavage enzyme, CYP11A1. Conversion of cholesterol to pregnenolone is the rate-limiting step in testosterone synthesis[113,281]; however, it is thought that the rate of steroidogenesis is determined not by the activity of CYP11A1, but rather by delivery of cholesterol to the enzyme in the inner mitochondrial membrane by the steroidogenic regulatory protein (StAR)—a process thought to be regulated by LH.[282] Following the formation of pregnenolone, four additional enzymatic steps are required to convert cholesterol to testosterone. The pathway for testosterone formation is shown in Figure 56-1, with the preferred pathway defined by heavy red arrows.

Androgen Transport in Blood

Testosterone and DHT circulate in plasma freely (≈2 to 3%) or bound to plasma proteins. Binding proteins include the specific sex hormone–binding globulin (SHBG) and nonspecific proteins such as albumin. SHBG is an α-globulin that has low capacity for steroids but binds with very high affinity ($K_a = 1 \times 10^8$ to 1×10^9), whereas albumin has high capacity but low affinity ($K_a = 1 \times 10^4$ to 1×10^6).[281] SHBG has the highest affinity for DHT and the lowest for estradiol. In men, testosterone circulates bound 44 to 65% to SHBG and 33 to 50% to albumin, whereas in women, testosterone is bound 66 to 78% to SHBG and 20 to 30% to albumin.[222,230]

The biologically active fraction includes free testosterone; some have suggested that albumin-bound testosterone may also be available for tissue uptake.[63,229] Therefore, the bioavailable testosterone is equal to ≈35% of the total quantity (free + albumin-bound). Whether albumin-bound testosterone dissociates sufficiently fast to enter tissues is controversial.[192,200] However, concentrations of bioavailable testosterone correlate with those of free testosterone.[209,306]

Testosterone and SHBG exhibit rhythmic variation in their circulating concentrations. Testosterone concentrations peak at approximately 0400 to 0800 hours, and nadir concentrations occur at between 1600 and 2000 hours.[262,298] Daily variations in SHBG concentrations are similar to those of other proteins and albumin in serum, with major changes related to posture.[298] Concentrations of SHBG are elevated with hyperthyroidism and in hypogonadal men.

Metabolism of Testosterone

Circulating testosterone serves as a precursor for the formation of two additional active metabolites: DHT and estradiol (Figure 56-2). In one pathway, 5α-reductase converts 6 to 8% of testosterone to DHT. Both testosterone and DHT bind the androgen receptor, but DHT binds with higher affinity. In an alternative pathway, testosterone and androstenedione are converted to estrogens (≈0.3%) through aromatase (CYP19). DHT is formed in androgen target tissues such as the skin and prostate, whereas aromatization occurs in many tissues, especially the liver and adipose tissue. Peripheral aromatization occurs primarily in adipose tissue (of both men and women) because of the high concentration of aromatase in this tissue. The rate of extraglandular aromatization therefore increases with body fat.

Dihydrotestosterone is metabolized to 3α-androstanediol (see Figure 56-1) and then is conjugated to form 3α-androstanediol glucuronide. These metabolites have been used as markers of DHT production in peripheral tissues. Serum concentrations of 3α-androstanediol glucuronide or 3α-androstanediol reflect the production of DHT in peripheral tissues such as skin.[138,183] However, DHT may also arise from precursors other than testosterone. The reduction in serum 3α-androstanediol glucuronide concentrations noted in patients treated with glucocorticoids that suppress adrenal glucocorticoid and androgen production supports this conclusion.[199]

The main excretory metabolites of androstenedione, testosterone, and DHEA are shown in Figure 56-3. Except for epitestosterone, these catabolites constitute a group of

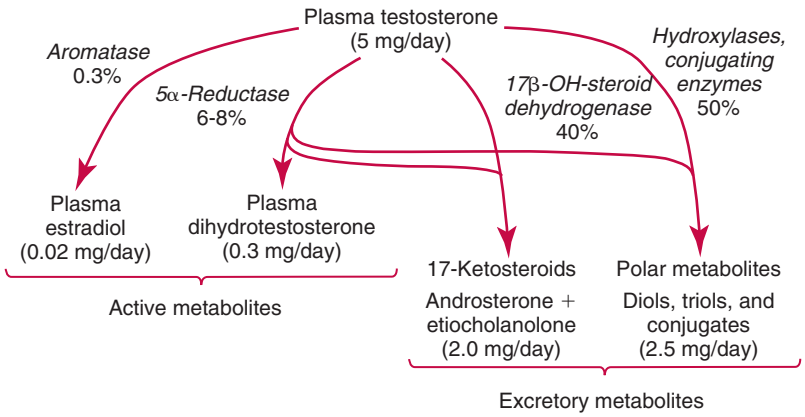

Figure 56-2 Pathways of peripheral metabolism of plasma testosterone. Testosterone can be metabolized to active metabolites or to excretory metabolites. *(From Griffin JE, Wilson JD. The testis. In: Bondy PK, Rosenberg LE, eds. Metabolic control and disease, 8th edition. Philadelphia, Pa: WB Saunders, 1980:1535-78; used with permission.)*

steroids known as *17-ketosteroids* (17-KS); they are excreted primarily in the urine.

Testosterone Concentrations

Testosterone is required for proper sexual development and function throughout all stages of life—fetal, pubertal, and adult (Figure 56-4). Fetal testes produce testosterone around the seventh week of gestation with peak serum concentrations of ≈250 ng/dL observed at the beginning of the second trimester, and with concentrations gradually returning to baseline by birth. Shortly after birth, the concentration of testosterone begins to increase, peaking again at ≈250 ng/dL at 2 to 3 months of age, and then falls to baseline again by 6 to 12 months. The function of this neonatal testosterone surge is not entirely clear, but it is thought to be important for bone growth and remodeling[272] and development of external male genitalia.[32] The concentration of testosterone remains low (<50 ng/dL) until puberty, when the concentration of testosterone rises to 500 to 700 ng/dL. Testosterone remains elevated through adulthood until around the third to fourth decade.

Men beyond the age of 30 to 40 years experience an age-dependent decrease in circulating testosterone concentration. This has been demonstrated consistently in both cross-sectional and longitudinal analyses. Collectively these studies have shown a 0.5 to 2% decrease per year in total serum testosterone from about the fourth decade onward.[93,126,208,304] This decline in testosterone is thought to be due to (1) a decrease in Leydig cell numbers, (2) decreased GnRH pulse amplitude, and (3) increases in SHBG.[208] In the past, these decreases in circulating concentrations of testosterone were viewed as a normal part of the aging process. Now, however, these decreases, when accompanied by symptoms of decreased libido, sexual dysfunction, decreased energy levels, and decreased muscle mass, are regarded as a syndrome with a variety of names, such as (1) androgen deficiency in the aging male (ADAM), (2) partial androgen deficiency of the aging male (PADAM), (3) late-onset hypogonadism (LOH),

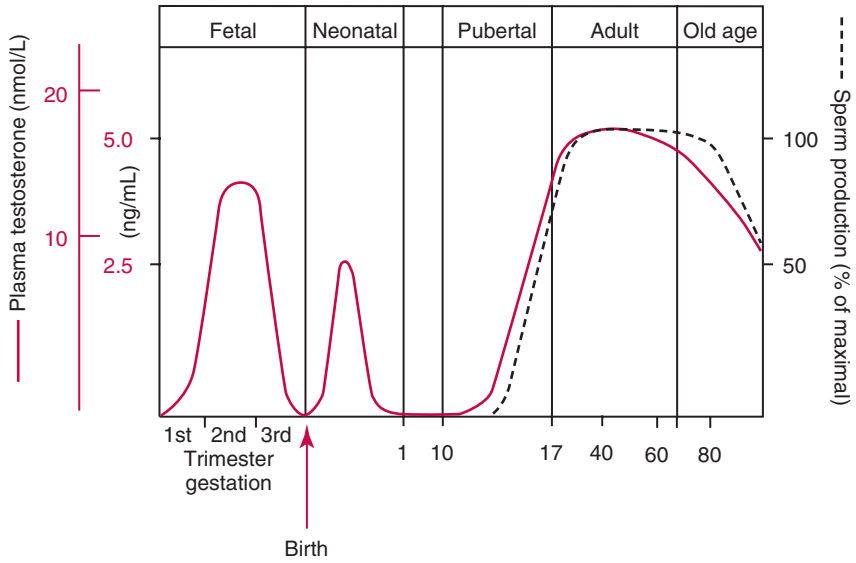

Figure 56-4 Schematic diagram of different phases of male sexual function during life as indicated by mean plasma testosterone concentration and sperm production at different ages. *[From Griffin JE, Wilson JD. The testis. In: Bondy PK, Rosenberg LE (eds). Metabolic control and disease, 8th edition. Philadelphia, Pa: WB Saunders, 1980:1535-78.]*

and, erroneously, (4) andropause. The name *andropause* is inaccurate and misleading, given that in contrast to menopause in women, concentrations of sex steroids in men do not decrease sharply with secondary cessation of reproductive function. A name put forward more recently is *testosterone deficiency syndrome (TDS),* highlighting a specific deficit in testosterone as part of the clinical picture.[207,294]

Diagnosis of LOH (TDS) should be based on both clinical and laboratory assessment.[40] Clinically, patients should exhibit symptoms suggestive of testosterone deficiency, such as (1) decreased libido, (2) erectile dysfunction, (3) decreased muscle mass and strength, (4) decreased bone mineral density, and (5) changes in mood. Patients should exhibit one to three of these symptoms with a concomitant low concentration of serum testosterone to fit various diagnostic criteria. Total serum testosterone is the most widely used biochemical parameter for assessment of hypogonadism; although there is no agreed upon lower limit of normal, recently published consensus recommendations drafted by five professional andrology/urology societies concur that total testosterone above 12 nmol/L (350 ng/dL) does not require testosterone supplementation, whereas patients whose concentrations fall below 8 nmol/L (230 ng/dL) may benefit from testosterone replacement. This value is similar to the 200 ng/dL intent-to-treat cutoff published in the 2002 practice guidelines of the American Association of Clinical Endocrinology.[234] The joint societies further recommend, for those patients falling in the gray zone between 8 and 12 nmol/L, repeat measurement of serum total testosterone with measurement of SHBG to calculate free testosterone, or direct measurement of free testosterone by equilibrium dialysis (if available). Measurement of free or bioavailable testosterone should be considered when total testosterone is not diagnostic despite the clinical presentation of hypogonadism.[101]

This is particularly true in the setting of obesity and advanced age, where concentrations of SHBG have been shown to be elevated. High concentrations of SHBG may mask a true deficit in testosterone. Transient decreases in testosterone secondary to acute illness should be excluded during this assessment. Moreover, underlying chronic disease that lowers concentrations of testosterone should be taken into consideration and treated appropriately. To assess whether hypogonadism is primary or secondary, serum LH should be measured; a serum prolactin measurement is indicated when serum testosterone concentrations are lower than 5.2 nmol/L (150 ng/dL), or when secondary hypogonadism is suspected.[312-314] In sum, no absolute cutoffs or specific tests (total vs. bioavailable vs. free testosterone) are available for the laboratory diagnosis of hypogonadism in the aging male. Each patient's laboratory results should be interpreted on an individual basis, with particular attention given to those parameters of the biochemistry of testosterone (e.g., obesity, age, comorbidities, medications) that may affect the findings.

Patients who meet these criteria may be candidates for treatment with testosterone replacement therapy (TRT). The goal of therapy is to improve the symptoms and signs associated with testosterone deficiency. For more information on TRT, readers may consult recently published guidelines and position statements.[312-314] Considerable controversy surrounds TRT, primarily regarding potential adverse effects, specifically, the effects of TRT on prostate and cardiovascular health. TRT in younger patients diagnosed with hypogonadism has proved both safe and effective. However, data from

prospective randomized controlled trials regarding the efficacy and safety of TRT in the aged population are lacking. Despite this lack of evidence, TRT prescriptions are on the rise; thus a sustained role for the laboratory in the diagnosis of LOH becomes evident, particularly given a growing aging population of males older than 65 years, projected to number some 31.3 million in the United States by the year 2030.[137]

Male Reproductive Abnormalities

A wide variety of abnormalities affect the male reproductive system before birth, in childhood, or in adulthood. For the purposes of this chapter, they have been divided into categories of (1) hypogonadotropic hypogonadism, (2) hypergonadotropic hypogonadism, (3) defects in androgen action (Box 56-1), (4) erectile dysfunction, and (5) gynecomastia.

BOX 56-1 Male Reproductive Abnormalities

Hypogonadotropic Hypogonadism
Panhypopituitarism (congenital or acquired)
Hypothalamic syndrome (acquired or congenital)
- Structural defects (neoplastic, inflammatory, and infiltrative)
- Prader-Willi syndrome
- Laurence-Moon-Biedl syndrome

GnRH deficiency (Kallmann syndrome)
Hyperprolactinemia (prolactinoma or drugs)
Malnutrition and anorexia nervosa
Drug-induced suppression of luteinizing hormone (androgens, estrogens, tranquilizers, antidepressants, antihypertensives, barbiturates, cimetidine, GnRH analogs, and opiates)

Hypergonadotropic Hypogonadism
Acquired (irradiation, mumps orchitis, castration, and cytotoxic drugs)
Chromosome defects
- Klinefelter syndrome (47,XXY) and mosaics
- Autosomal and sex chromosomes, polyploidies
- True hermaphroditism

Defective androgen biosynthesis
- 20α-Hydroxylase (cholesterol 20,22-desmolase) deficiency
- 17,20-Lyase deficiency
- 3β-Hydroxysteroid dehydrogenase deficiency
- 17α-Hydroxylase deficiency
- 17β-Hydroxysteroid dehydrogenase deficiency

Testicular agenesis
Selective seminiferous tubular disease
Miscellaneous
- Noonan syndrome (short stature, pulmonary valve stenosis, hypertelorism, and ptosis)
- Streak gonads
- Myotonia dystrophica

Acute and chronic disease

Defects in Androgen Action
Complete androgen insensitivity *(testicular feminization)*
Partial androgen sensitivity
- 5α-Reductase deficiency

GnRH, Gonadotropin-releasing hormone.

The effects of these abnormalities on infertility are discussed later in this chapter.

Hypogonadotropic Hypogonadism

Male hypogonadism is a condition caused by decreased function of the testes, which can lead to retardation of sexual development if manifested early in life. The disorder is classified as *hypo*gonadotropic or *hyper*gonadotropic.

Hypogonadotropic hypogonadism occurs when defects in the hypothalamus or pituitary prevent normal gonadal stimulation. Causative factors include congenital or acquired panhypopituitarism, hypothalamic syndromes, GnRH deficiency, hyperprolactinemia, malnutrition or anorexia, and iatrogenic causes. All of these abnormalities are associated with decreased testosterone and gonadotropin concentrations.

Kallmann syndrome, the most common form of hypogonadotropic hypogonadism, results from a deficiency of GnRH in the hypothalamus during embryonic development.[119] It is characterized by hypogonadism and anosmia (loss of the sense of smell) in male or female patients, and is inherited as an autosomal dominant trait with variable penetrance.[50,262] This syndrome arises from a defect in the migration of GnRH neurons to the hypothalamus. The pituitary disorders are characterized by isolated gonadotropin deficiency with or without growth hormone deficiency. Patients with isolated gonadotropin deficiency display sexual infantilism and long arms and legs; those with combined deficiency do not have long arms and legs. These patients must be distinguished from those with growth delay. In all of these patients, LH, FSH, and testosterone concentrations are lower than normal. However, heterogeneity exists in the degree of gonadotropin deficiency; hence concentrations of LH, FSH, and testosterone have been shown to differ among affected patients.

Hypergonadotropic Hypogonadism

Hypergonadotropic hypogonadism results from a primary gonadal disorder. Patients with primary testicular failure have increased concentrations of LH and FSH and decreased concentrations of testosterone. Causes for primary hypogonadism are categorized as (1) acquired causes (irradiation, castration, mumps orchitis, or cytotoxic drugs), (2) chromosome defects (Klinefelter syndrome), (3) defective androgen synthesis (20α-hydroxylase deficiency), (4) testicular agenesis, (5) seminiferous tubular disease, and (6) other miscellaneous causes. Aging is associated with gonadal failure, specifically, decreased Leydig cell mass and reserve capacity with reduction in pulsatile secretion of GnRH by the hypothalamus, leading to decreased testosterone secretion.[191]

Defects in Androgen Action

The most common and severe defect in androgen action is *androgen insensitivity syndrome* (AIS), a disorder arising from mutations in the androgen receptor gene (AR). AIS may be classified as complete (CAIS) or partial (PAIS), depending on the amount of residual receptor function. Individuals with complete AIS (formerly known as testicular feminization) have a male karyotype (46,XY) with female external genitalia

(labia, clitoris, and vaginal opening). The testes are present intra-abdominally, and because they produce anti-Müllerian hormone (AMH) (also known as Müllerian inhibitory substance), no uterus, fallopian tubules, or proximal vagina is present. The circulating concentration of testosterone in these patients is greater than or equal to that of a healthy male.[145] Concentrations of LH are increased, presumably because of resistance of the hypothalamic-pituitary system to androgen inhibition.

Males with *5α-reductase deficiency* (5-ARD) do not convert testosterone to the more potent DHT. Because DHT leads to masculinization of external genitalia in utero, males are born with ambiguous genitalia.[325] High ratios of the circulating concentrations of testosterone to DHT are indicative of 5-ARD. Moreover, evidence indicates that DHT formation is deficient in the tissues of the urogenital tract in these patients.[145]

In patients with cryptorchidism or ambiguous genitalia, identification of abdominal gonads is essential for proper diagnosis and treatment. The presence of testicular tissue has traditionally been detected by measurement of Leydig cell testosterone production after stimulation with hCG. A growing appreciation of assessment of Sertoli cell function has been noted. Inhibin and AMH reflect Sertoli cell function and may offer a noninvasive evaluation of seminiferous tubular integrity.[99,174,206,244] In one study, the mean plasma AMH concentration in anorchid patients was 0.8 ng/mL, compared with 48.2 ng/mL in patients with normal testes.[174] AMH concentrations are also elevated in boys with delayed puberty and partial androgen insensitivity. Inhibin B may be used as a basal serum marker for the presence and function of testicular tissue in boys with nonpalpable testicles.[12,118,164]

Studies have shown that boys with anorchia have undetectable serum inhibin B concentrations.[164] Boys with severe testicular damage or gonadal dysgenesis also have undetectable or very low concentrations of inhibin B, whereas normal serum inhibin B concentrations are observed among boys with abdominal "normal" testes.[164]

Erectile Dysfunction

Erectile dysfunction (formerly referred to as impotence) is the persistent inability to develop or maintain a penile erection that is sufficient for intercourse and ejaculation in 50% or more of attempts.[163,262] A wide variety of organic and psychological abnormalities may cause changes in sexual drive and in the ability to have an erection or to ejaculate. Psychogenic erectile dysfunction is the most common diagnosis. Other causes include vascular disease, diabetes mellitus, hypertension, uremia, neurologic disease, hypogonadism, hyperthyroidism and hypothyroidism, neoplasms, and drugs. The physician must pursue a careful evaluation of possible psychological factors, neuropathy, or vascular abnormalities that may be interfering with proper sexual function. If no obvious explanation for erectile dysfunction can be found, measurement of morning serum testosterone, LH, and thyroid-stimulating hormone (TSH) concentrations has been suggested.[111,262] Elevated gonadotropin concentrations indicate primary hypogonadism. Total and even free testosterone concentrations may be within normal reference intervals, yet still may be subnormal for a given patient if found in the presence of elevated LH or FSH. Hyperprolactinemia is an infrequent cause of erectile dysfunction but should be considered in unusual situations.

Sildenafil (sold under the trade names Viagra, Revatio, and others) was approved by the U.S. Food and Drug Administration (FDA) in April 1998 for use as an oral therapeutic agent for male erectile dysfunction.[33,34,130,212,264] This agent and the drugs tadalafil (Cialis) and vardenafil (Levitra) are selective inhibitors of phosphodiesterase 5 (PDE5).[34] By inhibiting PDE5 in the corpus cavernosum of the penis, these drugs block degradation of cyclic guanosine monophosphate (GMP), which is increased during sexual arousal. Increased cyclic GMP results in relaxation of vascular smooth muscle and increased inflow of blood. A high-performance liquid chromatography (HPLC) method for sildenafil has been developed.[62]

Gynecomastia

Gynecomastia, the benign growth of glandular breast tissue in men, is a common finding among males of varied ages.[39,103,194] Gynecomastia, which is associated with an increase in the estrogen/androgen ratio, is commonly associated with three distinct periods of life. First, transient gynecomastia can be found in 60 to 90% of all newborns because of high estrogen concentrations that cross the placenta. The second peak occurs during puberty in 50 to 70% of normal boys. It is usually self-limited and may be due to low serum testosterone, low DHT, or a high estrogen/androgen ratio. The last peak is found in the adult population, most frequently among men aged 50 to 80 years. Gynecomastia may be due to testicular failure, resulting in an increased estrogen/androgen ratio, or to increased body fat, resulting in increased peripheral aromatization of testosterone to estradiol.[39,103,194]

Gynecomastia may also develop as the result of iatrogenic causes, hyperthyroidism, or liver disease. Liver disease impairs estrogen clearance and SHBG production, leading to increased bioavailable estrogen and subsequent gynecomastia. Finally, germinal cell or nonendocrine tumors that produce human chorionic gonadotropin (hCG), as well as estrogen-producing tumors of the adrenal glands, the testes, or the liver, will cause gynecomastia. hCG stimulates testicular aromatase activity and estrogen production, resulting in gynecomastia.[103] In cases of striking gynecomastia in which history and physical examination point to no specific disorder, measurements of hCG, plasma estradiol, testosterone, and LH concentrations are appropriate.[39] It is important to note that prolactin plays an important role in *galactorrhea* (milk production), but only an indirect role in gynecomastia.

FEMALE REPRODUCTIVE BIOLOGY

The ovaries produce ova and secrete the sex hormones progesterone and estrogen. Every healthy female neonate possesses approximately 400,000 primordial follicles, each

containing an immature ovum. During the reproductive life span of an adult woman, 300 to 400 follicles will reach maturity.[97,110] A single mature follicle is produced during each normal menstrual cycle at approximately day 14. Surrounding the oocyte of the mature follicle are three distinct cell layers: (1) *theca externa,* (2) *theca interna,* and (3) *granulosa cells.* The theca interna cells are the primary source of androgens, which are transported to adjacent granulosa cells, where they are aromatized to estrogens.[50]

The mature follicle undergoes ovulation by the process of rupture, thereby releasing the oocyte into the proximity of the fallopian tubes. The follicle then fills with blood to form the corpus hemorrhagicum. The granulosa and theca cells of the follicle lining quickly proliferate to form lipid-rich luteal cells, replacing the clotted blood and forming the *corpus luteum* (yellow body). The luteal cells produce estrogen and progesterone. If fertilization and pregnancy occur, the corpus luteum persists and continues to produce estrogen and progesterone. If no pregnancy occurs, the corpus luteum regresses, and the next menstrual cycle begins.

The uterine cavity is lined by the endometrium. The endometrium undergoes cyclic changes in preparation for implantation and pregnancy in response to cyclic changes in estrogen and progesterone. During the follicular phase, the endometrial lining increases in thickness and vascularity in response to increasing circulating concentrations of estrogen; after regression of the corpus luteum, menstruation begins, and the endometrium is shed in response to the withdrawal of progesterone.

Hypothalamic-Pituitary-Gonadal Axis

In adult women, a tightly coordinated feedback system exists between hypothalamus, anterior pituitary, and ovaries to orchestrate menstruation. FSH serves to stimulate follicular growth, and LH stimulates ovulation and progesterone secretion from the developing corpus luteum. These actions are discussed in greater depth later in this chapter.

Estrogens

Estrogens are responsible for the development and maintenance of female sex organs and female secondary sex characteristics. In conjunction with progesterone, they participate in regulation of the menstrual cycle and of breast and uterine growth, and in the maintenance of pregnancy.

Estrogens affect calcium homeostasis and have a beneficial effect on bone mass. They decrease bone resorption, and in prepubertal girls, estrogen accelerates linear bone growth, resulting in epiphyseal closure. Long-term estrogen depletion is associated with loss of bone mineral content, an increase in stress fractures, and postmenopausal osteoporosis.

Estrogens also have well-established effects on plasma proteins that influence endocrine testing. They increase concentrations of SHBG, corticosteroid-binding globulin, and thyroxine-binding globulin. Hence, boys and girls have comparable concentrations of SHBG, but adult men have SHBG concentrations that are about one half those of adult women. Concentrations of plasma proteins that bind copper and iron

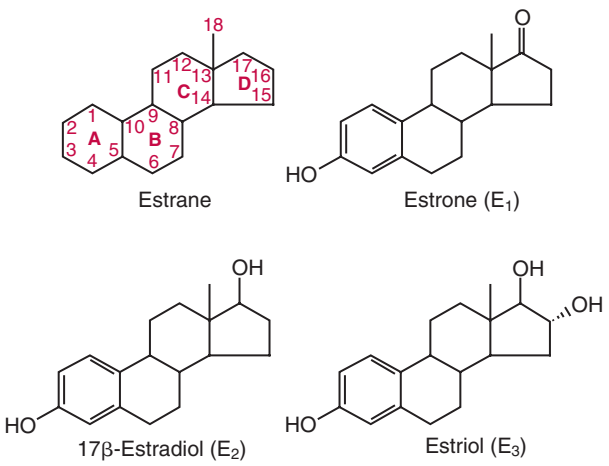

Figure 56-5 Biologically active estrogens.

are also elevated in response to estrogen, as are those of high-density and very high-density lipoproteins. In addition, estrogens are believed to play a preventive role in coronary heart disease.[114]

Chemistry

The three most biologically active estrogens in order of potency are estrone (E_1), estradiol (E_2), and estriol (E_3) (Figure 56-5). Structurally, estrogens are derivatives of the parent hydrocarbon *estrane,* which is an 18-carbon molecule with an aromatic ring A and a methyl group at C-13.[50,333] All estrogens possess a phenolic hydroxyl group at C-3, which gives the compounds acidic properties, and lack a methyl group at C-10. In addition, estrogens may possess a ketone (estrone) or hydroxyl group (estradiol) at position C-17. The phenolic ring A and the hydroxyl group at C-17 are essential for biological activity.

Biosynthesis

The biochemical pathway illustrating aromatization of testosterone to estradiol and androstenedione to estrone is shown in Figure 56-6. The role of estrogens in normal and abnormal menstrual cycles is described later in this chapter.

Estrogens are secreted primarily in healthy women by the ovarian follicles and the corpus luteum, and during pregnancy by the placenta. The adrenal glands and testes (in men) are also believed to secrete minute quantities of estrogens. The ovary synthesizes estrogens via aromatization of androgens. Synthesis of estrogens begins in the theca interna cells with the enzymatic synthesis of androstenedione from cholesterol. Androstenedione is then transported to the granulosa cells, where it is further metabolized directly to estrone (androstenedione → estrone), or first to testosterone and then to estradiol (androstenedione → testosterone → estradiol). These conversions are catalyzed by the enzyme aromatase. The healthy human ovary produces all three classes of sex steroids: estrogens, progestagens, and androgens; however, estradiol and progesterone are its primary secretory products. Because the ovary lacks

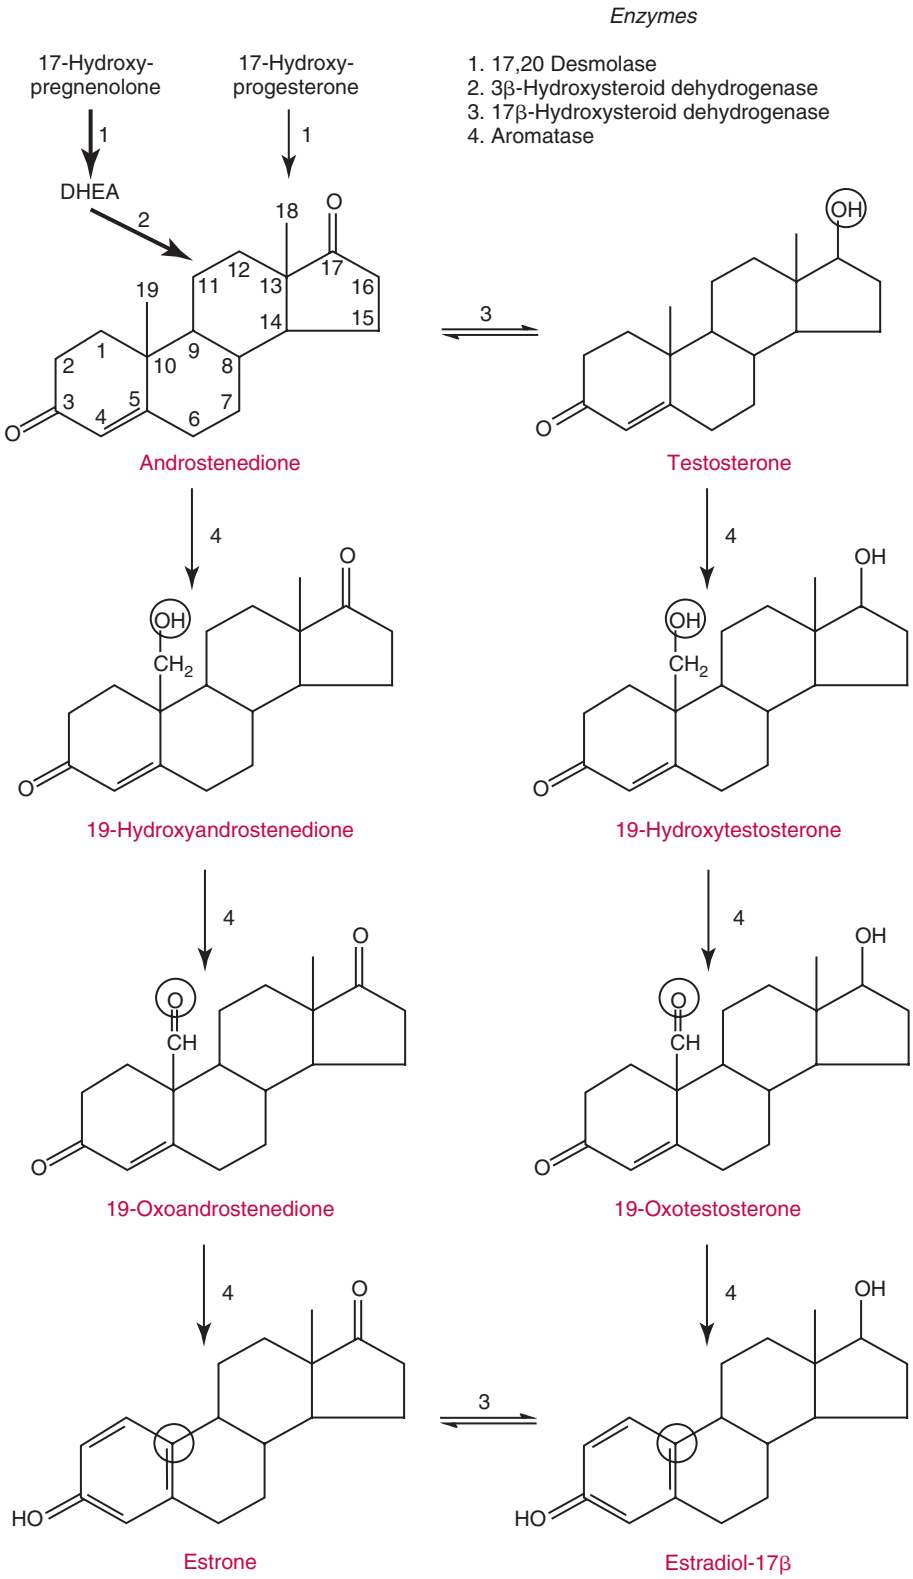

Figure 56-6 **Biosynthesis of estrogens. *Heavy arrows* indicate the Δ5-3β-hydroxy pathway. The *circled area* represents the site of chemical change. See Figure 56-1 for early synthetic steps.**

both the 21-hydroxylase and 11β–hydroxylase enzymes, glucocorticoids and mineralocorticoids are not produced in the ovary.[50,333] More than 20 estrogens have been identified, but only 17β-estradiol (E_2) and estriol (E_3) are routinely measured clinically. The most potent estrogen secreted by the ovary is 17β-estradiol. Because it is derived almost exclusively from the ovaries, its measurement is often considered sufficient for evaluation of ovarian function.

Estrogens are also produced by peripheral aromatization of androgens, primarily androstenedione. In healthy men and women, ≈1% of secreted androstenedione is converted to estrone.[50,333] Although the ovaries of postmenopausal women do not secrete estrogens, these women have significant blood concentrations of estrone originating from the peripheral conversion of adrenal androstenedione. Because a major site of this conversion is adipose tissue, estrone is increased in obese postmenopausal women, sometimes yielding enough estrogen to produce bleeding.[50,333,336]

Biosynthesis During Pregnancy

Research has shown that biosynthesis of estrogens differs qualitatively and quantitatively in pregnant women compared with nonpregnant ones. In pregnant women, the major source of estrogens is the placenta, whereas in nonpregnant women, the ovaries are the main site of synthesis.[50,333,336] In contrast to the microgram quantities secreted by nonpregnant women, the quantity of estrogens secreted during pregnancy increases to milligram amounts. The major estrogen secreted by the ovary is estradiol (E_2), whereas the major product secreted by the placenta is estriol (E_3). E_3 is formed in the placenta by sequential desulfation and aromatization of plasma dehydroepiandrosterone sulfate (DHEA-S). Except during pregnancy, measurements of E_3 have little clinical value because in nonpregnant women, E_3 is derived almost exclusively from E_2 (see also Chapter 57).

E_3 is the predominant hormone of late pregnancy. Maternal E_3 is almost entirely (≈90%) derived from fetal and placental sources. It is first detected during the ninth gestational week and gradually increases during the first and second trimesters. Plasma and salivary E_3 concentrations peak approximately 3 to 5 weeks before labor and delivery.[108] This characteristic surge in E_3 has been observed in term, preterm, and post-term pregnancies. Some reports have suggested utility in the measurement of salivary E_3 in the prediction of risk for spontaneous preterm birth.[107,132-134,167,195] This test has a high negative predictive value but a low positive predictive value. Consequently, the American College of Obstetricians and Gynecologists does not now suggest measuring salivary E_3 concentrations, except for research purposes.[2] Details regarding techniques used to determine serum and salivary E_3 concentrations are discussed later in the section on analytical methods.

Serum unconjugated E_3 measurements, along with alpha fetoprotein, hCG, and inhibin A, are commonly used as part of the "quad" maternal screens for Down syndrome–affected fetuses. On average, unconjugated E_3 is 0.72 times less than normal (median value at 16 weeks: 0.30 to 1.50 μg/L) when fetal Down syndrome is present.[47,198,287,309] For more on maternal serum screening, see Chapter 57.

Transport in Blood

More than 97% of circulating E_2 is bound to plasma proteins. It is bound specifically and with high affinity to SHBG, and nonspecifically to albumin.[222,281] SHBG concentrations are increased by estrogens and therefore are higher in women than in men. They are also increased during (1) pregnancy, (2) oral contraceptive use, (3) hyperthyroidism, and (4) administration of certain antiepileptic drugs such as dilantoin. SHBG concentrations may decrease in hypothyroidism, obesity, or androgen excess. In women, E_2 circulates bound 40 to 60% to SHBG, and 40 to 60% to albumin. SHBG has a higher affinity for testosterone than E_2; therefore, in men, E_2 circulates 20 to 30% bound to SHBG, and 70 to 80% bound to albumin.[222,230] Only 2 to 3% of total E_2 circulates in free form. In contrast, estrone and estrone sulfate circulate bound almost exclusively to albumin. As with testosterone, both free and albumin-bound fractions of E_2 are thought to be biologically available,[230] but measurement of this fraction has not been shown to be clinically important.

Diurnal variation in blood estrone concentrations occurs in postmenopausal women, presumably reflecting the variation in the androstenedione precursor that originates in the adrenal glands. However, no such diurnal rhythms have been demonstrated for E_2.

Metabolism

The metabolism of E_2 is chiefly an oxidative process dominated by three pathways, of which the fastest is oxidation of the β-hydroxy group at C-17 to a ketone (estradiol → estrone). This process is reversible; however, equilibrium favors the estrone species. Estrone is further oxidized along two pathways: the *2-hydroxylation pathway,* leading to formation of catechol estrogens (2-hydroxyestrone, 2-hydroxyestradiol, and 2-hydroxyestriol and their corresponding methoxy derivatives), and the *16α-hydroxylation pathway,* leading predominantly to formation of E_3[50,333] (Figure 56-7).

Normally, blood estrone concentrations parallel E_2 concentrations throughout the menstrual cycle, but at one third to one half their magnitude. Estrone metabolism is affected by the pathophysiologic state. For example, obesity and hypothyroidism are associated with an increase in E_3 formation, whereas low body weight and hyperthyroidism are associated with formation of catechol estrogens.[50] Although assays for catechol estrogen measurement are available,[55,196] they have no known current clinical value.

In addition to the oxidative pathways already described, formation of estrogen conjugates has been reported as a major route of estrogen metabolism. The most abundant circulating estrogen conjugates are the sulfates, followed by the glucuronides, with estrone sulfate circulating at concentrations tenfold higher than unconjugated estrone.[236] Initially, it was thought that sulfate conjugation would lead to an increase in polarity, making the compound more readily excretable; however, estrogen sulfates actually exhibit a longer half-life

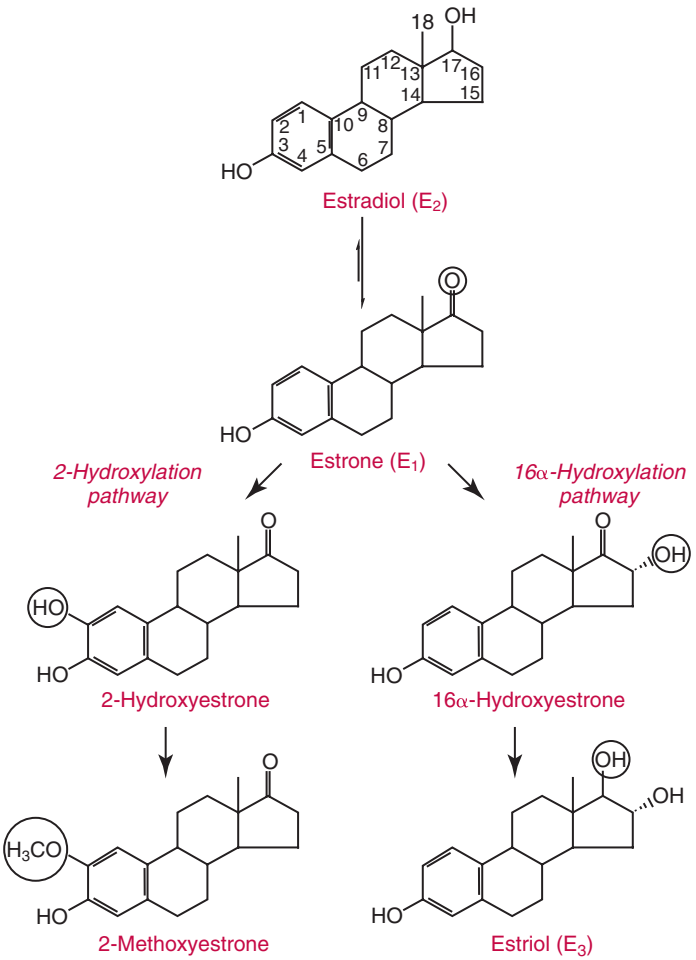

Figure 56-7 Main pathways of estradiol metabolism in humans. The *circled area* represents the site of chemical change.

than do parent estrogens.[236] These observations have led to the idea that estrone sulfate may serve as a precursor for the bioactive estrogens via desulfation and conversion to E_2 by 17β-hydroxysteroid dehydrogenase. In contrast to estrogen sulfates, glucuronidation of estrogens generally is accepted to serve a classic excretory role. Estrogen glucuronides are detectable in both urine and bile.

Progesterone

Progesterone, similar to the estrogens, is a female sex hormone. In conjunction with estrogens, it helps to regulate the accessory organs during the menstrual cycle.[333,336] This hormone is especially important in preparing the uterus for implantation of the blastocyst and in maintaining pregnancy. In nonpregnant women, progesterone is secreted mainly by the corpus luteum. During pregnancy, the placenta becomes the major source of this hormone. Minor sources are the adrenal cortex in both sexes and the testes in men.

Chemistry

The structural formula of progesterone, a C_{21} compound, is shown in Figure 56-8. Similar to the corticosteroids and testosterone, progesterone (pregn-4-ene-3,20-dione) contains a keto group (at C-3) and a double bond between C-4 and C-5 (Δ^4); both structural characteristics are essential for progestational activity. The two-carbon sidechain (CH_3CO) on C-17 does not seem to be very important for its physiologic action. Indeed, the synthetic compound 19-nortestosterone (see Figure 56-8) and its derivatives, which are widely used as oral contraceptives, are more potent progestational agents than progesterone itself.

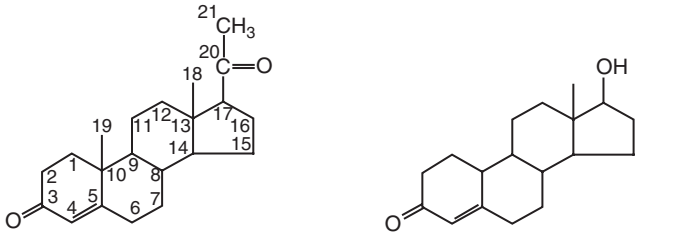

Figure 56-8 Structural formulas of progesterone and 19-nortestosterone.

Biosynthesis

Biosynthesis of progesterone in ovarian tissues follows the same path from acetate to cholesterol through pregnenolone as it does in the adrenal cortex (see Figure 56-1).[50,333,335] In luteal tissue, however, low-density lipoprotein cholesterol is thought to serve as the preferred precursor despite the potential of the corpus luteum to synthesize progesterone de novo from acetate.[271] Initiation and control of luteal secretion of progesterone are regulated by LH and FSH.[50,283,333]

Transport

Progesterone does not have a specific plasma-binding protein but, similar to cortisol, is found bound to corticosteroid-binding globulin. Reported concentrations for plasma free progesterone vary from 2% to 10% of total concentration, and the percentage of unbound progesterone remains constant throughout the normal menstrual cycle. The production rate of progesterone during the luteal phase reaches as high as 30 mg/d, whereas the production rate of progesterone by the placenta during the third trimester of pregnancy is ≈300 mg/d.

Metabolism

The important metabolic events leading to inactivation of progesterone are reduction and conjugation. The main metabolic pathway for the metabolism of progesterone is outlined in Figure 56-9.

Metabolites of progesterone are classified into three groups based on the degree of reduction:

1. *Pregnanediones*. The C4-5 double bond is reduced, producing two compounds: pregnanedione (hydrogen atom at C-5 is in β-orientation) and allopregnanedione (hydrogen atom at C-5 is in α-orientation).
2. *Pregnanolones*. The keto group at C-3 is reduced, producing hydroxyl groups in α- or β-orientation. However, most urinary pregnanolones exist in the α-configuration.
3. *Pregnanediols*. The keto group at C-20 is also reduced. As in the previous case, metabolites containing the 20-hydroxyl group in α-orientation are quantitatively more important. In fact, urinary measurement of pregnanediol (5β-pregnane-3α,20α-diol) can be used as an index of endogenous production of progesterone, because this metabolite is quantitatively very significant, and its concentration correlates with most clinical conditions.

Reduced metabolites are eventually conjugated with glucuronic acid and excreted as water-soluble glucuronides.

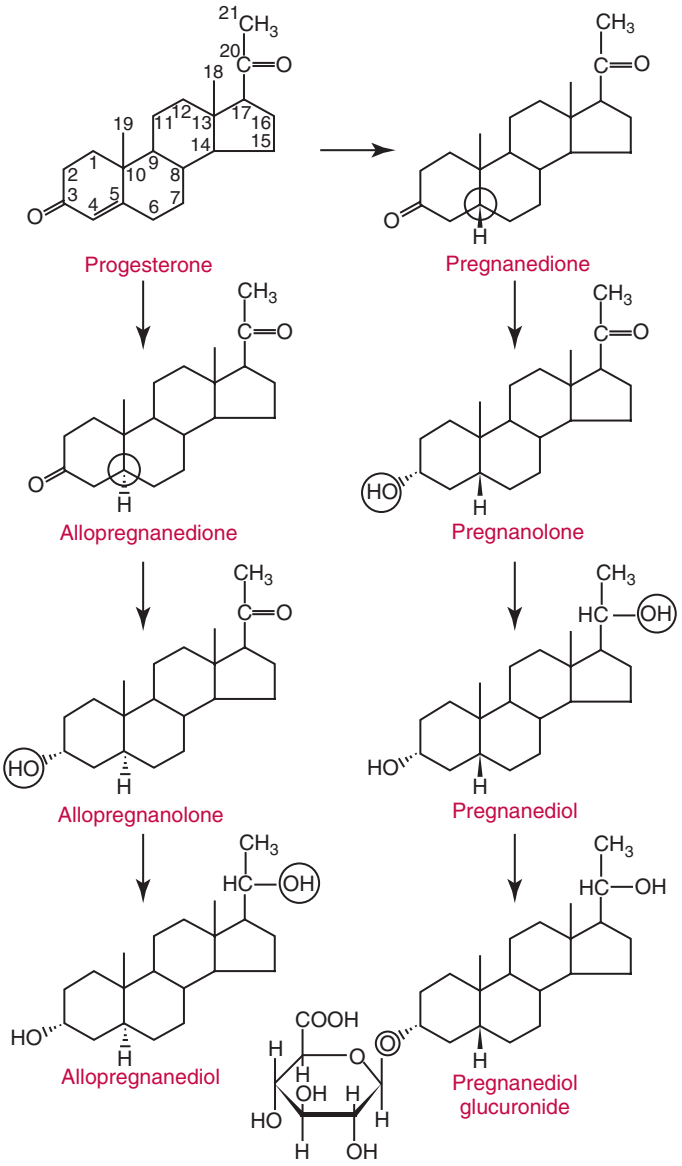

Figure 56-9 Metabolism of progesterone. The *circled area* represents the site of chemical change.

Female Reproductive Development

Reproductive development begins with anatomy during the fetal period, a postnatal period of adaptation to reduced maternal sex steroids, and finishes with sexual maturation during puberty. Normal females remain fertile and menstruating until menopause.

Fetal

In the genotypic female, lack of testosterone and AMH causes regression of the wolffian ducts and maintenance of the Müllerian ducts, thus forming the female reproductive tract. Gonadotropin activity in utero is suppressed because of high concentrations of circulating estrogens derived from the mother.[50,333]

Postnatal

When the placenta separates, concentrations of fetal sex steroids drop abruptly. Serum E_2 in neonates is decreased to basal concentrations within 5 to 7 days after birth and persists at this concentration until puberty. The negative feedback action of steroids is now removed, and gonadotropins are released. Postnatal peaks of LH and FSH are measurable for a few months after birth, peaking at 2 to 5 months and then dropping to basal concentrations. During childhood, circulating concentrations of sex steroids and gonadotropins are low and are similar for both sexes. However, in patients with hypogonadism (Turner syndrome), LH and FSH concentrations are higher than in healthy children.[50,333]

Puberty

The transition from sexual immaturity appears to begin with diminished sensitivity of the pituitary gland or hypothalamus, or both, to the negative feedback effect of sex steroids. The mechanism for this change is unclear. As puberty approaches, nocturnal secretion of gonadotropins occurs. Concentrations for LH, FSH, and gonadal steroids rise gradually over several years before stabilizing at adult concentrations when full sexual maturity is reached. In girls, puberty is considered precocious if onset of pubertal development (secondary sex characteristics) occurs before the age of 8 years (see later section on precocious puberty), and delayed if no development has occurred by the age of 13 years, or if menarche has not occurred by age 16.5 years.[67,205] It was reported in 2003 that the median age of menarche in the United States is 12.43 years, which is 0.34 year earlier than that reported in 1973.[57,189] This study also found that the median age at menarche of non-Hispanic black (12.06 years) girls is significantly earlier than that of non-Hispanic white (12.55 years) and Mexican-American (12.25 years) girls.[57]

Adrenarche precedes puberty by a few years. In girls, the rise in adrenal androgen concentrations (DHEA, DHEA-S, and androstenedione) begins at age 6 to 7 years.[231] This rise in adrenal androgen concentrations lasts until late puberty. A cortical androgen-stimulating hormone may contribute to the rise in adrenal androgens at puberty in both sexes.[231] In girls, puberty is associated with elevations in estrogen secretion by the ovary in response to gonadotropin concentrations that increase in response to GnRH. Estrogen secretion by the ovary increases, causing enlargement of the uterus and breasts. In the breast, estrogen enhances growth of ducts; progesterone augments this effect. As the breast develops, estrogen increases adipose tissue around the lactiferous duct system, contributing to the further enlargement of breast tissue.[50,333] These physiologic and physical processes associated with puberty in girls culminate in *menarche*—the beginning of menstrual function and the first menstrual period.

Normal Menstrual Cycle

During a normal menstrual cycle, a closely coordinated interplay of feedback effects occurs between the hypothalamus, the anterior lobe of the pituitary gland, and the ovaries. In addition, cyclic hormone changes lead to functional and structural changes in the ovaries (follicle maturation, ovulation, and corpus luteum development), uterus (preparation of the endometrium for possible implantation of the fertilized ovum), cervix (to permit transport of sperm), and vagina (Figure 56-10).

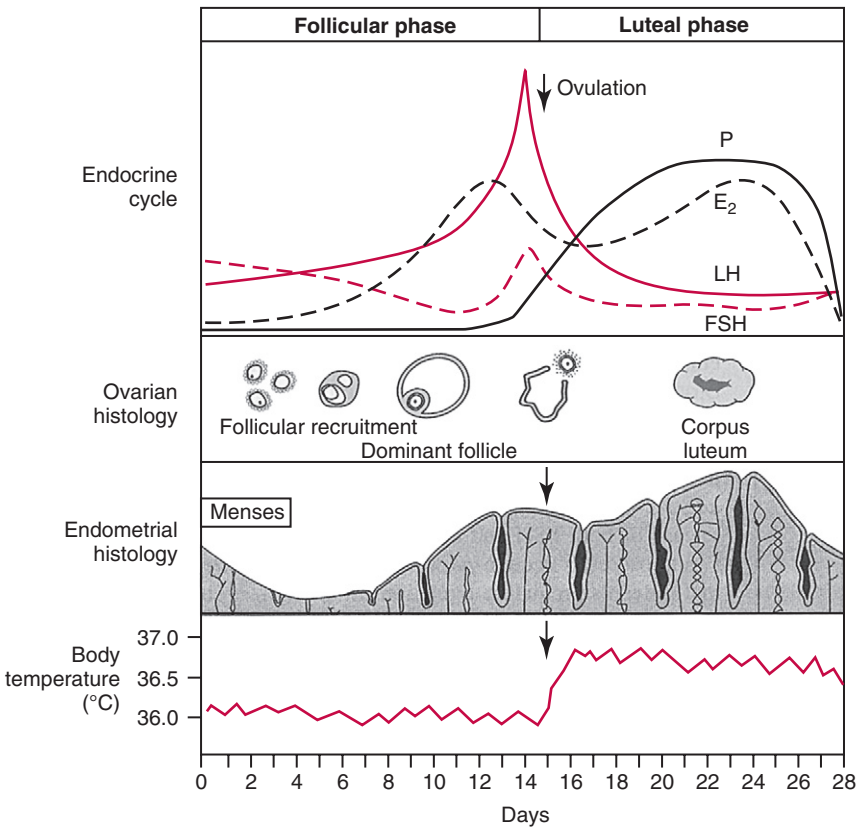

Figure 56-10 Hormonal, ovarian, endometrial, and basal body temperature changes throughout the normal menstrual cycle. *(From Carr BR, Bradshaw KD. Disorders of the ovary and female reproductive tract. In: Braunwald E, Fauci A, Kasper D, Hauser SL, Longo DL, Jameson JL, eds. Harrison's principles of internal medicine, 15th ed. New York, NY: McGraw-Hill, 2001:2158; used with permission.)*

Phases

The menstrual cycle is measured beginning on day 1 as the first day of menstrual bleeding. Each cycle consists of a follicular phase followed by ovulation and then a luteal phase.

Follicular Phase. The *follicular phase,* that is, the initiation of follicular growth, actually begins during the last few days of the previous luteal phase and terminates at ovulation (see Figure 56-10). During the early part of the follicular phase, concentrations of FSH are elevated, but they decline up until ovulation (see Figure 56-10). LH secretion begins to increase around the middle of the follicular phase. Just before ovulation, estrogen secretion by the follicle increases dramatically; this positively stimulates the hypothalamus and triggers the LH surge. The LH surge is a reliable predictor of ovulation, with onset of the surge for 90% of women occurring 16 to 58 hours before, and the peak occurring 3 to 36 hours before, ovulation.[50] Ovulation occurs around day 14 of the menstrual cycle.

Luteal Phase. The *luteal phase,* the last half of the cycle, is characterized by increasing production of progesterone and estrogen from the corpus luteum with consequent gradual lowering of LH and FSH concentrations. The concentration of progesterone reaches a peak at about 8 days post ovulation. If ovulation does not occur, the corpus luteum fails to form, and a cyclic rise in progesterone is subnormal. If ovulation and pregnancy occurs, hCG maintains the corpus luteum and progesterone continues to rise. In the absence of conception, the corpus luteum resolves, resulting in a decrease in estrogen and progesterone concentrations and a breakdown of the endometrium. The average duration of menstrual flow is 4 to 6 days, and average menstrual blood loss is 30 mL.[50]

Role of Individual Hormones

To explain further the intricacies of the normal menstrual cycle, fluctuations in each major hormone are discussed separately in the following sections with regard to control and effects (see Figure 56-10).

Gonadotropin-Releasing Hormone. Gonadotropin-releasing hormone triggers the surge of LH that precedes ovulation.[50,333,336] There appear to be two separate feedback centers in the hypothalamus: (1) a tonic negative feedback center in the basal medial hypothalamus, and (2) a cyclic positive feedback center in the anterior regions of the hypothalamus. Low concentrations of E_2, such as those that are present during the follicular phase, affect the negative feedback center, whereas high concentrations of E_2, such as those seen just before the midcycle LH peak, trigger the positive feedback center. Progesterone, in combination with estrogen, affects the negative feedback center in the luteal phase. GnRH is released in a pulsatile fashion and has a self-priming effect; the first dose potentiates the effects of subsequent doses. The magnitude of the LH response to GnRH increases steadily through the follicular phase and is greatest at the time of the preovulatory surge of LH, after which it declines again.

Follicle-Stimulating Hormone. A few days before day 1 of the cycle, FSH shows a slight but important peak (see Figure 56-10), probably triggered by a fall in E_2 concentration that briefly eliminates the negative feedback effect.[50,333,336] This peak in FSH initiates the growth and maturation of a cohort of ovarian follicles. LH and FSH release is pulsatile throughout the cycle; therefore, the values shown in Figure 56-10 represent integrated concentrations. As estrogen is released from the growing follicles, FSH concentrations fall again and remain low through the follicular phase. By days 5 to 7, a single follicle is selected for further growth. The effect of FSH on the maturing follicle is increased through estradiol-induced changes in FSH receptors. FSH, aided by E_2, acts on the cells of the follicle to increase the responsiveness of LH receptors by the time of the midcycle surge. FSH and LH receptors respond with an increase in their number or in their affinity for corresponding gonadotropin. A rise in FSH at midcycle is triggered by progesterone. The function of this peak is not entirely known, but it is thought to stimulate plasminogen activator and increase granulosa cell LH receptors.[50] During the luteal phase, FSH is suppressed by negative feedback from E_2 until a lesser FSH peak, occurring near the end of the cycle, starts off the follicular maturation of the next cycle.

Luteinizing Hormone. Luteinizing hormone secretion is suppressed in the follicular phase by negative feedback from E_2.[50,333,336] As E_2 production by the developing follicle increases, the effect of E_2 on the positive feedback center becomes important. Increasing release of GnRH from the hypothalamus and increasing the sensitivity of the anterior lobe of the pituitary gland to GnRH lead to the midcycle surge of LH. Ovarian follicle receptors for LH, sensitized by FSH and E_2, transmit the stimulus to enhance differentiation of the theca cell and production of progesterone by the developing corpus luteum. LH production is suppressed during the luteal phase by negative feedback from progesterone combined with E_2, but a low concentration of LH is probably necessary to prolong corpus luteum function.

Estradiol. E_2 production by the ovary decreases near the end of a cycle but begins to increase again under the influence of FSH (see Figure 56-10).[50,333,336] E_2 enhances the FSH effect on a maturing follicle through changes in FSH receptors of the follicular cells, but it suppresses pituitary FSH and LH release during the follicular phase through negative feedback. Before the mid–follicular phase, estrogen concentrations are less than 50 pg/mL, but they increase rapidly as the follicle matures. E_2 production increases, reaching a midcycle peak at between 250 and 500 pg/mL.[281] E_2 concentrations decrease abruptly after ovulation but increase again as the corpus luteum is formed, reaching concentrations of approximately 125 pg/mL during the luteal phase.[281] Progesterone produced by the corpus luteum, combined with E_2, exerts a negative effect on the hypothalamus and anterior lobe of the pituitary gland. As a result, LH and FSH secretion is suppressed again during the luteal phase. E_2 is essential for the development of proliferative endometrium and is synergistic with progesterone for the development of changes in the endometrium that initiate shedding; the decrease in negative feedback from E_2 on the anterior lobe of the pituitary gland triggers the FSH surge that begins the development of an ovarian follicle for the next cycle.

Changes in androgen production also occur during the menstrual cycle, with a peak at midcycle. E_2 is not the only estrogen produced; estrone secretion, mainly from peripheral sources, also is increased throughout the cycle. Estrogen and progesterone have visible effects on vaginal cytology and cervical mucus, and progesterone elevates body temperature (as discussed later).

Progesterone. Progesterone is not produced in significant amounts until the midcycle LH surge and ovulation. LH enhances theca cell differentiation and progesterone production, which increase by a factor of 10 to 20 to a maximum about 8 days after the midcycle peak of LH. Progesterone is thought to stimulate the ovulatory peak of FSH and to promote the growth of secretory endometrium, which is necessary for implantation of the fertilized ovum.[50]

Ovulation

An intricate interplay of endocrine events contributes to follicular maturation. Growth of ovarian follicles appears to be continuous. How an individual follicle is singled out for each menstrual cycle is not known; however, the late-cycle peak in FSH concentration is likely important in this process. Once a follicle has been stimulated, E_2 production causes that specific follicle to be more receptive to effects of FSH. The high concentration of E_2 just before midcycle is responsible for triggering positive feedback in the hypothalamus that leads to the midcycle LH surge. After ovulation, LH is suppressed by progesterone and E_2, but the effect of LH on the corpus luteum is increased.[50,283,333,336] In the event of successful fertilization and implantation, corpus luteum function is sustained by hCG produced by trophoblastic cells of the developing embryo with high molecular homology to LH, and is capable of binding and stimulating LH receptors. Otherwise, the declining concentration of E_2 leads to regression of the corpus luteum and to the late-cycle FSH peak that starts the process again.

Menopause

Menopause is defined as the permanent cessation of menstruation resulting from loss of ovarian follicular activity.[10] It begins with the ovaries failing to produce adequate amounts of estrogen and inhibin; as a result, gonadotropin production is increased in a continued attempt to stimulate the ovary (Figure 56-11). The mean age of menopause in the United States is 51 years but varies considerably.[41,50,112,146] Ovarian failure may occur at any age, but menopause before age 40 years is considered premature.[68]

Hormonal changes begin about 5 years before the actual menopause, as the response of the ovary to gonadotropins begins to decrease and menstrual cycles become increasingly irregular.[112,146,278] The term *perimenopausal* refers to the time interval from onset of these menstrual irregularities to menopause itself. This transition phase will last from 2 to 8 years.[112,278] At this time, FSH concentrations increase and E_2 concentrations decrease, whereas LH and progesterone concentrations remain unchanged, indicating that menstrual cycles are ovulatory. As estrogen continues to decline, an associated decrease in prolactin concentrations is noted. The decrease in estrogen concentrations gives rise to vasomotor instability and "hot flashes."

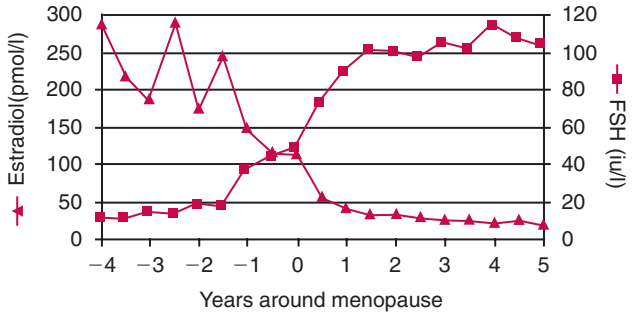

Figure 56-11 Geometric means for follicle-stimulating hormone (FSH) and estradiol in relation to the final menstrual period (FMP). The horizontal axis represents time (y) with respect to the FMP (0); negative (positive) numbers represent time before (after) the FMP. *(From Burger HG, Dudley EC, Hopper JL, Groome N, Guthrie JR, Green A, et al. Prospectively measured levels of serum follicle-stimulating hormone, estradiol, and the dimeric inhibins during the menopausal transition in a population-based cohort of women. J Clin Endocrinol Metab 1999;84:4025-30; Figure 1A, used with permission.)*

After menopause, the ovary continues to produce androgens, particularly testosterone and androstenedione, as a result of increased LH concentrations. In addition, the adrenal gland continues to secrete androgens. The resulting decrease in the estrogen/androgen ratio is the cause of the hirsutism often seen in postmenopausal women.[146] Prolonged estrogen deficiency results in increased resorption and bone remodeling, leading to accelerated bone loss and osteoporosis in postmenopausal women. Estrogen replacement therapy reduces bone loss and has been reported to reduce fracture risk by half.[112,146] The issue of hormone replacement treatment for (1) menopausal symptoms, (2) osteoporosis, (3) various cardiac problems, and (4) other disorders has received a great deal of attention, and data concerning the benefits and risks have changed ideas about indications and contraindications.[70,106,263] No single, reliable hormonal marker of menopause status is available for a given woman. Physicians should diagnose menopausal status on the basis of menstrual history and age without relying on laboratory test results.[27,45]

It is important to note that perimenopausal and postmenopausal women secrete pituitary hCG.[13,22,35,173] Serum concentrations generally are low (<13 IU/L), but positive hCG results often causes confusion and can delay important diagnostic tests or treatments. Pituitary versus placental hCG has been confirmed by measuring serum LH (concentrations of LH >45 IU/L are consistent with menopause and make pregnancy unlikely) or by 2 weeks of hormone replacement therapy (hormone replacement therapy should decrease LH, FSH, and hCG concentrations).[60,116]

Female Reproductive Abnormalities

A wide variety of abnormalities affect the female reproductive system and have been classified in a variety of ways. For the purposes of this chapter, they have been divided into

categories of (1) pseudohermaphroditism, (2) precocious puberty, (3) irregular menses, and (4) menopause. Infertility from the male and female perspective is discussed in a separate section.

Female Pseudohermaphroditism

In pseudohermaphroditism, the gonadal sex varies from the genital sex. The female pseudohermaphrodite is an individual who is genetically female, but whose phenotypic characteristics are, to varying degrees, male. In neonates with a 46,XX karyotype and ambiguous genitalia, *congenital adrenal hyperplasia* (CAH) should be considered. CAH is a family of autosomal recessive disorders of adrenal steroidogenesis (see Chapter 54). Each disorder has a specific pattern of hormonal abnormalities resulting in deficiency or excess of androgens. The molecular genetics of CAH is discussed in detail in several reviews.[64,140,141,169,322] In female fetuses, exposure to androgens before the 12th week of gestation causes ambiguous genitalia; after 13 weeks, it results in clitoral enlargement.[50,262] Because androgen excess occurs before the 12th week of gestation in those with CAH, ambiguous genitalia are almost always present. Only deficiencies of 21-hydroxylase and 11β-hydroxylase are predominantly virilizing disorders. Deficiency of 3β-hydroxysteroid dehydrogenase is rare, but when it occurs, affected girls may exhibit virilization.

Diagnosis of *21-hydroxylase deficiency* is made in infants and children with excess excretion of urinary 17-KS and pregnanetriol (a metabolite of 17-hydroxyprogesterone; see Chapter 54) and elevated concentrations of plasma 17-hydroxyprogesterone and androstenedione.[119,141,218] However, sick and premature infants may have elevated concentrations of 17-hydroxyprogesterone and androstenedione.[119,141] Elevation of 17-hydroxyprogesterone concentrations in early infancy (>3000 ng/dL) confirms the diagnosis of this disorder.[119,310] Additionally, molecular diagnostic testing is now available for detection of the mutations that account for most cases (80 to 90%) of 21-hydroxylase deficiency.[279]

An *11β-hydroxylase deficiency* is confirmed by finding elevated plasma concentrations of 11–deoxycortisol and deoxycorticosterone, increased concentrations of their metabolites in urine, and their suppression by glucocorticoid therapy (see Chapter 54). Plasma renin activity and aldosterone concentrations are low in this deficiency.[119,169,235]

Elevated plasma concentrations of 17-hydroxypregnenolone, DHEA, and DHEA-S are found in patients with 3β-*hydroxysteroid dehydrogenase deficiency* (see Chapter 54). Plasma concentrations of 17-hydroxyprogesterone may be elevated as a result of peripheral conversion of 17-hydroxypregnenolone. The ratio of 17-hydroxypregnenolone to 17-hydroxyprogesterone is strikingly elevated in these patients.[119,169,226]

Precocious Puberty

Precocious puberty is the development of secondary sexual characteristics in girls younger than 8 years old and boys younger than 9 years old.[247] In 1999, the Lawson Wilkins Pediatric Society issued new recommendations to lower the age standards at which puberty should be considered precocious from 8 to 7 in white girls and to 6 in black girls.[151] These recommendations have been met with criticism because they are based solely on a single epidemiologic study performed by Herman-Giddens and collaborators in 1997.[135] Many argue that the decreased age standards will result in underdiagnosis of this condition.[177,203,249]

Despite the debate over the age of onset, pediatric endocrinologists agree that it is important to distinguish between benign advanced pubertal conditions and true precocious puberty.[51,144,159,172,176,201] Early puberty is manifested by the appearance of secondary sexual characteristics such as premature thelarche (premature breast development), premature adrenarche (premature sexual hair development), or phallic enlargement. When presented as isolated cases, these secondary sexual characteristics are not considered to be pathologic, as none progresses to full-blown puberty, nor are they associated with increased rates of bone growth and maturation. However, if a child has at least two signs of puberty and also demonstrates increased rates of bone growth and maturation, the many causes of true precocious puberty must be considered.[201]

Precocious puberty has been classified as GnRH dependent or independent.[51,144,159,201] GnRH-dependent precocious puberty (also called *central precocious puberty*) is due to precocious activation of the hypothalamic-pituitary-gonadal axis. In girls, the cause is most commonly idiopathic (90%); however, idiopathic cases account for less than 10% of central precocious puberty in boys. Central nervous system tumors also have been known to cause central precocious puberty, the most common being hypothalamic hamartoma. Neurofibromatosis has been documented to lead to GnRH-dependent precocious puberty.

GnRH-independent precocious puberty (also called *pseudoprecocious puberty*) refers to precocious sex steroid secretion that is independent of pituitary gonadotropin release. Congenital adrenal hyperplasias (CAH) are a common cause of pseudoprecocious puberty. Classic forms of CAH present with virilization, growth acceleration, and accelerated bone maturation. Nonclassic or late-onset forms usually present in childhood or adolescence with premature adrenarche and acne. In fact, 5 to 10% of children who present with premature adrenarche have late-onset adrenal hyperplasia. Tumors of the adrenal gland, ovaries, and testes that secrete androgens or estrogens may result in GnRH-independent precocious puberty. Signs of puberty exhibited in males around 2 years of age are characteristic of testotoxicosis, a familial male-limited form of precocious puberty. This autosomal dominant disorder is due to activating mutations affecting LH receptors. The McCune-Albright syndrome is due to mutation of the *GNAS1* gene, which is involved in the signaling of G-proteins associated with gonadotropin receptors. The mutation causes the gonads to function as if both FSH and LH receptors are constitutively activated. Although this mutation results in GnRH-independent precocious puberty in both sexes, it is most common in girls. Precocious puberty, polyostotic fibrous dysplasia, and café au lait pigmentation

are hallmarks for McCune-Albright syndrome. Severe hypothyroidism is also associated with GnRH-independent precocious puberty, likely caused by intrinsic FSH activity of high circulating concentrations of TSH. Unlike the other causes, hypothyroid-induced precocious puberty is associated with skeletal and growth delays.

Diagnosis of precocious puberty is based on (1) clinical presentation, (2) a thorough pubertal history, (3) bone age determinations, and (4) laboratory tests performed to assess gonadotropin concentrations and response to exogenous GnRH.* The GnRH stimulation test is the gold standard for diagnosis of GnRH-dependent precocious puberty. Pubertal responses of LH and FSH to GnRH stimulation are considered diagnostic of precocious puberty when chronological age is inappropriate for the hormone response. The GnRH stimulation test is also used to monitor the effectiveness of GnRH agonist therapy.[170,258,259] Typically, an IV bolus of exogenous GnRH is administered (100 μg or 2.5 μg/kg, maximal dose 100 μg), followed by a single measurement (at 40 to 45 minutes) or serial measurements of LH and FSH concentrations.† A predominant LH response correlates with a pubertal pattern, and cutoffs vary depending on the assay, with sex differences noted. A typical pubertal response is characterized by a rise in LH to 8 IU/L or greater after IV administration of 100 μg GnRH.[205] In girls, peak LH/FSH ratios (>0.66 to 1.0) have been proposed to be diagnostic of central precocious puberty.[223,308] Highly sensitive fluorometric[43] and chemiluminetric[216] immunoassays are now available for use in measuring basal LH concentrations. Basal LH concentrations have been used instead of the GnRH stimulation test for diagnosis of central precocious puberty. A fluorometric assay resulting in a basal concentration of LH greater than 0.6 IU/L in either sex indicates a pubertal pattern and is consistent with precocious puberty. Values less than 0.6 IU/L have been seen with all forms of precocious puberty and require follow-up with a GnRH stimulation test.[43] A similar pattern is observed for immunochemiluminometric assays using a cutoff of 0.3 IU/L.[215,216]

Response to exogenous GnRH is suppressed and LH and FSH concentrations are low in individuals with GnRH-independent precocious puberty. The diagnosis of GnRH-independent precocious puberty must exclude nonclassic adrenal hyperplasia (NCAH). Basal 17-hydroxyprogesterone concentrations of early morning samples have been used to screen for 21-OH–deficient NCAH. A basal 17-hydroxyprogesterone concentration less than 6.0 nmol/L (200 ng/dL) almost always rules out 21-OH–deficient NCAH. Patients with intermediate (200 to 500 ng/dL) basal 17-hydroxyprogesterone concentrations should undergo an ACTH stimulation test to confirm the presence of 21-OH–deficient NCAH. This is achieved by measuring the 17-hydroxyprogesterone response to ACTH stimulation. An exaggerated response is expected in cases of NCAH. Guidelines (1983) use a 17-hydroxyprogesterone diagnostic cutoff of greater than 30 nmol/L (1000 ng/dL).[219] However, some argue that the cutoff should be raised to greater than 45 (1500 ng/dL) or 60 nmol/L (2000 ng/dL), as the value of 30 nmol/L was set before molecular genotyping became available, and studies have indicated that several nonaffected carriers exhibit 17-hydroxyprogesterone concentrations above 30 nmol/L.[15,16,18]

Therapy for precocious puberty is dependent on the presenting symptoms and underlying causes.[159,172,176,201,232] Isolated premature thelarche or adrenarche does not require therapy. Patients with premature thelarche should be followed for 3 to 6 months and require further evaluation for precocious puberty. Cases of premature adrenarche should be evaluated for NCAH and/or polycystic ovary syndrome in girls with determined insulin resistance. GnRH-dependent precocious puberty is treated with GnRH agonists to inhibit normal gonadotropin release, thereby slowing pubertal progression. Therapy for GnRH-independent precocious puberty is determined by the underlying cause.

Estrogens and Breast Cancer

Suspicions of estrogen-based causes in the development of human breast cancer stem from epidemiologic and experimental observations.[142,186] Early menarche and later natural menopause are associated with increased risk of breast cancer. A two-stage mechanism has been postulated: (1) initiation of a precancerous state by ovarian activity during the early reproductive years; and (2) continuation of ovarian activity in later years as a promoting influence on already initiated tumor cells. Ovarian estrogen has been assumed to be the causative factor because administration of estrogen negates the protective effects of early oophorectomy. Moreover, treatment of men with estrogen for prostatic cancer or after transsexual operations is associated with increased risk of breast cancer.

Low risk for breast cancer has consistently been connected with high parity. Increased risk is associated with early menarche, late (>30 years of age) first full-term pregnancy, and late menopause. Pregnancy occurring before age 25 to 30 years has a protective effect.

According to the theory, relative concentrations of individual estrogen fractions (E_1, E_2, and E_3) produced in the first decade or so after puberty are important determinants of a woman's lifetime risk of breast cancer.[61] In particular, pregnancy at a young age is associated with both favorable estrogen fraction ratios and decreased risk. Further discussion of the role of estrogen in the genesis of breast cancer is found in monographs and review articles.[59,127-129,153,154,182]

The rationale for using endocrine therapy in women with breast carcinoma is based on the fact that estrogen stimulates biochemical processes in cells of the uterus, pituitary gland, hypothalamus, and breast that normally contain the estrogen receptor. A reduction in circulating estrogen concentrations would be expected to decrease the biochemical activity of these cells. Approximately one third of women with metastatic breast carcinoma experience an objective remission after various types of endocrine therapy directed

*References 51, 144, 159, 172, 176, and 201.
†References 53, 85, 144, 160, 175, 215, and 216.

at lowering their estrogen concentrations. Such therapy includes oophorectomy, hypophysectomy, and adrenalectomy (ablative therapy), as well as administration of antiestrogens, androgens, and aromatase inhibitors (additive therapy).[29,46,168,245]

Cytoplasmic estrogen receptors are important prognostic indicators that are now routinely measured in samples of breast tissue after surgical removal of the tumor. Sixty percent of patients with carcinoma of the breast have tumors that are estrogen receptor positive. Approximately two thirds of patients with estrogen receptor–positive tumors respond to endocrine therapy; 95% of those with estrogen receptor–negative tumors fail to respond. Therefore, the greater the estrogen receptor content of the tumor, the higher is the response rate to endocrine therapy and the lower is the incidence of recurrence.

Irregular Menses

Healthy women display considerable variation in cycle length ranging from 25 to 30 days (28 days on average).[50] Amenorrhea, the absence of menstrual bleeding, is traditionally categorized as primary (women who have never menstruated) or secondary (women in whom menstruation is present for a variable time and then ceases). Amenorrhea is a relatively common disorder, with an estimated prevalence of 5% in the general population and as high as 8.5% in an unselected adolescent postpubescent population.[193]

Primary Amenorrhea

Primary amenorrhea is defined as failure to establish spontaneous periodic menstruation by the age of 16 years regardless of whether secondary sex characteristics have developed.[67,156,197] About 40% of phenotypic females who have primary amenorrhea (nearly always associated with absence of development of secondary sex characteristics) have *Turner syndrome* (45,X karyotype) or *pure gonadal dysgenesis* (46,XX or XY karyotype).[50,335] *Müllerian duct agenesis* or *dysgenesis* with absence of the vagina or uterus is the second most common manifestation, and the third most common is *androgen insensitivity syndrome* (androgen receptor deficiency and normal or elevated plasma testosterone concentrations if the patient is past puberty and is karyotype XY).

A *17α-hydroxylase deficiency* is a rare form of CAH that is associated with delayed puberty, primary amenorrhea, and hypertension. Patients have a 46,XX karyotype with elevated gonadotropins, low sex steroids, hypertension, and hypokalemia.[67,169]

Another rare cause of amenorrhea is the so called *resistant ovary syndrome.* This primary hypogonadal condition is associated with increased concentrations of plasma FSH and LH, and ovaries that contain predominantly primordial follicles. It is thought to arise from a defect in FSH receptors.[50] This disorder can be diagnosed only by examination of an ovarian biopsy specimen, which will exhibit functioning ovarian follicles despite the presence of amenorrhea. Ovulation sometimes is induced in these patients with administration of high doses of gonadotropins.

As discussed earlier, *Kallmann syndrome* involves hypogonadotropic hypogonadism associated with anosmia or hyposmia and is caused by a defect in the formation and migration of GnRH neurons. Sexual infantilism is the prominent manifestation, and primary amenorrhea is common.[50,335] Finally, delayed pubertal development should be considered.

Evaluation. When puberty is delayed in a girl, serum gonadotropins should be measured. Low concentrations may indicate pituitary failure, whereas concentrations elevated into the postmenopausal interval indicate definite gonadal failure.[50,238,335] In the latter case, chromosome studies are indicated. In the former case, pituitary function testing and radiography may be helpful. Patients with short stature without Turner syndrome but with primary amenorrhea may have multiple deficiencies of pituitary hormone secretion. In these patients, a craniopharyngioma or pituitary tumor should be suspected.

The diagnosis of *17α-hydroxylase deficiency* is made when the concentration of (1) serum progesterone is greater than 3 ng/mL; (2) 17α-hydroxyprogesterone is less than 0.2 ng/mL; (3) aldosterone is low; and (4) 11-deoxycorticosterone is elevated. Plasma concentrations of 11-deoxycortisol, testosterone, E_2, and DHEA-S are also low. The diagnosis is confirmed with an *ACTH stimulation test* in which baseline concentrations of progesterone and 17α-hydroxyprogesterone are measured first, followed by administration of 0.25 mg ACTH. Diagnosis is made if serum concentrations of progesterone are significantly elevated and 17α-hydroxyprogesterone concentrations are unchanged at 60 minutes after ACTH administration.[67,224]

Secondary Amenorrhea

Secondary amenorrhea is defined as absence of periodic menstruation for at least 6 months in women who have previously experienced menses.[68,156,197,241,316] *Oligomenorrhea* is infrequent menstruation that occurs fewer than nine times per year.[250] With few exceptions, the causes of primary and secondary amenorrhea overlap (Box 56-2). Pregnancy, the most common cause of secondary amenorrhea, must be considered first and ruled out.[156,197,316] Elevated concentrations of prolactin—iatrogenic or induced by a prolactin-secreting tumor—have been found to result in oligomenorrhea or amenorrhea.[156,197,316] About one third of women with no obvious cause of amenorrhea have elevated prolactin concentrations.[156] It is thought that hyperprolactinemia inhibits the release of LH and FSH.[161] Both hyperthyroidism and hypothyroidism are associated with a variety of menstrual disorders because of their effects on metabolism and interconversion of androgens and estrogens.[156,197,334] In practice, it is helpful to separate patients with secondary amenorrhea into those with and without signs of hirsutism and androgen excess.

Evaluation. Evaluation of women with amenorrhea should begin with a careful history that includes a complete description of menstrual patterns. In addition, the patient should be evaluated for (1) galactorrhea, (2) hot flashes, (3) symptoms of hypothyroidism, (4) hirsutism, (5) prior

BOX 56-2 Causes of Amenorrhea

Primary Amenorrhea
- Lower tract defects
  - Vaginal aplasia
  - Imperforate hymen
  - Congenital vaginal atresia
- Uterine disorders
  - Congenital absence of the uterus
  - Endometritis
  - Müllerian agenesis (Mayer-Rokitansky-Kuster-Hauser syndrome)
- Ovarian disorders
  - XO gonadal and X dysgenesis and variants
  - XX gonadal dysgenesis
  - Turner syndrome
  - Androgen insensitivity syndrome (AIS)
  - 17-Hydroxylase deficiency of the ovaries and adrenal glands
  - Autoimmune oophoritis
  - Resistant ovary syndrome
  - Polycystic ovary syndrome
- Adrenal disorders (congenital adrenal hyperplasia)
- Thyroid disorders (hypothyroidism)
- Pituitary-hypothalamic disorders
  - Hypopituitarism
  - Constitutional delay in the onset of menses (physiologic)
  - Nutritional disorders
  - Kallmann syndrome

Secondary Amenorrhea
- Pregnancy/lactation
- Uterine disorders
  - Post-traumatic uterine synechiae (Asherman syndrome)
  - Progestational agents
- Ovarian disorders
  - Polycystic ovary syndrome (hypothalamic)
  - Ovarian tumor
  - Primary ovarian insufficiency (idiopathic, autoimmune, chemotherapy, radiation, injury)
  - Antimetabolite therapy
- Adrenal disorders
  - Late-onset adrenal hyperplasia
  - Cushing syndrome
  - Virilizing adrenal tumors
  - Adrenocorticoid insufficiency
- Thyroid disorders
  - Hypothyroidism
  - Hyperthyroidism
- Pituitary disorders
  - Acquired hypopituitarism (trauma, tumor, Sheehan syndrome, lymphocytic hypophysitis)
  - Physiologic or pathologic hyperprolactinemia
- Hypothalamic disorders
  - Tumor and infiltrative disease
  - Nutritional disorders
  - Hypophysitis
  - Excessive exercise
  - Stress
- Iatrogenic
  - Antipsychotics (phenothiazines, haloperidol, clozapine, pimozide)
  - Antidepressants (tricyclics, monoamine oxidase inhibitors)
  - Antihypertensives (calcium channel blockers, methyldopa, reserpine)
  - Drugs with estrogenic activity (digitalis, flavonoids, marijuana, oral contraceptives)
  - Drugs with ovarian toxicity (busulfan, chlorambucil, cisplatin, cyclophosphamide, fluorouracil)

abdominal surgery, (6) pelvis or uterus trauma, (7) medications prescribed, (8) nutritional history, (9) patterns of exercise, (10) previous contraceptive use, (11) weight changes, (12) stress, and (13) chronic disease. The physical examination should determine the visual fields, thyroid size and function, cushingoid appearance, galactorrhea, hirsutism, abdominal masses, pelvic masses, clitoral enlargement, and evidence of malnutrition. Serum or urine β-hCG should be measured to rule out pregnancy. Because both hypothyroidism and hyperprolactinemia have been known to cause amenorrhea, they are easily excluded by measuring concentrations of serum thyroid-stimulating hormone and prolactin.

A 24 hour urine sample for cortisol measurement or an overnight dexamethasone suppression test is performed in those patients suspected of having Cushing syndrome (see Chapter 54). On the basis of the preliminary assessment, computed tomography of the sella turcica should be performed in patients with evidence of pituitary or hypothalamic disease. A GnRH stimulation test with measurement of LH and FSH concentrations in those patients with gonadotropin deficiency assists in differentiating hypothalamic disease from pituitary disease. For diagnosis of polycystic ovary disease (PCOS), see the later section, "Laboratory Evaluation of Hirsutism/Virilization."

Progesterone Challenge for Evaluating Amenorrhea

When the cause of amenorrhea is unclear after the initial assessment, relative estrogen status should be determined. Serum E_2 can be measured, or a *progesterone challenge* may be performed.[50,335] Women with an estrogen-primed uterus have withdrawal vaginal bleeding after treatment with oral progestin (medroxyprogesterone acetate; Provera), 30 mg daily for 3 days, or 10 mg daily for 5 to 10 days, or 100 to 200 mg of progesterone in oil given intramuscularly. If estrogen concentrations are adequate and the outflow tract is intact, menstrual bleeding should occur within a week of treatment. In patients with withdrawal bleeding, the plasma

E_2 concentration is usually greater than 40 pg/mL.[50,68] Measurement of serum E_2 can be made instead of the progesterone challenge but is not preferred because estrogen concentrations fluctuate throughout the day, and withdrawal bleeding is an indication of a normal outflow tract.

If bleeding fails to occur after progestin challenge, then additional laboratory tests are indicated, including measurement of LH and FSH to localize the problem to the follicle, pituitary, or hypothalamus. High gonadotropin and low estrogen concentrations indicate that the ovarian follicle is not responding to gonadotropin stimulation. A single measurement of LH or FSH greater than 50 mIU/mL is a reliable indicator of ovarian failure. Because of the association of *primary ovarian insufficiency* (POI) with thyroid, parathyroid, or adrenal insufficiency secondary to autoimmune disease, it has been suggested that patients younger than 35 years should be screened for thyroid antibodies.[68] The differential diagnosis for evaluation of amenorrhea is listed in Table 56-1. As indicated by the clinical presentation, special additional testing may be required.

If the patient demonstrates withdrawal bleeding after the progestin challenge test, this indicates that the ovaries are producing sufficient estrogen to cause endometrial proliferation, and no anatomic obstruction is present. Most of these women have a history of oral contraceptive use, stress, weight loss, or excessive exercise.

Androgen Excess

Amenorrhea due to androgen excess can be due to (1) adult-onset CAH, (2) corticotropin-dependent Cushing syndrome, or (3) polycystic ovary syndrome (PCOS). Patients with androgen excess often will present with acne, obesity, and variable degrees of excess hair on the face, chest, abdomen, and thighs. Some individuals with 21-hydroxylase deficiency

TABLE 56-1 Differential Diagnosis of Amenorrhea

Causes	FSH	LH	Estrogen (E_2)	Uterine Bleeding After Progesterone
Hypothalamic

do not manifest any developmental abnormalities or salt wasting, but they present with signs of androgen excess. This clinical syndrome, referred to as *nonclassic, adult-onset,* or *late-onset CAH,* may be clinically indistinguishable from PCOS.[15,79,100]

PCOS occurs in ≈4% of premenopausal women, and its basic pathophysiologic defect is not known.[50,109,280,337] PCOS is clinically defined by hyperandrogenism with chronic anovulation in women with no other cause.[123] This syndrome is characterized by (1) infertility, (2) hirsutism, (3) obesity (in approximately half of those affected), and (4) various menstrual disturbances ranging from amenorrhea to irregular vaginal bleeding (Table 56-2). These women have an increased prevalence of diabetes, along with increased risk for coronary heart disease and endometrial cancer. Although this syndrome is associated with polycystic ovaries, they often are not present in women with this syndrome. The name is actually a misnomer in that the ovaries are covered with follicles, not cysts. Relatively low FSH and disproportionately high LH concentrations are common in PCOS. Serum androstenedione and testosterone concentrations (total and free concentrations) are elevated, with mean concentrations 50 to 150% higher than normal.[26,50,100]

PCOS patients have substantial estrogen production because of the peripheral conversion of androgens to estrogens. Abnormal bleeding patterns seen in PCOS are due to chronic anovulation and lack of progesterone stimulation and withdrawal. Chronic estrogen exposure without progesterone may predispose patients to endometrial cancer. Some attempt has been made to link PCOS to *leptin,* a hormone that is secreted by adipocytes and is thought to play a role in regulating food intake and metabolism.[44] Animals that lack leptin are infertile; leptin injection increases gonadotropin secretion and restores fertility.[23,56] However, the literature suggests that leptin concentrations are normal in patients with PCOS.[49] Veldhuis and collaborators note that although serum leptin concentrations were the same in PCOS patients and controls, the pattern of leptin secretion was abnormal in girls with PCOS.[303] For PCOS patients who are not interested in conceiving, the mainstay of therapy is oral contraceptive pills. For those who are overweight or obese, weight loss and exercise are essential. For women with PCOS who wish to conceive, treatment is aimed at ovulation induction. Weight reduction should be attempted first in those women who are overweight, as it often helps to promote ovulation. If ovulation does not occur, then medications such as clomiphene citrate, metformin, and aromatase inhibitors may be useful.[123] *Ovarian hyperthecosis,* a non-neoplastic lesion of the ovary characterized by the presence of islands of luteinized thecal cells in the ovarian stroma, is sometimes confused with PCOS. Features that distinguish it from PCOS include higher concentrations of testosterone, androstenedione, and DHT derived from ovarian secretion. Thus, androgenization is greater than is usually observed in patients with PCOS. Both LH and FSH concentrations are low or low-normal. Insulin resistance and hyperinsulinism are present to a greater degree than in PCOS. Finally, patients with ovarian hyperthecosis fail to ovulate when treated with an antiestrogen such as clomiphene citrate.[337]

TABLE 56-2 Clinical Features of the Polycystic Ovary Syndrome*

Clinical Feature	Frequency, %
Hirsutism	65
Acne	26
Obesity	37
Infertility	48
Amenorrhea	35
Oligomenorrhea	42
Regular menstrual cycle	20

*Data were compiled from three studies. Two used ultrasonography as the primary method of diagnosis, one used ovarian histology. Total $N = 1935$. Modified from Franks S. Polycystic ovary syndrome. N Engl J Med 1995;333:853. Copyright © 1995 Massachusetts Medical Society. All rights reserved.

Hirsutism and Virilization

Hirsutism is defined as excessive growth of terminal hair in women and children in a distribution similar to that occurring in postpubertal men.[14,246,257] True hirsutism, which is androgen responsive, has to be distinguished from hypertrichosis, which consists of excessive growth of vellus or non–androgen-responsive hair. Vellus is fine, downy hair that is usually unpigmented, whereas terminal hairs are thick and are found in androgen-responsive areas of the skin.[251,257] Growth of vellus hair diffusely over the trunk and face may be familial or drug induced, and is treatable only by mechanical hair removal or withdrawal of the inducing drug. Women with androgen-dependent hirsutism may have exposure to excess androgens or may have heightened sensitivity to normal circulating concentrations of androgen. As a consequence, vellus follicles develop into terminal hair follicles in areas of androgen-sensitive skin.

The causes of hirsutism are listed in Box 56-3. The estimated prevalence for idiopathic hirsutism ranges from 6 to 50% of women evaluated for hirsutism, depending on the definition.[17,48,257,261] Typically, idiopathic hirsutism is defined by normal physical and laboratory findings in hirsute women. However, it has been reported that the prevalence of idiopathic hirsutism changes drastically, whether or not factors such as ovulatory function and androgen concentrations are considered.[17] It is thought that increased sensitivity of the hair follicle to normal circulating androgens causes the excess hair growth.[257] Non-neoplastic forms of hirsutism are slow to progress and usually manifest at the time of puberty, when circulating concentrations of androgens increase, or after a period of weight gain, or when oral contraceptives have been stopped.[246] Rapid onset of hirsutism suggests an iatrogenic cause or, if associated with virilization, a neoplastic source of androgens. The most common cause of androgen hypersecretion in women is PCOS; 70 to 80% of hirsute women are

BOX 56-3 Causes of Hirsutism

Ovarian
- Severe insulin resistance
- Hyperthecosis, hilus cell or stromal cell hyperplasia
- Androgen-producing ovarian tumor
- Menopause

Adrenal
- Classic congenital hyperplasia
  - 21-Hydroxylase deficiency
  - 11-Hydroxylase deficiency
  - 3β-Hydroxysteroid dehydrogenase deficiency
- Adult or attenuated adrenal hyperplasia
- Androgen-producing adrenal tumor

Familial Hirsutism

Endocrine Disorders
- Polycystic ovary syndrome
- Hyperprolactinemia
- Acromegaly
- Cushing syndrome

Idiopathic Hirsutism (includes increased skin sensitivity to androgens)

Iatrogenic
- Androgens
- Dilantin
- Diazoxide
- Minoxidil
- Streptomycin
- Cyclosporine
- Danazol
- Metyrapone
- Phenothiazides
- Progestagens (19-nonsteroid derivatives)

reportedly afflicted with this disorder.[261] Hyperandrogenism usually arises from both ovaries and the adrenal glands (for more on PCOS, see previous section). Late-onset CAH (see Chapter 54), acromegaly, hyperprolactinemia, menopause (see earlier section, "Menopause"), and ACTH-dependent Cushing syndrome have been observed to cause hirsutism.

Virilization is characterized by clitoral hypertrophy, deepening of the voice, temporal hair recession, baldness, increased libido, decreased body fat, and menstrual irregularities or amenorrhea. Hirsutism is usually associated with normal or slightly elevated serum androgens, whereas virilization is associated with marked increases in ovarian or adrenal androgen production.[50]

Laboratory Evaluation of Hirsutism/Virilization

The two most important screening tests used in the evaluation of women for hirsutism and virilization are serum total or free testosterone and DHEA-S.[50,251] Elevation of DHEA-S concentration suggests an adrenal origin of androgens, whereas elevations in testosterone indicate an adrenal or ovarian source. Neoplastic disease is unlikely if the serum testosterone concentration is less than 2 ng/mL, the DHEA-S concentration is less than 700 μg/dL, or 17-KS concentrations are less than 30 mg/d.[50,100,257] Regardless of the source of excess androgen production, the androstanediol glucuronide concentration is elevated in more than 90% of women with hirsutism, because it is a marker of excessive DHT production in skin. Because concentrations of SHBG can be decreased in hirsute women, there has been some debate over whether total testosterone or bioavailable testosterone (free and weakly bound testosterone) is more clinically informative in diagnosing hirsutism. The reader is directed to a review by Wheeler that discusses many of these issues.[319]

Polycystic ovary syndrome is primarily a clinical diagnosis, and few laboratory tests are needed. Given a history of androgen excess and chronic anovulation (usually since menarche), the only condition that needs to be excluded is 21-hydroxylase–deficient nonclassic CAH; this can be done by measuring 17-hydroxyprogesterone (early morning; follicular phase). If the result is less than 2 ng/mL, nonclassic CAH can be excluded. Serum testosterone measurement is not necessary if clear hirsutism is present. Testosterone concentrations greater than 60 ng/dL are consistent with PCOS.[123] FSH concentrations are often disproportionately normal or low. It has been suggested that a ratio of LH to FSH greater than 2 or 2.5 indicates the presence of PCOS.[50,257] However, because of the pulsatile nature of gonadotropins, this ratio is insensitive. Patients with PCOS usually have E_2 concentrations greater than 40 pg/mL and therefore experience withdrawal bleeding in response to a progestin challenge.

Morning plasma 17α-hydroxyprogesterone concentrations are measured to evaluate *nonclassic* or *late-onset 21-hydroxylase deficiency* (NCAH). A concentration less than 200 ng/dL (6.1 nmol/L) excludes this diagnosis, and a concentration greater than 1500 ng/dL (30 nmol/L) in nonpregnant women is confirmatory. When basal concentrations between 200 and 1500 ng/dL are found, an ACTH stimulation test should be performed. NCAH typically has a 17α-hydroxyprogesterone concentration greater than 1500 ng/dL, and classic CAH has a response over 2000 ng/dL.[205,246,251] Patients with attenuated forms of CAH usually have normal concentrations of FSH and LH. About one half have elevated testosterone and androstenedione concentrations.[336] Most of these patients also have increased concentrations of DHEA-S, and more than 90% have supranormal concentrations of androstanediol glucuronide.[199,227]

Other Factors

Many other factors or conditions have been observed to cause secondary amenorrhea, including disorders of the ovary, uterus, pituitary, and hypothalamus, and the use of drugs.

Disorders of the ovary, such as *primary ovarian insufficiency (POI)* [formerly referred to as premature ovarian failure (POF)] and loss of ovarian function, have been known to cause amenorrhea. POI has been defined as failure of ovarian estrogen production that occurs in a

hypergonadotropic state at any age between menarche and 40 years.[50,68,156,316] If the patient is younger than 25 years, karyotyping should be performed to rule out the presence of a variety of chromosomal abnormalities involving duplications or absence of the X chromosome or the presence of a Y chromosome. Screening for the fragile X premutation *(FMR1)* should also be performed.[217] Patients with POI may present with symptoms of hypoestrogenism, including hot flashes and high gonadotropin concentrations. Autoimmune disorders have been associated with 20 to 40% of cases of POI that result in destruction of the ovary and in amenorrhea.[50,68,156,316] Patients also may have antibodies to other endocrine and nonendocrine tissues. Other causes for ovarian failure include (1) oophorectomy, (2) cystic degeneration, (3) trauma, (4) infection, (5) interference with blood supply, (6) radiotherapy treatment, and (7) treatment with cytotoxic chemotherapeutic agents. In rare patients, ovarian resistance to gonadotropins may be evident.[50,316]

Secondary amenorrhea is also caused by uterine failure. The patient with a uterine problem is normal hormonally but does not menstruate. *Asherman syndrome*, or intrauterine adhesions, is the most common outflow tract abnormality that causes amenorrhea. Endometrial damage may occur in response to a dilatation and curettage, and to infection of the endometrium.[68,156] Pituitary dysfunction will also cause secondary amenorrhea. This is most often due to intrinsic pituitary tumors. However, Sheehan syndrome and pituitary apoplexy will also result in hormone deficiency. Empty sella syndrome has been reported in 4 to 16% of patients with amenorrhea and galactorrhea.[156]

Hypothalamic dysfunction consists of those disorders that disrupt the frequency or amplitude of GnRH. Rarely is this due to a lesion or tumor. However, most commonly, disruption occurs in response to psychological stress, depression, severe weight loss, anorexia nervosa, or strenuous exercise.[68,156] A syndrome known as the *female athletic triad* has been described. This syndrome is prevalent in women who exercise vigorously, and is associated with amenorrhea, disordered eating, and osteoporosis. Competitive long-distance runners, gymnasts, and professional ballet dancers appear to be at highest risk. Although the mechanism for the disturbance is unclear, symptoms and laboratory profiles are similar to those of other forms of hypothalamic amenorrhea. LH and FSH concentrations are normal or low, and E_2 concentrations are low. As a result of chronic low estrogen, bone mineral content is low and the incidence of stress fractures is increased.[68,193]

Several hormone-producing tumors of the ovary, pituitary gland, and adrenal glands occur in combination with amenorrhea.[50,185,296,335] This amenorrhea may be confused with pregnancy if the tumors produce hCG. Choriocarcinoma of the uterus or ovary may produce large amounts of hCG that cause hyperthyroidism, because of the slight thyrotropic action of hCG. Granulosa–theca cell tumors are usually associated with estrogen secretion that results in amenorrhea and irregular menses and, rarely, excessive androgen with associated virilization.[50,335]

Many drugs produce amenorrhea (see Box 56-2), particularly phenothiazines and other psychotropic drugs such as haloperidol, pimozide, or clozapine.[156] Phenothiazine-induced amenorrhea is usually associated with hyperprolactinemia and galactorrhea. Drugs that affect the normal pathway of dopamine secretion will produce amenorrhea by decreasing the secretion of norepinephrine. Because norepinephrine is important in controlling the synthesis and secretion of GnRH, any alteration in its synthesis or secretion will result in menstrual abnormalities.[68,161] Amenorrhea may follow discontinuation of contraceptive steroids—so-called *post-pill amenorrhea.* Contraceptive steroids have a suppressive effect on the pituitary that sometimes persists after medication has been discontinued. In most women, menses resumes within 6 months after discontinuation of oral contraceptives.[68] If menses has not resumed within this time frame, evaluation is warranted. If other causes of amenorrhea are suspected, evaluation should not be delayed.

INFERTILITY

Infertility is defined as the inability to conceive after 1 year of unprotected intercourse.[24,50,307] It has been estimated that 93% of healthy couples practicing unprotected intercourse should expect to conceive within 1 year, and 100% will be successful within 2 years.[91] A specific cause of infertility is identified in ≈80% of couples: one third are due to female factors alone, one third to male factors alone, and one third to a combination of problems.

Primary infertility refers to couples or patients who have had no previous successful pregnancies. Secondary infertility encompasses patients who have previously conceived, but are currently unable to conceive. These types of infertility generally share common causes.

Infertility problems often arise as a result of hormonal dysfunction of the hypothalamic-pituitary-gonadal axis. Measurements of peptide and steroid hormones in the serum are therefore essential aspects of the evaluation of infertility. This section focuses on hormonal and biochemical aspects of evaluating infertility.

Male Infertility

A list of the most common male infertility factors is given in Box 56-4. One algorithm for the evaluation of male infertility is shown in Figure 56-12. Initial evaluation of male infertility should include a detailed history and physical examination. The physical examination should pay particular attention to (1) the external genitalia—for evidence of proper androgenization, (2) hair pattern—degree of virilization, (3) breast abnormalities—gynecomastia and or discharge, and (4) neurologic findings—sense of smell and visual impairments. The history must include (1) reproductive history, including living children and any pregnancies that resulted in miscarriage, (2) prescribed medications, (3) recreational and performance-enhancing drug and alcohol use, (4) systemic illness, and (5) potential toxin exposure. Sexual history should include sexual technique,

BOX 56-4 Male Infertility Factors

Endocrine Disorders
Hypothalamic dysfunction (Kallmann syndrome)
Pituitary failure (tumor, radiation, surgery)
Hyperprolactinemia (drug, tumor)
Exogenous androgens
Thyroid disorders
Adrenal hyperplasia
Testicular failure

Anatomic
Congenital absence of vas deferens
Obstructed vas deferens
Congenital abnormalities of ejaculatory system
Varicocele
Retrograde ejaculation

Abnormal Spermatogenesis
Unexplained azoospermia
Chromosomal abnormalities
Mumps orchitis
Cryptorchidism
Chemical or radiation exposure

Abnormal Motility
Absent cilia (Kartagener syndrome)
Antibody formation

Psychosocial
Unexplained impotence
Decreased libido

TABLE 56-3 Normal Seminal Fluid Values

Parameter	Value
Ejaculate volume	>2 mL*
Sperm density	>20 million/mL*
Total sperm count	>40 million/ejaculate*
Motility	>50% with forward progression or >25% with rapid progression within 60 minutes of ejaculation*
Morphology	>30% normal*
pH	7.2-8.0*
Color	Gray-white-yellow
Liquefaction	Within 40 minutes
Fructose	>1200 µg/mL
Acid phosphatase	100-300 µg/mL
Citric acid	>3 mg/mL
Inositol	>1 mg/mL
Zinc	>75 µg/mL
Magnesium	>70 µg/mL
Prostaglandins (PGE_1 + PGE_2)	30-200 µg/mL
Glycerylphosphorylcholine	>650 µg/mL
Carnitine	>250 µg/mL
Glucosidase	>20 mU per ejaculate

*Values from World Health Organization. Laboratory manual for the examination of human semen and semen–cervical mucus penetration, 3rd edition. Cambridge, UK: Cambridge University Press, 1992.

frequency of intercourse, and use of any lubricants. Issues of potency must be distinguished from those of infertility or subfertility. All abnormalities in the history and physical examination should be pursued. Testosterone should be measured, especially when the patient history or physical examination suggests deficient development of secondary sex characteristics.

Laboratory evaluation of male infertility should begin with evaluation of semen, which should be followed by evaluation of endocrine parameters.

Evaluation of Semen

Semen analysis measures ejaculate volume, pH, sperm count, motility, forward progression, and morphology. Semen should be analyzed within 1 hour after collection. Although semen analysis is not a test for infertility, it is considered the most important laboratory test in the evaluation of male fertility. Controversy exists as to what constitutes a "normal" semen profile. With the exception of the *azoospermic* male (defined as no sperm in the ejaculate), the lines between fertility and infertility are blurred and are intimately associated with the status of the female partner's reproductive function. However, clinical studies of infertile men and World Health Organization (WHO) guidelines have helped establish limits of adequacy (Table 56-3).[11,95] If semen analysis is normal, it is unlikely that other laboratory testing will be useful. If semen analysis is abnormal, it should be repeated in ≈6 weeks. A new approach to semen analysis for investigation of infertility uses a monoclonal antibody to sperm protein SP-10. A version of the test is available to check the success of vasectomy. A home-use version (http://www.contravac.com/) was cleared by the FDA in 2010 as substantially equivalent to a sperm count and is expected to be marketed widely.

Evaluation of Obstruction

Obstruction of the male reproductive tract will result in male infertility, and analysis of specific semen parameters has proved a useful adjunct to physical examination in the evaluation of male reproductive tract obstruction. Testosterone produced after administration of hCG causes the seminal vesicles, epididymis, and prostate to increase the volume of ejaculate. An appropriate increase in serum testosterone without change in the ejaculate volume may indicate mechanical blockage. Absence of, or a decrease in, specific biochemical markers such as acid phosphatase and citric acid (from

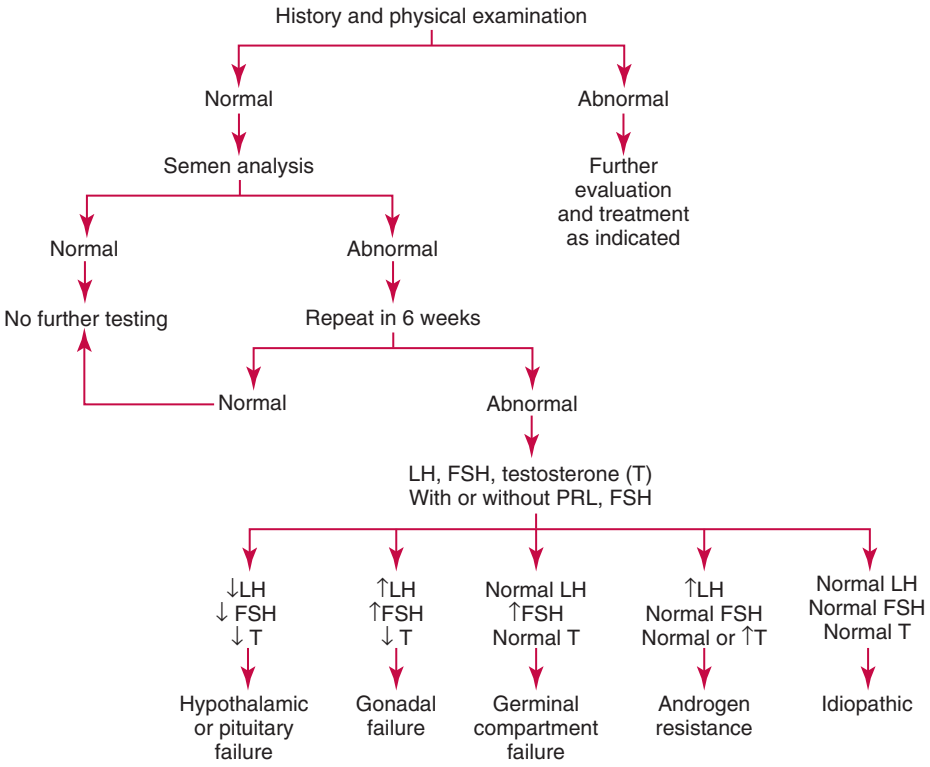

Figure 56-12 Algorithm for the evaluation of male infertility. *FSH,* Follicle-stimulating hormone; *LH,* luteinizing hormone; *T,* testosterone.

prostate), fructose, and prostaglandins (from seminal vesicles) can assist determination of the location of blockage.[104] Low seminal glucosidase concentrations, in the presence of testes of normal size and consistency, normal semen volume, and normal serum FSH, have been used as an indication of obstruction (usually in the epididymis) or congenital bilateral absence of the vas deferens (a condition associated with mutations of the cystic fibrosis gene).[6]

Evaluation of Endocrine Parameters

If severe oligospermia or azoospermia is found, then measurement of serum testosterone, LH, and FSH concentrations is warranted, with or without measurement of prolactin and TSH. Hyperprolactinemia is a cause of secondary testicular dysfunction.[113] Prolactin excess likely causes hypogonadism by impairing GnRH release. It also leads to underandrogenization and erectile dysfunction (see earlier section, "Erectile Dysfunction"). If hyperprolactinemia is found, it is imperative to check for hypothyroidism, because elevated TRH concentrations can result in hyperprolactinemia. Pituitary adenomas and drugs such as anxiolytics, antihypertensives, serotonergics, and histamine H_2 receptor antagonists also increase serum prolactin.[332] Hyperthyroidism and hypothyroidism will alter spermatogenesis. Hyperthyroidism affects both pituitary and testicular function, with alterations in the secretion of releasing hormones and increased conversion of androgens to estrogens.

Patients with borderline or suppressed testosterone concentrations can be evaluated with an *hCG stimulation test.* With this test, an injection of 5000 IU hCG is administered intramuscularly following collection of a basal, early morning testosterone sample. Serum testosterone is measured 72 hours later. Hypogonadal men show a depressed rise in testosterone concentration in response to this challenge. Doubling of testosterone concentration over baseline is consistent with normal Leydig cell function. Failure to increase testosterone to greater than 150 ng/dL indicates primary hypogonadism.[147]

Testosterone is essential for normal sperm development (see Figure 56-4). Therefore, any disorder that results in hypogonadism (and hence low testosterone concentrations) results in infertility. Among the causes are hypogonadotropic and hypergonadotropic hypogonadism.

Hypergonadotropic Hypogonadism

Measurement of the concentration of FSH is indicated in men with sperm count lower than 5 to 10 million/mL. Elevated concentrations of FSH indicate Sertoli cell dysfunction and, in azoospermic men, primary germinal cell failure, Sertoli cell–only syndrome, or genetic conditions such as Klinefelter syndrome.[105] Elevated FSH (>120 mIU/mL) in the setting of decreased testosterone (<200 ng/dL) and oligospermia indicate primary testicular failure.

Hypogonadotropic Hypogonadism

Decreased concentrations of testosterone (<200 ng/dL) and decreased concentrations of FSH (<10 mIU/mL) are suggestive of hypogonadotropic hypogonadism. Administering

GnRH may help to distinguish between gonadal insufficiencies caused by pituitary versus hypothalamic failure. Because the pituitary is sensitive to sex steroids for appropriate gonadotropin secretion, patients with long-standing hypogonadism should be given exogenous testosterone for 1 week before the GnRH stimulation test is administered. One approach to this test involves the intravenous injection of 100 μg of GnRH with measurement of FSH and LH concentrations at 0, 30, 60, 120, and 180 minutes after injection. Results of the GnRH test are classified as follows. An increase in serum gonadotropins of 10 mIU/mL or more over baseline is normal. If little to no increase in gonadotropins is seen, pituitary disease is likely. Patients with hypothalamic disease will demonstrate a delayed but significant increase of 7 mIU/mL or more within 180 minutes.[147] The most common cause of hypothalamic hypogonadism is *congenital idiopathic hypogonadotropic hypogonadism* (IHH) or its variant, Kallmann syndrome (see earlier section, "Male Reproductive Abnormalities").[220] An adult-onset form of IHH has been recognized as a potentially treatable form of male infertility.[213] Molecular diagnosis using fluorescence in situ hybridization (FISH) analysis is now offered to families with X-linked Kallmann syndrome. This is the most common type of testing performed, but it will detect only major deletions in the *KAL* gene. Genome microarray analysis and prenatal diagnosis also are now available.

Mutations in the X chromosome gene, *Dax1,* also have been known to cause hypogonadotropic hypogonadism in association with congenital adrenal hypoplasia. This gene encodes an orphan nuclear hormone receptor that has a critical role in development of the hypothalamus, pituitary, adrenal, and gonads.[105] FISH analysis is also available for the diagnosis of *Dax1* mutations.

Y-Chromosome Microdeletions

Deletions in either of the azoospermia factor regions (AZF1 and AZF2) on the long arm of the Y chromosome are associated with an inability to make sperm. In addition, genes such as *SRY* (sex-determining region Y) are on the short arm of chromosome Y. Deletion of these regions is associated with azoospermia or, less frequently, oligospermia. The incidence of Y microdeletions in idiopathic nonobstructive azoospermic men is 8% to 18%.[105] Testing for Y-chromosome microdeletions includes polymerase chain reaction (PCR) of specific regions of the Y chromosome to identify microdeletions. Tests should span AZFa and AZF2 and other regions thought to encode putative spermatogenesis genes.[105]

Immunologic Parameters

Antibodies to sperm surface antigens have been explored as a cause of infertility. They are thought to impair fertility by decreasing motility, increasing agglutination, and impairing the ability of sperm to penetrate human ova.[295] However, this is controversial, and laboratory testing for antisperm antibodies is rarely performed. The reader is directed to the previous edition of this chapter for further details about methods.[131]

BOX 56-5 Female Infertility Factors

Ovarian or Hormonal Factors
- Metabolic disease
  - Thyroid
  - Liver
  - Obesity
  - Androgen excess
  - Polycystic ovarian syndrome
- Hypergonadotropic hypogonadism
  - Menopause
  - Luteal phase deficiency
  - Gonadal dysgenesis
  - Primary ovarian insufficiency (autoimmune, cytotoxic, chemotherapy, radiation, tumor)
  - Resistant ovary syndrome
- Hypogonadotropic hypogonadism
  - Hyperprolactinemia (tumor, drugs)
  - Hypothalamic insufficiency (Kallmann syndrome)
  - Pituitary insufficiency (tumor, necrosis, thrombosis, stress, exercise, anorexia)

Tubal Factors
- Occlusion or scarring
- Salpingitis isthmica nodosa
- Infectious salpingitis

Cervical Factors
- Stenosis
- Inflammation or infection
- Abnormal mucous viscosity

Uterine Factors
- Leiomyomata
- Congenital malformation
- Adhesions
- Endometritis or abnormal endometrium

Psychosocial Factors
- Decreased libido
- Anorgasmia

Iatrogenic

Immunologic (Antisperm Antibodies)

Modified from Morell V. Basic infertility assessment. Primary Care 1997;24:195-204.

Female Infertility

Evaluating female infertility is more complex than evaluating infertility of the male. A list of the most common female infertility factors is given in Box 56-5. One algorithm for the evaluation of female infertility is shown in Figure 56-13. This evaluation should be considered after 1 year of unprotected intercourse in women with regular menses younger than 35. If a woman is over the age of 35, or if the woman or her partner has a history of issues that would contribute to infertility, this work-up should ensue sooner. Examples of issues that would prompt earlier work-up include (1) irregular menses, (2) history of pelvic inflammatory disease or

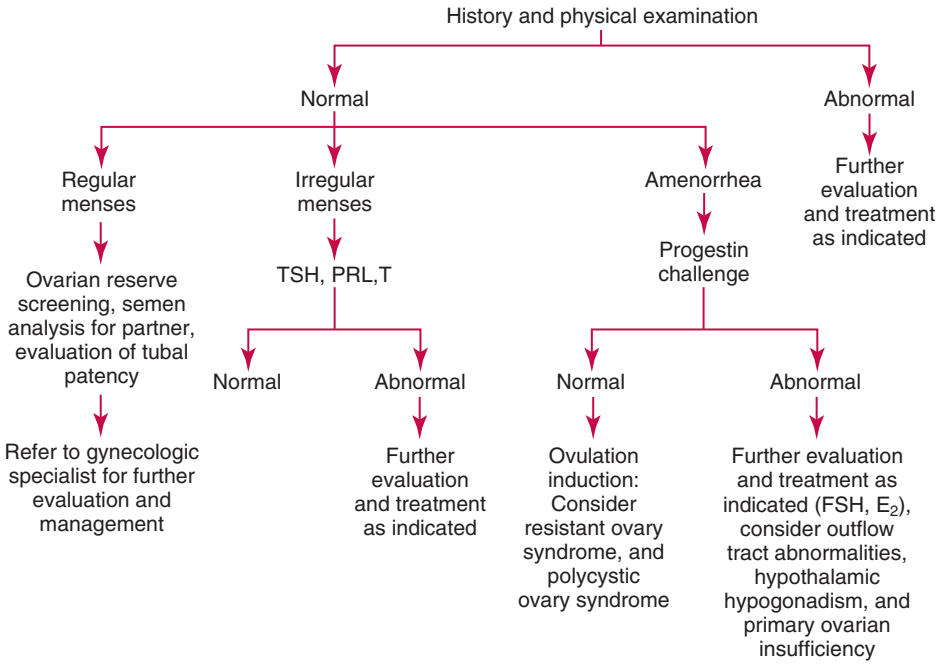

Figure 56-13 Algorithm for the evaluation of female infertility. ***FSH,*** **Follicle-stimulating hormone;** ***LH,*** **luteinizing hormone;** ***PRL,*** **prolactin;** ***T,*** **testosterone;** ***TSH,*** **thyroid-stimulating hormone.**

(3) sexually transmitted infection, and (4) history of exposure to gonadotoxic agents.

Initial Evaluation of Female Infertility

The initial evaluation of female infertility should include a detailed history and physical examination. The physical examination should include evaluation of (1) the external genitalia and hair pattern (for signs of androgen excess, including clitoromegaly, hirsutism, and virilization), (2) the pelvis (for masses, nodularity, or tenderness), (3) the breasts (for signs of galactorrhea), (4) neurologic findings (sense of smell and visual impairments), (5) the thyroid (for enlargement or nodules), and (6) body mass index. All abnormalities in the history and physical examination should be pursued. A thorough medical and surgical history is also necessary, including an assessment of the patient's (1) gravidity and parity, (2) coital frequency, (3) duration of infertility, and (4) prior work-up and treatment for infertility. History of sexually transmitted infections, assessment of previous cervical cytologic and human papillomavirus (HPV) testing and treatment, and a menstrual history also should be obtained. Concentrations of TSH, testosterone, and prolactin should be measured if menstrual cycles are absent or irregular, or if signs of galactorrhea or thyroid abnormalities are present. Ovulation reserve testing as discussed here should be considered in cases where diminished ovarian reserve is suspected.

Evaluation of Ovulation

In the menstruating woman, the next step would be to determine whether ovulation occurs. No current laboratory tests will confirm ovum release. However, measurement of the concentration of mid-luteal plasma progesterone does indicate that a corpus luteum was formed. Other methods such as measurement of the LH surge (to predict ovulation) and basal body temperature (to detect a rise in progesterone) have been used to assess ovulation.

Progesterone Measurement. Measurement of the concentration of serum progesterone is the primary assay used for the evaluation of ovulation.[149,265] It is important to note that an increase in progesterone concentration indicates that a corpus luteum has been formed, but does not confirm that the egg was actually released. Beginning immediately after ovulation, serum progesterone concentrations rise (see Figure 56-10); they peak within 5 to 9 days during the mid-luteal phase (days 21 to 23).[265] If ovulation does not occur, the corpus luteum fails to form, and the expected cyclic rise in progesterone concentration is subnormal. If pregnancy occurs, hCG maintains the corpus luteum, and progesterone production continues to rise. Mid-luteal progesterone concentrations greater than 3 ng/mL indicate that ovulation has taken place, although concentrations of 10 ng/mL or more are more common in conception cycles. Concentrations less than 10 ng/mL indicate the possibility of inadequate luteal phase progesterone production, or inappropriate timing of sample collection.[323]

Basal Body Temperature. Basal body temperature charts have long been accepted as simple, cost-effective indicators of ovulation. Ovulation is associated with a rapid rise in body temperature (by 0.5 °F), which persists through the luteal phase. The rise in temperature is due to increased progesterone concentration. However, similar to progesterone, the rise in body temperature is evident only retrospectively and therefore does not predict imminent ovulation in a way helpful for timing intercourse.

Measurement of the Luteinizing Hormone Surge. Luteinizing hormone appears in the urine just after the serum LH surge and 24 to 36 hours before ovulation (see Figure 56-10). Measurement of LH does not confirm ovulation or provide insight into the cause of anovulation, but rather indicates when ovulation should occur and provides a guide with which to time intercourse. Methods for laboratory measurement of LH are given in Chapter 53.

Monoclonal technology has led to the use of *home LH kits* that not only provide accurate information as to the timing of ovulation, but may reduce stress and costs associated with infertility programs, because these tests are performed at home and are comparatively inexpensive.[171] Most home ovulation kits consist of a "dipstick" that uses a two-site, double monoclonal enzyme-linked immunoassay. Urine is applied to the test pad, and capillary action draws fluid across the pad. LH in the urine first is bound to an anti-LH antibody that is coupled to an enzyme conjugate, or colloidal gold. The LH-antibody complex then migrates to a region coated with a second anti-LH antibody. Once bound to this site, the substrate-enzyme reaction or colloidal gold complexes result in a color change that is proportional to the amount of LH present. A reference region is provided. A test result that matches or is darker in color than the reference region is considered a positive result, indicating that the LH surge is occurring. These tests effectively predict ovulation in 70% of women.[86] In one study of 26 normal women, home LH kits had a 92% positive predictive value for ovulation to occur within 48 hours of a positive urine LH screen.[204] The clinical utility of these devices is controversial, however,[225] and no studies have been performed to determine whether the use of home LH devices alters outcomes in women not being treated for infertility. A few studies have been published to look at outcomes in infertility patients, but the results are mixed when compared with serum LH testing or basal body temperature.[225]

Evaluation of Endocrine Parameters

Disorders of hypothalamus, pituitary, and ovary are endocrine causes of infertility.

Hypergonadotropic Hypogonadism

Premature ovarian failure is indicated by repeatedly elevated basal FSH concentrations (>30 IU/L) or a single elevation of greater than 40 IU/L in a woman younger than 40 years. These patients are hypoestrogenic (E_2 < 20 IU/L)[265] and do not respond to a progestin challenge because their endometrium is atrophic (see earlier section on evaluation of secondary amenorrhea). Basal serum FSH has been used as an indicator of relative ovarian reserve. Figure 56-14 shows the relationship between rising serum FSH and the reduced rate of successful pregnancy. A precipitous drop occurs at concentrations greater than 20 IU/L.

Assessing Ovarian Reserve

Women in their mid to late 30s and early 40s with infertility constitute the largest portion of the total infertility population. These women are also at increased risk for pregnancy loss. This reflects a diminished ovarian reserve as a result of follicular depletion and a decline in oocyte quality. As women age, serum FSH concentrations in the early follicular phase begin to increase. It has been suggested that this is due to a decline in the number of small follicles secreting inhibin B.

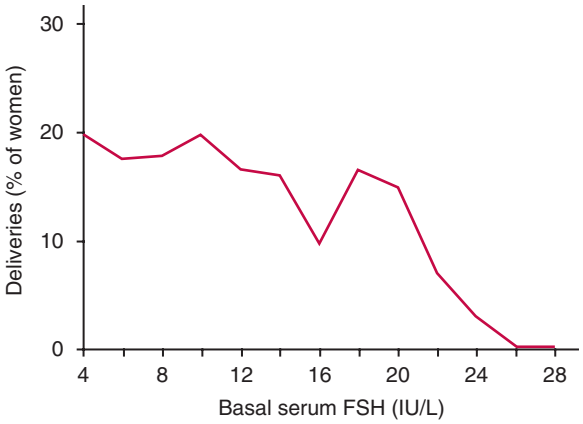

Figure 56-14 The relationship between increasing follicle-stimulating hormone (FSH) concentrations and decreased percentage of successful pregnancies. *(From Jones H, Toner JP. The infertile couple. N Engl J Med 1993;329:1710-5. Copyright © 1993 Massachusetts Medical Society. All rights reserved.)*

Basal serum FSH and E_2 measurements are a popular screening test for assessing ovarian reserve before fertility treatment is initiated. The rise in basal FSH is an excellent indicator of ovarian aging. In general, day 3 FSH concentrations greater than 20 to 25 IU/L are considered to be elevated and associated with poor reproductive outcome.[158] Concomitant measurement of serum E_2 concentration adds to the predictive power of an isolated FSH determination. Basal E_2 concentrations greater than 75 to 80 pg/mL are associated with poor response to ovarian stimulation and pregnancy outcome.[181]

Inhibin B is produced by developing follicles, and concentrations peak during the follicular phase. Concentrations of inhibin B can be used in conjunction with serum FSH and E_2 to assess ovarian function. Because inhibin is produced by gonadal tissue, it is thought to be a more direct marker of gonadal activity and ovarian reserve than pituitary hormones alone. In addition, cycle day 3 inhibin B concentrations may demonstrate a decrease before day 3 FSH concentrations.[268]

It has been reported that women undergoing in vitro fertilization (IVF) with day 3 inhibin B concentration less than 45 pg/mL had a pregnancy rate of 7% and a spontaneous abortion rate of 33% as compared with a pregnancy rate of 26% and an abortion rate of 3% in women with day 3 inhibin B concentrations greater than 45 pg/mL.[267] However, measurement of inhibin adds little to the more established use of serum FSH and E_2 and transvaginal ultrasound. Measurement of inhibins, therefore, remains of research interest only.

Anti-Müllerian hormone (AMH) [also known as Müllerian-inhibiting substance (MIS)] has been promoted as a marker of ovarian reserve and decline in reproductive

capacity,[30,92,300,301] as well as response to assisted reproductive technologies.[166,178] Although assays are commercially available, cutoffs have yet to be established.

Increasing evidence indicates that young women with spontaneous premature ovarian failure are at increased risk of developing autoimmune adrenal insufficiency.[20,31,65,217] It has been suggested that adrenal antibodies (21-hydroxylase antibodies or adrenal cortex autoantibodies) should be measured as a screening test for all women with spontaneous premature ovarian failure. Patients with antibodies present and patients with signs and symptoms of adrenal insufficiency should be tested using a standard ACTH stimulation test.

Luteal phase deficiency is diagnosed when the time between ovulation and menses is 10 days or less. The most specific diagnostic information may be gained from an endometrial biopsy obtained on day 26 of a 28 day cycle.[318] If peak progesterone concentrations are repetitively below 10 ng/mL, it is possible to diagnose luteal phase deficiency without an endometrial biopsy. Decreased progesterone production is presumed to be responsible, but this may follow (1) insufficient follicular phase FSH secretion, (2) abnormal LH surge, or (3) other endocrine abnormalities.[277] Some studies show that luteal phase deficiency is no more prevalent in infertile women than in normal women.[273,317] Other studies have shown an association with increased risk of infertility, ectopic pregnancy, and spontaneous abortion.[28,122] Luteal phase dysfunction may be secondary to excess androgen production, which suppresses follicle development. Prolactin excess may also contribute to the development of this disorder.[283]

Hypogonadotropic Hypogonadism

In hypogonadotropic hypogonadism, serum E_2 concentrations are less than 40 pg/mL (110 pmol/L); therefore, there is no withdrawal bleeding with a progestin challenge.[255] Decreased LH (<10 IU/L) and decreased FSH (<10 IU/L) are also present.[265] Hyperprolactinemia can cause hypergonadotropic hypogonadic infertility. The upper limit of normal plasma prolactin in an amenorrheic, hypoestrogenic, nonpregnant woman is 400 to 500 mIU/mL (20 to 25 ng/mL). If estrogen status is normal, maximum prolactin concentrations vary from 600 to 800 mIU/mL (30 to 40 ng/mL).[179] Thyroid-stimulating hormone should be measured to exclude hypothyroidism. Prolactin concentrations can be elevated in patients with PCOS and those taking medications such as antidepressants, cimetidine, and methyldopa, and in stressful conditions. Radiographic imaging of the pituitary is indicated to rule out pituitary adenoma or empty sella syndrome.

Ovulatory Factors

Ovulatory dysfunction is difficult to diagnose because it will manifest in the presence or absence of normal menses. Metabolic diseases of many types affect ovulatory function, including those that result in androgen excess. PCOS, which results in androgen excess, is the most common cause of anovulation and was discussed in detail earlier in the chapter. In women with hirsutism, CAH should be considered. 21-Hydroxylase deficiency or 3-β-hydroxysteroid deficiency may be present in up to 26% of cases.[228] Elevated serum follicular 17-hydroxyprogesterone concentrations require further evaluation for these conditions. In addition, it is possible for ovulatory dysfunction to be secondary to liver or thyroid disorders.

As with male infertility, hypogonadism (hypergonadotropic or hypogonadotropic) results in female infertility. Causes of hypergonadotropic hypogonadism include (1) primary ovarian insufficiency (POI), (2) gonadal dysgenesis, (3) resistant ovary syndrome, (4) menopause, and (5) luteal phase deficiency. Causes of hypogonadotropic hypogonadism include pituitary or hypothalamic insufficiency and hyperprolactinemia. Many of these pathologic states have been discussed in the earlier section, "Irregular Menses."

Ovulation with inadequate luteinization and reduced progesterone secretion during the luteal phase has been termed *luteal phase deficiency*. The contribution of luteal insufficiency to infertility is controversial. It is manifested by a short luteal phase, in which the interval between LH peak and onset of menses is 10 days or longer, or is a luteal phase of normal length with reduced progesterone secretion.[50] Decreased progesterone production is presumed to be responsible, but this may follow insufficient follicular phase FSH secretion, abnormal LH surge, or other endocrine abnormalities.[277] The most specific diagnostic information may be gained from an endometrial biopsy obtained on day 26 of a 28 day cycle.[318] Some studies show luteal phase deficiency to be no more prevalent in infertile women than in normal women.[273,317] Other studies have shown an association with increased risk of infertility, ectopic pregnancy, and spontaneous abortion.[28,122] Luteal phase dysfunction may also be secondary to excess androgen production, which suppresses follicle development. Prolactin excess may contribute to the development of this disorder.[283] An inadequate luteal phase and a deficit of progesterone lead to poor proliferation of the endometrium and, therefore, an unsuitable environment for the early embryo.[50,336] Luteal dysfunction is believed to cause infertility in 5% of infertile women. It is found periodically in 30% of women and is not considered to contribute to infertility unless diagnosed twice in separate cycles.[307]

Postcoital Test

The postcoital test has been used historically to evaluate infertility; however, it has been shown to have limited utility. The reader is directed to the previous edition of this chapter for further reading on this test.[131]

Immunologic Factors

Antisperm antibodies have been proposed to contribute to female infertility. However, this topic is controversial, and laboratory testing for antisperm antibodies is rarely performed. The reader is directed to the previous edition of this chapter for further details about methods.[131]

Assisted Reproduction

Couples with a multitude of infertility problems, including unidentified causes and persistent infertility despite standard treatments, may benefit from assisted reproductive techniques. If no definable cause is identified, standard initial therapy consists of ovulation induction and artificial insemination for at least 6 months before progression to more expensive and exotic techniques. If very low sperm counts or tubal pathology is present, it may be reasonable to proceed directly to in vitro fertilization.

The laboratory plays an important role in the process of ovulation induction. The principle involves administration of gonadotropins to stimulate follicular growth, followed by hCG to stimulate ovulation follicular maturation. Clinical, laboratory, and ultrasound monitoring of the treatment cycle is necessary to (1) identify the dose and length of therapy, (2) determine when or whether to administer hCG, and (3) obtain an adequate ovulatory response while avoiding hyperstimulation.[266]

Infertility treatments involve procedures that deliver a concentrated sperm sample directly to the uterus (artificial insemination) or assisted reproductive techniques. The latter are techniques that involve acquiring fertile ova using transvaginal ultrasound and assisting fertilization in the laboratory with conventional IVF or intracytoplasmic sperm injection (ICSI) in the fallopian tubes using gamete intrafallopian transfer (GIFT) or zygote intrafallopian transfer (ZIFT).[210] In vitro fertilization then requires embryo transfer back into the uterus. Very few GIFT or ZIFT procedures are performed today owing to the availability of improved embryo culture techniques. The latest successful techniques include direct ovum fertilization using direct micropipette ICSI of the sperm.[269] This procedures provides hope to even the azoospermic man for whom testicular aspiration may yield a few nonmotile sperm. ICSI is widely used today for non–male factor infertility cases as well, and is employed in about 50% to 60% of IVF cycles.

ANALYTICAL METHODS FOR REPRODUCTIVE HORMONES

A variety of methods are available for measuring sex steroids in body fluids. Currently, the most common method is nonisotopic immunoassay. However, use of mass spectrometry to measure sex steroids is increasing. Advantages and disadvantages will be discussed in this chapter. Methods used for reproductive protein hormones are discussed in Chapters 53 and 57. Methods used for reproductive steroid hormones are discussed here.

Methods for Determination of Total Testosterone in Blood

Circulating testosterone comprises three different forms or pools: (1) a non–protein-bound or "free" form, (2) a weakly bound form, and (3) a tightly bound form. The weakly bound form is associated with albumin, and the tightly bound form with sex hormone-binding globulin (SHBG), which is also known as testosterone/estradiol-binding globulin. The term *total testosterone* refers to serum measurements of free testosterone, albumin-bound testosterone, and SHBG-bound testosterone. Bioavailable testosterone includes circulating free testosterone and albumin-bound testosterone. Testosterone bound to SHBG is not biologically active, whereas the free form is available for target cells. Albumin-bound testosterone is also available to target tissues because testosterone can dissociate from the albumin carrier and rapidly diffuse into target cells.[192]

Methods

A 2008 College of American Pathologists (CAP) survey reports that nonisotopic enzyme immunoassays have replaced radioimmunoassay (RIA) as the most widely used technique for measuring the concentration of circulating testosterone (both protein-bound and non–protein-bound forms).[3]

For more about RIAs for testosterone, the reader is directed to the previous edition of this chapter.[131]

Direct (no extraction required) immunoassay methods have been developed for the determination of testosterone in serum or plasma.[143,157] The steroid must be displaced from its binding proteins (albumin and SHBG). In this method, results of the assay depend on the effectiveness of the displacement. Methods used to release testosterone from endogenous binding proteins include use of (1) salicylates, (2) surfactants, (3) pH alterations, (4) temperature changes, and (5) competing steroids such as estrone or estradiol. Most of the direct immunologic methods use antisera generated against a C_{19} testosterone-protein conjugate. These assays have demonstrated variable precision agreement with mass spectrophotometry and established RIA methods.[96,260,321] However, most routine immunoassays are not sensitive enough to measure very low testosterone concentrations such as those found in women, children, or hypogonadal men. The Endocrine Society recommends use of a highly sensitive method such as a liquid chromatography/mass spectrometry/mass spectrometry (LC/MS/MS) method whenever low testosterone concentrations are suspected.[254]

Gas chromatography combined with mass spectrometry (GC-MS) remains the reference method for testosterone measurement and is often used to assess the bias of routine immunoassay methods.[83,94,96] Several mass spectrometry–based methods have been described.[270,291] The use of mass spectrometry is discussed in greater detail in Chapter 14 and later in this section.

Regardless of immunoassay type, almost all testosterone antisera show some degree of cross-reactivity with DHT (typically 3 to 5%) but show negligible cross-reactivity with other androgens. Assays that use antisera generated against the C-19 position provide maximum analytical specificity with respect to endogenous steroids. However, cross-reactions with 19-nonsteroids used in contraceptive preparations sometimes cause a problem. In most clinical situations, estimation of testosterone without prior separation of DHT is permitted because plasma concentrations of DHT are only 10 to 20% of those for testosterone. Moreover, testosterone and DHT are the two most important androgens in the systemic circulation; even when a method measures the

concentrations of both, clinically useful information about the total androgen load is obtained. DHEA-S has been reported to cross-react in some testosterone assays.[202] If specific estimation of testosterone concentration is required, mass spectrometry is recommended.

Specimen Collection and Storage

Serum or heparinized plasma is used to measure total testosterone. Testosterone is subject to diurnal variation, reaching a peak concentration at between 0400 and 0800 hours. Therefore, morning specimens are preferred. Serum/plasma samples are stable for up to 24 hours at room temperature, up to 1 week refrigerated, and up to 1 year frozen at −20 °C.[80,121] DHEA supplementation should be avoided before testing.[320]

Reference Intervals

Reference intervals for total testosterone in serum are listed in Table 56-4.[9,293]

Comments

Estimation of SHBG in serum is useful for interpreting blood concentrations of total testosterone and for calculating androgen index and bioavailable testosterone. Immunoassays for measurement of SHBG in the routine laboratory have been developed.[148] SHBG concentrations change with age.[88]

Methods for the Determination of Free and Bioavailable Testosterone in Blood

In cases where SHBG concentrations are altered, as in women, aging men, and illness, measurements of free or bioavailable testosterone are thought to more accurately reflect androgen status. Excellent reviews of various methods used to measure this fraction of testosterone are available.[319]

Various methods are available for determining the concentrations of free or bioavailable forms of testosterone in serum or plasma. They include the following:

1. Estimation of the free testosterone fraction by equilibrium dialysis or ultrafiltration.
2. Estimation of free hormone using a direct (analog tracer) radioimmunoassay.
3. Estimation of combined free and weakly bound (bioavailable) testosterone fractions by selective precipitation of the tightly bound form.
4. Calculation of the androgen index using indices that reflect the ratios of testosterone pools.
5. Calculation of free and weakly bound testosterone concentrations by mathematical modeling.

Each approach will be discussed in turn in the following sections. Reference intervals for free testosterone and percent free testosterone in serum are listed in Table 56-5. Reference intervals for bioavailable testosterone in serum are listed in Table 56-6.

Equilibrium Dialysis/Ultrafiltration

Only a small fraction (1 to 2%) of unconjugated testosterone exists in the free state (non–protein-bound) in serum or plasma. None of the conventional assay methods, including

RIA, is sufficiently sensitive to quantify free steroid directly in a protein-free ultrafiltrate of plasma. Instead, free steroid is estimated in plasma by adding a known amount of radiolabeled compound to the sample and allowing labeled and unlabeled compounds to reach equilibrium in their competition for the same binding sites on proteins. Bound and free radiolabeled fractions are then separated, and the ratio of free labeled to total labeled compound is determined. At equilibrium, this ratio is taken as a measure of the free testosterone fraction. An estimate of serum free testosterone can be calculated by multiplying the free testosterone fraction by the total testosterone concentration. A detailed procedure for the equilibrium dialysis method is included in the third edition of this textbook.[117]

Most of the problems with this procedure have involved tracer impurities and separation of bound and free labeled fractions. Several separation techniques have been used, including (1) equilibrium dialysis, (2) membrane ultrafiltration, and (3) steady-state gel filtration. Deficiencies associated with these techniques include (1) a requirement for a large sample volume, (2) the need for complicated correction of sample volume changes that occur during the separation, and (3) difficulties involved in collecting and measuring radioactivity in numerous fractions of each sample. Equilibrium dialysis has been used most often in the past, but serious errors often arise from the sample dilution required by this method.[305] Symmetric dialysis of undiluted samples is reported to be less susceptible to tracer contamination and dilution effects.[284] Ultrafiltration appears to overcome these problems and to obviate errors due to dilution.[125]

Direct (Analog Tracer) Radioimmunoassay

Several RIA procedures are commercially available for the direct estimation of free testosterone.[157,209,256,319,326] These assays use a labeled derivative (analog) of testosterone that, in theory, retains the ability to react with exogenous antitestosterone antibodies but is restricted from interacting with testosterone-binding proteins in the serum sample.

Advantages of RIA analog methods include a small sample requirement, relatively rapid results, a simple procedure, and the option to measure free testosterone without the need to measure total testosterone.[157,209,306,326] Thus, RIA analog assays are the most commonly used method for determining free testosterone. Although there is reportedly good correlation between values obtained by RIA and equilibrium dialysis, some have reported that RIAs are grossly inaccurate, underestimating free testosterone concentrations by many-fold.[209,252,253,306] For example, one study in females revealed that free testosterone concentrations obtained by two different analog assays were 15 to 35% and 25 to 30% of those obtained by ultrafiltration.[120] Calculated free testosterone is considered more reliable than values obtained by the RIA method.

Selective Precipitation

Selective precipitation of SHBG with ammonium sulfate is also used to measure bioavailable testosterone. With this technique, aliquots of serum or plasma are first incubated with radiolabeled testosterone. Testosterone bound to SHBG is then precipitated with 50% ammonium sulfate. The samples are centrifuged, and aliquots of the supernatant containing free and albumin-bound testosterone (also known as *non–SHBG-bound testosterone*) are radioactively counted. The percentage of radio label not bound to SHBG is subsequently

multiplied by the total testosterone concentration to obtain the bioavailable testosterone.[319] The amount of bioavailable testosterone also is measured directly, by RIA, in the supernatants of plasma after ammonium sulfate precipitation and solvent extraction.[74] An indirect method using a commercially available enzyme immunoassay to measure bioavailable testosterone has been described.[69] Alternatively, it is possible to estimate the fraction of testosterone not bound to SHBG by a technique that involves saturating SHBG-binding sites with 5α-DHT, the natural steroid bound with highest affinity by SHBG. Then the non–protein-bound fraction is measured in treated and untreated samples by centrifugal ultrafiltration dialysis[233] or by semiautomated equilibrium dialysis.[25]

Androgen Index

This index is a ratio of testosterone and SHBG multiplied by 100.[319] Although this is only an indicator of free testosterone, some have found it to be useful in the evaluation of hirsutism.[214] Other reports have indicated that the free androgen index is not a reliable parameter of free testosterone because of its variability as a function of SHBG concentration.[152,209,306]

Mathematical Modeling

Methods based on mathematical modeling use algorithms to derive non–SHBG-bound testosterone. These algorithms assume that when concentrations of total testosterone, SHBG, and albumin and the constants for binding of testosterone to SHBG and albumin are known, free testosterone and bioavailable testosterone are calculated. These calculations are based on a proper estimation of the association constant for binding of testosterone to SHBG and albumin. However, various association constants for SHBG have been reported. The reader is directed to the previous edition of this book and other references for further details on this method.[131,274,319] Conditions resulting in abnormal plasma protein concentrations such as nephritic syndrome, cirrhosis, and pregnancy require adjustments in the assumption for albumin concentration.

Other algorithms based on concentrations measured with a gold standard technique have been proposed.[89,187,211]

Algorithms for calculating bioavailable testosterone are available free on the Internet (http://www.issam.ch/freetesto.htm); however, these sources do not always provide a reference for which an algorithm is being used.

In practice, it should be noted that no consensus has been reached about the use of these bioavailable testosterone algorithms. de Ronde and associates compared five algorithms and concluded that they are not transferable to samples from other laboratories unless revalidation using laboratory-specific assays has been performed.[71] Likewise, Giton and colleagues reported that instead of using theoretical association constants, optimal paired association constants should be determined for each studied population.[102] Because this is impossible for the average clinician to do, these authors suggest using ammonium sulfate precipitation. Finally, Dechaud and coworkers reported an age-associated discrepancy between calculated and measured bioavailable testosterone, suggesting that a simplified law of mass action cannot predict variations in steroid distribution in serum.[73] These authors state that consensus is needed regarding the proper measurement of bioavailable testosterone for therapeutic decisions.

Methods for the Determination of Testosterone Precursors and Metabolites in Blood

Several biosynthetic precursors and metabolites of testosterone are measured using (1) specific immunoassays (directly or after sample extraction), (2) chromatography, or (3) LC-MS/MS.[239,270,275,288] Examples include DHT, 3α-androstanediol glucuronide, and androstenedione.

Reference intervals for these analytes in serum are listed in Table 56-7.

Methods for the Determination of Dehydroepiandrosterone and Its Sulfate

Measurements of DHEA or its sulfated conjugate, DHEA-S, in serum and plasma are important for investigations of adrenal androgen production, such as assessment of (1) adrenal hyperplasia, (2) adrenal tumors, (3) adrenarche, (4) delayed puberty, or (5) hirsutism. DHEA-S in circulation originates primarily from the adrenal glands, although in men some may be derived from the testes; none is produced by the ovaries. DHEA is secreted almost entirely by the adrenal glands.

DHEA concentrations exhibit a circadian rhythm that reflects the secretion of ACTH; these concentrations vary during the menstrual cycle. DHEA-S concentrations, however, do not exhibit a circadian rhythm because of their longer circulating half-life.[224] Concentrations in serum are increased in cord blood and drop precipitously at birth. Concentrations in premature infants in general are much higher than those in full-term infants. Pregnancy and oral contraceptives induce a modest reduction, and glucocorticoids a marked decrease. Patients with polycystic ovary disease often have elevated concentrations of DHEA-S, suggesting an adrenal androgen contribution to the defect in this disorder.[221] Concentrations of DHEA-S are also elevated in CAH and with adrenal cortical tumors (concentrations higher with adrenal carcinoma than with adrenal adenoma).[224] However, concentrations are not elevated in women with virilizing ovarian tumors. Glucocorticoid administration for several days suppresses concentrations in patients with adrenal hyperplasia. DHEA is commercially available in health food stores; therefore, increased serum concentrations may be due to exogenous use.

Methods

Although both isotopic and nonisotopic methods are available, according to a 2008 CAP survey, the latter are most frequently utilized for measurement of DHEA-S.[11] Other methods include competitive protein-binding assays[40,42,248] and GC-MS.[330,339] Immunoassays for DHEA-S demonstrate significant cross-reactivity with DHEA, androstenedione, and androsterone, yet the relative concentrations of these steroids have a minimal effect on assay performance.

Specimen Collection and Storage

Serum or plasma [preserved with ethylenediaminetetraacetic acid (EDTA)] is suitable for DHEA or DHEA-S immunoassays.[4,7] Early morning collection, before 1030 hours, is preferred for DHEA.[4,8] DHEA-S specimens are stable for at least 1 day at room temperature. Refrigerated serum/plasma samples (4 to 8 °C) are stable for up to 14 days, and those frozen at −20 °C are stable for longer than 1 year.[80,121,338]

Reference Intervals

Reference intervals for serum concentrations of DHEA-S and DHEA are listed in Table 56-8.[7,293]

Comments

Analysis of DHEA by immunoassay usually requires pretreatment of serum samples because the serum concentration of DHEA is 1000-fold lower than that of DHEA-S. Several extraction and chromatographic procedures have been suggested for this purpose. Celite is the preferred adsorbent, and dichloromethane and ethyl acetate are common choices for extraction solvents. Commercial RIA kits using solid-phase separation techniques and ^{125}I-labeled DHEA are widely available for convenient measurement of serum concentrations. A typical kit method will detect as little as 3 ng/dL (0.1 nmol/L) of DHEA.[4] Cross-reactivity of antisera with related steroids is relatively low, with some exceptions (androstanediol, about 6%; androstenedione, about 2%; and testosterone, about 1%). Interextraction precision, expressed as a coefficient of variation, is less than ±12% at a DHEA concentration of 120 ng/dL (4.1 nmol/L).

Determination of 17-Ketosteroids in Urine

The 17-ketosteroids (KS) are metabolites of steroids that contain a keto group at C-17 and include (1) androsterone, (2) epiandrosterone, (3) etiocholanolone, (4) DHEA, (5) 11-keto- and 11β-hydroxyandrosterone, and (6) 11-keto- and 11β-hydroxyetiocholanolone. In men, approximately one third of total urinary 17-KS represents metabolites of testosterone secreted by the testes, whereas most of the remaining two thirds is derived from steroids produced by the adrenal glands. In women, who normally excrete smaller quantities than men, total 17-KS concentrations are derived almost exclusively from the adrenal glands. Thus, the main purpose of measuring these steroid metabolites is to assess adrenal androgen production.

Measurement of DHEA-S in serum serves as a more convenient marker for adrenal androgen production than does urinary 17-KS excretion because 24 hour urine collection is not required, and because many drugs interfere with the 17-KS assay.[184] For these reasons, many clinicians now prefer concentrations for plasma DHEA-S to those for urinary 17-KS. For a description of the method used to measure 17-KS in urine, please refer to the fourth edition of this textbook.[131]

Methods for the Detection of Anabolic Steroids

Detection of exogenous steroids used to improve athletic performance poses a challenge for the laboratory given the variety of exogenous anabolic steroids, which include both natural and synthetic testosterone analogs. Since the 1980s, GC-MS has been the method of choice to detect anabolic steroids.[38] The ratio of testosterone to epitestosterone (17 α-epimer) in urine has been used as a screening test for the detection of anabolic steroid abuse. A ratio of testosterone to epitestosterone greater than 6:1 suggests exogenous steroid use, and further testing should be performed for confirmation.[52] Others have suggested the ratio of testosterone to LH in the urine as an indication of testosterone doping. Detailed studies of these ratios are available.[155] For a more in-depth discussion of analytical considerations around drug monitoring in athletes, the reader is referred to the review by Bowers.[38]

Methods for the Determination of Estradiol in Blood

Both chromatography-mass spectrometry and immunoassay-based methods are used to measure estrogens in blood. GC-MS methods utilizing isotope dilution provide the most accurate and reliable measurement of E_2.[75,269,292,329] The main steps in these reference methods include solvent extraction, chromatographic fractionation, and chemical derivatization before analysis. Validation of immunoassay methods by this technique has become important in many external quality assurance programs.

Immunoassays consist of both indirect (extraction required) and direct (no extraction required) methods. The most common antigen used to prepare antibodies for E_2 assays is estradiol-6-(*O*-carboxymethyl)oxime conjugated to bovine serum albumin.[237] Cross-reactivity with other C-18 steroids is usually very minor because the 3- and 17-hydroxyl

tahir99-VRG & vip.persianss.ir

groups are left free. A 2008 CAP survey reported that direct enzyme immunoassays have largely replaced RIAs for routine measurement of E_2 concentrations.[11] For more information about RIA assays, the reader is directed to the previous edition of this chapter.[131] Evaluation of estrogen concentrations in men, postmenopausal women, and children requires the use of more sensitive RIA- or mass spectrometry–based methods.

To measure E_2 directly without extraction and chromatography, the steroid must be displaced from its binding proteins. The displacing agents used in commercial methods often are not disclosed, but in some systems, effective displacement is achieved by adding 8-anilino-1-naphthalene sulfonic acid (ANS) or a large excess of a competing steroid such as dihydrotestosterone to the sample.[237]

Caution should be exercised when assaying samples from subjects who are receiving oral contraceptives or estrogen replacement therapy because cross-reacting steroids may cause elevated results. Most notably, cross-reactivity with estrone is as high as 10% for some assays, but much lower (<1%) for others. This is likely due to a difference in the specificity of the antibody used for E_2. Similar effects have been observed for metabolites conjugated at the 3 position, such as estrone-3-sulfate and estrone-3-glucuronide.[136,180]

Several immunoassays for E_2 have been developed and adapted for use on fully automated immunoassay systems.[331] All are heterogeneous assays (separation step needed), but most are direct assays and do not require preliminary extraction. Most procedures offer the convenience of solid-phase separation methods. For routine clinical applications, the greatest experience is with enzyme immunoassays. Most commercial enzyme immunoassays use horseradish peroxidase or alkaline phosphatase to label E_2 antigens; enzyme activity is determined using a variety of photometric,[37,115,180] fluorescent,[19,21,240,242] or chemiluminescent substrates.[66] A semiautomated "ultrasensitive" chemiluminescent immunoassay for E_2 has been described.[90] This method is advantageous because it is reportedly capable of accurately measuring low concentrations (<50 pmol/L) of E_2 observed in perimenopausal and postmenopausal women, healthy men, and children.

Taieb and coworkers compared detection limits and functional sensitivities of nine automated E_2 immunoassays.[285] They concluded that functional sensitivities, defined as the lowest concentration of analyte that can be measured with a run-to-run imprecision of 20%, were twofold to fourfold higher than detection limits of the tests. It is also important to note that none of the assays analyzed in this study had the functional sensitivity required for evaluation of serum E_2 measurements in men, menopausal women, and children.[81] Functional sensitivities ranged from 20 to 169 pmol/L (5.5 to 46 pg/mL). These assays have been optimized for clinical applications such as monitoring of ovarian stimulation for IVF, in which high E_2 concentrations are expected, but the values obtained depend on the method used.[286] The authors suggest that until E_2 assays are better standardized, reference intervals and cutoff points used as clinical decision criteria must be evaluated and modified, if necessary, for each assay.

Specimen Collection and Storage

Serum have plasma (with EDTA or heparin as anticoagulant) have been used. Specimens should be centrifuged and separated within 24 hours. Serum/plasma specimens may be stored at room temperature for 1 day, refrigerated for 3 days, or frozen for up to 1 year.[80,121,338] Oral contraceptives have been known to alter E_2 concentrations.

Reference Intervals

Reference intervals for serum concentrations of E_2 are listed in Table 56-9.

Methods for the Determination of Estriol in Blood

Except for purposes of fetal aneuploidy screening, measurement of E_3 has little clinical value because in nonpregnant women, E_3 is derived almost exclusively from E_2. Both RIA and nonisotopic immunoassay methods for E_3 measurement in serum and plasma are commercially available. A 2008 CAP survey reports that automated enzymatic immunoassay methods account for all unconjugated E_3 measurements.[11] Several of these assays have been validated for use in maternal serum screening.[162,190]

Specimen Collection and Storage

E_3 serum or plasma specimens are stable at room temperature for 24 hours; they can be refrigerated for 2 days and frozen at −20 °C for up to 1 year.[121]

Methods for the Determination of Estrone in Blood

Estrone determinations have limited clinical utility. Normally, blood estrone concentrations parallel E_2 concentrations throughout the menstrual cycle, but at slightly lower concentrations. For a specific analysis of estrone, the interested reader is directed to other references.[58,82]

Methods for the Determination of Progesterone in Blood

A 2008 CAP survey reports that enzyme immunoassays account for most of the progesterone assays used today.[11] Initial immunoassays for serum progesterone measurement used organic solvents to remove the steroid from endogenous binding proteins such as corticosteroid-binding globulin and albumin. Direct (nonextraction) measurement of progesterone in serum or plasma is considered the method of choice for routine applications. Various antigens have been used to prepare antisera for progesterone assays. Cross-reactivity is most prominent with 5α-pregnanediol ranging from 6% to 11%. Both RIAs and nonisotopic immunoassays are available for measuring progesterone. For details on RIAs, the reader is directed to the previous edition of this chapter.[131]

Several immunoassays are available on fully automated immunoassay systems.[87,243,289,324] All are heterogeneous assays that require separation of free and antibody-bound fractions. Enzymes appear to be the most widely used nonradioactive label. Alkaline phosphatase and horseradish peroxidase

12-14 y, males	≤24	≤88
females	≤142	≤521
15-17 y, males	≤31	≤114
females	≤283	≤1040

From Fisher DA, ed. The Quest Diagnostics manual: endocrinology, test selection and interpretation, 4th edition. Capistrano, Calif: Quest Diagnostics/Nichols Institute, 2007.

coupled to progesterone or antiprogesterone antibodies are particularly popular. An assortment of photometric,[139,180,299] fluorescent,[98,243,324] and luminescent[36,188] substrates are available for monitoring the enzyme activity of the antibody-bound fraction. Direct time-resolved fluoroimmunoassays for progesterone have been described.[72,150]

Although automated immunoassays are less labor intensive than RIAs and yield results in less time without the need for radioactivity, these assays do not have adequate functional sensitivity for the measurement of low progesterone concentrations in men, postmenopausal women, and children. Taieb and coworkers analyzed the detection limits and functional sensitivities of eight automated progesterone methods.[285] They reported that functional sensitivities (0.32 to 1.43 nmol/L), defined as the lowest concentration of analyte that could be measured with a run-to-run imprecision of 20%, ranged from twofold to fourfold higher than the manufacturer-stated detection limit (0.19 to 0.48 nmol/L). Automated progesterone assays have been optimized for use in in vitro fertilization protocols as a rapid, cost-effective way to evaluate ovarian stimulation and monitor ovulation.

Double-isotope derivative methods[328] and competitive protein-binding assays[78] have been applied to the measurement of serum progesterone, but these methods require extensive purification of the steroid and are labor intensive. GC procedures using flame ionization, electron capture, or nitrogen detection have been used to improve the accuracy of progesterone analysis.[42,78] However, these methods are time-consuming and often require solvent extraction, chromatography, and derivatization before the steroid is quantitated. GC-MS has been recommended as a reference method for progesterone determination. The GC-MS method of Thienpont and associates[290] makes use of heptafluorobutyric ester derivatives and 19-$^2H_3$-progesterone as internal standards. Mass spectrophotometry is discussed further later in this chapter.

Plasma concentrations of 17α-hydroxyprogesterone are measured to evaluate 21-hydroxylase deficiency. For specific methods regarding this analyte, the reader is referred to a review by Wallace.[310]

Specimen Collection and Storage

Serum or plasma (with heparin or EDTA as anticoagulant) is used and should be separated within 24 hours.[7] The patient need not be fasting, and no special handling procedures are necessary.[1,5] Serum/plasma specimens may be stored at room temperature for 24 hours and refrigerated at 4 to 8 °C for up to 3 days or at 20 °C for up to 1 year.[80,121,338]

Reference Intervals

Reference intervals for serum concentrations of progesterone are listed in Table 56-10.[293]

Measurement of Sex Steroids by Mass Spectrometry

Although immunoassays are the predominant method for the detection and measurement of sex steroids (E_2, testosterone, progesterone, etc.), they are associated with considerable analytical problems. For example, automated immunoassays (nonisotopic) have accuracy and imprecision problems, particularly at the low end of detectability. Studies by Wang and associates comparing testosterone measurement by the four most commonly used automated direct immunoassay platforms against an LC-MS/MS reference method indicate acceptable correlation only in the adult male range.[311] Immunoassay methods failed to accurately and precisely detect concentrations of testosterone below 100 ng/dL (3.47 nmol/L).[311] Because concentrations of testosterone in women, children, and hypogonadal men typically fall below 100 ng/dL (3.47 nmol/L), measurement by immunoassay is not recommended. In addition, there is a clinical demand for the measurement of low concentrations of E_2 (<25 pg/mL or <90 pmol/L), for example, in the setting of breast cancer risk assessment among postmenopausal women or following response to aromatase inhibitor treatment.[77] Again, these demands are met by current automated immunoassays and call for a more sensitive approach.

Mass spectrometry–based methods have been described for several of the sex steroids, including testosterone, DHT, E_2, and progesterone.[165,270,290,291,315] In addition, methods are available to measure precursors and metabolites, including DHEA, DHEA-S, androstenedione, and androstenedione glucoronide.[239,275,288] Tandem mass spectrometry coupled with liquid chromatography (HPLC) offers several advantages over traditional immunoassays, including lower limits of detection, enhanced specificity, small sample size, and the possibility of analyzing multiple steroids within the same sample. This ability to simultaneously measure a variety of

tahir99-VRG & vip.persianss.ir

analytes provides the opportunity for steroid profiling, which may enhance diagnostic capabilities. For a more thorough discussion of tandem mass spectrometry and steroid analysis, the reader is directed to a review by Soldin and Soldin.[276] However, this technology has some disadvantages, including lack of standardization, high costs of equipment and maintenance, and the requirement for highly trained personnel. Despite these disadvantages, professional societies are beginning to recognize the utility of mass spectrometry. For example, the Endocrine Society suggested using extraction and chromatography followed by MS or MS/MS as a potential gold standard for measurement of testosterone.[254]

Measurement of Salivary Sex Steroids

Measurement of salivary concentrations of steroids has the potential to serve as a noninvasive and convenient procedure for the assessment of "serum free" steroid concentrations. However, primarily because of rapid fluctuations in salivary concentration necessitating the collection of multiple samples, salivary testing for sex steroids is not commonplace. For example, Chatterton and colleagues showed that salivary E_2 concentrations in individual women reflected a pulsatile pattern over a 60 to 90 minute window, thereby requiring serial sampling for accurate measurement of E_2.[54] Fluctuations have also been observed for progesterone, with studies indicating that salivary progesterone shows much greater 24 hour variation than is seen with serum concentrations.[76] Similarly, salivary testosterone has been noted to fluctuate. Consequently, single salivary samples are not considered informative. For a more complete discussion of salivary steroid measurements, the reader is referred to a review by Wood.[327]

CHAPTER 57

Pregnancy and Its Disorders

*Edward R. Ashwood, M.D., David G. Grenache, Ph.D., M.T.(A.S.C.P.), D.A.B.C.C., F.A.C.B., and Geralyn Lambert-Messerlian, Ph.D.**

The clinical laboratory has an important role in managing pregnancy.[25] In contrast to most clinical situations, when treating an expectant mother, a physician must simultaneously care for more than one patient. The health of the mother and that of her fetus are intertwined, each affecting the other; thus pregnancy management must consider both. This chapter reviews the biology of pregnancy and discusses laboratory tests used to detect, evaluate, and monitor both normal and abnormal pregnancies. Included are common tests, such as (1) chorionic gonadotropin (CG); (2) hematocrit; (3) blood type; (4) glucose tolerance testing; (5) prenatal testing and screening and diagnosis of fetal aneuplodies; and (6) esoteric tests, such as fetal lung maturity tests and amniotic fluid bilirubin examination.

HUMAN PREGNANCY

To appreciate the role of laboratory tests in pregnancy health care, it is necessary to understand fundamental topics such as (1) conception, embryo development, and fetal growth; (2) the role of the placenta; (3) the importance and composition of amniotic fluid; (4) maternal adaptation to pregnancy; and (5) functional maturation of the fetus.

Conception, Embryo, and Fetus

Normal human pregnancy (i.e., gestation) lasts approximately 40 weeks, as measured from the first day of the last normal menstrual period, a date commonly represented by the abbreviations LMP or LNMP. The anticipated date of birth of an infant is commonly referred to as the *expected date of confinement*, or EDC. During pregnancy, a woman undergoes dramatic physiologic and hormonal changes. When talking with patients, physicians customarily divide pregnancy into four time intervals. The first three time intervals are called *trimesters,* each of which is ≈13 weeks. The last time interval, 37 to 42 weeks, is coined *term*. By convention, the first trimester, 0 to 13 weeks, begins on the first day of the last menses.

Ovulation occurs on approximately the 14th day of the regular menstrual cycle (see Chapter 56). If conception occurs, the ovum is fertilized, usually in the fallopian tube, and becomes a *zygote,* which is then carried down the tube into the uterus. The zygote divides, becoming a *morula.* After 50 to 60 cells are present, the morula develops a cavity, the primitive *yolk sac,* and thus becomes a *blastocyst,* which implants into the uterine wall about 5 days after fertilization. The cells on the exterior wall of the blastocyst, *trophoblasts,* synergistically invade the uterine endometrium and develop into chorionic villi, creating the placenta. Trophoblasts are subdivided into syncytiotrophoblasts and cytotrophoblasts, depending on location and cellular morphology.

At this stage, the product of conception is referred to as an *embryo.* A cavity called the *amnion* forms and enlarges with the accumulation of *liquor amnii,* commonly referred to as *amniotic fluid.* Nourished by the placenta and protected by the amniotic fluid, an embryo undergoes rapid cell division, differentiation, and growth. From combinations of three primary cell types, *ectoderm, mesoderm,* and *endoderm,* organs begin to form through a process called *organogenesis.* At 10 weeks, an embryo has developed most major structures and is now referred to as a *fetus.* At 13 weeks, the fetus weighs approximately 13 g and is ≈8 cm long.

Rapid fetal growth occurs during the 13 to 26 weeks of the second trimester. By the end of the second trimester, the fetus weighs approximately 700 g and is 30 cm long. Many fetal organs begin to mature. The 26 to 38 weeks of the third trimester is the period in which fetal organs complete their prenatal maturation. During this trimester, the growth rate decelerates. At the end of the third trimester, the fetus weighs approximately 3200 g and is about 50 cm long. *Term* is the interval from 37 to 42 weeks. Normal labor, rhythmic uterine contractions, and birth occur during this period.

Placenta

The placenta and the umbilical cord form the primary link between fetus and mother. The placenta grows throughout pregnancy and is normally delivered through the birth canal immediately after the birth of the infant.

Function

The placenta (1) keeps the maternal and fetal circulation systems separate, (2) nourishes the fetus, (3) eliminates fetal wastes, and (4) produces hormones vital to pregnancy. It is composed of large collections of fetal vessels called *villi,* which are surrounded by intervillous spaces in which maternal blood flows. For substances to move from the maternal circulation to the fetal circulation, they must cross through the trophoblasts and several membranes. The transfer of any substance depends largely on the (1) concentration gradient between the maternal and fetal circulatory systems, (2) presence or absence of circulating binding proteins, (3) lipid solubility of the substance, and (4) presence of facilitated transport, such as ion pumps or receptor-mediated endocytosis (Box 57-1). The placenta is an effective barrier to the movement of large proteins and hydrophobic compounds bound to plasma proteins. Maternal immunoglobulin (Ig)G crosses the placenta via receptor-mediated endocytosis. Because of its long half-life, maternally produced IgG protects a newborn for the first 6 months of life. Antibody assays with low limits of detection may be positive in infants up to age 18 months because of maternal antibodies.

BOX 57-1 Normal Placental Transport

No Transport
- Most proteins
- Thyroid hormones
- Maternal IgM, IgA
- Maternal and fetal erythrocytes

Limited Passive Transport
- Unconjugated steroids
- Steroid sulfates
- Free fatty acids

Passive Transport
- Molecules up to 5000 Da having lipid solubility
- Oxygen
- Carbon dioxide
- Sodium and chloride
- Urea
- Ethanol

Active Transport Across Cell Membranes
- Glucose
- Many amino acids
- Calcium

Receptor-Mediated Endocytosis
- Maternal IgG
- Insulin
- Low-density lipoprotein

Ig, Immunoglobulin.

Placental Hormones

The placenta produces several protein and steroid hormones (Figure 57-1). The major protein hormones are CG and placental lactogen (PL). The steroids include progesterone, estradiol, estriol, and estrone. The placenta secretes most of its products into the maternal circulation; only small amounts reach the fetal circulation. Close proximity of the maternal blood vessels to the site of placental hormone production may explain some of this preferential accumulation of hormones in the maternal blood circulation. Generally, hormone production by the placenta increases in proportion to the increase in placental mass. Therefore concentrations of hormones derived from the placenta, such as PL, increase in maternal peripheral blood as the placenta increases in size. CG, which peaks at the end of the first trimester, is an exception.

Chorionic Gonadotropin

One of the most important placental hormones is CG. It stimulates the ovary to produce progesterone, which, in turn, prevents menstruation, thereby protecting the pregnancy. The chemistry, biochemistry, and methods for CG are discussed later in this chapter.

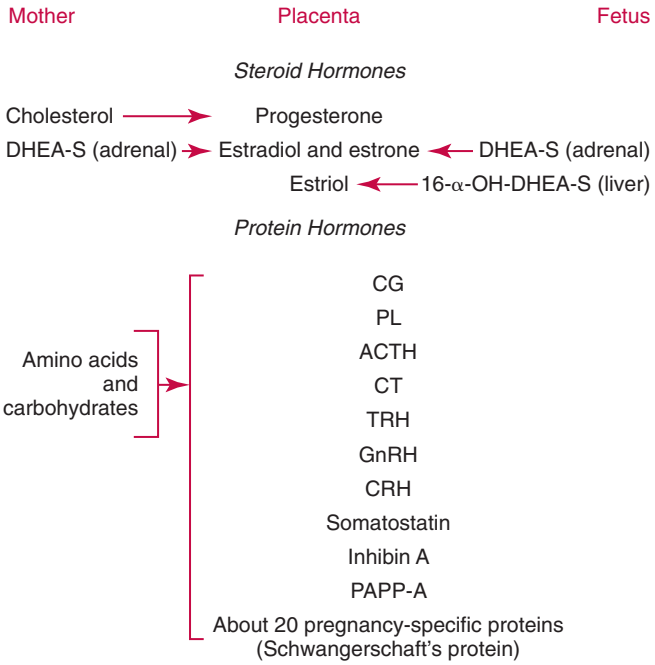

Figure 57-1 Schematic representation of steroid and protein hormone production by the placenta. *ACTH,* Adrenocorticotropic hormone; *CG,* chorionic gonadotropin; *CRH,* corticotropin-releasing hormone; *CT,* chorionic thyrotropin; *DHEA-S,* dehydroepiandrosterone sulfate; *GnRH,* gonadotropin-releasing hormone; *PAPP-A,* pregnancy-associated plasma protein-A; *PL,* placental lactogen; *TRH,* thyroid-stimulating hormone.

Placental Lactogen

PL, also known as human placental lactogen (hPL) and human chorionic somatomammotropin (hCS), is a single polypeptide chain of 191 amino acids having two intramolecular disulfide bridges and a molecular mass of 22,279 Da. The structure of PL is exceptionally homologous (96%) with growth hormone (GH) and less so with prolactin (67%). Also, PL has potent growth and lactogenic properties. Five genes on chromosome 17 compose a gene family that codes for both GH and PL.[279] PL production has been localized by immunofluorescence studies to the syncytiotrophoblast cells of the placenta. The increase in maternal serum PL concentration with advancing gestational age is directly correlated with the increasing mass of placental tissue and of functional syncytiotrophoblast tissue.[333] Placental secretion near term is 1 to 2 g/d, the largest of any known human hormone.

PL has many biological activities, including (1) lactogenic, (2) metabolic, (3) somatotropic, (4) luteotropic, (5) erythropoietic, and (6) aldosterone-stimulating effects. In addition, either directly or in synergism with prolactin, PL has a significant role in preparing the mammary glands for lactation. The many metabolic activities of PL closely resemble those of GH, including (1) inhibition of glucose uptake, (2) enhanced lipolysis leading to increased mobilization of free fatty acids, and (3) enhancement of nitrogen retention. Because glucose is the primary energy substrate for a fetus, it has been suggested that the glucose-sparing action of PL may provide a strategy to direct maternal metabolism toward greater use of fat for the mother's requirements, thereby sparing maternal glucose for fetal use. Rare normal pregnancies have been reported in which complete absence of PL was noted. Although PL was used in the past to evaluate fetal well-being, currently no apparent clinical reason exists to measure PL.[101]

Placental Steroids

The placenta produces a wide variety of steroid hormones, including estrogen and progesterone with large amounts of estrogens produced at term. The chemistry of these steroids is described in Chapter 56. Maternal cholesterol is the main precursor for placental progesterone production. Biosynthesis of estrogens by the placenta differs from that of the ovaries because the placenta has no 17α-hydroxylase. Thus, each of the estrogens—estrone (E_1), estradiol (E_2), and estriol (E_3)—must be synthesized from C-19 intermediates that already have a hydroxyl group at position 17. In nonpregnant women, the ovaries secrete 100 to 600 μg/d of estradiol, of which about 10% is metabolized to estriol. During late pregnancy, the placenta produces 50 to 150 mg/d of estriol and 15 to 20 mg/d of estradiol and estrone. Secretion of estrogens and progesterone throughout pregnancy ensures (1) appropriate development of the endometrium, (2) uterine growth, (3) adequate uterine blood supply, and (4) preparation of the uterus for labor. Although measurement of estriol in the third trimester was used in the past to assess fetal well-being, most obstetricians now consider this practice obsolete.[100] Estriol measurements in the second trimester of pregnancy are useful in predicting fetal trisomy 21 and 18 (see later discussion on maternal serum screening for fetal defects).

Amniotic Fluid

Throughout intrauterine life, the fetus lives within a fluid-filled compartment. The amniotic fluid provides a medium in which a fetus readily moves; it cushions a fetus against possible injury and helps maintain a constant temperature. This fluid is a dynamic medium whose volume and chemical composition are controlled within relatively narrow limits.

Volume and Dynamics

The volume of amniotic fluid increases progressively until 34 weeks' gestation, when it decreases slightly through the 40th week and then more sharply declines until the 42nd week.[312] The volume is 200 to 300 mL at 16 weeks, 400 to 1400 mL at 26 weeks, 300 to 2000 mL at 34 weeks, and 300 to 1400 mL at 40 weeks. The volume at any given moment is a function of several interrelated fluid fluxes. Direct measurements in primates and indirect measurements in humans have been used to derive a mathematical model of amniotic fluid volume.[239] At term, total fluid fluxes into and out of the amniotic cavity are large (≈60 mL/h) and result in complete exchange of the amniotic fluid volume twice per day. Gross unidirectional fluid volume shifts occur episodically: into the amniotic cavity by fetal urination and out of the cavity by fetal swallowing. These unidirectional shifts begin at the end of the first trimester and increase linearly until approximately 30 weeks. Fetal swallowing and urination then exponentially increase, peaking at term at about 1000 mL/d. Bidirectional water exchanges—so-called intramembranous fluxes—occur across the following surfaces: (1) placenta (mother-fetus); (2) umbilical vessels, through the substance of the umbilical cord (fetus–amniotic fluid); (3) fetal skin (fetus–amniotic fluid); and (4) fetal membranes (amniotic fluid–mother). These exchanges increase in a linear fashion throughout pregnancy. At term, they are approximately 400 mL/d. The fetal tracheobronchial tree is filled with amniotic fluid. Although lung fluid transport contributes a small volume, fetal breathing of this fluid is the mechanism of surfactant transport from the fetal lungs into the amniotic fluid.

Pathologic decreases and increases in amniotic fluid volume are encountered frequently in clinical practice. Intrauterine growth retardation and anomalies of the fetal urinary tract, such as bilateral renal agenesis or obstruction of the urethra, are associated with *oligohydramnios,* an abnormally low amniotic fluid volume. Increased fluid volume is known as *hydramnios* (also termed *polyhydramnios*). Conditions associated with hydramnios include (1) maternal diabetes mellitus, (2) severe Rh isoimmune disease, (3) fetal esophageal atresia, (4) multifetal pregnancy, (5) anencephaly, and (6) spina bifida.

Composition

Early in gestation, the composition of the amniotic fluid resembles a complex dialysate of the maternal serum. As a fetus grows, the amniotic fluid changes in several ways

TABLE 57-1 Composition of Amniotic Fluid (Mean Values)

Component	Gestational Age, Wk		
	15	25	40
Sodium, mmol/L	136	138	126
Potassium, mmol/L	3.9	4.0	4.3
Chloride, mmol/L	111	109	103
Bicarbonate, mmol/L	16	18	16
Urea nitrogen, mg/dL (mmol urea/L)	11 (3.9)	11 (3.9)	18 (6.4)
Creatinine, mg/dL (μmol/L)	0.8 (71)	0.9 (80)	2.2 (194)
Glucose, mg/dL (mmol/L)	47 (2.6)	39 (2.2)	32 (1.8)
Uric acid, mg/dL (mmol/L)	4.0 (0.24)	5.7 (0.34)	10.4 (0.61)
Total protein, g/dL (g/L)	0.5 (5)	0.8 (8)	0.3 (3)
Bilirubin, mg/dL (μmol/L)	0.13 (2.2)	0.14 (2.4)	0.04 (0.7)
Osmolality, mOsm/kg H_2O	272	272	255

(Table 57-1). Most notably, sodium concentration and osmolality decrease and concentrations of urea, creatinine, and uric acid increase.[39] The activities of many enzymes in amniotic fluid have been studied with respect to both gestational age and fetal status but have not been found to be clinically useful. The major lipids of interest are the phospholipids, whose type and concentrations reflect fetal lung maturity (discussed further later). Numerous steroid and protein hormones are also present in amniotic fluid.[418] Concentrations of androgens and estrogens have been measured in futile attempts to predict fetal sex. The rare syndrome of congenital adrenal hyperplasia (CAH) has been diagnosed antenatally by measuring 17-hydroxyprogesterone and pregnanetriol in the amniotic fluid near term.[190] Measurements of thyroid-stimulating hormone (TSH) and thyroxine in amniotic fluid may be useful in cases of fetal thyroid disease.[348] No other diagnostic uses for amniotic fluid hormone measurements are in common use. Prostaglandins E_1, E_2, $F_{1\alpha}$, and $F_{2\alpha}$ all are found in low concentrations in amniotic fluid and increase gradually during pregnancy. PGE_2 and $PGF_{2\alpha}$ concentrations are very high during active labor.[109] Attempts to demonstrate an acute rise in PGE_2 or $PGF_{2\alpha}$ immediately before the onset of labor, at the initiation of parturition, have been unsuccessful.

Early in pregnancy, little or no particulate matter is found in the amniotic fluid. By 16 weeks of gestation, large numbers of cells are present, having been shed from the surfaces of the amnion, skin, and tracheobronchial tree. These cells have proved to be of great utility in antenatal diagnosis. As pregnancy continues to progress, scalp hair and *lanugo* (fine hair on the body of the fetus) are shed into the fluid and contribute to its turbidity. Production of surfactant particles in the lung, termed *lamellar bodies,* greatly increases the haziness of the fluid. At term, amniotic fluid contains gross particles of *vernix caseosa,* the oily substance composed of sebum and desquamated epithelial cells covering the fetal skin.

Normal fetuses do not defecate during pregnancy. If severely stressed, a fetus may pass stool that is called *meconium.* This heterogeneous material contains many bile pigments and therefore stains the amniotic fluid green. Meconium-stained amniotic fluid is a sign of fetal stress.

Maternal Adaptation

During pregnancy, a woman undergoes dramatic physiologic and hormonal changes. The large quantities of estrogen, progesterone, PL, and corticosteroids produced during pregnancy affect various metabolic, physiologic, and endocrinologic systems. In addition, the woman experiences (1) an increase in resistance to angiotensin; (2) a predominance of lipid metabolism over glucose use; and (3) increased synthesis by the liver of thyroid- and steroid-binding proteins, fibrinogen, and other proteins characteristic of pregnancy. As a result of such changes, many of the laboratory reference intervals for nonpregnant patients are not appropriate for pregnant patients. Lockitch[229] has developed reference intervals for more than 70 analytes in normal pregnancy. Her study group included 29 pregnant subjects tested from 16 weeks to term and also postpartum. Mean values for selected tests expressed as a percentage of control means are presented in Table 57-2.

Hematologic Changes

Maternal blood volume increases during pregnancy by an average of 45%. Plasma volume increases more rapidly than red blood cell mass; therefore, despite augmented erythropoiesis, hemoglobin concentration, erythrocyte count, and hematocrit decrease during normal pregnancy. Hemoglobin concentrations at term average 12.6 g/dL, compared with 13.3 g/dL for the nonpregnant state. The leukocyte count varies considerably during pregnancy, from 4000 to 13,000/μL. During labor and puerperium (the interval immediately after delivery), leukocyte counts may be markedly elevated.

The concentrations of several blood coagulation factors are increased during pregnancy. For example, plasma fibrinogen increases by approximately 65%, from 275 to 450 mg/dL; this increase contributes to the increase in sedimentation rate. Other clotting factors also increase, including factors VII, VIII, IX, and X. Prothrombin and factors V and XII do not change, whereas factors XI and XIII decrease slightly. Even though the platelet count remains unchanged in most

women and prothrombin time and activated partial thromboplastin time shorten slightly (see Table 57-2), pregnancy increases the risk of thromboembolism to up to five times that of nonpregnant women.

Biochemical Changes

During pregnancy, electrolytes show little change, but an approximately 40% increase in serum triglycerides, cholesterol, phospholipids, and free fatty acids is seen. Plasma albumin is decreased to an average of 3.4 g/dL in late pregnancy; plasma globulin concentrations increase slightly. Several of the plasma transport proteins, including thyroxine-binding globulin (TBG), cortisol-binding globulin (CBG), and sex hormone-binding globulin (SHBG), increase markedly. Serum cholinesterase activity is reduced, whereas alkaline phosphatase activity in serum is tripled, mainly as the result of an increase in very heat-stable alkaline phosphatase of placental origin. In addition, creatine kinase can markedly increase upon delivery.

Renal Function

Pregnancy increases the glomerular filtration rate (GFR) to about 170 mL/min/1.73 m^2 by 20 weeks, and therefore increases the clearance of urea, creatinine, and uric acid. Concentrations of these three analytes are slightly decreased in serum for much of the pregnancy. As term approaches, GFR begins to return to nonpregnant values. Urea and creatinine concentrations rise slightly during the last 4 weeks. During this time, tubular reabsorption of uric acid increases dramatically, which increases serum uric acid compared with the nonpregnant state. Glucosuria, up to 1000 mg/d, may be present owing to increased GFR, which presents more fluid to the tubules and therefore lowers the renal glucose threshold. Protein loss in the urine can increase to up to 300 mg/d.

Endocrine Changes

The action of progesterone prevents menses and thus allows pregnancy to continue. In early pregnancy, progesterone is produced by the corpus luteum of the maternal ovary in response to CG. In later stages, the placenta directly produces enough progesterone to maintain the pregnancy.

Throughout pregnancy, the plasma parathyroid hormone (PTH) is increased by approximately 40%, with almost no change in the plasma free ionized calcium fraction, thus suggesting a new set point for the secretion of PTH. Calcitonin does not increase predictably during pregnancy, whereas 1,25-dihydroxyvitamin D is increased during pregnancy and promotes increased intestinal calcium absorption. These changes permit the transfer of large amounts of calcium to the developing fetus.

Elevated estrogen concentration stimulates increased hepatic production of CBG. The hepatic clearance of cortisol decreases. Thus, the absolute plasma concentrations of both total and free cortisol are several times higher during pregnancy. The diurnal rhythm of cortisol, higher in the morning and lower in the evening, is maintained. Increased

plasma aldosterone and deoxycorticosterone concentrations are observed.

Increasing estrogen concentrations throughout pregnancy increase the secretion of prolactin up to tenfold. Conversely, high estrogen concentrations during pregnancy suppress the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) below the detection limit. Baseline concentrations of other pituitary hormones such as TSH remain nearly unchanged (see Table 57-2), but the GH response to provocative stimuli is blunted.

Although normal pregnancy is a euthyroid state, many changes occur in thyroid function. High concentrations of TBG raise the concentration of total thyroxine (T_4) and triiodothyronine (T_3), but a slight decrease in free T_4 concentration occurs during the second and third trimesters. A slight reciprocal increase in TSH was reported by Lockitch.[229] Thyroglobulin is significantly increased, especially in the third trimester.[151] Very few (<0.2%) pregnant individuals develop hyperthyroidism, and hypothyroidism is very rare.[67] Postpartum thyroid dysfunction is common and is frequently unrecognized. The fetal thyroid-pituitary axis functions independently from the mother's axis in most cases. However, if the mother has preexisting Graves disease (hyperthyroidism caused by autoantibodies that stimulate the thyroid), those antibodies can cross the placenta, causing hyperthyroidism in the fetus. If the mother has anti-TSH autoantibodies, the infant can develop transient hypothyroidism.[229]

Functional Development of the Fetus

Fetal organs mature during the third trimester but not at the same rate. This section reviews the lung, liver, and kidneys, and blood maturation, in the fetus.

Lungs and Pulmonary Surfactant

In normal air-breathing lungs, a substance called *pulmonary surfactant* coats the alveolar epithelium and responds to alveolar volume changes by reducing surface tension in the alveolar wall during expiration. Surfactant is needed because surface tension is an inverse function of the radius of the airway. Thus small alveoli have a higher collapsing force than larger alveoli. Surfactant opposes the force and keeps the small alveoli from collapsing. Specialized alveolar cells called *type II granular pneumocytes* synthesize pulmonary surfactant and package it into laminated storage granules called *lamellar bodies*.[186,351] These storage granules are 1 to 5 μm in diameter and contain phospholipids, cholesterol, and protein.[276] Production starts as early as 20 weeks' gestation,[351] but adequate amounts do not accumulate until about 36 weeks. Exudation of pulmonary fluid (via the trachea) and fetal breathing movements transport lamellar bodies into the amniotic fluid. The internal structure of the particles is rearranged into a formation described as *tubular myelin* by those using electron microscopy.[186] The newborn lung contains 100 times more surfactant per cm^3 than the adult lung. Excessive surfactant is needed at birth as the newborn is transformed from breathing water to breathing air. Surfactant overcomes the surface tension produced in water-filled alveoli that are admitting air for the first time.

Pulmonary surfactant is a complex mixture of lipids and proteins; less than 5% is composed of carbohydrates. Most of the lipid is phospholipid, and most of that is lecithin (phosphatidylcholine).[65] Unlike lecithin from other tissues, pulmonary lecithin has two saturated fatty acids, usually palmitoyl groups. Other lipids present are phosphatidylglycerol (PG), phosphatidylinositol (PI), and phosphatidylethanolamine (see Chapter 27). Sphingomyelin is present in very small amounts (<2%). The protein fraction of lamellar bodies is approximately 4% and is composed of four surfactant-specific proteins: SP-A, SP-B, SP-C, and SP-D.[177,297]

Type II pneumocytes synthesize phosphatidylcholine in a manner quite different from that seen in other cells. Most other cells synthesize phosphatidylserine from cytidine diphosphate diacylglycerol and serine. The phosphatidylserine then is decarboxylated to yield phosphatidyl ethanolamine. The final step is the successive donation of three methyl groups via *S*-adenosylmethionine to form phosphatidylcholine. The pulmonary biosynthetic pathway is shown in Figure 57-2. The enzyme choline phosphotransferase forms PC directly from cytidine diphosphocholine and diacylglycerol. Phosphatidylinositol formation peaks at about 35 weeks. As PI decreases in concentration, PG begins to increase.

Liver

Hematopoiesis occurs in the liver during the first two trimesters and is transferred to the fetal bone marrow during the third trimester. The liver is also responsible for production of specific proteins (such as albumin and clotting factors), metabolism and detoxification of many compounds, and secretion of substances such as bilirubin. A clinically useful protein produced by the liver is alpha fetoprotein (AFP). Detoxification and bilirubin secretion mechanisms are immature until late in pregnancy and even in the first few months after birth. Thus premature infants often have high serum bilirubin concentrations and metabolize drugs poorly.

Kidneys

Toward the end of the first trimester, the fetal kidneys begin to produce urine, which is the main component of amniotic fluid. Early nephrons cannot produce concentrated urine, and pH regulation is also limited. Complete maturation occurs after birth. Although kidneys are not required for fetal survival, amniotic fluid is required. Without fluid to breathe, the fetal lungs fail to properly develop. Thus newborns without kidneys die of pulmonary failure.

Fetal Blood Development

Fetal blood is produced first by the embryonic yolk sac, then by the liver, and finally by the fetal bone marrow. The yolk sac produces three embryonic hemoglobins: Portland ($\zeta_2\gamma_2$), Gower-1 ($\zeta_2\varepsilon_2$), and Gower-2 ($\alpha_2\varepsilon_2$). These normal embryonic hemoglobins are of little importance in clinical chemistry because they are present in fetal blood only in the first trimester.

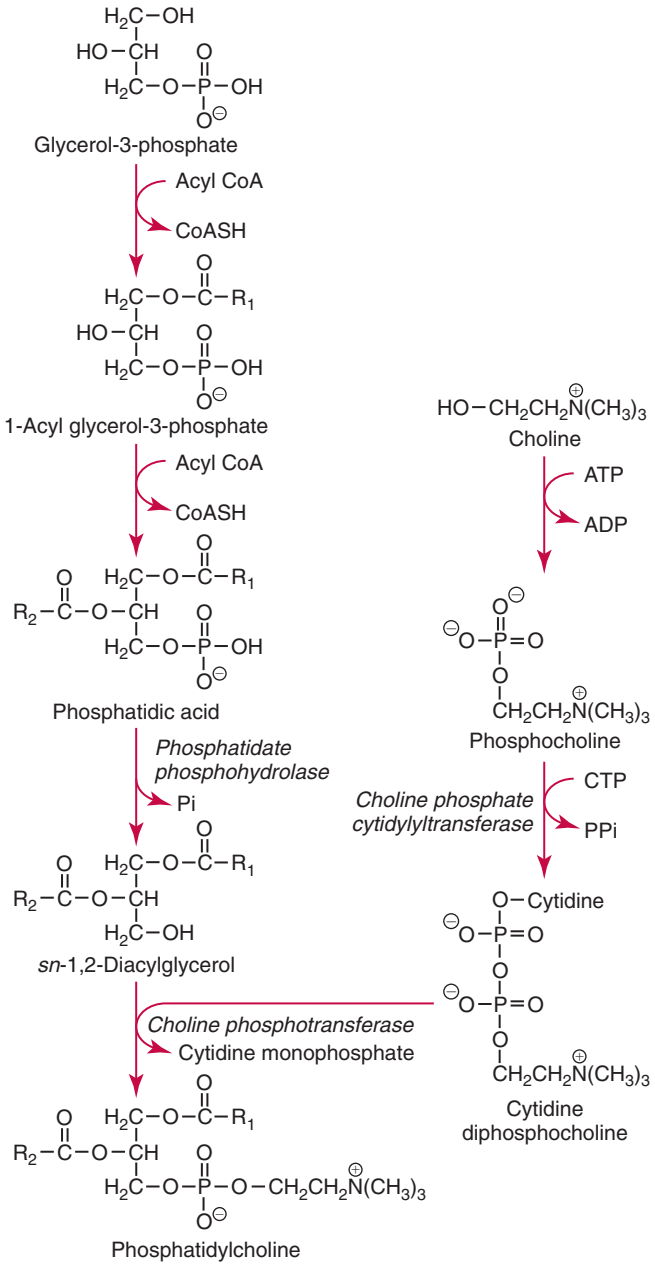

Figure 57-2 The biosynthetic pathway for phosphatidylcholine in type 2 pneumocytes.

With the switch of erythropoiesis to the fetal liver and spleen, fetal hemoglobin (Hb F) production begins. Hb F consists of two α- and two γ-chains ($\alpha_2\gamma_2$). Small amounts of adult hemoglobin, Hb A ($\alpha_2\beta_2$), are also produced, but Hb F predominates during the remainder of fetal life.

As the fetal bone marrow begins red cell production, Hb A production increases. At birth, fetal blood contains 75% Hb F and 25% Hb A. Hb F production rapidly diminishes during the first year of postnatal life. In normal adults, less than 1% of hemoglobin is Hb F. The difference between fetal and adult hemoglobin is very significant as Hb F has a higher affinity for oxygen than does Hb A. Thus in the placenta, oxygen is released from the maternal Hb A, diffuses into the chorionic villi, and binds to the fetal Hb F. In addition, 2,3-diphosphoglycerate (2,3-DPG) does not bind Hb F and therefore cannot decrease its affinity for oxygen.

MATERNAL AND FETAL HEALTH ASSESSMENT

For optimum healthcare during pregnancy, a woman should consult her physician before conception.[8,253] Unfortunately, 49% of pregnancies in the United States are unintended—higher for unmarried women.[179] Preconception evaluation should include a medical, reproductive, and family history; physical examination; and laboratory tests.

Laboratory Testing

The following laboratory tests are recommended as part of a preconception evaluation: (1) hematocrit, (2) blood type and Rh compatibility, (3) erythrocyte antibody screen, (4) Papanicolaou smear [or human papillomavirus (HPV) test], (5) urinalysis, (6) rubella titer, (7) Rapid Plasma Reagin (RPR) test, (8) gonococcal and chlamydia DNA test, (9) cystic fibrosis carrier status,[162] (10) human immunodeficiency virus (HIV) antibody,[7] and (11) hepatitis B surface antigen.[14] Depending on demographic risks, genetic testing for disorders such as Tay-Sachs disease, thalassemia, and sickle cell disease may be offered.[13] A careful diet history is warranted. Folic acid supplementation should be recommended to reduce the risk of neural tube defects.[248] Women at high risk for diabetes mellitus should be screened for this disorder (see Chapter 46).

Most individuals consult a physician a few days after a missed menses if they suspect they might be pregnant. Many laboratory tests are useful for managing normal and abnormal pregnancies. A urine pregnancy test result is positive (meaning that the test can detect a CG concentration of about 25 IU/L) in about half of pregnant females at the beginning of the missed menses—at about 2 weeks after conception.[90] Screening for fetal neural tube defects and Down syndrome should be offered to all pregnant patients. Until 2002, screening was recommended at 16 to 18 weeks' gestation,[10] but Down syndrome screening can now be performed as early as 10 weeks.[400] Depending on diabetes risk, glucose tolerance testing should be performed immediately or at 24 to 28 weeks (see Chapter 46 for details). Some physicians screen selected patients for preterm labor risk at 24 to 30 weeks using fetal fibronectin.[18] Although PL and estriol measurements were used previously to predict fetal well-being, both tests are now obsolete for this purpose.[100,101] Maternal observation and recording of fetal movements,[9] ultrasound examination, and tests that monitor the fetal heart rate[17] during random uterine contractions or fetal movement are the currently accepted methods for monitoring fetal well-being.

Clinical Specimens

Many different samples are used in clinical laboratory analysis before and during pregnancy. These include (1) paternal saliva, serum, and blood; (2) maternal saliva, serum, blood, and urine; (3) amniotic fluid obtained by amniocentesis[101,347] or from pools of fluid in the vagina after rupture of the fetal

membranes; (4) chorionic villi; (5) fetal blood obtained by percutaneous umbilical blood sampling; and (6) fetal tissue obtained by biopsy.[105]

The technique of amniocentesis is described in Chapter 7. Additional information is found in the section on tests for evaluating fetal lung maturity, later in this chapter.

Diagnosis and Dating of Pregnancy

The most important aspects of pregnancy management are detection of pregnancy and establishing accurate estimates of fetal age. Obstetricians measure the length of pregnancy in terms of *weeks,* not trimesters. The most useful test for detecting pregnancy is the CG test.

Qualitative tests for CG in blood or urine are used primarily to screen for pregnancy. Urine CG tests usually suffice to diagnose normal pregnancy when it has progressed beyond the first week after the first missed period. However, qualitative serum pregnancy tests may detect pregnancy earlier, and quantitative serum tests can help reveal problems in early pregnancy. False-positive or increased serum CG test results have been obtained from qualitative and quantitative assays when human antimouse antibodies (HAMA) or heterophile antibodies are present.[91,157] If suspected, investigative experiments include testing a urine specimen for the presence of CG, serially diluting the serum to confirm an appropriate dose response, testing the serum using a different CG method, and retesting the serum after treatment with interfering antibody blocking agents.

To establish accurate dates, obstetricians rely on (1) menstrual history, (2) physical examination, (3) fetal heart tones, (4) ultrasonography, and (5) detection and quantification of CG. In the first 8 weeks of pregnancy, the CG concentration in maternal serum rises geometrically (Figure 57-3). Detectable amounts (≈5 IU/L) are present in the serum 8 to 11 days after conception,[234] which is in the third week of pregnancy as measured from the LMP.[221] CG usually becomes detectable in the urine 1 to 3 days later, although this interval is highly variable.[234] For women aged 13 to 40, serum CG concentrations of 5 IU/L or greater are consistent with pregnancy. Higher values are infrequently seen in older, nonpregnant women and are thought to be caused by CG secreted by the pituitary gland.[350] Concentrations in approximately half of pregnant women reach 25 IU/L on the first day of their missed period. The peak concentration occurs at about 8 to 10 weeks and is about 100,000 IU/L. Subsequently, CG concentrations start to decline in serum and urine, and by the end of the second trimester, a 90% reduction from peak concentration has usually occurred. In the first trimester, maternal serum CG is about 96% to 98% intact, 1% to 3% β subunit, and up to 1% α subunit. During the second trimester, subunit synthesis becomes unbalanced and the serum distribution shifts to 92% to 98% intact, 1% to 7% α subunit, and up to 1% β subunit.[280] Concentrations are approximately constant during the third trimester, with the predominant species being intact CG. The presence of twins approximately doubles CG concentrations.[389]

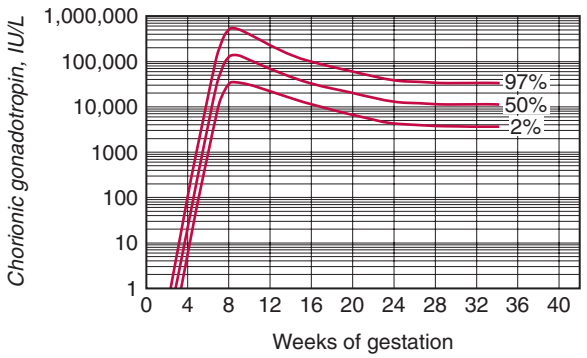

Figure 57-3 Concentration of chorionic gonadotropin (CG) in maternal serum as a function of gestational age. Lines represent the 2nd, 50th, and 97th percentiles. Maternal serum values from 14 to 25 weeks are medians calculated from 24,229 pregnancies from testing performed at ARUP Laboratories Inc. from January to October 1997. *(Redrawn from Ashwood ER. Evaluating health and maturation of the unborn: the role of the clinical laboratory. Clin Chem 1992;38:1523-9. Permission granted from Clinical Chemistry.)*

COMPLICATIONS OF PREGNANCY

Although most pregnancies progress without problems, complications can arise in the mother, placenta, or fetus.

Abnormal Pregnancies

Conditions arising primarily in the mother include (1) ectopic pregnancy, (2) hyperemesis gravidarum, (3) preeclampsia, (4) HELLP syndrome (see later), (5) liver disease, (6) Graves disease, and (7) hemolytic disease of the newborn. The clinician must distinguish abnormal changes in laboratory tests from normal physiologic changes induced by pregnancy (see Table 57-2).

Ectopic Pregnancy and Threatened Abortion

When a fertilized egg implants in a location other than the body of the uterus, the condition is called an *ectopic pregnancy.* Most abnormal implantations occur in the fallopian tube; they can also occur in the abdomen, although this is rare. Tubal rupture and hemorrhage are common serious complications of ectopic pregnancy. About 25% of individuals with an ectopic pregnancy have three classic symptoms: lower abdominal pain, vaginal bleeding, and an adnexal mass.[332] Of all individuals with these symptoms, about 15% have an ectopic pregnancy, and a smaller percentage have incomplete or complete spontaneous abortion. In 2006, the United States had 13.3 pregnancy-related deaths per 100,000 live births[257]—3% caused by ectopic pregnancy.[181] A pregnant patient has about a 1 in 200 chance of dying from an ectopic pregnancy.[155] Management of ectopic pregnancy is surgical (by laparoscopy) or medical (with intramuscular administration of methotrexate).[15,21] Early detection and proper management of ectopic pregnancy are the most effective means of preventing maternal morbidity and mortality. Some have

suggested that asymptomatic women at high risk for ectopic pregnancy should be screened with the use of ultrasound and laboratory tests.[69]

Ultrasound examination is used to evaluate women with symptoms. When ultrasound is nondiagnostic, quantitative measurements of serum CG are used to identify women with ectopic pregnancy or abnormal intrauterine pregnancy. These conditions frequently produce abnormal CG concentrations and slow rates of increase.[58]

An accurate gestational age is the best predictor of when an intrauterine pregnancy should be detected with transvaginal ultrasound. Failure to detect a gestational sac by sonography 24 days or longer after conception provides presumptive evidence of an ectopic pregnancy or fetal demise.[193] In the absence of an accurate gestational age, a serum CG concentration is required to assist in interpreting a nondiagnostic ultrasound. An intrauterine pregnancy should be visible by ultrasonography at a CG concentration of 1500 to 2000 IU/L, but this concentration has a clinical sensitivity of only 42% and a clinical specificity of 81% for the detection of ectopic pregnancy when no intrauterine gestational sac is visualized.[205]

When CG concentrations are less than 1500 IU/L and ultrasonography is nondiagnostic, serial testing of CG may be very helpful. In normal intrauterine pregnancy, during the second through fifth weeks, the CG doubles every 1.5 days. After 5 weeks' gestation, the doubling time gradually lengthens to 2 to 3 days.[305] Before 7 weeks, calculation of the slope of log(CG) versus time in days is useful for identifying normal pregnancies.[192] At least two CG determinations should be obtained from specimens collected 1 to 7 days apart. The log-linear slope, $\Delta\log(CG)/\Delta\text{time}$ [in log(IU/L)/d], is greater than 0.11 in the vast majority of normal pregnancies. In cases of ectopic pregnancy or spontaneous abortion, the slope is usually less than 0.11, and the CG concentrations often decrease. An increase in CG of at least 53% over 48 hours is 99% specific for excluding an ectopic pregnancy,[33] but as many as 35% of ectopic gestations produce an increase greater than this.[345]

Serum progesterone concentration is often low in mothers with abnormal pregnancy.[314] For example, a serum progesterone less than 6 ng/mL predicts an abnormal pregnancy outcome with 81% confidence for asymptomatic women within 8 weeks of their last menses,[106] but average serum progesterone in nonviable pregnancies is 10 ng/mL. For women with clinical symptoms of abnormal pregnancy, measurement of both CG and progesterone is more predictive of abnormal pregnancy than a single CG measurement. In a large outcome study, 97% of patients with CG less than 3000 IU/L and progesterone less than 12.6 ng/mL had an abnormal pregnancy outcome, whereas those with CG greater than 3000 IU/L or progesterone greater than 12.6 ng/mL had a normal pregnancy.[272] McCord and associates[242] reported that in women at risk for ectopic pregnancy, a progesterone cutoff of 17.5 ng/mL detected 92% of ectopic cases (clinical sensitivity) but had a very poor clinical specificity of about 14%. Investigators concluded that patients with progesterone greater than 17.5 ng/mL needed no additional laboratory tests. Finally, in symptomatic patients, Stewart and colleagues[362] reported a clinical sensitivity of 99% and a clinical specificity of 65% when a $\Delta\log(CG)/\Delta\text{time}$ greater than 0.14 is used to distinguish normal intrauterine pregnancy from ectopic pregnancy combined with inevitable abortion. A progesterone cutoff above 8 ng/mL had a clinical sensitivity of 81% and a clinical specificity of 88%.

Preeclampsia and Eclampsia

Preeclampsia is a pregnancy condition characterized by hypertension, proteinuria, and often edema, usually occurring late in the second trimester or early in the third trimester, and affecting 5 to 10% of pregnancies. It is a major cause of maternal and perinatal mortality. If the mother develops convulsions, the condition is called *eclampsia*. The cause has not been elucidated,[359] but research suggests that increased circulating soluble fms-like tyrosine kinase 1 (sFlt-1) may have a role.[222]

The disorder manifests with placental ischemia and endothelial dysfunction that leads to intravascular deposition of fibrin with subsequent end-organ damage.[320] Most maternal deaths are due to central nervous system complications, but ischemic liver damage may also occur. The only cure for preeclampsia is delivery of the placenta.[359]

HELLP Syndrome

The HELLP syndrome (**h**emolysis, **e**levated **l**iver enzymes, and **l**ow **p**latelet counts in association with preeclampsia) is a life-threatening obstetric complication that occurs in 0.1% of pregnancies. Its most prominent features are thrombocytopenia and disseminated intravascular coagulation (DIC; see Chapter 59). Most cases occur between the 27th and 36th weeks of pregnancy, but the syndrome also may occur postpartum. Women typically present with epigastric or right upper quadrant pain, malaise, nausea, vomiting, and headache.[240,343] Jaundice occurs in 5% of patients. Lactate dehydrogenase (LD) concentrations may be very high, and alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are usually 2 to 10 times their upper reference limits. Treatment is delivery. Postpartum management of the patient may require plasmapheresis or organ transplantation. Recurrence rates are 3 to 27%.

Liver Disease

Several liver disorders are unique to pregnancy.[191,204] These include (1) hyperemesis gravidarum, (2) cholestasis of pregnancy, and (3) fatty liver of pregnancy. These disorders must be distinguished from the normal physiologic changes of pregnancy (see Table 57-2). Significant changes normally seen in pregnancy include a dilutional decrease in serum albumin and elevation of alkaline phosphatase (from the placenta). Notably, total bilirubin; 5′-nucleotidase, gamma-glutamyltranspeptidase (GGT), ALT, and AST are unchanged in mothers with a normal pregnancy. Changes in these analytes reflect hepatobiliary disease. Also discussed in this section are (1) non–pregnancy-related liver disease in

pregnancy, (2) differential diagnosis, and (3) effect of pregnancy on preexisting liver disease.

Hyperemesis Gravidarum

Hyperemesis gravidarum is characterized by nausea and vomiting and, in severe cases, dehydration and malnutrition. It typically occurs in the first trimester. When hyperemesis is severe enough to cause dehydration, abnormal liver enzyme values—usually less than four times the upper reference limit—are seen in approximately 50% of patients.[191] Mild hyperbilirubinemia may occur. However, significant liver disease does not occur, and liver biopsy results are normal. Low birth weight babies are common, especially for women who develop malnutrition.

Cholestasis of Pregnancy

Cholestasis of pregnancy usually occurs in the third trimester and is manifested clinically by diffuse pruritus and, in 10% of patients, jaundice. Typical features of cholestasis, including pale stools and dark urine, are present and last until delivery. Women who experience cholestasis while taking oral contraceptives usually develop cholestasis of pregnancy. Serum bilirubin rarely exceeds 5 mg/dL. Alkaline phosphatase is typically two to four times the upper reference limit. Aminotransferase enzyme concentrations are mildly elevated. Prothrombin time may be elevated because of vitamin K malabsorption. Although many clinicians order serum bile acids in this setting,[130] this test is offered by only a few clinical laboratories and is rarely necessary for diagnosis. The condition itself is benign, but is associated with increased risk of premature birth and fetal death. It recurs with subsequent pregnancies.[317]

Fatty Liver of Pregnancy

Fatty liver of pregnancy occurs in approximately 1 in 10,000 pregnancies and is characterized by accumulation of microvesicular fat in the hepatocytes.[77] Many cases of this maternal disorder are caused by an inherited mitochondrial fatty acid oxidation disorder in the fetus, long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency (LCHAD).[379] Mothers carrying fetuses with this disorder are 50 times more likely to develop fatty liver of pregnancy.[66] The disease typically occurs at week 37 and is manifested clinically by rapid onset of malaise, nausea, vomiting, and abdominal pain. Mild elevations in aminotransferase enzyme concentrations occur, with the AST elevation typically greater than the ALT elevation but with both less than six times the upper reference limit. Serum bilirubin is usually greater than 6 mg/dL. Life-threatening hypoglycemia may occur.[320] Hyperuricemia, presumably from tissue destruction and renal failure, is characteristic. Liver histology shows acute fatty infiltration with little necrosis or inflammation. The fat is microvesicular and pericentral in the cell, similar to what is seen in Reye syndrome. If untreated, fulminant hepatic failure with hepatic encephalopathy ensues. Treatment is immediate termination of the pregnancy, at which time rapid recovery usually occurs. Infant and maternal mortality is approximately 50% and 20%.

Non–Pregnancy-Related Liver Disease in Pregnancy

Pregnancy does not preclude the acquisition or aggravation of non–pregnancy-related liver disease. Thus, cholestasis during pregnancy may reflect the presence of (1) hepatotoxicity from drugs, (2) primary biliary cirrhosis, (3) Dubin-Johnson syndrome, or (4) cholelithiasis (see Chapter 50). Abdominal ultrasound, endoscopic retrograde cholangiography, or liver biopsy may be necessary to exclude these conditions.

Viral hepatitis occurs with the same frequency in pregnancy as would be expected in a comparable age group.[323] It is manifested by malaise, nausea, vomiting, dark urine, and mild fever. AST and ALT are virtually always more than 10 times the upper reference limit and are usually greater than 20 times the upper reference limit. The prognosis, with the exception of hepatitis E and herpes simplex, is the same as in nonpregnant women. Hepatitis E, an enteric infection occurring in India, Africa, the Middle East, and Central America, has a mortality rate of 15 to 20% in the pregnant patient.[208] Herpes simplex hepatitis, usually accompanied by oral or vulvar vesicles, has a mortality rate of 43%.[201] Distinguishing features include mild bilirubin elevation and marked aminotransferase elevations. Liver biopsy is usually required for diagnosis and demonstrates typical intranuclear inclusions and the other usual features of viral hepatitis. Antiviral therapy greatly improves the prognosis.

Women who acquire hepatitis B late in pregnancy or who are chronic carriers are likely to transmit the disease to their babies. This is especially so if the mother is hepatitis B e antigen (HBeAg) positive (see Chapter 50). The outcome in the infant varies from fulminant hepatitis (rare and usually in anti–HBe-positive mothers) to mild hepatitis to chronic hepatitis (the usual outcome in 90% of chronically infected woman). All pregnant women should be screened for hepatitis B with hepatitis B surface antigen (HBsAg).[14] If positive, their babies should be immunized with hepatitis B immune globulin and hepatitis B vaccine. Babies born to hepatitis C–positive mothers usually have the passively transmitted antibody for several months, but transmission of active hepatitis is unusual.[372] Because there is no known treatment for the newborn, screening is not recommended for hepatitis C virus infection.

Differential Diagnosis

It is often difficult to distinguish the various liver diseases of pregnancy from each other and from naturally occurring liver diseases. Acute fatty liver is suggested when nausea, vomiting, and abdominal pain are followed by jaundice, and encephalopathy occurs in the presence of a small or normal-sized liver. The white blood cell count is usually elevated above 15,000 cells/μL, and ALT concentrations are typically four to six times the upper reference limit. Hypoalbuminemia, hyperuricemia, hypoglycemia, and DIC are typical. Hepatic ultrasound and computed tomography (CT) usually demonstrate fatty liver when present. In preeclampsia and the HELLP syndrome, the liver is usually enlarged, ALT concentrations are usually lower, and bilirubin concentrations are

mildly elevated or normal. Hyperuricemia is uncommon. Marked elevations in aminotransferase enzyme concentrations suggest hepatic infarction or viral hepatitis. Liver biopsy may be needed to differentiate non–pregnancy-related causes of liver disease, but should not be used to differentiate acute fatty liver from preeclampsia or HELLP syndrome because treatment is the same for all of these conditions—delivery of the infant.[249]

Effect of Pregnancy on Preexisting Liver Disease

Conception and full-term parturition do not usually occur in women who have cirrhosis. However, liver disease is not a reason for termination. The hypervolemia associated with pregnancy may aggravate cirrhosis and predispose to bleeding from esophageal varices.[61]

Autoimmune chronic hepatitis is usually associated with amenorrhea, but pregnancy may occur after treatment to remission with corticosteroids. Steroids should be continued during pregnancy. Pregnancy should be avoided in patients being treated with azathioprine.

Neonatal Thyroid Function

During the first trimester of pregnancy, the fetus is dependent on the mother for its supply of thyroid hormone. Low maternal thyroid hormone concentrations (overt or subclinical hypothyroidism) have been associated with adverse outcomes, such as preterm delivery,[76] fetal death, and a reduced intelligence quotient (IQ) in children.[4,168] Women with untreated thyroid deficiency in pregnancy are more likely to have permanent hypothyroidism after pregnancy (64%) than are euthyroid mothers.[168]

Later in pregnancy, the fetal thyroid-pituitary axis functions independently from the mother's axis in most cases. However, if the mother has preexisting Graves disease (see Chapter 55), her autoantibodies can cross the placenta and stimulate the fetal thyroid gland. Thus the fetus can develop hyperthyroidism. Measurement of thyrotropin-binding inhibitory immunoglobulins (TBII) is useful for assessing risk of fetal or neonatal Graves disease.

Thyroid screening in pregnancy is recommended for high-risk women but is controversial for others.[19,146] Regardless, when tested, thyroid hormone results should be interpreted using pregnancy-specific reference values.[213]

Hemolytic Disease of the Newborn

Hemolytic disease of the newborn (HDN) is a fetal hemolytic disorder caused by maternal antibodies directed against antigen on fetal erythrocytes. Commonly used synonyms for this disorder are *isoimmunization disease, Rh isoimmune disease, Rh disease,* and *D isoimmunization.* Any of a large number of erythrocyte surface antigens—Rh(CcDEe), A, B, Kell, Duffy, Kidd, and others—may be responsible for isoimmune hemolysis. When severe, the disorder is known as *erythroblastosis fetalis* and is life threatening to fetus and newborn. In the past, disease severity was assessed by measuring the amount of bilirubin in the amniotic fluid (AF). Presently ultrasonographic determination of middle fetal cerebral artery velocity is replacing AF bilirubin. Pioneering work by Bevis[44-47] uncovered the association between amniotic fluid bilirubin and D isoimmunization. Liley[224] extended this work by noting an association between gestational age, severity of the disease, and amniotic fluid bilirubin concentration.

Rh Blood Groups

Two genes, *RhD* and *RhCE,* encode for erythrocyte membrane proteins that are antigenic. Both are located on chromosome 1p about 30 kb apart. Approximately 15% of Caucasians, 5% of Africans, and less than 1% of Asians are RhD negative. The most prevalent RhD-negative allele is a deletion.[31] Exon 5 of *RhCE* has two common polymorphisms producing *E* or *e* antigen. Exon 2 of *RhCE* has two common polymorphisms producing *C* or *c* antigen.

Etiology

Maternal sensitization may occur in response to blood transfusion or a pregnancy in which the fetus has a blood cell antigen that the mother lacks. Antibodies against RhD are the most common cause of HDN, although antibodies against other erythrocyte antigens can also cause disease.

The resulting antibodies are actively transported across the placenta and into the fetus, where they cause destruction of fetal erythrocytes. The severity of the resulting hemolysis is influenced by antibody specificity, titer, and transfer rate, as well as by the functional maturity of the fetal spleen in which sensitized erythrocytes are destroyed.

Destruction of fetal erythrocytes, which is the central problem, produces several other problems. For example, fetal anemia imposes an extra burden on the fetal heart to provide an adequate oxygen supply to fetal tissues. Anemia stimulates the fetal marrow and extramedullary erythropoiesis in the liver and spleen to replace destroyed erythrocytes. Extramedullary erythropoiesis destroys hepatocytes and leads to decreased production of serum albumin and decreased oncotic pressure in the intravascular space.

When severe, these changes lead to congestive heart failure and generalized fetal edema, a condition referred to as *hydrops fetalis,* which carries a very grave prognosis. Without therapeutic intervention, intrauterine demise soon follows.

If a fetus survives, the newborn will encounter a number of problems. In utero, the placenta and the mother perform the functions of respiration and removal of bilirubinoid pigments resulting from hemolysis. Newborns must assume these functions for themselves in the presence of hydrops. The lungs are edematous, and pleural effusions and ascites physically restrict their ability to expand. The damaged liver is unable to conjugate and excrete bilirubin adequately. When bilirubin accumulates in the blood to excessive concentrations, it passes through the blood-brain barrier to deposit in the brain and destroy brain cells. This form of brain damage is termed *kernicterus.* Although kernicterus was not a concern in the hydropic fetus, it is a significant concern in these sick newborns. A severely erythroblastotic baby can be one of the most challenging cases in a neonatal intensive care unit.

Prophylaxis

An anti-RhD immune globulin, RhoGAM (Ortho Clinical Diagnostics, Raritan, NJ), has been used in the United States since 1968[56]; other similar products were introduced in 1971 and later. A 300 μg dose is administered intramuscularly to a mother potentially exposed to 15 mL or less of RhD-positive fetal erythrocytes following abortion, fetomaternal hemorrhage, amniocentesis, chorionic villi sampling (CVS), or delivery.[11] Use of anti-RhD immune globulin has been responsible for the dramatic reduction in the incidence of HDN. In addition to recognized fetomaternal hemorrhage, undetected transplacental fetomaternal bleeding during an apparently normal pregnancy can lead to antepartum sensitization. This would not be prevented by immediate postpartum administration of RhD immunoglobulin; therefore antepartum administration at 28 weeks' gestation is recommended for RhD-negative women. Despite this immune prophylaxis, a small number of sensitized pregnancies continue to occur.

Clinical Management of Sensitized Mothers

To identify sensitized women, an alloantibody screen is performed at the first prenatal visit.[250] If an antibody to an erythrocyte antigen is identified, the titer is determined.[11] The critical anti-RhD titer, defined as the titer associated with risk for fetal hydrops, is usually 1:8 to 1:32, although studies of critical titer are quite disparate.[159] For all sensitized women, the paternal erythrocyte phenotype is determined. If the father is RhD negative, then no follow-up studies are required. If he is D positive, then zygosity is determined. Although this has historically been estimated from Rh antigen phenotypes (D, C/c, E/e) in conjunction with gene frequency tables based on race, DNA testing for RhD zygosity is more reliable. If the father is homozygous, all of his offspring can be assumed to be RhD positive, negating the need for fetal RhD testing. Fetal RhD genotyping from cultured amniocytes is required if the father is heterozygous or is not available for testing. To guard against a false negative caused by a paternal RhD gene rearrangement (occurring in about 1.5% of Caucasians), the father can also be genotyped. A frequent occurrence in those of African ancestry is an RhD pseudogene; the patient is RhD negative by serology, but RhD positive on genotype. If the fetus is RhD genotype positive, the mother (who is RhD negative serologically) should be tested for RhD genotype. Laboratories have begun to offer fetal Rh genotyping using cell-free fetal DNA that circulates in maternal blood (see Chapter 45).[133]

For sensitized mothers with an at-risk fetus, serial titers are performed on maternal serum every month until 24 weeks' gestation, then every 2 weeks thereafter. If a critical titer anti-D is detected, ultrasound Doppler measurements are used to determine the peak velocity of blood flow in the fetal middle cerebral artery. Higher velocity is a strong indicator of fetal anemia. If Doppler velocimetry is not available, amniocentesis is performed every 10 to 14 days to assess the bilirubin concentration in amniotic fluid. The procedure was originally called ΔOD_{450},[224] but the preferred clinical chemistry term is ΔA_{450}. This method is described later in the chapter in the section entitled "Laboratory Tests." Serial testing is indicated every 10 to 14 days. Decreasing values are reassuring and indicate an unaffected or RhD-negative fetus. Values that plateau or increase suggest active hemolysis, which may require therapeutic intervention including ultrasound-guided umbilical blood sampling to determine fetal blood type, hemoglobin, antibody screen, reticulocyte count, and total bilirubin. Intrauterine intravascular blood transfusion can be performed if indicated. If fetal pulmonary maturation has occurred (usually 35 weeks or greater), delivery is indicated.

Trophoblastic Disease

Serum CG determinations are very useful for monitoring patients with germ cell–derived neoplasms or other CG-producing tumors, such as lung carcinoma. Use of CG in these diseases is discussed in Chapter 24.

Fetal Anomalies

Open neural tube defects, Down syndrome, trisomy 18 and the Smith-Lemli-Opitz syndrome (discussed separately later) are fetal anomalies that are partially detectable by prenatal screening. However, because of the large number of pregnancies screened and the interest in other fetal conditions and their possible association with abnormal maternal serum analyte concentrations, a wealth of associations between rarer conditions and screening results has been published. These findings are never diagnostic and are reported rarely by the screening laboratory. In certain circumstances, however, the healthcare provider may recommend pursuing a more extensive medical evaluation.

Neural Tube Defects

Neural tube defects are serious abnormalities that occur early in embryonic development. By 19 days after fertilization, the area that is to form the central nervous system (brain and spinal cord) has differentiated into a plate of cells. The flat plate then rolls up, and its edges fuse into a hollow neural tube that drops into the embryo to develop just underneath what will become the skin of the back. Neural tube formation is normally complete 4 weeks after fertilization. Failure of neural tube fusion leads to permanent developmental defects of the brain, spinal cord, or both. These defects are called *anencephaly, meningomyelocele* (which is commonly called *spina bifida*), and *encephalocele*. Although many heterogeneous causes are known, about 90% fall into the classification of multifactorial inheritance.[183] Folic acid deficiency is clearly associated with increased frequency of neural tube closure defects.[387] The cause in these cases may be derangement of homocysteine metabolism caused by folate deficiency.[358] Estimates attribute 70% or more of all neural tube defects to folate deficiency.[394] Since 1997, grain products in the United States and Canada have been fortified with 140 μg folic acid/100 g,[383] but the amount added is unlikely to be sufficient

to reduce birth prevalence by more than about 30%—the reduction that is commonly reported in observational trials.[290] Organizations such as the March of Dimes are conducting vigorous campaigns to educate women about the need for folic acid supplementation before becoming pregnant, as recommended by the Centers for Disease Control and Prevention.[79] Most vitamin supplements contain 400 μg of folic acid, which is what is recommended daily by authorities.[256] Data published in 2009 suggest that vitamin B_{12} is also necessary.[251]

The birth prevalence of open neural tube defects varies with factors such as (1) geographic location (higher in the Eastern United States, lower in the West), (2) race (lower in African Americans), (3) ethnicity (higher in Scotch-Irish), (4) family history (higher with prior births of affected individuals),[96] and (5) maternal weight (higher in obese women).[335,403] An average figure for the United States is 1 open neural tube defect per 1000 pregnancies (about 1 in 2000 for each individual defect). Almost all cases of anencephaly and about 95% of meningomyeloceles are open, with no overlying skin, and therefore are in direct communication with the amniotic fluid. Thus fetal serum proteins normally present in amniotic fluid at low concentrations gain access in large quantities to the amniotic fluid. The elevated amniotic fluid AFP concentration leads to increased amounts in the maternal circulation. Only open neural tube defects are detected by maternal serum AFP screening.[390]

Down Syndrome

Down syndrome is the most common serious disorder of the autosomal chromosomes, occurring in 1 in 700 live births. An extra copy of the long arm region q22.1 to q22.3 of chromosome 21 results in a phenotype consisting of moderate to severe mental retardation, hypotonia, congenital heart defects, and a flat facial profile. Chromosome 21 is the smallest chromosome, making up about 1.7% of the human genome. Most often an affected child has three copies of chromosome 21 (i.e., trisomy 21), but 5% of cases are caused by translocations and 1% of cases are mosaics. The risk increases slowly up to age 30 and then steadily increases between ages 30 and 45 (Figure 57-4) to a plateau.[255]

Trisomy 18

Trisomy 18 (Edwards syndrome) is caused by a nondisjunction event during meiosis that results in a fetus having an extra copy of chromosome 18. Although it occurs in only 1 in 8000 births, it is probably the most common chromosome defect at the time of conception. The dramatic change in prevalence is due to the very high fetal loss rate both before 8 weeks (>80%) and during the second and third trimesters (≈70%). Approximately 25% of affected fetuses have meningomyelocele (spina bifida) or omphalocele (abdominal wall defect). A high cesarean section rate has been reported for undiagnosed cases.[284] Following birth, half of infants die within the first 5 days and 90% die within 100 days.[75]

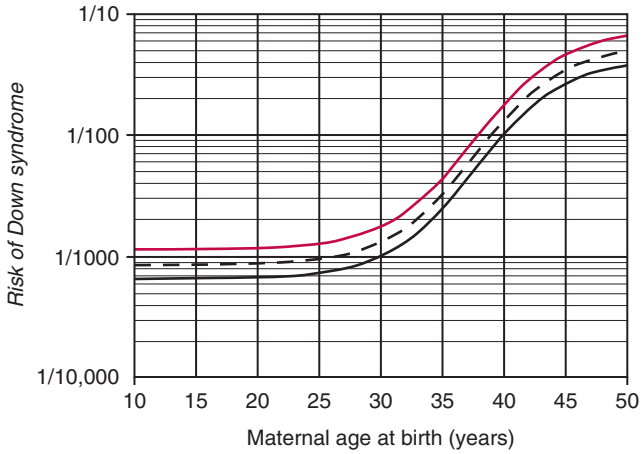

Figure 57-4 The relationship of maternal age to the risk of having a pregnancy affected with Down syndrome. *Dashed line*, Second trimester risk; *red line*, first-trimester risk; *solid black line*, term risk. The term risk is calculated from $1/[1 + \exp(7.33 - 4.211/\{1 + \exp[-0.2815 \times (\text{age} - 37.23 - 0.5)]\})]$.[255]

Smith-Lemli-Opitz Syndrome

Smith-Lemli-Opitz syndrome (SLOS) is caused by a defect in cholesterol synthesis. SLOS is inherited as an autosomal recessive mutation and occurs rarely, in about 1 of every 100,000 Caucasian pregnancies.[95] Children affected with SLOS have mental and growth deficiencies and other structural malformations of the skeleton, kidneys, genitals, lungs, and heart.[199]

Preterm Delivery

The leading cause of neonatal morbidity and mortality in the United States is preterm delivery, defined as delivery before 37 weeks' gestation. Approximately 300,000 to 500,000 preterm births occur each year.[16] Rupture of the fetal membranes before the onset of uterine contractions is known as premature rupture of membranes (PROM). When this occurs at less than 37 completed weeks' gestation, it is referred to as preterm PROM and is responsible for nearly one third of preterm deliveries.[245]

Infants born before 37 weeks' gestation are usually of low birth weight (<2500 g) and are vulnerable to numerous complications, including (1) infection, (2) necrotizing enterocolitis, and (3) intraventricular hemorrhage, and often develop (4) *respiratory distress syndrome* (RDS). Some are of very low birth weight (<1500 g). According to the National Center for Health Statistics,[181] in 2006, 8.2% of all U.S. live-born infants were of low birth weight and 1.5% were of very low birth weight. Most of these infants will spend time in intensive care units at a cost of up to $3500 per day.

The cause of preterm labor is unknown, but it is likely that many factors are involved and several mechanisms have been supported by a considerable amount of clinical and experimental evidence. These include (1) pathologic distention

of the uterus, (2) decidual hemorrhage, (3) activation of the maternal-fetal hypothalamic-pituitary-adrenal axis, and (4) intrauterine infection or inflammation.[346] Fetal fibronectin and cervical ultrasound have proven value for evaluating patients suspected of having preterm labor. The fetal fibronectin test is described later, in the section entitled "Laboratory Tests."

Premature Rupture of Membranes

Preterm PROM is a complication in 3% of pregnancies.[245] Risk factors for preterm PROM include (1) a history of preterm PROM, (2) genital tract infection, (3) antepartum bleeding, and (4) smoking. Most women who experience PROM will deliver their infants within 1 week. Management of preterm PROM varies according to the gestational age of the fetus and the presence or absence of maternal/fetal infection. When PROM occurs at 34 to 36 weeks' gestation, the infant should be delivered, as this has been shown to reduce maternal and fetal infection rates compared with expectant management.[246] When it occurs at 32 to 33 weeks, fetal lung maturity should be determined and the infant delivered if maturity is indicated. If the fetal lungs are immature, conservative management with close fetal monitoring is necessary in conjunction with antibiotic therapy and administration of corticosteroids to accelerate lung development.[245] Because of the high risk of severe neonatal morbidity and mortality, women with PROM at less than 32 weeks' gestation must be managed conservatively in an attempt to prolong pregnancy to 32 weeks. Interventions include antibiotic therapy, administration of tocolytics, and fetal monitoring.[245]

The diagnosis of PROM is often difficult, and commonly used observations or tests to detect it lack clinical sensitivity and specificity.[265,282] These include (1) direct observation of fluid leaking from the cervix or pooling in the posterior fornix of the vagina, (2) ultrasound for the detection of oligohydramnios, and (3) nitrazine (pH), and (4) fern tests. An immunochromatographic test for the rapid detection of placental alpha microglobulin-1 protein in amniotic fluid is described later, in the section entitled "Laboratory Tests."

Fetal Lung Maturity

RDS, also called *hyaline membrane disease,* is the most common critical problem encountered in clinical management of preterm newborns. The worldwide incidence of RDS is 1% of live births and 10 to 15% of live preterm births (<37 weeks or <2500 g).[261] The risk of RDS is affected strongly by gestational age at the time of birth: 1% at 37 weeks, 20% at 34 weeks, and 60% at 29 weeks.[129] In 2006, RDS killed over 800 infants in the United States.[181] Affected infants require supplemental oxygen and mechanical ventilation to remain properly oxygenated. The disorder is caused by a deficiency of *pulmonary surfactant.* In normal lungs, surfactant coats the alveolar epithelium and responds to alveolar volume changes by reducing surface tension in the alveolar wall during expiration. When the quantity of surfactant is deficient, many of the alveoli collapse on expiration and thereby overinflate the remaining airways. This process is known as *focal atelectasis.* The lungs become progressively noncompliant (stiff), and blood flowing through the capillary beds of collapsed alveoli fails to oxygenate. During the first few hours of life, affected infants develop tachypnea with or without cyanosis, nasal flaring, expiratory grunting, and intercostal retractions. The disease worsens during the next few days and usually is worse on the third or fourth day of life. Infants at risk for developing RDS have been treated with intratracheal administration of exogenous surfactant immediately at birth.[174]

Very rarely is the respiratory distress in a term newborn caused by a mutation in the gene encoding for SP-B.[268] This condition, termed *congenital alveolar proteinosis,* is often fatal. A significant derangement in lamellar body production occurs in these cases. Study of the genetic variation suggests that there may be mild, nonfatal cases of this disorder.[113]

PRENATAL SCREENING FOR FETAL DEFECTS

Prenatal screening is the process of identifying pregnancies at sufficiently high risk of a serious birth defect such as an open neural tube defect or Down syndrome. Before 2003, most obstetricians offered amniocentesis for fetal karyotype determination to all mothers who would be 35 years of age or older at the time of birth. However, in 2002, almost 14% of pregnant women in the United States were 35 or older, and these women accounted for 51% of Down syndrome pregnancies.[316] Therefore, if maternal age alone were used for screening, half of Down syndrome pregnancies would not be detected, and no cases in younger women would be identified. The risk for Down syndrome calculated using screening tests is more accurate than the use of maternal age alone, and it is now recommended by the American College of Obstetricians and Gynecologists (ACOG) to offer screening to women of all ages.[12]

Terminology and Method of Risk Calculation in Prenatal Screening

Calculation of risk in prenatal screening depends on the pregnancy's prior risk and the pattern of test results.

Multiple of the Median

Understanding the published literature and clinical screening requires an understanding of the multiple of the median (MoM), the statistic used to normalize analyte values. The initial step in calculating an MoM is to develop a set of median values for each week (or day) of gestation, using the laboratory's own assay values measured on the population to be screened. Individual test results are then expressed as MoM by dividing each individual test result by the median for the relevant gestational age. This convention was originally developed to take into account large differences among centers in AFP assay values seen in the 1977 U.K. collaborative study.[390] The MoM is now universally used as a common factor for converting analyte values into an

interpretative unit and serves as the starting point for calculating screening results for neural tube defects, Down syndrome, and trisomy 18.[284,391,393]

Calculating Individualized Patient-Specific Risks Using Multiple Biochemical Measurements

Measurements of each analyte are made on a serum sample, and the results in mass units are converted to MoM for the appropriate week (or day) of gestation. This MoM value is then adjusted for other variables, such as maternal weight and race (as described later in this chapter). Patient-specific Down syndrome risks are calculated using adjusted MoM values along with the woman's maternal age at expected delivery by employing an algorithm for multivariate analysis that uses overlapping log Gaussian distributions.

The individualized risk (patient-specific risk) for any given condition is determined by multiplying the a priori risk for that condition by a likelihood ratio that is calculated using the woman's analyte measurements (i.e., Patient risk = A priori risk × Likelihood ratio). This basic equation is used to calculate patient-specific risk for neural tube defects, Down syndrome, trisomy 18, or any other condition in which the distributions of analytes for the unaffected and the affected population have been determined. The a priori risk is obtained from large epidemiologic studies that ascertain the prevalence for the condition under consideration. For example, a woman's age is used to define her a priori risk for having a fetus with Down syndrome. Furthermore, because of spontaneous fetal loss during pregnancy, age-related risks are higher in the first trimester than at term. The likelihood ratio is determined by calculating the ratio of the heights of the affected and unaffected overlapping population distributions for any specified MoM value. When multiple tests are used, a single likelihood ratio is calculated using the overlapping distributions for each test but with the correlation between tests taken into account. This final risk, rather than the analyte concentrations themselves, is the screening variable upon which clinical decisions are made. The final risk should indicate the trimester for which it was calculated (i.e., 1 in 100 first-trimester risk).

The test performance (detection and false-positive rates) achievable depends on many factors, including (1) the analyte combination chosen, (2) the risk cutoff chosen, (3) the method of dating used to establish gestational age, and (4) the maternal ages of the women being tested. Table 57-3 summarizes the impact of these factors in a hypothetical cohort of women having the maternal age distribution found in the United States in 2000.[171] The table demonstrates how choices of a second-trimester test combination and risk cutoff affect detection and screen-positive rates.

Reporting Individual Results

The maternal serum screening report should contain the following information: (1) the concentrations and MoM values for measured analytes, (2) an interpretation as screen positive or screen negative, (3) the Down syndrome risk estimate (along with risks for other abnormalities such as trisomy 18), and (4) recommendations for possible further action. Physician-provided information should include (1) the specimen collection date, (2) identification as a first or second specimen, (3) the date of LMP or gestational age confirmed by ultrasound, and maternal birth date (or age), (4) relevant pregnancy history, (5) number of fetuses (if known), (6) maternal race, and (7) the presence or absence of preconceptional maternal diabetes requiring insulin therapy.

Second-Trimester Screening Tests

Maternal serum screening began in the 1970s with the use of second-trimester serum specimens for neural tube defects and progressed to include screening for Down syndrome.

Neural Tube Defects

In the early 1970s, Brock and colleagues demonstrated increased AFP concentrations in the amniotic fluid of mothers carrying fetuses affected with an open neural tube defect (NTD, e.g., anencephaly, open spina bifida).[64] Subsequently,

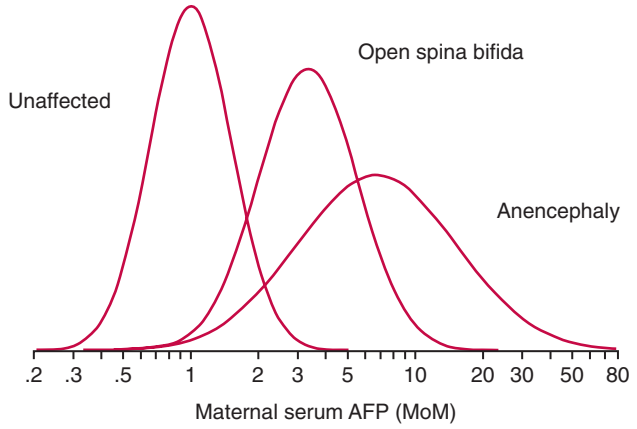

Figure 57-5 Distribution of maternal serum alpha fetoprotein (AFP) measurements in unaffected pregnancies and pregnancies affected with open spina bifida or anencephaly.

it was shown that AFP concentrations also were increased in maternal serum (in the second trimester).[62] Concentrations in serum in affected and unaffected pregnancies overlapped considerably, however, indicating that maternal serum AFP would be useful only as an initial screening test to identify women at high risk for having an affected fetus (Figure 57-5). These women would then need to be referred for diagnostic procedures (e.g., high-resolution ultrasound and, if indicated, amniocentesis for measurement of AFP and acetylcholinesterase in amniotic fluid) to determine whether the fetus had an open neural tube defect. A large collaborative study conducted in the United Kingdom in 1977 showed that maternal serum AFP screening for open neural tube defects in the second trimester of pregnancy was feasible. The final report provided estimates of screening performance in terms of detection and false-positive rates.[390] A family history of neural tube defects in either parent increases the risk that the fetus is affected 5-fold to 15-fold, but more than 90% of all infants with neural tube defects are born to unsuspecting parents who have no recognized risk factor for the disorder.[138,378] Maternal serum AFP testing thus provided a screening method that was available to all women to identify pregnancies at high risk, or to estimate the numeric risk of having a fetus with an open neural tube defect.[391] In the 1980s, the use of maternal serum AFP to screen for open neural tube defects became a standard of care in the United States. The ACOG,[12] the American Society of Human Genetics,[20] and the American Academy of Pediatrics[5] have issued official statements supporting its use.

Optimal screening occurs at between 16 and 18 completed weeks' gestation—a time when the distributions of results for affected and unaffected pregnancies are maximally different, and when time for follow-up studies is adequate. Screening at 15 weeks is acceptable, but screening for open neural tube defects before 14 weeks is difficult to justify.[390,394] Although a patient-specific risk can be used when screening for open neural tube defects,[391] nearly all laboratories define a screen-positive result as AFP at or above a fixed MoM cutoff. The two most commonly used AFP MoM cutoffs in the United States are 2.0 and 2.5 MoM, yielding initial screen-positive rates of 3% to 5% and 1% to 3%, respectively. Observed rates are more likely to be at the lower end of the cited ranges if many pregnancies are dated by ultrasound. This improvement is a result of the finding that increased AFP values attributable to underestimated gestational age, fetal demise, and twin gestation usually will have been identified. The lower initial positive rate at 2.5 MoM is associated with a reduced detection rate for open spina bifida: 70% to 75% as compared with 80% to 85% at 2.0 MoM.[102,390] Nearly all cases of anencephaly are detecting with maternal serum AFP screening.

Down Syndrome

In 1984, a major expansion of biochemical prenatal screening became possible when an association between second-trimester maternal serum AFP and fetal Down syndrome was reported.[247] Maternal serum AFP concentrations are about 25% lower in Down syndrome than in unaffected pregnancies. The association of AFP and Down syndrome was found to be independent of maternal age.[99] Before this discovery, the only available screening test for Down syndrome involved asking a woman her age. Women 35 years or older at the time of delivery would be offered amniocentesis and fetal karyotyping. Down syndrome screening using maternal age is based on the well-documented increase in risk for having a baby with Down syndrome as maternal age increases (see Figure 57-4). The independence of maternal serum AFP measurements and maternal age established that it was possible to offer a screening method to younger women, in whom most cases of Down syndrome occur. Maternal serum AFP screening for Down syndrome also introduced the concept of using risk, rather than analyte concentration, as the screening variable for identifying high-risk women.[99] The effectiveness of maternal serum AFP screening in younger women was subsequently established.[264]

The discovery that a protein produced in pregnancy could be altered in the presence of a fetal chromosomal defect stimulated a search for other substances in pregnancy serum that would have predictive value. Of the many that were examined, two additional analytes emerged quickly as sufficiently discriminatory and independent to be useful additions in screening for Down syndrome in the second trimester. Unconjugated estriol (uE_3),[71] a product of the fetoplacental unit, is about 25% lower in pregnancies with Down syndrome. In contrast, concentrations of CG were found to be about twice as high.[52] In 1988, a method was proposed for combining maternal age with measurements of these three analytes (the triple test) into a single Down syndrome risk estimate.[393] A fourth analyte, inhibin A (inhA), was introduced as a clinical marker for Down syndrome screening in the late 1990s. Concentrations are two times higher in Down syndrome versus unaffected pregnancies.[398] The "quadruple test" is commonly offered and provides approximately 80% detection at a 5% false-positive rate. Two large trials have confirmed its performance.[36,397] Table 57-4 shows general

TABLE 57-4 Conditions Associated With Various Maternal Serum Screening Result Patterns

patterns of first- and second-trimester analytes associated with various disorders.[72,142]

Trisomy 18

Prenatal screening studies have found that fetal trisomy 18 has a distinctive triple marker pattern that is different from the Down syndrome pattern (see Table 57-4).[74] It is, however, the least common of the three disorders considered for second-trimester maternal serum screening. It also is the one that is least compatible with life. For these reasons, a screening program exclusively devoted to the prenatal identification of trisomy 18 is unjustified. However, given that serum analytes are already being measured to screen for Down syndrome and open neural tube defects, an additional interpretation of these analytes to quantify the risk of fetal trisomy 18 is warranted. Because the birth prevalence of trisomy 18 is one tenth that of Down syndrome,[284] the percentage of women identified as screen positive must be correspondingly lower than that for Down syndrome.

In trisomy 18 pregnancies, AFP (median = 0.65 MoM) and uE_3 (0.43 MoM) concentrations are low, but CG concentrations (0.36 MoM) are also very low.[284] A method for trisomy 18 risk calculation was published and is often included in prenatal screening programs.[37,284] The risk-based algorithm showed that at a second-trimester risk cutoff of 1:100, 60% of trisomy 18 pregnancies could be identified, with about 0.5% of women having an initial positive screen.[284]

SLOS

Second-trimester risk assessment for the Smith-Lemli-Opitz syndrome is possible using a multivariate Gaussian algorithm specific for this disorder. The marker pattern in affected pregnancies includes low AFP and hCG (median = 0.72 and 0.76 MoM, respectively), with very low unconjugated estriol (0.21 MoM) concentrations (see Table 57-4).[283] Only pregnancies with a very high risk (1 in 50 or greater) are classified as screen positive for SLOS and are recommended for diagnostic testing by amniocentesis. In this manner, 83% of SLOS cases can be identified at a 0.3% positive rate.[95] It is noteworthy that there is a high rate of fetal loss and other chromosomal (3.3%) or structural abnormalities (5.8%) among false-positive patients.

Other Aneuplodies

Although chromosome disorders other than trisomies 21 and 18 are not part of routine screening, the marker patterns exhibited in maternal serum for some aneuploidies are similar. In particular, hydropic Turner syndrome and triploidy of paternal origin have serum marker patterns resembling that of Down syndrome pregnancy and sometimes are identified as high risk using this algorithm. Similarly, Turner syndrome without hydrops and triploidy of maternal origin are sometimes identified by the trisomy 18 risk algorithm. The pattern for trisomy 13 is variable (see Table 57-4).

Newer Screening Algorithms

Following extensive use of screening tests in the second trimester, new tests have been introduced that use serum collected in the first trimester.

First-Trimester Combined Test

For patients seeking early diagnosis, screening for Down syndrome in the first trimester (10 to 13 weeks' gestation) is available. First-trimester screening involves measurement of maternal serum pregnancy-associated plasma protein-A (PAPP-A) concentration, which is relatively low in Down syndrome pregnancy (median = 0.4 to 0.5 MoM between 10 and 13 weeks), and CG (free beta subunit or total) concentration, which is relatively high in Down syndrome (median = 1.7 to 2.2 MoM).[287] In combination with maternal age, these two serum tests yield a detection rate of 60% at a 5% false-positive rate.[172] A third marker used to improve first-trimester screening performance is the ultrasound measurements of nuchal translucency (NT), the subcutaneous space between the skin and the cervical spine; this marker has been shown to be increased (about 2.0 MoM) in fetuses with Down syndrome.[266,368] Increased NT measurements are also a nonspecific finding for many fetal structural abnormalities,[404] and therefore are useful only as a screening test.[281] NT measurement alone detects 60% or more of Down syndrome cases at a 5% screen-positive rate, making NT the best single screening test described to date.[395]

However, neither ultrasound findings nor serum tests in the first trimester have sufficient predictive power to be used alone. In 2003 and 2005, two independent large multicenter trials demonstrated that a combination of NT and serum tests (the combined test) was comparable or slightly better than the second-trimester quadruple test for Down syndrome screening, detecting about 85% of cases at a 5% false-positive rate. These trials were critical in proving the efficacy of first-trimester screening because they accounted for fetal losses between the first and second trimesters. The National Screening Committee of the U.K. National Health Service advocates use of the combined test for Down syndrome prenatal screening.[258]

Reports have described trisomy 18 detection using first-trimester combined screening.[382] The pattern of markers in affected pregnancies consists of an increased NT measurement (median about 3.2 MoM), with reduced PAPP-A (0.18 MoM) and CG (0.28 MoM) in the first trimester.[382] Estimates for the performance of first-trimester combined testing in the detection of trisomy 18 are varied, likely as the result of a high fetal loss rate and difficulties in complete ascertainment. The most optimistic estimates suggest that 90 to 100% of trisomy 18 cases can be detected, with only 0.2 to 2.0% being called screen positive,[194,296] but a large multicenter study with more comprehensive outcome tracking suggests that detection rates are closer to 80% for a 0.3% positive rate.[59]

Although first-trimester screening has obvious advantages, it also has limitations. First, unlike the second-trimester screening test, detection and false-positive rates are dependent on the gestational week of testing, as shown in Table

TABLE 57-5 Expected Down Syndrome False-Positive Rates (FPRs) for a Detection Rate of 85% During the First Trimester

Test Combinations*	Weeks' Gestation 11	12	13	11 to 13 Combined

57-5. Screening performance of PAPP-A and CG measurements improves with advancing gestational age within the first trimester, while the performance of NT sonography decreases. If these markers are used simultaneously, first-trimester screening performance is optimal at 12 to 13 weeks' gestation. Second, immunoassays for PAPP-A and the free beta subunit of CG are currently available on a limited basis in the United States because they have not been cleared by the U.S. Food and Drug Administration (FDA). This has been a particular difficulty for the free beta CG assay—a problem that has been addressed in some laboratories by the use of total CG immunoassay during gestational weeks 11 to 13 as an alternative.[73] Furthermore, to be reliable, NT measurements must be performed at specialized referral centers that employ sonographers who have undergone rigorous training and participate in ongoing quality control programs. Routine office ultrasound is unsuitable for obtaining NT measurements. Therefore, access for women in some rural areas is limited. NT measurements are relatively expensive, as first-trimester ultrasound examinations are not routine, and third party payers may be reluctant to reimburse these costs. The ACOG[12] recommends that first-trimester screening should be offered only with appropriately trained sonographers, a quality assurance program for NT, and access to diagnosis by chorionic villus samplings (CVS). Last, routine screening for open neural tube defects using maternal serum AFP would still need to be performed, as such screening is not effective in the first trimester.[390,394]

Adding First- and Second-Trimester Markers Into a Single Integrated Screening Test

The integrated test takes advantage of first- and second-trimester markers and avoids most of the limitations of stand-alone first-trimester screening.[402] With this approach, measurements of NT and PAPP-A are made in the first trimester but are not interpreted or acted upon until testing in the second trimester is complete. In the second trimester, a serum is drawn and a quadruple test performed. Results from all six tests (NT, PAPP-A, AFP, uE_3, CG, and inhA) are then combined into a single risk estimate. This approach detects 85% of Down syndrome cases with only a 1% false-positive rate.[402] Studies involving more than 47,000 and 38,000 pregnancies at multiple centers, obtained results consistent with this estimate.[237,400]

Given the low false-positive rate of the integrated test, it may be considered the safest maternal serum screening test. Because fewer amniocenteses are needed, fewer fetal losses occur per Down syndrome case diagnosed. The integrated test has been shown to be a cost-effective approach to Down syndrome screening, again on the basis of fewer costly diagnostic tests and affected liveborns.[399] Most of the cost in integrated screening comes from the NT ultrasound. Although NT alone is the best univariate screening marker, integrated screening can be offered effectively and at a lower cost by using a modified test based only on serum markers (serum integrated). Maternal serum PAPP-A concentrations are measured at 10 to 13 weeks and combined with a second-trimester quad test for a five-marker screening panel. The serum integrated test gives 85% detection of Down syndrome cases with about a 4% false-positive rate. The relative performance of first-trimester, second-trimester, and integrated screening tests is shown in Figure 57-6.

An alternative approach to integrated screening is the sequential integrated test, in which women at the very highest risk for Down syndrome pregnancy (e.g. 1 in 25 or higher) after the first-trimester phase are alerted and recommended for diagnostic testing.[289,401] All remaining women (≈98%) proceed to second-trimester blood collection for a full integrated risk analysis. The advantages of this approach are that very high risk women are afforded the opportunity for early diagnosis, and most patients have the safest and most effective screening strategy. The sequential integrated test offers an 85% detection rate with a 2 to 3% false-positive rate. This assumes that all patients have a first-trimester NT scan because a serum PAPP-A alone in the first trimester is not sufficient for calculation of interim risk. Contingent screening has been proposed, whereby patients at very high and at very low risk receive results in the first trimester, while those with an interim risk go on to have the second part of the full integrated screening test.[289,401] It should be noted, however, that this protocol has yet to be evaluated using an intervention trial.

Follow-up Testing for Women With Screen-Positive Results

Recommended follow-up testing depends on the types of positive results obtained.

Neural Tube Defects

Women who have a positive screening test result for an open neural tube defect should be offered genetic counseling and further testing. A low-resolution ultrasound examination

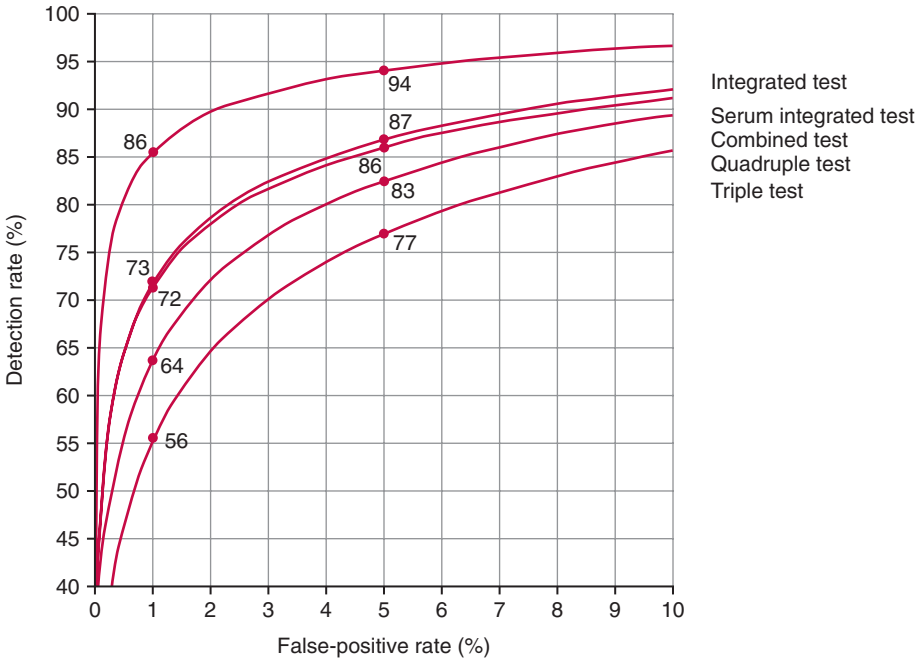

Figure 57-6 Receiver operating characteristic curves for tests used to screen for Down syndrome. *(Reprinted with permission from Wald NJ, Rodeck C, Hackshaw AK, Rudnicka A. SURUSS in perspective. Semin Perinatol 2005;29:225-35.)*

may verify gestational age and identify other possible reasons for the increased AFP test results (e.g., inaccurate gestational dating, recent fetal demise, twins). Patients who have an unexplained high maternal serum AFP result are offered high-resolution ultrasound, amniocentesis for measurement of amniotic fluid AFP and acetylcholinesterase (AChE), or both.

Compared with maternal serum, the distribution of amniotic fluid AFP concentrations in pregnancies affected by open neural tube defects is far more separated from unaffected pregnancies.[388] However, amniotic fluid AFP measurements are not by themselves diagnostic because of rare false-positive results. If the amniotic fluid is contaminated with even a small amount of fetal blood, as many as 2 to 3% of results can be falsely positive.[388] All abnormal amniotic fluid AFP results must be confirmed by measurement of amniotic fluid AChE. The combination of amniotic fluid AFP and AChE is virtually diagnostic for an open neural tube defect.[315,388]

High-resolution ultrasound will almost always confirm a chemical diagnosis of a neural tube defect. Anencephaly is readily identifiable, and ultrasound diagnosis of open spina bifida is considerably enhanced by the presence of two cranial signs (known as fruit signs) resulting from the Arnold-Chiari malformation associated with this defect.[110,267] The first sign is a "pinched" skull in the frontal region, resulting in a "lemon" shape compared with the normal egg shape. The second sign is a reduction in the transverse diameter of the cerebellum, causing the two cerebellar hemispheres to assume a bow shape—the "banana sign." Ultrasound diagnosis of open neural tube defects is now so reliable that it is sometimes used for diagnosis in women with elevated maternal serum AFP without waiting for amniotic fluid measurements.

Down Syndrome

Women who have a positive screening test result for increased risk of Down syndrome are usually referred for genetic counseling and further testing. A low-resolution ultrasound examination may be offered as a way to verify gestational age and to identify other possible reasons for the positive test result. One of the most common reasons for increased Down syndrome risk is overestimated gestational age. Up to one third of women with positive second-trimester Down syndrome screening results who are dated by the last menstrual period will be found to be too early in their pregnancies for reliable screening (<15 weeks) or will be reclassified as low risk after ultrasound revision of gestational age.[173] Women who are still at increased risk after the ultrasound examination should be offered amniocentesis to obtain fetal cells for karyotyping. Although some second-trimester ultrasound findings are associated with Down syndrome (e.g., nuchal fold and shortened femur and humeral length), these findings are not diagnostic.[342] The only way to diagnose Down syndrome is via fetal karyotype. However, the benefits of accurately diagnosing a chromosome abnormality in gestation must be weighed against the potential for harming a normal fetus during amniocentesis. This invasive procedure carries a small but real risk of harming the fetus or causing spontaneous abortion. Even amniocentesis performed by an experienced obstetrician using ultrasonography for guidance may have a procedure-related rate of fetal loss as high as 1 in 200.[347] Given

that about 1 in 30 women with an initial screen-positive test result (high risk) will have a fetus with a chromosome abnormality, the offer of the invasive procedure is justifiable.

Women who have a screen-positive result in the first trimester may be offered CVS to diagnose Down syndrome. This procedure is performed between the 10th and 12th weeks, carries a slightly higher risk of fetal loss than amniocentesis,[366] and is not available to patients in some geographic regions.

Trisomy 18

In contrast to screening protocols for open neural tube defects and Down syndrome, a dating ultrasound is not recommended as the first step after a finding of increased risk of trisomy 18. The second-trimester serum marker pattern is not consistent with incorrect gestational dating, and amniocentesis should be offered.[131,286] A high proportion of fetuses with trisomy 18 will have abnormal but nondiagnostic second-trimester ultrasound findings (e.g., heart defects and clenched fists).[32] CVS may be offered to patients at high risk of trisomy 18 based on first-trimester screening results.

SLOS

Patients at risk for SLOS should be offered genetic counseling to discuss the risks and benefits of diagnosis by amniocentesis. High amniotic fluid concentrations of the precursor 7-dehydrocholesterol are diagnostic of the disorder.[1]

Adjustments for Factors That Influence Analyte Measurements

Prenatal screening for both open neural tube defects and Down syndrome is optimized when each woman's analyte concentration is compared with those of other women (the reference group) who are "similar" to her in many respects.[169] In addition to gestational age, this "similarity" extends to other factors that have been shown to affect analyte concentrations, including (1) maternal weight, (2) race, (3) insulin-dependent diabetes (IDD), and (4) multiple pregnancy. Taking into account these factors enhances the accuracy of the interpretation.

Maternal Weight

As maternal weight increases, the average concentration of analyte values decreases, because a fixed amount of analyte is diluted in an increased maternal blood volume. For example, heavier women have, on average, lower AFP values and are less likely than lighter-weight women to be screen positive for neural tube defects. Without taking maternal weight into account, screening is less effective in heavier women because their MoM values are inappropriately low. The importance of adjusting AFP MoM values for weight is reinforced by studies showing that heavier women have about a twofold to fourfold increased risk for open spina bifida.[335,403] No association between maternal weight and Down syndrome has been reported. The weight effect is also significant for CG, inhA, and PAPP-A, but less so for uE_3. Maternal weight is taken into account for all serum markers by adjusting each woman's MoM values by a factor corresponding to the expected MoM value (Figure 57-7) for women with her weight. These factors are empirically derived from the screened population in a manner that is similar to deriving median analyte concentrations for each gestational age. Optimally, each laboratory should derive its own maternal weight adjustment factors for each analyte, because the average maternal weight may differ from that seen in other laboratories. These adjustment factors should be applied only over the maternal weight range in which they have been shown to be appropriate. For example, if few or no data are available to derive adjustment factors for women weighing more than 300 pounds, then the laboratory should be careful in extrapolating factors to these women from data on women of lower weight. Laboratories should limit the range of adjustment using upper (and lower) truncation limits. If a woman's weight is outside these limits, adjustment should be applied as if the woman were at the respective limit. An effective model for all analytes is a linear reciprocal model. Maternal weights are stratified into weight groups and are regressed against the reciprocal of maternal weight. This model and its application have been described in detail elsewhere.[169,263] Distributions of maternal weight vary within each racial group, with Asian women tending to have lower maternal weights than Caucasians, and with African Americans weighing more. It is optimal to apply adjustment equations for each racial group to correct marker concentrations for weight.

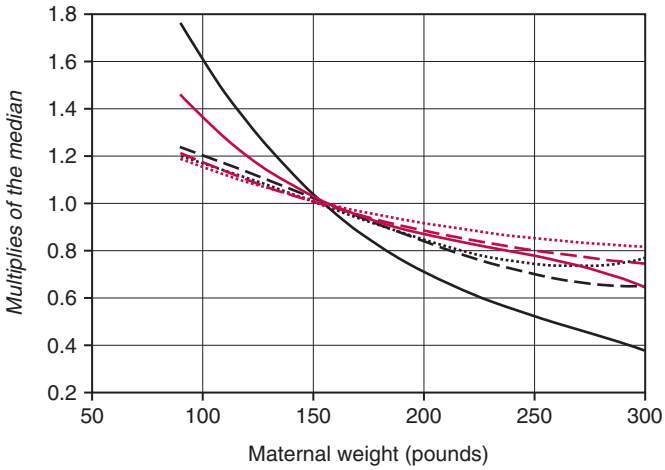

Figure 57-7 The relationship of AFP, uE_3, CG, inhA, and PAPP-A [expressed as multiples of the median (MoM)] and maternal weight. The horizontal line at 1.0 MoM is the value found for a woman of average weight. *Red solid line,* AFP; *red dashed line,* inhA; *red dotted line,* uE_3; *black solid line,* PAPP-A; *black dashed line,* first-trimester CG; *black dotted line,* second-trimester CG.

Maternal Race

For second-trimester markers, African American women have maternal serum AFP and CG concentrations that are 10 to 15% higher than those found in Caucasian women.[169] InhA concentrations are about 8% lower in African Americans,[406]

and uE_3 concentrations are not different in these two populations. In the first trimester, serum PAPP-A (1.35 to 1.57 MoM) and CG (1.11 to 1.21 MoM) concentrations are significantly increased in African American women.[207,353,356] For other racial/ethnic groups, data are limited or small effects have been noted on marker concentrations; therefore routine adjustments are not generally performed.

Adjustment for these differences can be accomplished in two ways. The first is to calculate an MoM value for African American women using medians derived from the Caucasian population, and then to divide the resulting MoM by a factor corresponding to the ratio between values in the two populations (i.e., 1.10 to 1.15). For example, if an African American woman has a maternal serum AFP MoM of 1.60 calculated using median values from the Caucasian population, her adjusted MoM is 1.45 (1.60/1.10). The second approach is to calculate a separate set of medians using values measured on the African American population.

Strong evidence suggests that the birth prevalence of open neural tube defects in African American women is half or less than that in Caucasian women from the same geographic region.[156] Thus, at any given maternal serum AFP MoM, an African American woman has half the risk of a Caucasian woman of having a pregnancy affected by an open neural tube defect. Limited information is available on AFP concentrations in African American women with an open neural tube defect, but what is published indicates that screening in this population should be equally effective. The prevalence of neural tube defects has declined since the practice of folic acid fortification was introduced, particularly in African American women.[80] Data from California suggest that Hispanic women have the highest rates of NTD (0.112%) as compared with Caucasians (0.096%) and Black or Asian women (0.075%).[132]

Insulin-Dependent Diabetes

Maternal serum AFP values in women who require insulin before pregnancy (type 1) have been reported to be systematically lower by about 20% (0.88 MoM).[187] Women with type 2 diabetes, taking insulin or other oral agents, or on dietary restriction before pregnancy, also show reduced second-trimester maternal serum AFP concentrations.[374] However, controversy is ongoing regarding the need for adjustment of AFP concentrations in diabetic women when weight correction has been applied.[124] Some studies show that reduced AFP concentrations persist in diabetic women even after weight adjustment[374]; others suggest that reduced AFP concentrations can be completely explained by weight effects.[124] Debate also continues regarding whether the degree of glycemic control has an impact on maternal serum AFP concentrations in diabetic mothers.[327]

Second-trimester concentrations of uE_3 were also significantly reduced (0.95 MoM) in women with preexisting diabetes and may warrant adjustment. In contrast, alterations of second-trimester CG and inhA concentrations are small, and whether or not they are taken into account will have little impact on the resulting Down syndrome risk. Similarly, first-trimester PAPP-A and CG concentrations were not significantly altered in women with IDD.[214]

No compelling evidence indicates that the rate of Down syndrome births in women with IDD is substantially different from that in the general population.[189] However, evidence suggests that birth prevalence of open neural tube defects is higher by up to a factor of 5.[2] Thus at a given AFP MoM concentration, women with IDD are at substantially higher risk of open neural tube defects than the general population. This can be taken into account by lowering the AFP MoM cutoff from, for example, 2.0 to 1.5. It is not possible to define the associated detection rate for diabetic mothers because no large series of maternal serum AFP measurements in IDD women with a fetus affected with an open neural tube defect have been published.

Twin Pregnancy

Maternal serum AFP concentrations in twin pregnancies are about twice the concentration found in singleton pregnancies (i.e., ≈2.0 MoM).[169] Among singleton pregnancies with open spina bifida, the median serum AFP MoM is about 3.5.[390] Thus the expected maternal serum AFP in the average twin pregnancy affected with open spina bifida is thought to be around 4.5 MoM (1.0 MoM contributed by the unaffected fetus, and 3.5 MoM from the fetus with open spina bifida). Screening performance in twin pregnancies therefore will not be as effective as in singleton pregnancies because the AFP distributions are less separated. Although most affected twin pregnancies are discordant for open neural tube defects, if both twins are affected (seen in about 5% of affected twin pregnancies), screening performance can be expected to approach that in singleton pregnancies.

Calculation of Down syndrome risk requires that the distribution of analyte values for all tests in both unaffected and affected pregnancies is known. These distributions are well defined for AFP, uE_3, CG, inhA, and PAPP-A in singleton pregnancies; thus reliable risks can be calculated. The distributions of these analytes also are available for twin pregnancy unaffected by Down syndrome; the median MoMs in unaffected twin pregnancy for AFP, uE_3, CG, inhA, and PAPP-A are about 2.0, 1.7, 1.9, 2.0, and 1.8, respectively.[169,214,356] Fewer data are available for concentrations of these analytes in twin pregnancies affected with Down syndrome. A further complication is that in approximately one third of pregnancies, both twins will be affected (monozygotic), and in two thirds of pregnancies, only one twin will be affected (dizygotic). Screening will be less effective when only one twin is affected. Reports suggest that first-trimester serum marker concentrations differ in monozygotic and dizygotic twin pregnancies, with lower values in the former group.[226,355] Another difficulty is that the prevalence of Down syndrome is not well defined in twin pregnancies. Based on the rate of monozygotic and dizygotic twins, the prevalence of Down syndrome would be predicted to be 1.67 times higher in twin pregnancies. However, published data indicate that the prevalence of Down syndrome in twin pregnancies is actually similar to that found in singleton pregnancies.[117,143]

Given these limitations, calculation of only an approximate risk (sometimes called a *pseudorisk*) for twin pregnancy is possible.[262] This is accomplished by dividing the MoM value for each analyte by the corresponding median found in unaffected twin pregnancies. The twin pregnancy risk is then computed in the same way as for singleton pregnancies. If fetus-specific nuchal translucency measurements are available, adjusted serum marker results are used with *each* NT value to get a fetus-specific risk. The overall risk for the pregnancy is then calculated by adding the risk for each fetus in a dichorionic (presumed dizygotic) pregnancy, and averaging them for a monochorionic (presumed monozgotic) pregnancy. The resulting pseudorisk is compared with the same risk cutoff used for women with singleton pregnancies to identify twin pregnancies as screen positive. This twin screening protocol will (1) correctly rank pregnancies from highest to lowest risk, and (2) yield a screen-positive rate similar to the rate found for singleton pregnancies at any given screening cutoff. The Down syndrome pseudorisk, however, may not be correct. Screen-positive women with twin pregnancies can be informed that their test results place them in a high-risk group, but that their actual risk is uncertain. Interpretation of risk for triplets and higher gestations is not recommended because of limited available data. Additional factors that need to be considered when such screening is offered are the increased difficulty and fetal loss associated with multiple needle insertions required during amniocentesis, and loss of the unaffected twin should an affected twin be identified and selectively terminated.[123]

Pregnancies Achieved by Assisted Reproductive Technologies

As women are choosing pregnancy at more advanced chronological ages, the use of assisted reproductive technologies (ART), such as in vitro fertilization (IVF), for conception is increasing. Previous studies have shown that women who achieve pregnancy by IVF are about twice as likely to have a positive result after second-trimester Down syndrome screening than are women who achieve pregnancy spontaneously.[140] The increased rate is avoided with adjustment of certain MoM values. In particular, concentrations of uE_3 tend to be reduced (0.9 MoM), and CG and inhA increased (1.1 to 1.2 MoM), in pregnancies achieved by IVF.[140,212] Correction of these MoMs restores an appropriate screen-positive rate. Pregnancies achieved by intrauterine insemination, with or without ovulation induction, show a similar trend in marker concentrations; however, this reproductive technology is less often reported to screening programs and therefore is difficult to take into account for risk analysis. In contrast, IVF pregnancies involving donation of oocytes have a unique marker pattern with relatively elevated maternal serum AFP and inhA concentrations. Because these results provide opposing effects on risk, screen-positive rates are not increased and adjustment is not needed.[212]

The effects of ART on first-trimester screening markers are less pronounced. Although serum PAPP-A and CG concentrations are slightly altered in IVF pregnancies[212] (PAPP-A = 0.9 MoM; CG = 1.1 MoM) relative to spontaneously achieved pregnancies, most studies show that these changes are not sufficient to lead to increased screen-positive rates.[212,415] Adjustment of first-trimester screening markers for ART pregnancies is less critical than adjustment of second-trimester markers and, if done, would provide only a minimal improvement in screening performance. Expected and observed screen-positive rates in various ART pregnancies are shown in Table 57-6.[212]

Use of Epidemiologic Monitoring in Quality Control

In prenatal screening, the interpretative unit for each analyte is the MoM, which takes into account variables such as gestational age, maternal weight, race, and other factors. Expressing these results in MoMs allows the calculation of a patient-specific risk for Down syndrome. One of the most common causes of poor laboratory performance is the use of incorrect median values, either because those values are inappropriate for the kit being used, or because systematic

TABLE 57-6 Screen-Positive Rates (%) Observed (95% Confidence Intervals) and Expected for Assisted Reproductive Technologies

Type of Assisted Reproductive Technology	*N*	First Trimester		Second Trimester	
		Observed	Expected	Observed	Expected
In vitro fertilization with ovulation induction	277	8.6 (5.3 to 11.9)	5.5	20.2 (15.4 to 25.0)	14.7
Intrauterine insemination with ovulation induction	323	3.4 (1.4 to 5.4)	4.2	21.2 (16.6 to 25.7)	11.9
Intrauterine insemination without ovulation induction	247	6.1 (3.1 to 9.1)	4.3	19.1 (14.1 to 24.0)	12.3
In vitro fertilization with ovulation induction and egg donation	59	3.4 (0.0 to 8.0)	2.5	12.3 (3.8 to 20.8)	7.4
In vitro fertilization with egg donation	56	1.8 (0.0 to 5.3)	1.0	7.4 (0.4 to 14.4)	3.9

shifts in assay values have occurred. Poor analytical performance also occurs when an assay is nonspecific or relatively inaccurate. Ensuring that median values (and by extension, MoM values) are accurate is one of the most important responsibilities of the screening laboratory. The following discussions are adapted from Knight and Palomaki,[202] a publication that discusses in detail the process of epidemiologic monitoring.

Definition of Epidemiologic Monitoring

A powerful method for evaluating and monitoring the appropriateness of medians is epidemiologic monitoring. This process involves gathering data from the screened population to calculate detection (proportion of affected pregnancies with positive test results) and screen-positive (proportion of screened pregnancies with a positive test result) rates. These rates are then to be compared with expectations based on the maternal age distribution of the population studied. Obtaining a detection rate is difficult because complete ascertainment of all pregnancy outcomes is required, and it can take years before a sufficient number of affected pregnancies occur to allow reliable estimates. In practice, the screen-positive rate is used for epidemiologic monitoring because a reliable estimate can be calculated in a short time, and it is not necessary to have outcome information. For prenatal screening, the positive rate is defined as the proportion of women with test results falling at or above a specified AFP MoM (for open neural tube defect screening), or a specified risk cutoff (Down syndrome screening). These rates are in fact similar to false-positive rates because few screen-positive individuals have true-positive results (i.e., they do have an affected fetus). For this reason, the term *initial positive rate (IPR)* has been suggested, because it more accurately describes what is being calculated. The IPR can be used to assess whether medians are appropriate, because it will be shifted upward or downward if medians are incorrect for the population being screened. Further, once the IPR is shown to be within acceptable limits, continuous monitoring can help detect shifts in assay values.

Establishing Assay-Specific and Population-Specific Median Values

Another important responsibility of the prenatal screening laboratory is to establish kit-specific and population-specific median values for each analyte used in screening, or to show that median values obtained from another source are appropriate. Relatively small errors in median values have a disproportionate impact on both the accuracy of the calculated risk and the number of women identified as screen positive. Values measured on the same patients and the same proficiency testing samples have been known to differ among methods by 5 to 200%, depending on the analyte measured.[92] Median values therefore are not directly transferable between reagent sets from different methods. Median values sometimes differ among laboratories even when the same method is employed. This difference is caused by such factors as the reliability of gestational dating, race, maternal weight, and even apparently subtle differences in assay instrumentation, or changes in manufacturer lot numbers of reagents or calibrators.[122]

Median values must be routinely monitored and updated as necessary. Median values provided in package inserts are not acceptable for many of the reasons already given. It has been recommended that median values should be established using at least 100 values for each week of gestation in the screening period. In practice, however, obtaining 100 serum samples for each gestational week is very difficult even for large laboratories. Given these constraints, the following strategies are recommended for obtaining reliable median values, categorized according to whether a laboratory is implementing a screening test for the first time, or is updating an existing set of median values.

Two alternatives are available when a laboratory is establishing median values for the first time. The first and optimal method is to obtain measurements on 300 to 500 patient specimens using the assay selected for screening. Establishing that all of these samples come from unaffected singleton pregnancies is not necessary, because the prevalence of conditions that produce abnormal values (e.g., twins, fetal demise, open fetal defects) is small and will have minimal impact.[169] Data are used to derive median values for each completed week of gestation. Appropriate weighted regression analysis is then used to fit the observed data. The regression equation is used to predict "smoothed" medians for each week of gestation. Usually the median value is found at each completed week and is regressed against the average gestational age for that week. This technique helps reduce the effects of outliers. Weighting takes into account the reliability of these summary estimates and usually is based on the square root of the number of samples observed at each week.

Measurements of the concentrations AFP, uE_3, and PAPP-A increase by a constant proportion—about 15% per week for AFP, 25% per week for uE_3 measurements, and 50% for PAPP-A. A log-linear model best fits this relationship [log of the measurements (y-axis) is regressed against gestational age (x-axis)]. The regression model for CG versus gestational age fits an exponential model similar to that used for radioactive decay. Measurements of inhA are relatively flat, but experience has shown that a cubic model fits the data, with a minimum found between 16 and 18 weeks' gestation.[396] Figures 57-8 to 57-11 are graphical representations of weighted regression equations and resulting smoothed medians for the second-trimester markers (the legends contain the respective median regression equations). The data are provided in Table 57-7. Figure 57-12 shows medians and weighted regression lines for first trimester PAPP-A and total CG.

Some laboratories use "day-specific" medians rather than weekly medians where a different median value is used for each day of pregnancy. Although individual pregnancies cannot be reliably dated to within 1 day, a consistent day-by-day change in analyte concentrations is noted when data from a group of pregnant women is observed. Table 57-8 shows observed and regressed medians for uE_3 for a group of

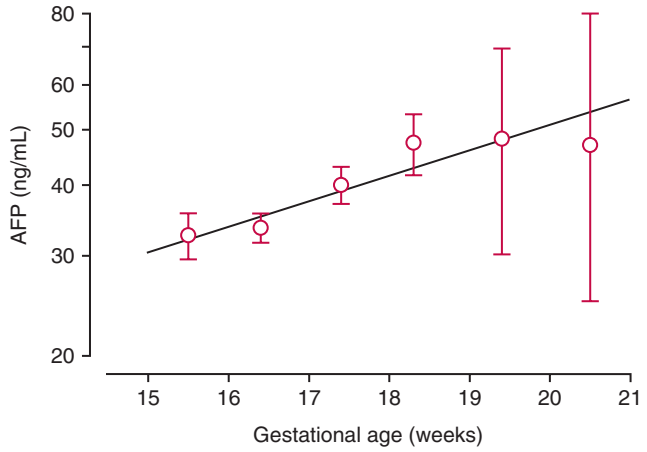

Figure 57-8 **Computation of median values for maternal serum alpha fetoprotein (AFP) in the second trimester. Figure 57-12 Typical median values for maternal serum pregnancy associated plasma protein-A (PAPP-A) and total CG in the first trimester. The observed average gestational age is plotted on the horizontal axis and the median of that week's PAPP-A or total CG measurements on the vertical logarithmic axis. The PAPP-A median = $10^{(1.4633 + 0.144501 \times \text{weeks})}$. The total CG median = $385.1 \times 0.98069^{\text{days}}$.

ultrasound-dated women in their 17th week of gestation. The observed median concentrations clearly increase during that week. The regressed median for 16 weeks, 0 days, is quite different from the median for 16 weeks, 6 days. If weekly medians were to have been used instead, all of these samples would have been interpreted against a single median—≈0.74 ng/mL (0.74 µg/L).

An acceptable alternative for the generation of new median data is to identify an established laboratory that is willing to share its reliable median values. Then, 25 to 50 specimens are assayed at each laboratory. These specimens are selected so that their results span the analytical measurement range. The two sets of values are then compared using linear regression analysis (after appropriate transformations) to establish the relationship between the two assays. The regression equation is then applied to the reliable set of median values to derive a set of medians appropriate for the new laboratory. These median values are used temporarily until values from 300 to 500 patients are available for the analysis provided earlier.

Laboratories must update existing median values in several situations. Significant differences in values on the same patient specimens are common when a new lot of the reagents or reagents from a different manufacturer are used. In this situation, the relationship between new and old methods is established by regression analysis of values measured on the same patient specimens. If a periodic adjustment is required, the laboratory should carefully choose the characteristics of the population to be used (e.g., race, method of dating, time period) and should verify that the assay has been providing consistent results over the time period of interest. This is done by routinely monitoring the median MoM over time (epidemiologic monitoring), as is discussed in greater detail later in this chapter. Resulting data are then analyzed, as described previously.

Epidemiologic Monitoring of Open Neural Tube Defect Screening

In maternal serum AFP screening for open neural tube defects, the IPR is the proportion of women with values above the specified MoM cutoff. For example, at a screening cutoff of 2.5 MoM, IPRs should be 1 to 3%. When new medians are implemented, the IPR can be used to determine whether the medians are appropriate by comparing the expected with the observed IPRs. If the IPR falls outside the expected range, it is possible that the medians are incorrect for the assay being used or for the population being screened. For example, if the IPR at a cutoff of 2.5 MoM is 5%, median values may be too low, resulting in too many high MoMs and too many women having screen-positive results.

Once the IPR is shown to be within an acceptable range, ongoing monitoring of this rate serves as a check on shifts in assay calibration caused by changes in (1) kit lots, (2) reagent deterioration, (3) poor technical performance, and (4) other factors. Simultaneous monitoring of the IPR and the results of quality control samples can facilitate identification of shifts in assay values. If, for instance, the IPR at a 2.5 AFP MoM cutoff increases from 2 to 4%, and at the same time some or all of the values of quality control (QC) samples shift significantly upward by 10% or more, the change is consistent with an upward shift in assay calibration. The IPR increases when assay values increase, because individual AFP values are interpreted by using medians generated from data gathered in the past. In the example given previously, it may be necessary to calculate new medians or to adjust existing median values to take into account the assay shift.

It is difficult to establish an absolute rule as to how large a change in the IPR is sufficient to warrant recomputing medians. Factors other than the assay can affect the IPR. For example, a significant increase in the number of pregnancies dated by ultrasound will reduce the IPR, because incorrectly dated pregnancies will be identified before the AFP test is done. However, consider that an upward shift in AFP values of just 10% can increase the IPR by more than 50% (e.g., from 2 to 3%) with little gain in detection. In effect, more interventions (ultrasound examinations or amniocenteses or both) will be required to detect each case of neural tube defect. Therefore, if a change in the IPR of 50% or more occurs simultaneously with an identifiable shift in assay values of 10% or more, medians need to be recalculated. Laboratories may wish to have stricter warning limits (e.g., shifts of 25% or more in the IPR occurring simultaneously with a change of 7% or more in quality control samples). When these rules are applied, enough values should be used to ensure that a reliable IPR can be calculated (generally 300 to 500 values will ensure reliability) and that observed changes are statistically significant. Further, the change should occur over several kit lots. Otherwise the laboratory may be tracking random error. The IPR can also be calculated using a moving window to improve reliability. For example, consider a laboratory that screens 300 women per month. In addition to calculating a monthly IPR, the laboratory could calculate a cumulative 3-month moving window by adding the current month's data and dropping data from the oldest month. The actual time period for both the individual and a cumulative moving window will be determined by how many samples are screened per unit time by any given laboratory.

Epidemiologic Monitoring of Down Syndrome Screening

In screening for Down syndrome, the IPR is the proportion of women with a risk at or above the cutoff. In contrast to neural tube defect screening, the IPR for Down syndrome screening is influenced by each of the analytes used in the risk calculation. Therefore, monitoring the IPR does not provide information on which assay(s) might be responsible when an inappropriate IPR is obtained. Consequently, it is necessary to monitor each assay separately. Individual monitoring of each assay can be accomplished according to the following rationale. When individual MoM values are calculated for each patient using gestational age–specific medians, MoM values can be analyzed collectively without regard for the gestational week. If the medians are appropriate, the resulting distribution of MoM values will have a grand median MoM of 1.00. The center of the distribution is typically expressed as the median, rather than the mean, because MoM distributions are not Gaussian on the linear scale.

Initial application of the grand MoM is done to ensure that when medians are first implemented, they are appropriate for the assay and the population being screened. This is accomplished by calculating the grand MoM using values from 300 to 500 individuals screened after the new set of medians is implemented. The grand MoM should be 1.00, within statistical limits. A convenient approach is to plot the grand MoM values on a graph, thus facilitating the detection of trends. IPR observations can be plotted on the same graph. If the IPR begins to trend in a positive or negative direction, the grand MoM for each assay can be examined to determine whether one of the analytes is paralleling the IPR change. If a significant change in one of the assays has occurred, corrective action should be taken (e.g., recalculating medians). For example, suppose the IPR shows a significant upward trend (e.g., from 6 to 9%), and over the same time period, the median MoM of the uE_3 assay significantly decreases (e.g., from 1.03 to 0.91). Because low uE_3 values are associated with increased risk for fetal Down syndrome, it is probable that the change in the uE_3 assay is responsible for the increase in IPR. The next step would be to examine quality control specimen values to determine whether a corresponding downward shift in values has occurred. If a shift has occurred, it is appropriate to recalculate and implement a new set of uE_3 medians using data collected after the time when the change in the uE_3 assay occurred (or to apply an adjustment factor to the old medians). A simultaneous change in two assays can complicate monitoring because the IPR might not change if the shift in one analyte value increases risk and the shift in the other analyte decreases risk. Simultaneous monitoring of the IPR and the median MoM for each analyte is recommended. IPRs should be calculated only when sufficient patient values are available (typically, 300 to 500 samples) to ensure a statistically reliable rate. Further, a single IPR or median MoM that

deviates from expected should serve only as a warning to examine quality control data more closely.

Laboratories need to have an action limit in place to determine how much variability is to be allowed in the grand MoM. To accomplish this, one should consider the impact on the Down syndrome detection rate and the IPR of a 10% downward shift in uE_3 values (grand MoM of 0.90). This is simulated by recalculating MoM values after assay values are artificially shifted down by 10%, followed by mathematical modeling of the detection rate and the associated IPR. Such an assay shift effectively changes the MoM for any given sample, because current assay values are interpreted using reference data collected in the past. When uE_3 values shift downward by 10%, the detection rate increases only slightly from 59 to 62%. However, the IPR increases from 4.8 to 6.7%—a 40% increase. Thus, what might be viewed as a small shift in assay values has a large impact on the IPR, with little corresponding gain in detection. Relatively large changes in the IPR accompanying small shifts in assay values are one of the primary reasons for closely monitoring assays to ensure that the amniocentesis referral rate is maintained within reasonable limits. Given these facts, screening laboratories should consider important, as a minimum, a consistent deviation of 10% from 1.00 MoM (range, 0.90 to 1.10). Laboratories may wish to consider setting up stricter warning limits, such as 7% (assuming that this percentage is based on sufficient numbers of samples to yield statistically significant results). With this limit, median MoM values outside the range of 0.93 to 1.07 would be considered sufficiently deviant to warrant further investigation to determine whether a problem exists.

Although the IPR for laboratories screening for Down syndrome using multiple tests is generally about 5% in an unselected pregnancy population, it may be affected by various factors (other than incorrect medians), including the type of tests used, the screening cutoff chosen, and the maternal age distribution of the screened population. For example, if screening is applied primarily to older women, the IPR will be substantially higher, because older women are collectively more likely to be screen positive as a result of their higher age-specific risks. For example, if the triple test is being used to screen women age 35 and older at a term risk cutoff of 1:250, approximately 25% of women will be screen positive.[170] The method of gestational dating will also affect the IPR. Laboratories with a high percentage of pregnancies dated by the first day of the LMP will have a higher IPR than do laboratories where most gestational ages have been provided from ultrasound measurements because there is more variability in the accuracy of dating a population by LMP than by ultrasound.[173]

Epidemiologic Monitoring of NT Measurements

The introduction of ultrasound measurement of NT as part of the Down syndrome screening test has led to a new era in epidemiologic monitoring. Although serum screening analytes are under the day-to-day control of the laboratory, NT ultrasound is performed outside of the laboratory, at multiple locations and by many individuals. This situation is comparable to trying to report uniform screening results with each patient's AFP measurement being run in a different laboratory using a different assay and kit lot.

To bring uniformity to NT measurements, credentialing agencies have been established to train and certify sonographers. Examples of these agencies include the Fetal Medicine Foundation and the Nuchal Translucency Quality Review program, a subsidiary organization of the Society for Maternal-Fetal Medicine (SMFM). Certification involves didactic and hands-on training, along with image review. NT should be used in screening by sonographers only after training has been provided and when quality assurance measures are in place.[12] Previous studies have clearly shown that without such training, the performance of NT as a marker for Down syndrome is erratic, with anywhere from 0 to 100% of cases detected prenatally.[172]

The laboratory has the responsibility to establish NT median data for each sonographer and to monitor performance over time. To determine a median equation, preliminary data should be submitted to the laboratory that includes a series of paired NT and crown-rump length (CRL) measurements. Regression analysis as described earlier provides an appropriate median equation. NT data should fit a log-linear regression and should increase by about 25% per gestational week (Figure 57-13).[330] A single median equation may be used for all sonographers but is not likely to provide optimal interpretations for each individual sonographer. Even when all sonographers are trained using a single method, median NT results often show marked variation.[328] A better approach is to generate an NT median equation for each sonographer or each group of sonographers for whom measurements are similar. Improved screening performance is observed when median data are made more specific.[166,238]

The task of monitoring NT performance over time is daunting given the variable relationship between sonography

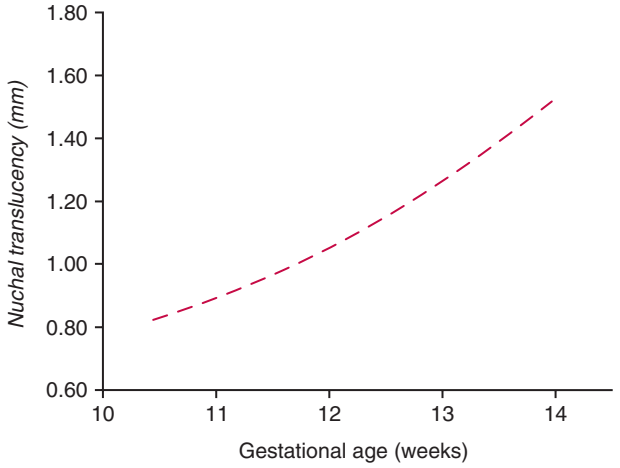

Figure 57-13 Typical medians for nuchal translucency during the first trimester.

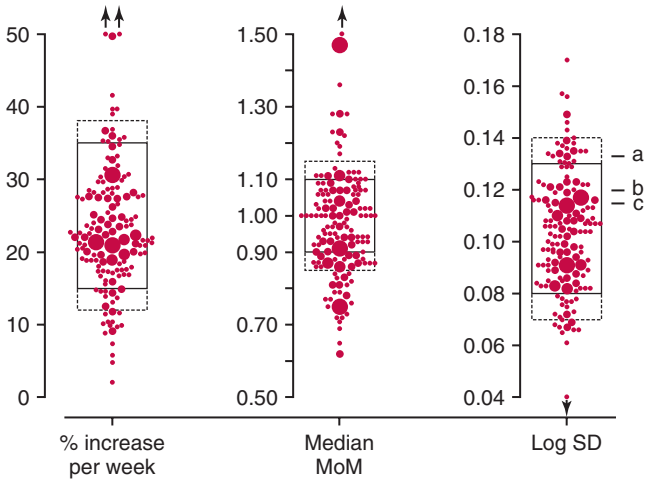

Figure 57-14 Summary of quality assessment parameters for 140 sonographers, showing the increase per week *(left column)*, the median NT MoM *(center column)*, and logarithmic standard deviation *(right column)*. *[Reprinted from Palomaki GE, Neveux LM, Donnenfeld A, Lee JE, McDowell G, Canick JA, et al. Quality assessment of routine nuchal translucency measurements: a North American laboratory perspective. Genet Med 2008;10:131-8.]*

and laboratory staff at different institutions and the sheer numbers of sonographers who may be submitting data to one laboratory. A further complication is that a single sonographer may submit very few data points to a laboratory, and long time intervals may be required before it is possible to conduct a meaningful review of results. Nevertheless, objective criteria upon which sonography data should be judged have been identified. As with serum markers, NT data, once normalized for gestational age, should center at a median of 1.0 MoM. The distribution of NT values in unaffected pregnancies generally has a standard deviation of the log MoM in the range of 0.1. The rate of increase with advancing gestational age between 10 and 13 weeks' gestation should be about 25% per week, as shown in Figure 57-14.[288] Examination of NT data over time can be performed in-house or obtained externally through services provided to laboratories by the Nuchal Translucency Quality Review (NTQR) (www.ntqr.org/ accessed August 26, 2011) or the NT Monitor (www.ipmms.org/ accessed August 26, 2011) program. Regardless of method, ongoing quality assessment of NT data is essential for screening accuracy.[104]

External Proficiency Testing

All laboratories performing prenatal screening should participate in an external proficiency testing program that distributes unknown specimens reflecting the concentrations of analytes found in pregnancy. These programs will evaluate the laboratory's ability to convert analyte values into a MoM using the laboratory's own median equations, to make screening recommendations, to adjust for variables that influence analyte values, and to calculate patient-specific risks. In the United States, the College of American Pathologists (CAP) provides a second-trimester program (CAP Maternal Screening Survey FP) with approximately 200 enrolled laboratories. Five second-trimester serum and two amniotic fluid proficiency samples are distributed three times each year. The CAP program has information on its Website (www.cap.org/ accessed September 23, 2011) that assists participants with risk calculation verification depending on the parameter set used. New York State also has an external proficiency testing program that is required for laboratories serving New York State residents. Five serum and five amniotic fluid samples are distributed three times each year. A similar interlaboratory proficiency program for first-trimester screening markers is available through the Women and Infants Hospital of Rhode Island at www.ipmms.org/ accessed August 26, 2011.

New Techniques

In 1997, fetal DNA was found to circulate in small amounts, along with maternal DNA, as fee fragments in maternal plasma. This led to the measurement of Y-chromosome sequences as an aid in the diagnosis of gender-linked fetal disorders.[182] Noninvasive determination of fetal Rhesus factor status in RhD-negative mothers has also been implemented clinically.[137] Active research is under way to find a method for the detection of fetal Down syndrome and other aneuploidies, using only maternal blood. Early studies described separation of fetal cells and cell-free fetal nucleic acids in maternal blood (see reviews[334,417]). Application of newer, sophisticated molecular techniques such as (1) massive sequencing of DNA fragments in maternal blood with chromosome quantification,[86,126] (2) selective amplification of placental methylated DNA with quantification by mass spectrometry,[270] and (3) calculation of haplotype ratios using tandem single-nucleotide polymorphisms[145] hold promise for high-quality noninvasive screening or diagnosis of Down syndrome in the near future. A more detailed discussion is provided by Lo and Chiu in Chapter 45.

LABORATORY TESTS

In this section of the chapter, we review methods for measurement of (1) CG, (2) AFP, (3) uE_3, (4) inhA, (5) PAPP-A, (6) fetal fibronectin, (7) amniotic fluid bilirubin, and (8) six tests for fetal lung maturity.

Chorionic Gonadotropin

Measurement of CG is used to (1) detect pregnancy and its abnormalities (e.g., ectopic and molar pregnancies), (2) screen for Down syndrome and trisomy 18, and (3) monitor the course of a patient with a CG-producing cancer. Because CG has these diverse uses, many assays are used, including qualitative urine and serum kits and quantitative serum assays.

This hormone is commonly called *human chorionic gonadotropin* and often is abbreviated as hCG or HCG. This term and its abbreviations should be abandoned because the adjective "human" is superfluous. Nonetheless, when

communicating with clinicians (at least in the United States), hCG is the preferable term to avoid misunderstanding.

Chemistry

CG is a glycoprotein containing a protein core with branched carbohydrate sidechains that usually terminate with sialic acid. The hormone is a heterodimer composed of two nonidentical, non–covalently bound glycoprotein subunits—alpha (α) and beta (β). When the CG dimer is dissociated, hormone activity is lost. However, a major part of the original activity is restored by equimolar recombination of the two subunits. The CGα subunit contains 92 amino acids, 2 carbohydrate sidechains, and 5 disulfide bridges. The molecular mass of the α subunit is estimated to be 14,900 Da, of which 10,200 is the protein component. CGβ consists of 145 amino acids and has 6 carbohydrate sidechains and 6 disulfide bridges. The molecular mass of the β subunit is estimated to be 23,000. Thus the heterodimer has a molecular weight of approximately 37,900 Da and a higher carbohydrate proportion than any other human hormone.

The CG carbohydrate composition changes as pregnancy progresses. In the first few weeks of pregnancy, more than 80% of immunoreactive CG is a large molecular mass form (Mr 41,000 to 42,000 Da), with additional monosaccharides in its carbohydrate chains, called *hyperglycosylated CG* (CG-H).[271] Serum concentrations of CG-H decline rapidly after the fourth week, and the 37,900 Da molecular mass form predominates for the remainder of the pregnancy.[88] In addition to CG and CG-H, maternal serum includes numerous other CG variants. To avoid confusion, the International Federation of Clinical Chemistry (IFCC) has recommended specific nomenclature for the identification of intact CG (hCG) and its variants.[60] These include (1) nicked CG (hCGn), (2) the free α subunit (hCGα), (3) the free β subunit (hCGβ), (4) the nicked free β subunit (hCGβn), and (5) the beta core fragment (hCGβcf). CGn is produced from enzymatic cleavage of peptide bonds in CGβ at position 44-45 (and, after prolonged incubation, at position 51-52).[197] Nicking inactivates the hormone and may reduce the ability to bind some CG antibodies. Other nicking sites are at β44-45, β47-48, and α70-71.[49] CGβcf is the terminal degradation product of CGβ and represents the 73 amino acid core of CGβ. It is composed of two pieces of the β subunit, residues 6-40, and residues 55-92, held together by disulfide bridges.[48] CGβcf is detected only in urine and has a molecular mass of 13,000 Da.

Urine contains predominantly CGβcf and to a lesser degree unmodified CG and CGn. Clearance occurs both in the liver and through the kidneys and varies for the different CG forms. Hepatic clearance[407] is approximately 2 mL/min/m^2, and renal clearance is approximately 0.4 mL/min/m^2; thus early morning urine specimens have CG concentrations comparable with those in serum. A study using highly specific immunoassays for CG, CGβ, and CGα found that disappearance after term pregnancy was triphasic.[206] Rapid, medium, and slow half-lives were, respectively, CG, 3.6, 18, and 53 hours; CGβ, 1.0, 23, and 194 hours; and CGα, 0.63, 6, and 22 hours.

Biochemistry

CG is synthesized in the syncytiotrophoblast cells of the placenta. Minute amounts are also made in the pituitary of men and nonpregnant women,[50,350,361] and, similar to many other pituitary hormones, it is secreted in a pulsatile fashion.[273] A single gene located on chromosome 6 encodes the α subunit of all four glycoprotein hormones [TSH, LH (luteinizing hormone), FSH, and CG]. Chromosome 19 contains a family of seven genes that encode the CGβ subunit, although only three appear to be active.[306] Separate messenger RNAs are transcribed from the respective genes, and the α and β subunits are translated from each. The subunits spontaneously combine in the rough endoplasmic reticulum and are continuously secreted into the maternal circulation.

Synthesis of CGβ peaks at about 8 to 10 weeks, but production of the α subunit continues to increase and appears to be a function of the mass of the placenta. The production of CGβ in the syncytiotrophoblasts may be under paracrine control of gonadotropin-releasing hormone (GnRH) produced in cytotrophoblasts. Studies suggest that the cytotrophoblasts produce inhibin, which stimulates CG production.[299] The number of cytotrophoblasts peaks at about the same time the CGβ production peaks. In the second trimester, more than 99% of CG is the dimer form; only a small amount circulates as free CGβ.[280]

Extensive homology exists between the peptide portions of CGβ and LHβ subunits. Investigators have proposed that a single base pair deletion in the ancestral LHβ gene lengthened the subunit from 115 amino acids to 145 amino acids; 80% of the first 115 amino acids in both β subunits are identical, but 20 additional amino acid residues are unique in CGβ.[371]

Physiology

CG stimulates the corpus luteum in the ovary to make progesterone during the first weeks of pregnancy. The placenta makes inadequate amounts of progesterone during this time. No specific receptor for CG is known; it binds to and activates the LH receptor in cells of the corpus luteum in the maternal ovary. Species other than primates and horses use LH for this function. Glycation of the α subunit has a dominant role[325] in signal transduction—an increase in intracellular cyclic adenosine monophosphate (cAMP). The cAMP increase in turn stimulates the production of progesterone, a steroid that prevents menses and thus facilitates pregnancy. CG binds weakly to TSH receptors in the maternal thyroid, and extremely elevated CG concentrations have the potential to be thyrotropic. A study of 63 women with a CG concentration greater than 400,000 IU/L revealed that TSH was suppressed and free thyroxine was increased in 100 and 80% of specimens, respectively. However, only four women had clinical signs and symptoms of hyperthyroidism.[232]

CG-H is synthesized by invasive cytotrophoblast cells and appears to have an autocrine function that modulates cytotrophoblast invasion of the myometrium in early pregnancy.[89]

CG Assays

Many assay techniques have been used to determine CG, and all modern techniques are based on immunoassay.

Of historical note, Vaitukaitis and colleagues took advantage of the uniqueness of CGβ to produce the first specific assay for CG, which used polyclonal antibodies raised against the β subunit.[384] Subsequently, highly specific monoclonal antibodies have been produced that recognize epitopes on the CG dimer and CGβ. The molecular epitope structure and the specificities of some of these antibodies have been described.[40]

Currently, bioassays, receptor assays, and agglutination inhibition assays are obsolete for detecting pregnancy. The historical bioassays are interesting, however, because they exploit the physiologic effect of CG.[78,83,120,329,375]

Qualitative CG Tests

Numerous tests for the qualitative detection of CG in urine or serum are available as over-the-counter (home) or point-of-care (POC) devices, and their use for the rapid identification of pregnancy is well established. Qualitative detection of CG in urine is a test granted waived status under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88); therefore this is performed at home and at the POC. In contrast, the use of serum as a sample matrix is considered a moderately complex test, even when the test device itself is approved for use with urine or serum. The difference in test complexity status is due to the requirement that serum, rather than whole blood, should be analyzed, and that centrifugation of the specimen is necessary. As such, most qualitative serum CG tests are performed in laboratories—not at home nor in POC situations.

POC devices are single-use tests that utilize immunochromatography for the rapid qualitative detection of CG when its concentration exceeds a detection threshold, frequently 25 IU/L. Cervinski and associates[81] evaluated the analytical lower limit of detection of 12 different brands of qualitative CG tests (6 over-the-counter and 6 point-of-care devices) using urine specimens collected from 10 women in early pregnancy (within 10 days of expected menses). Detection limits varied from 6 to 100 IU/L for POC devices and from 0.5 to 25 IU/L for over-the-counter devices.[81] Considerable variation was noted across devices tested with a single specimen and within a device tested with different specimens; this was attributed to the heterogeneous mixture of CG variants in pregnancy urine. The lower analytical limits of detection of over-the-counter devices was thought to be a function of the specimen volume used to perform those tests, which is approximately five times greater than volumes required for POC CG tests.

Because qualitative CG tests are used for the detection of pregnancy, they are designed to detect dimeric CG using a combination of anti-CGα and anti-CGβ antibodies. However, some devices detect nondimeric CG variants[81,344]—a fact that may be due to incompletely characterized reagent antibodies. Because of its relative abundance in early pregnancy, it has been suggested that qualitative CG tests should be designed to preferentially detect CG-H, a suggestion that was based on data derived from the addition of CG-H to CG-free urine.[68] Given the analytical performance that is currently observed using urine obtained during early pregnancy,[81] such a modification appears to be unnecessary.

First-morning specimens are preferred for qualitative POC urine pregnancy tests because they are concentrated and contain abundant CG. Urine applied to the device is absorbed into a nitrocellulose bed. CG is concentrated into a narrow band as the urine migrates. A dye- or latex bead–labeled anti-CG antibody in the device binds to the migrating CG and passes through a zone having solid-phase capture antibody to CG. The appearance of a colored line indicates a positive test. An area of solid-phase antibody with specificity for the labeled anti-CG antibody is located separate from the test band and controls for the addition of adequate specimen volume. False-positive results may occur because of the presence in serum of interfering substances such as interfering antibodies.[157] The test area of some devices may darken over time even in the absence of CG; therefore delayed interpretation of the test band has been known to produce a false-positive result. False-negative results are more commonly encountered and occur if the CG concentration is below the detection threshold (e.g., a dilute urine), or if it is extremely elevated as a result of the high-dose hook effect. False-negative results have also been caused by elevated concentrations of CGβcf because of its ability to bind one of the two anti-CG reagent antibodies, thus preventing the binding of dimeric CG.[163] Because CGβcf is a predominant CG variant in urine after the fifth week of pregnancy, this CG "variant effect" is an important consideration in healthcare settings where qualitative pregnancy tests are often performed beyond the first few weeks of pregnancy.

Exactly how soon after fertilization and implantation CG becomes detectable in the urine varies considerably between women. Wilcox and colleagues[413] demonstrated that 90% of pregnancies could be detected on the day of the missed menses, and 100% were detected 11 or more days later using a highly sensitive quantitative CG test.

The simplicity and speed with which results are obtained make these tests valuable for pregnancy confirmation, but they may miss the diagnosis of a very early or abnormal pregnancy. Qualitative *serum* assays are available and have better analytical performance.

Quantitative CG Tests

All commonly used quantitative CG tests are high-performance immunometric assays designed to measure CG over a wide range of concentrations. Upper limits of detection vary from 400 to 15,000 IU/L, and so specimen dilution is frequently required to obtain an absolute measurement. The lowest detectable concentration of these assays is from 1 to 2 IU/L.

Measurement of CG is complicated by its molecular heterogeneity, and considerable variation in measured CG concentrations is observed between the different assays. One reason for this variation is the use of different antibody pairs

in different CG assays. Antibodies to CG will recognize epitopes on the α subunit, the β subunit, or the αβ heterodimer,[40] and so analytical specificity is dependent on the specific pair of antibodies utilized. Another source of variation is the reference material used to calibrate CG assays. Most CG assays are calibrated against the World Health Organization (WHO) Third (75/537) or Fourth (75/589) International Standard, which contains purified urinary hCG with an activity value of 9300 IU/mg determined by bioassay.[70,363] However, these reference materials also contain substantial amounts of CGn and CGβ; this is problematic in that some CG assays over- or under-recognize these variants or may not detect them at all. As such, CG assays lack harmonization. Exacerbating this problem is the use of secondary CG reference materials that vary greatly in terms of the purity that assay manufacturers provide to the end-user for assay calibration. As a consequence, results from different CG assays are not the same and cannot be directly compared.[164,364,410]

In an effort to address some of these problems, the IFCC established the Working Group for the Standardization of hCG in 1994. This group prepared highly purified standards for 6 CG variants and calibrated them in molar concentration.[49,60] These preparations are designated *reference reagents* (RR) and contain CG (99/688), CGn (99/642), CGα (99/650), CGβn (99/692), CGβcf, and CGα (99/720). The impact of using RR for assay calibration and harmonization is under study.

Because of variation between CG assays, median CG values calculated for maternal serum screening are not transferable and should be considered method specific. CG measurements in early pregnancy generally are expressed as international units per liter (IU/L). A typical CG concentration at 16 weeks is approximately 30,000 IU/L, and many screening laboratories express CG concentrations in international units per milliliter (e.g., 30,000 IU/L is expressed as 30 IU/mL) (see Figure 57-3). A simple alternative is to use kilo-international units per liter, consistent with the international system for SI units, in which concentrations are expressed per liter.

Immunoassays specific for free CGβ are commercially available outside the United States (see las.perkinelmer.com/Catalog/accessed Sept. 23, 2011) and may be preferred for first-trimester screening.[73]

Specimen Collection and Handling

Serum is used for quantitative CG assays and are obtained from fasting or nonfasting women by standard phlebotomy techniques. Blood specimens are collected into suitable tubes without anticoagulants, are allowed to clot at room temperature, and are centrifuged to obtain clear serum. CG is stable in maternal serum and can be shipped at ambient temperature and stored at 4 to 8 °C for 1 week.[216] If testing is to be delayed beyond 1 week, serum should be stored at −20 °C. As with most biological materials, repeated freezing and thawing of the specimen should be avoided. Serum specimens showing gross hemolysis, gross lipemia, or turbidity should be avoided.

Specificity of CG Assays

Modern CG immunoassays should have little or no cross-reactivity with LH. Testing of serum samples with high physiologic LH concentrations has been used to ascertain that this hormone does not significantly influence the CG results. Serum from postmenopausal women is a convenient source of specimens with high LH.

As discussed earlier, considerable variation has been noted between different CG assays regarding their detection of specific CG variants. CG assays are classified on the basis of their analytical specificity into those that (1) detect only dimeric CG, (2) detect CG and CGβ, and (3) detect CG, CGβ, and CGβcf.[364,410]

Clinical Significance

Measurement of CG assists in diagnosing and dating pregnancy, identifying ectopic pregnancies and other abnormalities, managing certain neoplasms, and predicting the risk of Down syndrome and trisomy 18. Each of these clinical uses was discussed earlier in this chapter or in Chapter 24. Typical values during pregnancy are shown in Figure 57-3.

Alpha Fetoprotein

Measurement of AFP in maternal serum and amniotic fluid is used extensively throughout the United States and the United Kingdom for prenatal detection of some serious fetal anomalies. Use of AFP in nonpregnant patients for monitoring certain cancers is described in Chapter 24.

Chemistry

A fetal protein having α-electrophoretic motility was discovered in 1956 by Bergstrand and Czar.[41] Gitlin subsequently named this substance α-*fetoprotein*.[150,218] This glycoprotein has a molecular mass of ≈70,000 Da. The gene, located within q11-22 on chromosome 4, is part of a family of genes that also codes for albumin and vitamin D–binding protein (also called *group-specific component* and *Gc globulin*).[176] The protein is composed of carbohydrate and a single polypeptide chain containing 591 amino acids. The complete amino acid sequence was reported in 1987.[148] The carbohydrate composition varies depending on the organ of synthesis, the length of gestation, and the source of the specimen (fetal serum vs. amniotic fluid).[108] Although determination of the carbohydrate content does not appear to be useful diagnostically in the setting of pregnancy, it may be useful in the diagnosis of hepatocellular carcinoma.[307] Heterogeneity has been demonstrated by electrophoresis and dissimilar binding to various lectins, such as concanavalin A.

Biochemistry

AFP is produced initially by the fetal yolk sac in small quantities, and then by the fetal liver in larger quantities as the yolk sac degenerates. Trace amounts are also produced in the fetal gut and kidneys. Early in embryonic life, this protein has a high concentration in fetal serum, reaching about one tenth the concentration of albumin. Maximal concentration in fetal serum—≈3 million μg/L—is reached at about 9 weeks'

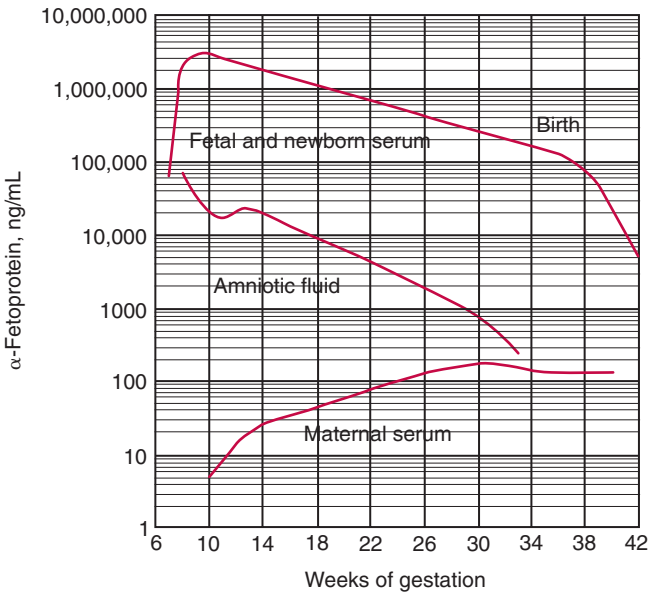

Figure 57-15 Concentrations of alpha fetoprotein (AFP) in fetal and newborn serum, maternal serum, and amniotic fluid. Maternal serum values are medians calculated from 24,232 pregnancies, and amniotic fluid values are medians calculated from 1544 pregnancies from testing performed at ARUP Laboratories Inc. from January to October 1997. Fetal serum values are from Gitlin.[150] Newborn serum values are from Wu et al.[419]

gestation. The concentration then declines steadily to about 20,000 μg/L at term (Figure 57-15).[150] The increase and decrease in concentration of AFP in the amniotic fluid roughly parallel those in the fetal serum, but the concentration is two to three orders of magnitude lower (≈15,000 μg/L at 16 weeks' gestation). The relationship with respect to maternal serum concentration is slightly more complicated because of several factors, including (1) fetal-maternal transfer, (2) rapid growth of the fetus, (3) relatively constant size of the mother, (4) maternal clearance of the protein, and (5) variation of the volume of distribution in the mother with maternal weight. AFP is first detectable (≈5 μg/L) in maternal serum at about the 10th week of gestation. The concentration increases about 15% per week to a peak of approximately 180 μg/L at about 25 weeks. A typical 16 week concentration is approximately 35 μg/L (see Figure 57-8).[169] The concentration in maternal serum then subsequently declines slowly until term. After birth, the maternal serum AFP rapidly decreases to less than 2 μg/L. In an infant, serum AFP declines exponentially to reach adult concentrations by the 10th month of life.[419]

The distribution of serum AFP concentrations in a population of pregnant mothers is Gaussian after logarithmic transformation.[390] Factors that affect the concentration of AFP in maternal serum include (1) gestational age, (2) maternal weight, (3) the presence of insulin-dependent maternal diabetes mellitus, (4) maternal race, (5) the number of fetuses present, (6) fetal renal disorders that cause proteinuria, and (7) fetal structural anomalies.

Amniotic fluid AFP has been measured as early as 8 weeks.[405] It rapidly decreases to its lowest point at 11 weeks, then increases to reach a second maximum at 13 weeks. The concentration then falls in a log-linear fashion until 25 weeks, when the decline steepens. Several studies have shown that AChE used in combination with amniotic fluid AFP can aid in the detection of open neural tube defects from 13 to 25 weeks of pregnancy.[97]

Methods for Determining Alpha Fetoprotein

Although AFP was traditionally measured by radioimmunoassay (RIA), newer methods use immunoenzymometric assay (IEMA) or chemiluminescent immunoassay (CIA) because of their (1) lower detection limits, (2) increased precision, (3) speed, (4) avoidance of radioactivity, and (5) ease of automation.[51] As indicated in a CAP survey, in 2010, most laboratories in the United States measure AFP by using automated systems available from a number of vendors. Judging from the results of proficiency testing offered by the College of American Pathologists (Survey FP), all of these systems perform satisfactorily.[92]

Calibration

Although two essentially equivalent international reference materials [WHO Reference Preparation for AFP (72-225) and British Standard (72-227)]—both calibrated in international units—are available, most laboratories in the United States report AFP in nanograms per milliliter (i.e., micrograms per liter). The relationship between nanograms and international units usually is given as 1.21 ng = 1 IU, but conversion factors may vary by manufacturer, perhaps reflecting differences in the carbohydrate content of respective calibrators.[22]

Specimen Collection and Handling

Serum specimens are obtained from nonfasting women through standard phlebotomy techniques. AFP is very stable in maternal serum and can be shipped at ambient temperature and stored at 4 to 8 °C for 1 week or at –20 °C for years.[216]

Clinical Significance

Maternal serum and amniotic fluid AFP are useful tests for detecting some serious fetal anomalies. Maternal serum AFP is elevated in 85 to 95% of cases of fetal open neural tube defect[390] and is low in about 30% of cases of fetal Down syndrome.[99,247] Because maternal serum screening for fetal defects involves multiple tests, this subject was discussed earlier under "Second-Trimester Maternal Serum Screening Tests." It is noteworthy that AFP is not even required for healthy pregnancy. For example, a mutation of the AFP gene, which resulted in the complete absence of this protein in maternal serum or amniotic fluid, was not associated with fetal malformations or pregnancy complications.[298]

Measuring Amniotic Fluid Alpha Fetoprotein

Amniotic fluid AFP is measured using the same immunoassays as for maternal serum AFP after a suitable dilution (usually 1:50 to 1:200). Results are expressed in nanograms

per milliliter, micrograms per liter, or kilo IU per liter, and most laboratories use mass units. AFP in amniotic fluid is less stable than in serum, and leaving samples at room temperature for prolonged periods, such as might occur during processing for chromosome analysis, results in degradation of amniotic fluid AFP. Refrigeration of amniotic fluid will compromise the chromosome analysis. Therefore a portion of the collected fluid should be placed in the refrigerator as soon as possible after collection. Samples sent to reference laboratories should be shipped for next day delivery at ambient temperature or on ice packs if the outside temperature is high. The presence of fetal blood in amniotic fluid samples has been known to increase AFP results, and laboratories should note the presence of blood on the report. In the event of an increased amniotic fluid AFP result (usually >2.0 or 2.5 MoM), the laboratory should test for the presence of fetal blood, or should refer this reflex test to another laboratory. Laboratories that measure amniotic fluid AFP need to establish medians for each week between 13 and 25 weeks' gestation. A method has been published that allows extrapolation to 13 weeks using data from 14 to 25 weeks.[285] Medians from ARUP Laboratories (Salt Lake City, Utah) are shown graphically in Figure 57-15.

Measuring Amniotic Fluid Acetylcholinesterase. AChE is an essential confirmatory test for samples with elevated amniotic fluid AFP. Normal amniotic fluid contains a group of nonspecific cholinesterases referred to as *pseudocholinesterase (PChE).* Cerebrospinal fluid contains high concentrations of the neural enzyme AChE, and in cases of fetal open neural tube defects (and in about 80% of cases with defects of the abdominal wall), fluid leaks from the open lesion, allowing AChE to enter the amniotic fluid.

The usual technique for identification of AChE is fractionation by polyacrylamide gel electrophoresis followed by incubation of the gel with the substrate acetylcholine and copper ions. AChE migrates more rapidly than PChE and appears as a distinct white precipitate band below the PChE band. That the second band is AChE is documented by inhibition of enzyme activity in the band by the specific AChE inhibitor 1,5-bis(4-allyldimethylammoniumphenyl)pentan-3-one dibromide—BW284C51. Because no method is available commercially, laboratories have to develop their own assay systems using published methods.[63,167] Enzyme immunoassay using a monoclonal antibody specific for neurally derived AChE has also been used.[269]

Unconjugated Estriol

Measurement of urinary and serum estriol (E_3), once used to assess fetal well-being, is no longer recommended for that purpose.[101] Measurement of unconjugated estriol (uE_3) is now used routinely by most U.S. laboratories that provide screening for Down syndrome. This steroid, rather than total estriol (unconjugated plus conjugated estriol), is the most specific of the estrogens for identifying a fetus with Down syndrome.

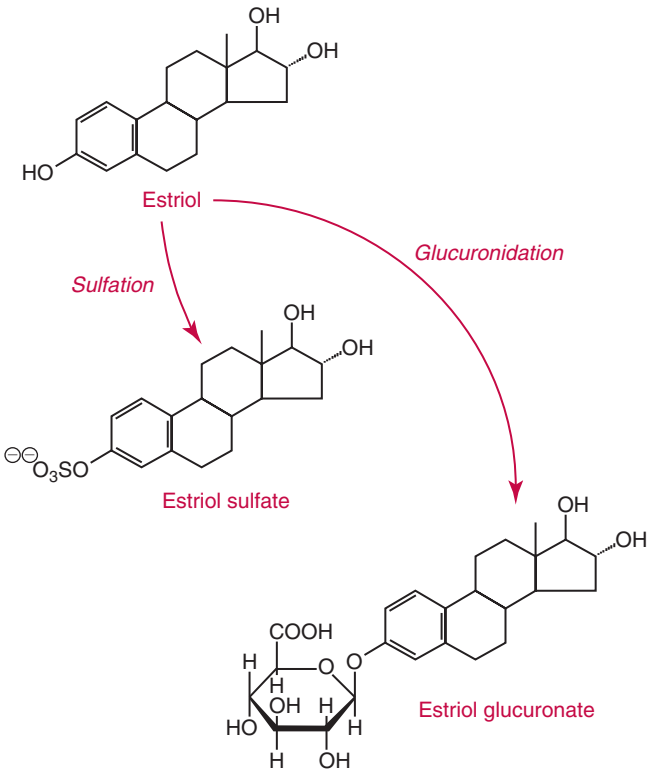

Figure 57-16 Forms of estriol present in maternal serum. Glucuronidation and sulfation can also occur at the other hydroxyl positions.

Chemistry

Estriol is an estrogen with hydroxyl groups at positions 3, 16, and 17 (see Chapter 56). Its systematic name is 1,3,5(10)-estriene-3,16-α,17-β-triol. Although present in nonpregnant patients in very low concentrations, during late pregnancy this estrogen predominates. Only a minor amount (≈10%) of the hormone circulates in plasma unconjugated[295] and, because of its low solubility, this form is strongly bound to SHBG. The majority exists as conjugates of glucuronate and sulfate (Figure 57-16). Conjugation occurs in the maternal liver, makes the hormone more soluble, and thus permits renal clearance.

Biochemistry

Estriol is produced in very large amounts during the last trimester of pregnancy. The biosynthetic pathway requires three organs to be fully functioning: fetal adrenal, fetal liver, and placenta (Figure 57-17). The fetal adrenal cortex possesses a unique zone for the production of steroids. The demand for estriol is so great that the fetal adrenal is massive compared with that of an adult. The fetal cortex accounts for approximately 80% of adrenal weight. The fetal adrenal avidly binds low-density lipoprotein to take in cholesterol, which is converted to two major steroid intermediates: pregnenolone sulfate and dehydroepiandrosterone sulfate (DHEA-S). These intermediates are secreted into the fetal circulation. The fetal liver, possessing 16α-hydroxylase, converts DHEA-S

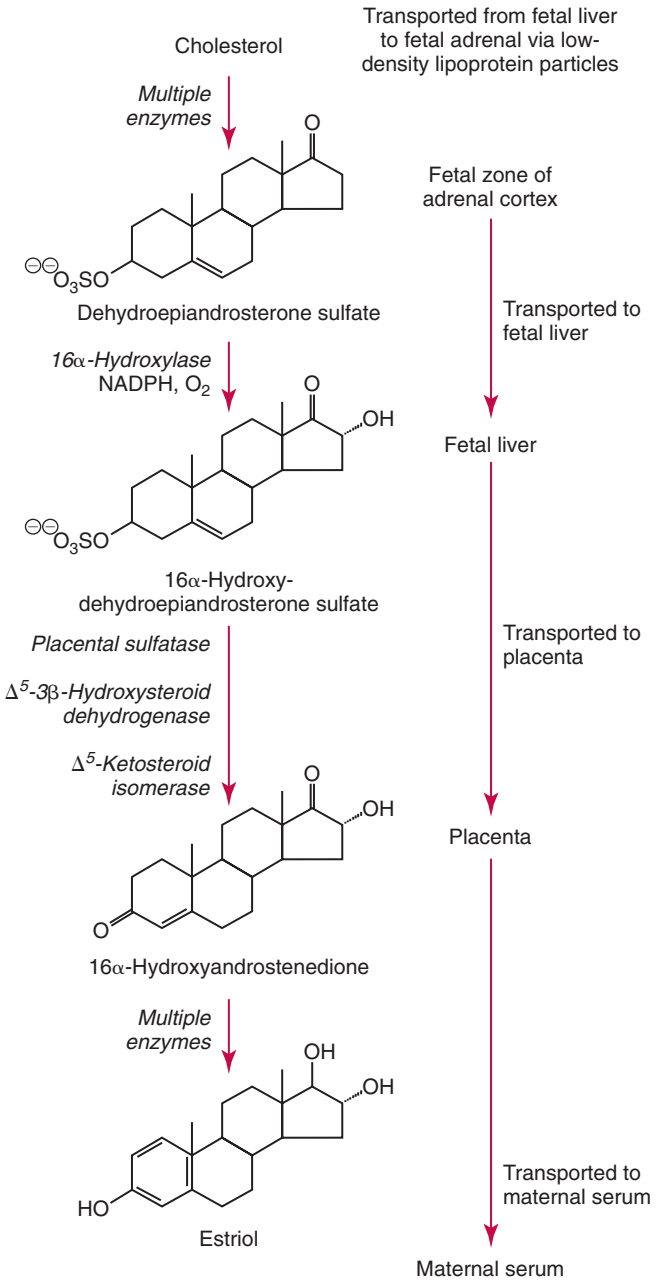

Figure 57-17 Biosynthetic pathway for estriol during pregnancy.

to 16α-hydroxy-DHEA-S, which is secreted back into the fetal circulation. Finally the placenta synthesizes estriol from 16α-hydroxy-DHEA-S. Approximately 90% of maternal serum estriol is derived from this pathway. A minor amount is made using precursors from the maternal ovary. The relationship of maternal serum uE_3 to gestational age in the second trimester is log-linear, increasing at a rate of 20 to 25% per gestational week[169] (Figure 57-18). Concentrations typical for the second trimester of pregnancy are 0.70 to 2.50 μg/L, depending on the assay used. Serum concentrations of estriol conjugates are fivefold to tenfold higher than serum concentrations of uE_3 during pregnancy.

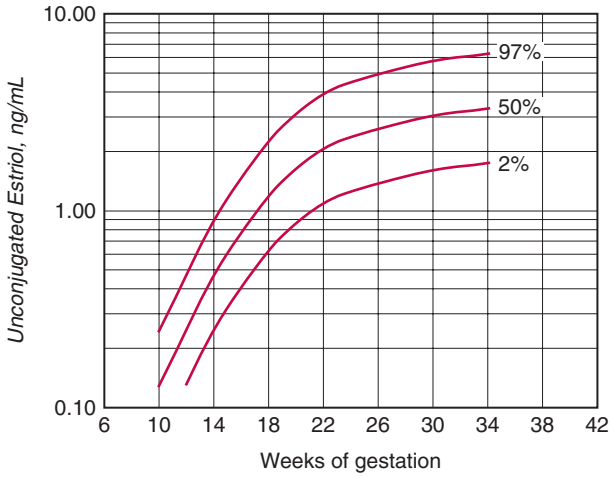

Figure 57-18 Concentration of unconjugated estriol (uE_3) in maternal serum as a function of gestational age. Lines represent the 2nd, 50th, and 97th percentiles. Maternal serum values from 14 to 25 weeks are medians calculated from 11,309 pregnancies from testing performed at ARUP Laboratories Inc. from January to October 1997.

Methods for Determining Unconjugated Estriol

Determination of uE_3 is made difficult by its low concentration. Until 2002, uE_3 was measured by ultrasensitive RIA methods [primarily the assay available from Diagnostic Systems Laboratories (DSL, Webster, Texas, no longer available)] that have been clinically validated extensively by case-control and intervention studies. Subsequently, nonisotopic assays became available, usually as part of automated systems. The correlation between these methods and RIA methods is generally only fair ($r^2 = 0.8$), and most have not been clinically validated. A clinical outcome study using a nonisotopic method yielded screening performance equivalent to a previously validated RIA.[236] In addition, concentrations of estrone, estriol-3-sulfate, and estriol-3-glucuronide up to 1000 ng/mL cross-react less than 0.03% in current assays. Values obtained with various uE_3 assays vary widely as judged using the CAP proficiency testing survey FP.[92] Conversion to MoM reduces between-method differences, but uE_3 is still the most variable of the screening analytes.

Calibration

Assays for uE_3 are calibrated by the use of chemically pure estriol. Estriol values are reported in mass units (nanograms per milliliter or micrograms per liter) or SI units (nanomoles per liter). The equation for converting mass to SI units is 1 nmol/L = 3.47 ng/mL = 3.47 μg/L. Although pure uE_3 is available for calibrating uE_3 assays, commercial kits yield values on clinical specimens that differ by factors of 2 to 3.[92]

Specimen Collection and Handling

Maternal serum specimens are obtained from nonfasting women by standard phlebotomy techniques. Of the four analytes currently used for screening, uE_3 is the least stable, and

consequently, requirements for collection, storage, and shipment are dictated by this analyte. The uE_3 concentration increases in blood at room temperature and at 4 °C, because the conjugated forms are able to spontaneously deconjugate to form the parent hormone.[169] Therefore collected blood should be allowed to clot, and then serum should be removed promptly. If serum separator tubes are used, specimens should be centrifuged promptly after collection. Shipment of whole blood is not preferred. If whole blood is shipped through the mail, next day delivery is essential. uE_3 is stable in serum for up to 7 days at 2 to 4 °C (unpublished data, Foundation for Blood Research, Woman and Infant's Hospital, and ARUP Laboratories). The concentration of uE_3 increases when sera have been stored for longer than 4 days at room temperature.

Clinical Significance

Any disruption in the biosynthetic pathway will lead to very low maternal serum uE_3. Conditions that cause disruption include (1) fetal anencephaly, (2) placental sulfatase deficiency, (3) fetal death, (4) chromosome abnormalities, (5) molar pregnancy, and (6) Smith-Lemli-Opitz syndrome.[57,376] Placental sulfatase deficiency presents in the infant as X-linked ichthyosis. It is present in approximately 1 in every 2000 males. Because of the lack of uE_3, the mother often has delayed onset of labor, and the cesarean section rate is significantly higher in these mothers. SLOS is a serious, rare birth defect that is the result of an inborn error in cholesterol metabolism, 7-dehydrosterol-7-reductase deficiency. Down syndrome leads to a modest decrease in uE_3. Screening for Down syndrome is now the most common application of uE_3 measurements.[392]

Inhibin A

Inhibins are members of the transforming growth factor-β (TGFβ) superfamily of proteins. As described in Chapter 56, inhibin is a negative feedback regulator of FSH secretion in both males and females. Inhibin A and B are proven bioactive forms. The placenta produces large quantities of inhibin A that completely suppress FSH.

Chemistry

Inhibins are proteins consisting of dimers of dissimilar subunits (α and β) linked by disulfide bridges. The β subunit occurs in two closely related forms (β_A and β_B), leading to two types of dimeric inhibin (dimeric inhibin A, $\alpha\beta_A$, and dimeric inhibin B, $\alpha\beta_B$). The mature form of inhibin, which has a molecular mass of approximately 30,000 Da, is produced by cleavage of larger precursor forms. In follicular fluid and serum, mature inhibins, precursors of inhibins (particularly the processed form of the free α subunit, pro-αC), and intermediate molecules of varying molecular weight are present.[373] Another group of related molecules, the activins, are dimers consisting of just the β subunits.[291] Inhibin/activin β_C, β_D, and β_E subunits have also been identified, but are less well understood. Inhibin A is the only form within the inbibin/activin family of proteins that provides sufficient discrimination to be useful in Down syndrome screening.[215]

Biochemistry

Inhibins and the closely related activins are proteins that suppress or stimulate follicle-stimulating hormone secretion. In the reproductive system, inhibin and activin subunits are expressed in the placenta, as well as in the granulosa cells of the ovary, and by the Sertoli cells of the testis. Inhibin A and inhibin B have distinctive serum profiles during the human menstrual cycle. Inhibin A rises from 10 to 20 ng/L in the follicular phase of the cycle to a maximum of 40 to 60 ng/L. Inhibin B is maximal in the midfollicular phase, with a peak at ovulation (about 60 ng/L), before decreasing to basal amounts in the luteal phase. In postmenopausal women, the concentrations of both forms of inhibin are below 5 ng/L.[233] Men secrete inhibin B, but not inhibin A, from the testis into serum. Inhibin A is produced by the fetoplacental unit beginning in early pregnancy. InhA concentrations exhibit a complex pattern during the course of pregnancy, rising to a peak at 8 to 10 weeks' gestation, declining to a minimum at 17 weeks of pregnancy, and then resuming to slowly increase at term (see Figure 57-11). Unlike the other screening tests, average inhibin concentrations change relatively little from 15 to 20 weeks' gestation. A typical value at 17 weeks' gestation is 175 ng/L (175 pg /mL). In 2010, inhibin/activin β_C and β_E subunits were localized in placental tissues, implying a potential role in pregnancy.[149,409]

Assay Methods for Inhibin A

Inhibin assays used for Down syndrome screening must measure only dimeric inhibin A and not the free α subunits and the precursors of higher molecular weight, which also circulate in blood. The original inhibin assays were enzyme-linked immunosorbent assay (ELISA) or RIAs, used antibodies directed against epitopes on the α-subunit, and measured all forms of inhibin, including precursors. These assays are referred to as total inhibin or immunoreactive inhibin assays. Highly specific assays using monoclonal antibodies are available that measure only dimeric inhibin A. Specific inhA assays provide better screening performance than the nonspecific total inhibin assays.[215] The widely used inhA method, originally from Diagnostic Systems Laboratories (Webster, Tex, now available from Beckman Coulter, Brea, Calif), has been clinically validated[203] and performs well in the College of American Pathologists Maternal Survey FP.[92] An automated method for inhibin A measurement was released by Beckman Coulter in 2007 and has been shown to have acceptable analytical and clinical performance.[217] Typical values in the second trimester of pregnancy range from 50 to 400 pg/mL (50 to 400 ng/L), as shown in Figure 57-11.

Specimen and Sampling Handling

Serum specimens are obtained from nonfasting women by standard phlebotomy techniques. InhA is stable in maternal serum and has been shipped at ambient temperature and stored at 4 to 8 °C for 1 week.[216]

Clinical Significance

In addition to the usefulness of inhA as a predictor of Down syndrome risk as discussed previously, inhibin A and B measurements have found applications in (1) ovarian cancer monitoring, (2) disorders of ovulation, (3) early detection of viable pregnancy following in vitro fertilization, and (4) evaluation of male infertility.[215,318]

Pregnancy-Associated Plasma Protein-A

Pregnancy-associated plasma protein A is a unique serum marker for Down syndrome pregnancy in that concentrations are low in the first trimester (median = 0.34 MoM) but are unchanged in the second trimester (1.11 MoM).[400] PAPP-A concentrations in the maternal serum of women during the first trimester of pregnancy are associated with fetal and placental health and development.

Chemistry

The human PAPP-A gene is found on chromosome 9 and consists of 22 exons. It is translated into a 1626 amino acid product, of which 1546 amino acids compose the mature protein. Circulating PAPP-A is part of a larger molecular complex that includes two subunits of PAPP-A covalently bound to two subunits of pro major basic protein (pro MBP), forming a heterotetramer (Figure 57-19).[53] The PAPP-A complex has a molecular mass of about 500 kDa.

Biochemistry

PAPP-A is a zinc-containing metalloproteinase glycoprotein. It is expressed at low concentrations in all tissues, but high amounts of PAPP-A protein and mRNA are localized in placental tissues throughout gestation. PAPP-A immunoreactivity is found in syncytiotrophoblast cells,[54] and the eosinophil major basic protein (pro-MBP) subunit is found in cytotrophoblast cells. Maternal serum PAPP-A concentrations increase as gestation proceeds to term. Concentrations of PAPP-A are critical to normal fetal growth because of its role as an insulin-like growth factor binding protein (IGFBP) protease. PAPP-A regulates the action of insulin-like growth factor II (IGF-II) by cleaving its binding protein and thereby increasing bioavailable forms. PAPP-A predominantly cleaves IGFBP-4, a reaction that is dependent on the presence of IGF-II.[53]

Of note, the pro MBP subunits are inactive precursor forms of MBP that are found in eosinophil crystalloid bodies and function in inflammatory responses.

Assay Methods for PAPP-A

PAPP-A was initially measured in pregnancy serum using antibody pairs in an ELISA format,[235] and was later optimized for limit of detection[310] and detection of the PAPP-A–pro MBP complex.[308]

PAPP-A immunoassays are now commercially available in the United States, for research use only, in both manual and automated formats. Outside the United States, other PAPP-A assay methods are available.[225,278,353,414]

Specimen and Sampling Handling

Serum specimens are obtained from nonfasting women by standard phlebotomy techniques. A small increase in PAPP-A concentrations has been reported for collection in plastic versus glass tubes,[349] along with a significant decrease in heparin or EDTA plasma tubes versus serum.[354] PAPP-A was

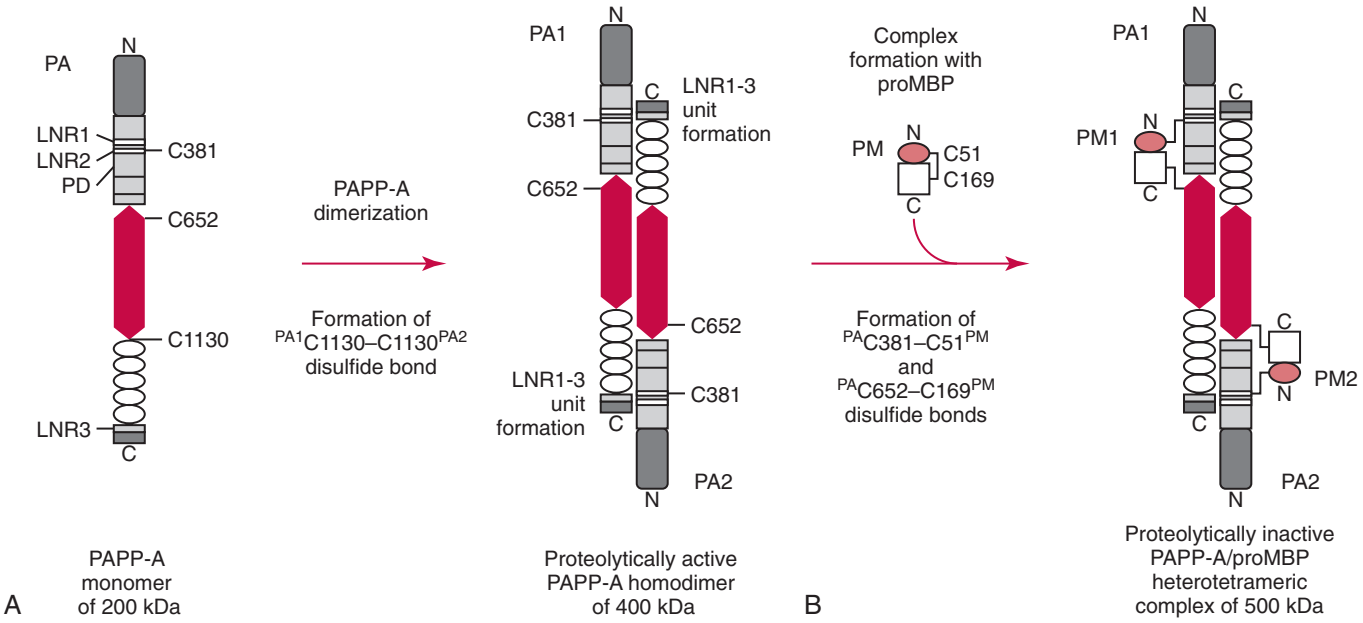

Figure 57-19 PAPP-A monomer, homodimer, and heterotetrameric complex.
[Reprinted from Boldt HB, Conover CA. Pregnancy-associated plasma protein-A (PAPP-A): a local regulator of IGF bioavailability through cleavage of IGFBPs. Growth Horm IGF Res 2007;17:10-8.]

stable with up to nine freeze-thaw cycles.[43] First-trimester serum PAPP-A concentrations are stable in serum at 4 °C for 1 week or longer, depending on the assay used for testing.[94,216]

Clinical Significance

Low PAPP-A concentrations early in pregnancy have been associated with (1) Down syndrome, (2) a high rate of fetal loss, and (3) other adverse pregnancy outcomes, including (4) poor fetal growth [intrauterine growth retardation (IUGR)], (5) premature delivery, (6) hypertension, and (7) preeclampsia.[121,352] Low PAPP-A concentrations have been reported in the second trimester of pregnancies with Cornelia de Lange syndrome, a serious developmental malformation syndrome of unknown origin.[3]

In addition to placental tissues, PAPP-A has been localized in (1) colon, (2) kidney, (3) endometrium,[277] (4) ovary, (5) fibroblasts, (6) vascular smooth muscle cells, and (7) osteoblasts.[53] Functional roles for PAPP-A in bone formation[311] and wound healing[84] have been described. Furthermore, ultrasensitive cardiac-specific measurements of PAPP-A have utility in the detection of acute coronary syndromes,[309] with higher concentrations indicative of a relatively poor prognosis.[34,198]

Fetal Fibronectin

Determining the risk of preterm labor would help clinicians manage those at high risk more aggressively, thereby lowering the incidence of preterm delivery. In 1991, fetal fibronectin concentration in cervical and vaginal secretions was proposed as a test to aid in predicting preterm delivery.[230]

Fibronectin is a term for a family of ubiquitous adhesive glycoproteins that cross-link to collagen to bind cells together. These proteins are found on cell surfaces and in plasma and amniotic fluid. The fetus has a unique fibronectin that is defined by a monoclonal antibody, FDC-6, which recognizes the epitope defined by α-*N*-acetylgalactosamine linked to threonine in a hexapeptide sequence (Val-Thr-His-Pro-Gly-Tyr), the IIICS domain.[241] When labor begins and cellular adhesion between the placenta and the uterine wall is disrupted, the concentration of fetal fibronectin in cervical and vaginal secretions increases. Mothers with more than 50 ng/mL (50 μg/L) of fetal fibronectin in these secretions during the second and third trimesters have a higher risk for preterm delivery, while those below that cutoff are at decreased risk. A majority of patients with results greater than 50 ng/mL will, however, repair any placental disruption and successfully continue the pregnancy.[153]

Assay Method

In 1995, the FDA approved the use of an ELISA technique for fetal fibronectin that used a 96-well microtiter plate format; in symptomatic women; in 1997, screening of asymptomatic women was approved. Currently, two rapid tests are available. The one that is available in the United States is a membrane immunoassay. The test utilizes a solid-phase polyclonal goat anti-fFN antibody and an enzyme-labeled monoclonal anti-fFN, FDC-6 detection antibody. The specimen is obtained by collecting cervical or vaginal mucus with a Dacron polyester swab. The fully saturated swab contains approximately 150 μL of fluid. The swab is placed into 750 μL of buffer, creating a 1:5 dilution. An aliquot of the specimen is added to the cassette containing the antibodies. Absorbance of the developed color is measured photometrically.

Asymptomatic Patients

In screening asymptomatic women, testing should take place sometime between 22 and 31 weeks' gestation. Women with a positive result (>50 ng/mL) have been shown to have a ninefold higher risk for delivery at or before 34 weeks.[154] A negative test following a positive test lowers the risk, and a second subsequent negative test returns the risk to baseline.[153] A systematic review revealed that among asymptomatic women, positive fFN results have a likelihood ratio of 4.01 (95% confidence interval, 2.93 to 5.49) for predicting birth before 34 weeks' gestation. For negative fFN results, the corresponding likelihood ratio is 0.78 (0.72 to 0.84).[185] The ACOG does not recommend routine screening of low-risk, asymptomatic women.[18]

Symptomatic Patients

In screening symptomatic women, testing should take place sometime between 24 and 35 weeks' gestation. Symptoms of preterm labor include (1) regular uterine contractions, (2) low back pain, (3) lower abdominal cramping, (4) vaginal bleeding, and (5) increased vaginal discharge. A systematic review revealed that among symptomatic women, positive fFN results have a likelihood ratio of 5.42 (95% confidence interval, 4.36 to 6.74) for predicting delivery before 34 weeks' gestation or within the next 7 days. For negative fFN results, the corresponding likelihood ratio is 0.25 (0.20 to 0.31).[185] Those patients with a negative test can safely return home because they have only an ≈1% chance of delivering in 1 week.[293] A meta-analysis of 32 studies concluded that fetal fibronectin had limited accuracy in predicting preterm birth within 7 days of specimen collection.[326]

Placental Alpha Microglobulin-1

Placental alpha microglobulin-1 (PAMG-1) is a placental glycoprotein first identified in 1977.[300] During pregnancy, PAMG-1 is secreted into the amniotic fluid, where it is present at a high concentration (2000 to 25,000 ng/mL) relative to that of maternal blood (5 to 25 ng/mL) or cervicovaginal fluid with intact membranes (0.05 to 2 ng/mL).[220] A test for PAMG-1 that exploits these large differences in concentration has been developed for clinical use as an aid for the detection of premature rupture of membranes.

A commercially available test is a rapid immunochromatographic method that utilizes two monoclonal antibodies for the rapid detection of PAMG-1 in cervicovaginal fluid. The specimen is collected using a polyester swab that is placed into the vagina for 1 minute. The fluid obtained is eluted off the swab by rinsing it in a vial containing a buffer solution for 1 minute. A test strip is then placed into the buffer for 10 minutes. The test result is determined by visual inspection of

a test and a control line on the lateral flow device. The analytical limit of detection of the test is 5 ng/mL.

Two studies have reported that this test is more sensitive and specific for the detection of PROM than clinical assessment or the nitrazine or ferning test.[93,220] A study by Cousins et al[93] included 203 women presenting with suspected PROM. The diagnosis of PROM was based on two positive results from a retrospective review of patient medical records and had to include two positive results from visual pooling of amniotic fluid, nitrazine testing, or fern testing. The clinical sensitivity of the test was 99% with a specificity of 100%.

In a prospective study of 184 women with suspected PROM, Lee et al[220] evaluated this test against conventional clinical criteria. Women were diagnosed with PROM if amniotic fluid was observed leaking from the cervix, or if any two of the following were true: (1) pooling of amniotic fluid in the posterior fornix, (2) positive nitrazine test, or (3) detection of microscopic ferning. The definitive diagnosis of PROM was made after delivery and was based on a review of the clinical record. The test was noted to be 99% sensitive and 88% specific compared with 87% and 100%, respectively, for the conventional assessment. Three false-positive results were unexplained, but it was speculated that they may have been caused by small leakages of amniotic fluid that were clinically unapparent. Compared with the nitrazine test alone, this test was significantly more sensitive (99% vs. 88%) with the same specificity (88%).

Contamination with large amounts of blood will cause a false-positive result. False-negative results may occur if the specimen is collected 12 or more hours after a rupture that is subsequently obstructed by the fetus or is resealed.

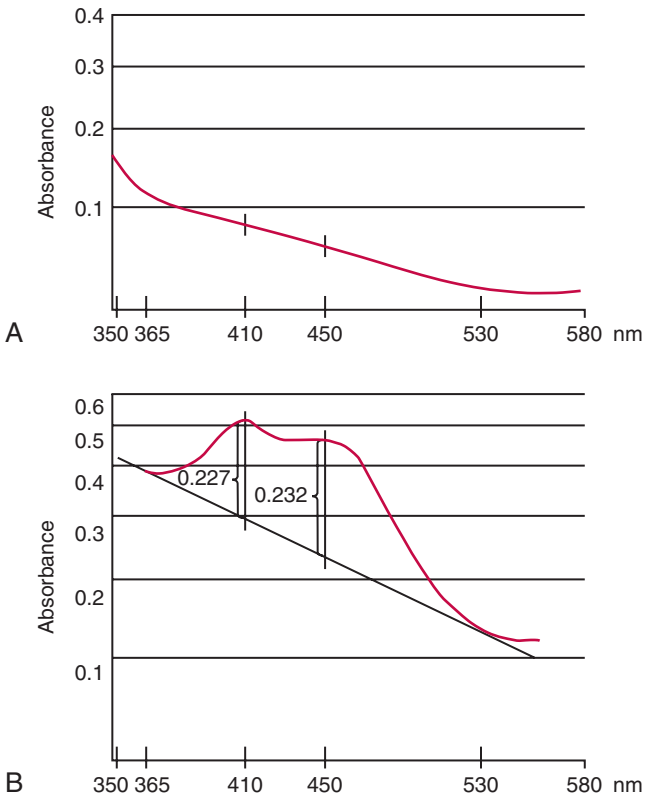

Figure 57-20 A, Normal amniotic fluid. Note near linearity of the curve when plotted on log-linear graph. B, Amniotic fluid showing the bilirubin peak at 450 nm and the oxyhemoglobin peak at approximately 410 nm. Note the baseline drawn between linear parts of the curve, from 530 and 365 nm.

Amniotic Fluid Bilirubin (ΔA_{450})

The concentration of bilirubin in amniotic fluid is generally too low (≈0.01 to 0.03 mg/dL; 0.17 to 0.51 µmol/L) to be measured by standard photometric techniques. It is possible, however, to rapidly, accurately, and directly measure amniotic bilirubin by absorption spectrophotometry.[224] Maximal absorbance of bilirubin is at 450 nm. In the absence of significant amounts of bilirubin, however, the absorbance spectrum for amniotic fluid between 365 and 550 nm defines a nearly exponential curve (Figure 57-20). On log-linear axes, the height of the curve at 450 nm above the straight line is linearly proportional to the concentration of bilirubin in the amniotic fluid. This is the difference in absorbance at 450 nm (ΔA_{450}), which is still occasionally referred to in the clinical literature as the ΔOD_{450} (change in optical density). Normally a small amount of bilirubin is present in amniotic fluid, and this amount changes with gestational age (Figure 57-21). Therefore, to interpret properly the ΔA_{450}, it is necessary to know the gestational age.

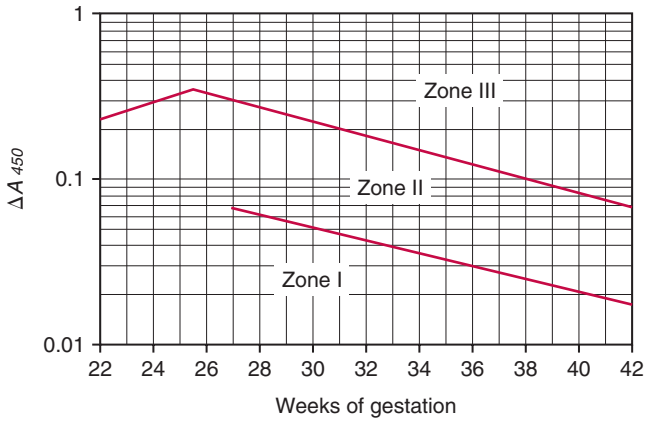

Figure 57-21 Liley's three-zone chart (with modification) for interpretation of amniotic fluid ΔA_{450}. For explanation of the three zones, see text. *(Modified from Liley AW. Liquor amnii analysis in the management of the pregnancy complicated by rhesus sensitization. Am J Obstet Gynecol 1961;82:1359-70.)*

Interpretation

The Liley or the Queenan chart is used for interpretation of ΔA_{450} data and their relationship to the gestational age of the pregnancy for unaffected and affected fetuses. The Liley chart (see Figure 57-21) was created in 1961 from data collected between 27 and 40 weeks' gestation.[224] Because of advances in neonatal care, it became necessary to utilize the Liley chart at gestational ages earlier than 27 weeks, and use of an extrapolated curve became widespread despite the fact that this modified curve was never validated. Consequently, Queenan

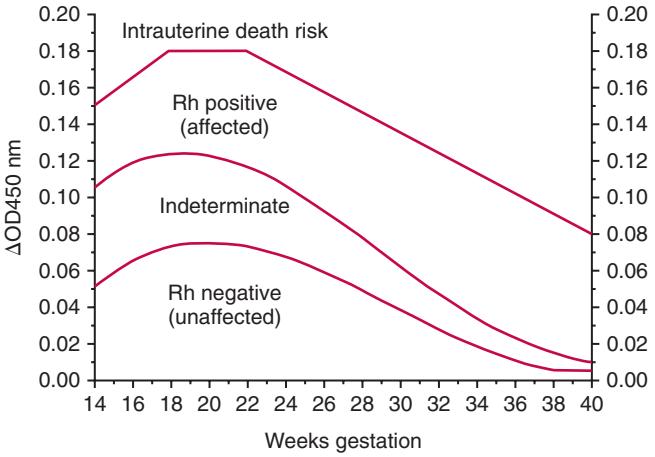

Figure 57-22 The Queenan chart. For explanation of the four zones, see text. *(Reprinted from Queenan JT, Tomai TP, Ural SH, King JC. Deviation in amniotic fluid optical density at a wavelength of 450 nm in Rh-immunized pregnancies from 14 to 40 weeks' gestation: a proposal for clinical management. Am J Obstet Gynecol 1993;168:1370-6.)*

published an alternative to the Liley chart in 1993 that was developed from data obtained between 14 and 40 weeks' gestation.[313]

Values that fall into Liley's bottom zone are considered to represent an unaffected or very mildly affected fetus. Values in the middle zone are still compatible with a minimally affected fetus, but as values rise within this zone, it is increasingly likely that the fetus is suffering moderate to marked hemolysis. Depending on the trend with time and the clinical circumstances, some clinicians recommend intervention when ΔA_{450} has climbed 80% up in the middle zone. Values in the top zone (zone III) denote severe disease. Without intervention, a fetus with values in the top zone will most likely die.[224]

Using the Queenan chart (Figure 57-22), values in the unaffected zone may be unaffected or may have mild HDN. Results in the intrauterine death risk zone tend to have severe HDN and are at high risk for mortality. Results in between these two extreme zones often include many fetuses representing all possible clinical outcomes.

Oepkes and coworkers demonstrated the superiority of the Queenan chart in a comparative study of the two charts using outcomes from 165 fetuses, 74 of which had severe anemia defined as a hemoglobin more than 5 standard deviations below the mean.[274] The Queenan and Liley charts were 81% and 76% clinically sensitive, respectively, for detecting severe anemia, with specificities of 81% and 77%, respectively. The Queenan chart is now considered the preferred chart for interpreting the ΔA_{450} result.

Contamination of an amniotic fluid specimen with fetal blood from an affected fetus with a high serum bilirubin concentration could introduce a substantial error, the magnitude of which cannot accurately be predicted. Blood contamination of amniotic fluid should be obvious from the red color and the presence of erythrocytes in the pellet after centrifugation. It is important to minimize hemolysis of the erythrocytes in such samples (by rapid processing) because the hemoglobin will interfere with the test. If the amniotic fluid remaining within the amniotic cavity has been contaminated with blood by traumatic amniocentesis, these erythrocytes lyse and contaminate the fluid with hemoglobin and bilirubinoid pigments. It takes 2 to 3 weeks for these pigments to be cleared, and for the fluid to return to the original state. Both mathematical corrections and chloroform extraction have been used for bloody specimens.[135]

Meconium staining of amniotic fluid increases the ΔA_{450} with a broad and variable peak at 400 to 415 nm[223] and it is not possible to compensate quantitatively for meconium contamination. Clearance of meconium from a single episode of passage into the amniotic fluid requires about 3 weeks.

In a pregnancy with twins within separate sacs, the individual sacs must be sampled. Inadvertent sampling of maternal urine is always a possibility,[223] although the risk of this error is reduced when ultrasonography is used.

Tests for Evaluating Fetal Lung Maturity

Fetal lung maturity (FLM) tests help a clinician decide whether the best perinatal survival will be achieved in utero or in the nursery. The most common situation in which a fetal lung maturity test is ordered is before repeat cesarean delivery when the age of gestation is uncertain. Another major indication is anticipated early delivery because of some medical or obstetrical indication, such as (1) preterm labor, (2) premature rupture of the membranes, (3) worsening maternal hypertension, (4) severe renal disease, (5) intrauterine growth retardation, or (6) fetal distress. Results indicating immaturity of the fetal lungs might cause postponement of elective delivery or prompt active interventions to suppress preterm labor. Pharmacologic administration of corticosteroids is recommended for women between 24 and 34 weeks' gestation who are likely to deliver in the next week.[6] This therapy is thought to accelerate pulmonary maturation and prevent respiratory distress syndrome. If delivery of an infant is inevitable, transfer to a tertiary healthcare center is appropriate.

Numerous tests of amniotic fluid for FLM have been developed. Tests that measure lamellar bodies directly, the surfactant they contain, or the biophysical property of surfactant are the most useful for evaluating FLM. Methods still in clinical use today include (1) fluorescence polarization, (2) lamellar body count (LBC), (3) detection of the phosphatidylglycerol lecithin/sphingomyelin (L/S) ratio, and (4) foam stability.

In a survey of laboratories that offered FLM testing, a commercial fluorescence polarization test was the most widely offered FLM test.[161] This was followed by rapid detection of phophatidylglycerol (21% of laboratories), L/S ratio (18% of laboratories), and LBC (13% of laboratories), and the detection of phosphatidylglycerol by thin-layer chromatography (TLC) (7% of laboratories) and the foam stability test (1% of laboratories).

The number of FLM tests performed each year in the United States is declining. Surveys of obstetricians suggest that the primary reason for the decline in utilization is that physicians feel the tests are not medically necessary for patient care.[161,244] The impact that removal of the TDx FLM II test will have on the utilization of FLM tests is uncertain. Faced with its loss, physicians have indicated that they would order the L/S ratio or the lamellar body count (LBC); however, few laboratories are currently offering either test.[161] The LBC is a logical replacement for the TDx FLM II test.

Standards of laboratory practice for FLM testing were published in 1997[25] and 2006[340] that made several recommendations regarding specimen collection, handling, centrifugation, and mixing that remain valid today. Hospital laboratories should offer a rapid test in their laboratory or from a reference laboratory, such as fluorescence polarization, phosphatidylglycerol, or LBC. These should be available daily on both a routine and emergency basis. Requests for L/S ratios may be sent to a reference laboratory. Analysts should communicate the results of any FLM test immediately to the ordering location, because the patient's status may be changing and the information might assist with management of labor.

In 2008, the ACOG issued a revised practice bulletin on fetal lung maturity.[16] This bulletin encourages the assessment of FLM prior to a scheduled delivery at less than 39 weeks' gestation, unless it could be inferred from clinical history. It also acknowledges the high negative (mature) predictive value of all FLM tests and encourages test selection based on sample quality. Readers may want to carefully read that bulletin, because many obstetricians rely on it.

Collection and Handling of Amniotic Fluid for Fetal Lung Maturity Assessment

Before the details of individual methods are given, details of the specimen and specimen handling are described. These topics are common to many methods.

Specimen Collection and Processing

Amniotic fluid is obtained by transabdominal amniocentesis, usually during real-time sonographic visualization (see Chapter 7). In a multifetal pregnancy, there are usually separate sacs, each of which should be sampled. Vaginal pool specimens are rarely adequate for testing. Clinicians should seriously consider amniocentesis in patients with ruptured membranes.[25]

Whenever possible, the fluid should be tested immediately. If there is to be a delay of a few hours, the fluid should be refrigerated at 4 °C.[331] The total phospholipid content of amniotic fluid does not change significantly during at least a week of storage,[385] and lamellar bodies are stable for at least 30 days.[231] If testing will be delayed longer than 1 week (e.g., fluids kept for research studies), fluids should be stored frozen at −20 or −70 °C. It should be noted that a single freeze-thaw cycle will decrease the LBC.[231] Immediately before the fluid is tested, it should be gently inverted 20 times to obtain a uniform suspension. At least 2 minutes on a test tube rocker is recommended.[25]

Procedures for measuring fetal lung maturity include a centrifugation step to remove debris. Careful attention to technique is needed to obtain reproducible results. Any centrifugation removes some pulmonary surfactant from the specimen. Accidentally prolonged centrifugation has been found to reduce recovery of the phospholipids to less than 50%.[275] For best results, the specimen should be well mixed, lightly centrifuged, decanted, and mixed again.

Fluorescence Polarization Fetal Lung Maturity Tests[30,134,370]

Fluorescence polarization is a dimensionless ratio with values from 0.000 to 0.500 for dilute solutions containing fluorescing compounds (see Chapter 10).[211] Polarization (P) measures the rotational diffusion of the fluorophore relative to its fluorescent half-life. If the half-life is short compared with the rate of rotational diffusion, P will be high. In contrast, if molecular rotation is faster than the excited state decay, then P will be low.

The test was originally described in 1976 by Shinitzky and colleagues, who used diphenylhexatriene (DPH) as the fluorescent dye and proposed that for amniotic fluid, lower polarization values reflected a decrease in the microviscosity of surfactant phospholipids.[341] The fluidity of these phospholipids paralleled the change in lipid composition with maturation of the fetal lungs.[341] Several disadvantages prevented widespread use of DPH fluorescence polarization in clinical laboratories. Tait and associates[370] improved the technique by using a more stable fluorescent dye, NBD-PC, and a commercial polarimeter. NBD-PC binds to albumin and to surfactant; thus the resulting polarization is a function of the surfactant/albumin ratio.[26] Russell[321] developed a commercial version of the assay using a slightly different dye, PC-16.[302]

TDx FLM II Method

The commercial fluorescence polarization test, TDx FLM II (Abbott Laboratories), is to be retired by the manufacturer at the end of 2011. It has an analytical measurement range of 0 to 160 mg surfactant/g albumin. Uncentrifuged amniotic fluid is used for this method. If specimens have been accidentally centrifuged, the surfactant should be resuspended before testing.[160] The TDx FLM II assay uses 25 µL of filtered amniotic fluid. Imprecision (CV) is 4 to 5% at 20 and 115 mg/g.

A first-generation instrument that was commercially available[184,322,360,416] recommended a maturity cutoff of 70 mg phospholipid/g of albumin or greater, a second-generation instrument with values less than or equal to 39 mg/g are considered immature, those greater than or equal to 55 mg/g mature, and others (40 to 54 mg/g) intermediate. Several clinical outcome studies of the first-generation test suggested that the upper cutoff could be lowered without impacting the sensitivity for RDS.[23,180,360] Similar studies of second generation machine showed that ≈45 mg/g could be used as a cut point, which will improve assay specificity to 85%, while maintaining sensitivity for clinically significant respiratory distress syndrome at 95 to 100%.[127,200]

Several investigators have recommended that FLM should be interpreted as a function of gestational age.[195,292,303] Instead of changing the decision limits for each gestational age, the authors recommend reporting the RDS risk for a given FLM result at a specific gestational age. Calculated absolute risks, however, will vary with the prevalence of RDS in the tested population.[165] This restricts their usefulness to populations that have an RDS prevalence similar to that from which the risks were derived. One study reported odds ratios that were independent of RDS prevalence at each gestational age and therefore are more broadly applicable.[292]

Most twins are delivered preterm, and many suffer from preterm complications. If those complications are excluded, twins have the same RDS incidence as singletons matched for gestational age.[139] After 31 weeks' gestation, however, average FLM results from twin pregnancies are 22 mg/g higher than those from singleton pregnancies.[243] Sampling both sacs is recommended when testing before 32 weeks' gestation.[411]

Several studies have concluded that diabetes does not affect the reference values of FLM.[112,227]

NBD-PC Fluorescence Polarization Method

The NBD-PC method is also called FPol. The specimen is amniotic fluid that has been centrifuged at 400 ×g for 2 minutes. Results are expressed using artificial units of millipolarization (P × 1000, mP). The analytical measurement range is 150 to 350 mP. No calibrators are used, but use of a Triton ×100 control ensures that the temperature is correct, and that the dye is not degraded. Comparison of the NBD-PC assay with a similar assay reveals, a strong nonlinear, inverse correlation.[24,28]

An NBD-PC fluorescence polarization value of less than 260 mP is considered mature, values between 260 and 290 mP are considered transitional, and values greater than 290 mP are considered immature.[85,369] Using 260 mP as the cutoff, this test has a clinical sensitivity of 94% and a clinical specificity of 84%. Supplemental use of the L/S ratio for those patients with transitional results is of little benefit. The 260 mP cutoff is appropriate for high-risk pregnancies. In the setting of a patient who needs a cesarean section at term, when there is no penalty for delaying delivery, a cutoff of 230 mP is more appropriate.

If there is less than 0.5% blood in the amniotic fluid, the results are not affected. Contamination with more than this amount tends to increase low results and decrease high results.[370] Results that are clearly mature (<230 mP) or immature (>290 mP) are reliable for predicting fetal lung status. Results between these values cannot be interpreted.

Because of improved pregnancy management, very few infants with RDS are born to women with diabetes. Thus exact estimates of clinical sensitivity and specificity are not available in this clinical setting. The predictive value of mature status in a patient with diabetes mellitus appears to be equivalent to that in a patient without diabetes.[85,112,227]

Lamellar Body Counts

Lamellar bodies have been counted directly using the platelet channel of most whole blood cell counters.[119] This technique is termed the lamellar body count (LBC).[29] None of the manufacturers of whole blood cell counters have claims to support the use of their instruments for the LBC, and so the test is considered a laboratory-developed test (LDT).

Lamellar bodies have a broad size distribution, ranging from 0.2 to 10 fL.[29] Whole blood cell counters used during development of the LBC method used a size gate from 2 to 20 fL. Therefore only a portion of lamellar bodies are counted in these instruments. Because the LBC is a direct reflection of surfactant concentration in amniotic fluid, fetal urination lowers the LBC.

Centrifugation of amniotic fluid should be omitted.[25,118,259] Mixing of the fluid is critical—2 minutes is recommended on a tube rocker or at least 20 inversions immediately before analysis.[259] Typical LBC results vary from 0 to 150,000/μL.

Because of different platelet identification algorithms, counts will be lower or higher on different instruments. Instruments that use similar algorithms (e.g., impedance) will show greater concordance than those that use different algorithms.[158,231,365]

Specimens containing mucus produce erratic results.[259] Contamination of the fluid with whole blood will decrease the LBC by presumably trapping them in a fibrin matrix, which occurs when the number of red blood cells exceeds 31,000/μL.[231] Even small amounts of meconium have been observed to produce dramatic increases in the LBC.[231]

Interpretation

Most outcome studies that have evaluated the LBC as a test of fetal lung maturity have utilized Beckman Coulter brand cell counters. Results of these studies support the consensus maturity cutoff of 50,000/μL.[259] However, given the variation in LBC results between cell counters, this cutoff should not be adopted by a laboratory without validation, because studies using different brands of cell counters have suggested different cutoffs for maturity.[82,188]

All clinical outcomes studies* have reported that LBC has high clinical sensitivity (95 to 100%) but low clinical specificity (about 70%) for prediction of RDS. A meta-analysis[412] reported that at a fixed clinical sensitivity of 95%, the LBC specificity was 80%, whereas the L/S ratio specificity was 70%.

Studies of the diagnostic accuracy of LBC assays for diabetic mothers have not been conducted. An assay comparison study of LBC, L/S ratio, and PG, however, reported good agreement among the tests for 90 diabetic subjects with no cases of RDS.[114] Similarly, in a study of 187 women, 22% of whom had inadequate glycemic control (defined as arithmetic glucose mean greater than 120 mg/dL from all

*References 27, 35, 55, 107, 115, 119, 125, 158, 178, 188, 196, 219, 260, and 294.

glucose tests performed during the third trimester), no significant differences in the LBC were observed between those with adequate and inadequate glucose control.[111]

Determination of Lecithin/Sphingomyelin Ratio and Saturated Phosphatidylcholine[357,377]

The major surface active component of the lung surfactant is palmitate disaturated-phosphatidylcholine (DSPC), which represents 85% of total lecithins. Its concentration in amniotic fluid tends to rise with increasing gestational age. Most of the DSPC in amniotic fluid comes from the fetal lungs via tracheal effluent. The concentration of DSPC in amniotic fluid is measured directly and is correlated with FLM, or its concentration is related to another lipid, sphingomyelin, and that ratio used to predict lung maturity. Although sphingomyelin is a minor component of pulmonary surfactant, it is ubiquitously distributed in cell membranes, especially those of erythrocytes, and is also found in plasma. Nearly all of the sphingomyelin in amniotic fluid is derived from nonlung sources; thus it has no role in the surfactant system in the lungs. The concentration of lecithin relative to sphingomyelin, the L/S ratio, tends to rise with increasing gestational age. This is not a uniform gradual increase; a rather sudden increase occurs at 34 to 36 weeks' gestation and correlates with the development of fetal lung maturity.[152]

Most laboratories use a commercially available method for L/S determination. However, because many techniques are available, laboratories should be very careful when establishing medical decision limits.[65,357,377] Some methods measure all phosphatidylcholine species, both saturated and unsaturated. Different staining methods will differentially stain phosphatidylcholine compared with the biological internal standard, sphingomyelin. The L/S ratio is a labor intensive test that has poor within- and between-laboratory precision, which may be why only 13% of laboratories perform it.[161]

Interpretation

The original maturity decision limit for the L/S ratio was 2.0 or greater.[380,381] Most laboratories use a method that omits the acetone precipitation step, which will produce slightly higher values. A conservative reference interval for lung maturity is an L/S ratio of 2.5 or greater. About 1% of babies delivered within 24 hours of obtaining an L/S ratio greater than 2.5 are expected to develop RDS; thus 99% of babies predicted to be mature are and will not develop RDS. Almost half of infants with L/S ratios between 1.5 and 2.5, however, will not develop RDS. Thus in contrast to the high degree of reliability of a prediction of maturity, only one third of babies predicted to be immature will in fact develop RDS.

Before the use of tight glycemic control during pregnancy, babies of diabetic mothers more frequently developed RDS.[319] A number of investigators have reported that infants of diabetic mothers more frequently develop RDS despite mature L/S ratios,[98] but other studies have reported no delay in lung maturity for infants of diabetic mothers.[141,367] In poorly controlled diabetic cases, both maturation delay[304] and lack of delay[252] have been reported. Although no RDS outcome studies exist, other studies of well-controlled diabetic mothers report no effect on the relationship between L/S ratio and gestational age.[42,252] For this reason, separate reference intervals are not recommended for well-controlled diabetic pregnancies.[25,340]

For multifetus pregnancies, separate specimens should be analyzed for each fetus. Infrequently, more than one fetus shares an amniotic fluid cavity. In this situation, a mature result is less predictive of maturity, because it represents a mixture of pulmonary surfactant from multiple fetuses. In the case of twins, the smaller one is more likely to develop RDS than the larger one.[254]

Serum has a large concentration of lecithin and sphingomyelin. The serum ratio varies between 1.5 and 2.0, depending on the individual. Values of blood-contaminated specimens therefore tend to be drawn into that range from higher or lower values. A high L/S ratio in the presence of even substantial blood contamination can safely be interpreted as reflecting mature lungs.[147] Similarly, contaminated samples with very low ratios clearly reflect immature lungs. Borderline values of bloody specimens should not be interpreted, because they may represent very immature values falsely elevated or mature values falsely depressed. Various effects of meconium contamination have been reported, including some evidence that the L/S ratio may be changed in the absence of contamination that is visible to the eye.[386] The chromatograms of fluids heavily contaminated with meconium are not interpretable.

Vaginal contamination of specimens obtained from a pool of fluid that has been present in the vagina for a relatively brief period does not affect either test.[116,301]

Phosphatidylglycerol

The detection of phosphatidylglycerol is a commonly used qualitative method used to assess FLM. Measurement of PG was classically performed in conjunction with the L/S ratio, and the combination of the two tests is known as the *lung profile*.[210] The rapid detection of phosphatidylglycerol is accomplished using a commercially available immunochemical test.

The concentration of PG in amniotic fluid increases with gestational age. Most TLC techniques are positive when PG exceeds about 2 µmol/L. At this cutoff, results indicating maturity are almost always correct, but results indicating immaturity are frequently incorrect.

AmnioStat-FLM

Most laboratories that offer PG testing use a qualitative rapid agglutination test (AmnioStat-FLM-PG, Irvine Scientific, Santa Ana, Calif). This test utilizes polyclonal anti-PG antibodies to agglutinate microscopic PG-containing lamellar

bodies into macroscopic clusters. The test is simple to perform and is accomplished by mixing equal volumes of amniotic fluid and a lecithin/cholesterol reagent with a buffer solution. An aliquot of this mixture is combined with anti-PG antibody reagent on a laminated card, and is mixed and rotated on a serologic rotator at 60 revolutions per minute (rpm) for 10 minutes. Agglutination is determined by visible inspection and indicates the presence of PG. Results for this test are reported as negative (immature) or positive (mature). Note that this nomenclature is opposite that used for other FLM tests, with positive meaning immature. RDS rarely develops in an infant when a positive PG result is obtained.

Interpretation

Several clinical outcome studies using AmnioStat have been reported.[128,136,144,175,228,408] Although positive PG results are about 99% predictive of maturity, negative results are highly unpredictive (RDS develops in about 25% of cases with a negative PG, depending on the population) and therefore are not useful clinically. A positive PG result is very useful in low-risk pregnancies that require cesarean section. Determination of PG is also useful for specimens contaminated with blood or meconium. PG is not found in blood nor meconium; therefore results are not affected by the presence of either of these contaminants.[38,128]

Many clinicians rely on PG whenever they need to assess FLM in a diabetic patient.[118] However, no modern studies support this practice. In normal pregnancy, PG is detected by TLC or AmnioStat-FLM-PG at approximately 35 weeks' gestation. In diabetic patients, regardless of glycemic control, PG is detected about 1.5 weeks later.[103,252,381] Many diabetic patients will deliver term infants unaffected by RDS before any PG is detected.[304] The diabetic status of the patient does not affect the method of detection.[324]

Determination of the Lung Profile[209,210]

This method for assessing FLM was invented by Marie Kulovich and Louis Gluck in the early 1970s. Although it is still offered by some reference laboratories, most hospital laboratories have converted to newer techniques. The pattern of L/S ratio, PI, and PG are used to determine the status of fetal pulmonary maturation.

Foam Stability Index[337]

When pulmonary surfactant is present in amniotic fluid in sufficient concentrations, the fluid is able to form a highly stable surface film that supports bubbles. Other substances in the fluid, including proteins, bile salts, and salts of free fatty acids, are also capable of forming stable bubbles, but they can be removed from the film by ethanol, which competes with the other substrates for a position in the surface film.[87] The test makes use of the principle that more surfactant activity is necessary to support a stable foam as the fraction of ethanol in the mixture is increased.[336-339] Therefore a fixed volume of undiluted amniotic fluid is mixed with increasing volumes of ethanol, and the largest fraction of ethanol in which the amniotic fluid is still capable of supporting a foam is determined. The highest fraction of ethanol at which a positive reading is obtained is the foam stability index (FSI). In practice, however, the FSI is not recommended because of several disadvantages. Evaluation of the meniscus for a stable ring of bubbles is a subjective test, and amniotic fluid samples contaminated with blood or meconium have been observed to produce false-mature results. Additionally, the use of hygroscopic ethanol presents a challenge, as it readily absorbs water from the atmosphere and decreases the relative percentage of ethanol in the reagent. This presents a considerable challenge to laboratories that wish to continue to offer this LDT.

Interpretation

An FSI value of 0.47 or greater is interpreted as mature. Several studies have demonstrated that the risk of RDS increases with decreasing FSI.[336-338] Similar to other tests of lung maturity, the FSI has excellent clinical sensitivity but frequently produces false-immature results from infants who do not develop RDS.

Tubes and stoppers must be clean and free of detergents to prevent false-positive readings. The final concentration of ethanol is critical. Ethanol is hygroscopic; therefore careful attention must be paid to its preparation and storage. Specimens contaminated with blood or meconium tend to give a falsely mature result.

CHAPTER 58

Newborn Screening and Inborn Errors of Metabolism

*Marzia Pasquali, Ph.D., F.A.C.M.G., and Nicola Longo, M.D., Ph.D.**

An inborn error of metabolism (IEM) is a genetically determined biochemical disorder that affects an individual's ability to convert nutrients or to use them for energy production. Typically, IEMs present in the newborn period or in infancy. Some diseases, however, such as fatty acid oxidation defects or milder variants of classic metabolic disorders, may not be detected until adulthood. Despite the long asymptomatic period, their consequences can still be devastating and may lead to death. Therefore identification and treatment of these diseases before irreversible damage occurs is critical. Clinical biochemical genetics is the discipline that deals with the diagnosis and treatment of patients with inborn errors of metabolism. In contrast to other, more common diseases, treatment of IEMs is lifelong and requires frequent monitoring. The biochemical diagnosis of IEMs and treatment monitoring involve analysis of (1) metabolites, (2) enzymatic activity, and/or (3) molecular structure. Because of technological advances [such as the introduction of tandem mass spectrometry (MS/MS), allowing the simultaneous detection of multiple analytes] and improved outcomes of patients with IEMs identified and treated early, many IEMs are now included in newborn screening programs.

CLINICAL PRESENTATION

Inborn errors of metabolism, which are due to impaired activity of enzymes, transporters, or cofactors, result in accumulation of abnormal metabolites (substrates) proximal to the metabolic block, or lack of necessary products. Figure 58-1 shows a hypothetical metabolic pathway in which the substrate A needs to be converted into the product D, with arrows representing individual enzymes. If an enzyme is defective (vertical rectangle), the concentration of substrate A will increase and the concentration of product D will decrease. It is then possible that high concentrations of substrate A will accumulate and become a source of substrate for enzymes not usually involved in its metabolism, thereby producing abnormal byproducts (E and F) through alternative pathways. Accumulation of specific metabolites and their byproducts within organs and tissues and/or the lack of reaction products are the chemical bases of the pathology observed in different inborn errors of metabolism. At the same time, measurement of some of these metabolites or their byproducts serves as the basis of biochemical diagnostic testing for inborn errors of metabolism and early detection by newborn screening programs.

Symptoms of inborn errors of metabolism usually appear early in infancy, although several types become symptomatic in late childhood or adulthood. Signs and symptoms include (1) failure to thrive, (2) seizures, (3) mental retardation, (4) organ failure, and even (5) death. Inborn errors of metabolism have been divided into three broad categories, based on the effects of their metabolic derangement[55]:

1. Intoxication effect: IEMs in this category are the result of metabolites accumulating in the body that produce a toxic effect on different organs. The patient may become acutely ill after a symptom-free period, usually 24 to 72 hours, and concomitantly with ingestion of metabolites that are not metabolized, such as proteins or sugars. Types of IEMs that belong in this group include (1) aminoacidopathies (e.g., phenylketonuria, maple syrup urine disease, homocystinuria), (2) urea cycle defects (e.g., citrullinemia, argininosuccinic aciduria, ornithine transcarbamylase deficiency), (3) organic acidemias (e.g., propionic acidemia, methylmalonic acidemia, glutaric acidemia type I), and (4) disorders of sugar metabolism (galactosemia, hereditary fructose intolerance). Some of these disorders, such as phenylketonuria, affect primarily the brain, causing severe mental retardation but without acute decompensation. In other

*The authors gratefully acknowledge the contributions of Drs. Piero Rinaldo, Si Houn Hahn, and Dietrich Matern to the previous edition of this text, on which portions of this chapter are based.

disorders (e.g., organic acidemias), symptoms appear shortly after protein intake (usually after the first few feedings) and include vomiting, lethargy, seizures, and coma leading rapidly to death if not recognized and treated appropriately.

2. Energy deficiency: Symptoms of disorders in this category are due to impaired energy production. In some cases, patients may be asymptomatic for a long time, until energy requirements are increased as the result of involuntary fasting, illness, infection, or strenuous exercise. A classic example of these disorders involves fatty acid oxidation (e.g., medium chain acyl–coenzyme A [CoA] dehydrogenase deficiency, very long chain acyl-CoA dehydrogenase deficiency, carnitine uptake defect, carnitine palmitoyl transferase deficiency I and II), although in this case, the block in the metabolic pathway, in addition to impairment in energy production, leads to the accumulation of intermediates that cause an intoxication effect.[52] Other diseases in this group include glycogen storage disorders, in which hypoglycemia can occur in the presence or absence of any stress, mitochondrial disorders, and congenital lactic acidosis, in which the clinical course is progressive even in the absence of triggering conditions.[43]

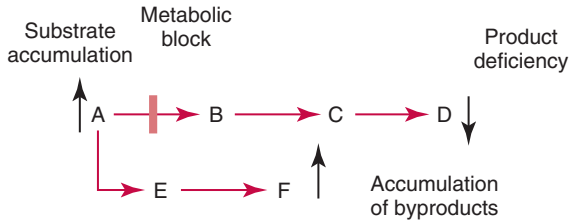

Figure 58-1 Schematic of metabolic pathway. The substrate *A* is converted by a series of reactions into product *D*. If one of the enzymes *(red arrows)* is defective (metabolic block), the substrate of the reaction will accumulate (*A* in this case) and can enter alternative pathways of metabolism, leading to the formation of byproducts (*E* and *F* in this case). At the same time, the concentration of the product of the reaction *(D)* will decrease.

3. Disorders of complex molecules: These disorders result from defects in the synthesis or catabolism of complex molecules. They are progressive, are independent of intercurrent events, and are not related to food intake. The metabolism of complex molecules is altered in all (1) lysosomal disorders, (2) peroxisomal disorders, and (3) disorders of intracellular trafficking and processing. For some of these disorders, a therapy is now available that is usually more effective if initiated before irreversible organ damage has occurred. For this reason, some of these conditions are also being considered for newborn screening.

DIAGNOSIS

With few exceptions, the diagnosis of IEM is primarily a laboratory process. For example, routine laboratory tests in the symptomatic IEM patient and a high index of suspicion often point the clinician toward a specific IEM. For example, (1) hyperammonemia without metabolic acidosis suggests a defect of the urea cycle; (2) hypoketotic hypoglycemia usually with hyperammonemia to various degrees suggests fatty acid oxidation impairment; and (3) hyperammonemia with metabolic acidosis and ketosis is suggestive of an organic acidemia (Table 58-1). The diagnosis of IEMs requires specific tests that usually are performed in Biochemical Genetics Laboratories. The core group of tests necessary for the diagnosis of IEMs includes (1) amino acid analysis in plasma, urine (in few cases), and cerebrospinal fluid (in even fewer cases), (2) organic acid analysis in urine, and (3) carnitine and acylcarnitine profile in plasma.

In contrast to common chemistry tests, biochemical genetics tests are complex and require specialized personnel to perform the tests and interpret the results. For example, it is recommended that each profile be interpreted in the context of clinical history, physical signs, and other laboratory studies by a board-certified doctoral scientist or physician with specialized training in metabolic disease and analytical testing. When the results are suggestive of a metabolic disorder, interpretation should include information about the disease and should suggest additional tests to confirm the diagnosis, when appropriate.

TABLE 58-1 Biochemical Findings in Disorders of Amino Acid, Fatty Acid, and Organic Acid Metabolism

	Organic Acidurias	Fatty Acid Oxidation Disorders	Urea Cycle Disorders	MSUD	NKHG
Neurologic distress	I	I/ED	I	I	I
Metabolic acidosis	+++	–	+	+	–
Ketonuria (ketone bodies)	+++	–	–	+	–
Hyperammonemia	+	+	+++	–	–
Hypoglycemia (fasting)	+	+++	–	–	–

Some metabolic disorders are treated by dietary modifications usually consisting of a life-long dietary regimen in which the nutrient in question is restricted, with supplementation of vitamins, cofactors, and, in some cases, medications. Because of the excellent outcomes of metabolic patients when treatment is initiated before symptoms or any damage has occurred, a major focus of Biochemical Genetics is on early identification of IEMs, prenatally and especially in the newborn period, through universal newborn screening.

Prenatal Diagnosis

Despite constant progress in medical treatment, several IEMs result in severe morbidity and inevitable mortality early in life. Most of these disorders are inherited as autosomal recessive traits (Table 58-2); therefore the recurrence risk in subsequent pregnancies of the same couple is 25%. Genetic counseling of parents consists of a balanced assessment of (1) familial risk factors (parental consanguinity and ethnic origin), (2) risk of pregnancy loss as a consequence of the sampling procedure [0.5 to 1% by chorionic villus sampling (CVS), 0.5% by amniocentesis], (3) risk of maternal complications,[53] (4) clinical validity of the prenatal test, (5) the burden of the disease, and (6) variable phenotypic expression of the disease even within the same family.

Methods used for prenatal diagnosis of IEMs have different requirements in terms of timing, sample collection, and options for independent confirmation. CVS is performed at 10 to 13 weeks' gestational age, has a higher risk of fetal loss as compared with classic amniocentesis, and might not provide accurate results because of possible contamination with maternal tissue. Alternatively, certain enzymes, such as those of the glycine cleavage pathway defective in glycine encephalopathy, are expressed only in cells of chorionic villi, rendering this procedure the only possibility when DNA testing is not possible.[4] Amniocentesis is performed later in pregnancy (14 to 20 weeks) and provides both amniocytes and amniotic fluid to be used for independent and complementary diagnostic methods. Reliance on separate tests based on independent methods performed by laboratories with adequate prior experience is strongly encouraged to avoid incorrect or inconclusive results. In some IEMs (e.g., organic acidemias), amniotic fluid is tested for the presence or absence of specific metabolites, in addition to providing amniocytes for enzyme assay, DNA analysis, or both. The combination of at least two independent tests (e.g., enzyme assay + DNA; metabolite analysis + enzyme or DNA) enhances confidence in establishing a prenatal diagnosis. Before entertaining a prenatal diagnosis, one should ensure that the proband (individual first brought to medical attention in whom the diagnosis was established) related to the index case has a diagnosis confirmed by traditional methods, including enzymology when appropriate. If DNA analysis is considered, mutations of the index case should be known and confirmed as causative of the disease. Major advantages of direct metabolite analysis in amniotic fluid include independence from tissue expression and rapid turnaround time. However, analysis of direct metabolites in amniotic fluid has been reported for only a very limited number of diseases.

Newborn Screening

Newborn screening is a public health activity aimed at early identification of conditions for which timely intervention is expected to result in elimination or reduction of morbidity, mortality, and disabilities. It is an important and effective component of preventive medicine. Originally instituted in the 1960s for the early detection of phenylketonuria (PKU), the number of diseases screened for in the newborn period has dramatically increased with the introduction of MS/MS multiplex analyses of acylcarnitine and amino acid profiles.[13] Inclusion of IEMs as a whole in newborn screening panels has been controversial, because with few exceptions, their incidence, natural history, and prospective screening experience, as well as the effectiveness of treatment, have not yet been defined.[10] However, implementation of this expanded screening allows collection of these data leading to a better understanding of these diseases. The complexity of the interpretation of MS/MS newborn screening results has prompted the development of algorithms for proper confirmatory testing and differential diagnosis of all detectable IEMs (http://www.acmg.net/resources/policies/ACT/condition-analyte-links.htm/accessed September 29, 2011).

Although metabolic disorders identified by MS/MS represent the largest group of diseases identifiable by newborn screening, other IEMs and endocrine and hematologic disorders (such as galactosemia, biotinidase deficiency, cystic fibrosis, congenital hypothyroidism, congenital adrenal hyperplasia, and hemoglobinopathies) are identifiable through more traditional screening methods (e.g., enzyme assays, immunoassays, electrophoresis). Advances in therapeutic interventions for IEMs are continuously expanding the role of newborn screening. Newborn screening does not identify all metabolic disorders, and some patients can be missed by newborn screening. Therefore a symptomatic patient, at any age, should be investigated despite normal newborn screening results.

Evaluation of Symptomatic Patients

The most informative samples are collected from patients during acute metabolic decompensation. When possible, urine and blood should be collected at the same time. In several diseases, especially in fatty acid oxidation disorders, diagnostic abnormalities may not be detected when the patient has recovered from the acute episode. Urine and plasma/serum samples are stored at −20 °C until the need for specialized tests has been determined. Quantitative profiling of amino acids, carnitine, acylcarnitines, and fatty acids in plasma, and organic acids and acylglycines in urine, is the biochemical investigation necessary to diagnose these disorders. Alternatively, a blood spot on filter paper may provide enough material for one or more of the investigations described in this chapter. In case of death, collection of body fluid and tissue should be secured according to available protocols.[12,54]

TABLE 58-2 Clinical and Laboratory Characteristics of Disorders of Amino Acid Metabolism

Common Name	OMIM* No.	Inheritance	Enzyme/Transport Defect	Incidence (USA)	Major Clinical Features	Major Biochemical Marker(s)
Disorders of Aromatic Amino Acid Metabolism						
Classic phenylketonuria (PKU)	261600	AR	Phenylalanine hydroxylase	>1:25,000	Mental retardation, fair complexion and pigmentation	Phenylalanine (B), phenylpyruvic (U), phenyllactic (U), 2-OH phenylacetic (U)
Defect of biopterin cofactor biosynthesis	233910	AR	GTP cyclohydrolase I	<1:100,000	Progressive mental retardation, seizures, muscle tone abnormalities, microcephaly, movement disorder	Phenylalanine (B), low neopterin and biopterin (U), low 5-HIAA and HVA (CSF)
Defect of biopterin cofactor biosynthesis	261640	AR	6-Pyruvoyltetrahydropterin synthase	<1:100,000	Progressive mental retardation, seizures, muscle tone abnormalities, microcephaly, movement disorder	Phenylalanine (B), high neopterin, low biopterin (U), low 5-HIAA, HVA (CSF)
Defect of biopterin cofactor regeneration	261630	AR	Dihydropterin reductase (DHPR)	<1:100,000	Progressive mental retardation, spasticity, dystonia, myoclonus, microcephaly, movement disorder	Phenylalanine (B), high biopterin (U), low 5-HIAA, HVA (CSF), low DHPR activity in DBS
Defect of biopterin cofactor regeneration	264070	AR	Pterin-4a-carbinolamine dehydratase	<1:100,000	Transient muscle tone abnormalities, long-term outcome usually benign	Phenylalanine (B), high neopterin and primapterin (U)
Tyrosinemia type I	276700	AR	Fumarylacetoacetase	<1:100,000	Cirrhosis, hepatocellular carcinoma, rickets, renal Fanconi syndrome, neuropathic pain	Tyrosine (B), succinylacetone (U), 4-OH phenylpyruvic, 4-OH phenyllactic (U)
Tyrosinemia type II	276600	AR	Tyrosine aminotransferase	<1:100,000	Corneal ulcers, keratosis on palms and soles, photophobia, pain to extremities	Tyrosine (B), 4-OH phenylpyruvic, 4-OH phenyllactic (U)
Tyrosinemia type III	276710	AR	4-Hydroxyphenylpyruvate dioxygenase	<1:100,000	Developmental delay	Tyrosine (B), 4-OH phenylpyruvic, 4-OH phenyllactic (U)

Hawkinsinuria	140350	AD	4-Hydroxyphenylpyruvate dioxygenase	<1:100,000	Failure to thrive, hepatocellular dysfunction	2-Cystenyl-1,4-dihydrocyclohexenylacetate (U), 4-hydroxycyclohexylacetic acid (U)
Disorders of Branched-Chain Amino Acid Metabolism						
Maple syrup urine disease (MSUD IA, IB, II)	248600	AR	Branched-chain ketoacid dehydrogenase complex	<1:100,000 (1:378 Mennonite)	Hypotonia, lethargy, seizures, coma, vomiting, ketosis, pancreatitis, brain edema	Branched-chain amino acids (B), allo isoleucine (B), branched-chain 2-ketoacids, and branched-chain 2-hydroxy acids (U)
E3 deficiency	246900	AR	Dihydrolipoyl dehydrogenase (E3)	<1:100,000	Failure to thrive, hypotonia, developmental delay, seizures, coma, lactic acidosis, hypoglycemia	Branched-chain amino acids (B), allo isoleucine (B), lactic and pyruvic acids (B,U), 2-ketoglutaric acid, branched-chain 2-ketoacids, and branched-chain 2-hydroxy acids (U)
Disorders of Sulfur Amino Acid Metabolism						
Hypermethioninemia	250850	AR	Methionine adenosyltransferase	<1:100,000	Fetid breath, demyelination	Methionine (B)
S-Adenosylhomocysteine hydrolase deficiency	180960	AR	*S*-Adenosylhomocysteine hydrolase	Unknown	Developmental delay, hypotonia, hepatocellular dysfunction, white matter atrophy, abnormal myelination	Methionine (B), total plasma homocysteine, mildly elevated (B), elevated *S*-adenosylhomocysteine, and *S*-adenosylmethionine (B)
Glycine-*N*-methyltransferase deficiency	606664	AR	Glycine *N*-methyltransferase	Unknown	Hepatomegaly	Methionine (B), *S*-adenosylmethionine (B)
Homocystinuria	236200	AR	Cystathionine beta-synthase	<1:100,000	Mental retardation, ectopia lentis, skeletal anomalies	Free homocystine, total homocysteine, and methionine (B,U)
Sulfite oxidase deficiency	272300	AR	Sulfite oxidase	<1:100,000	Mental retardation, seizures, ectopia lentis, dysmorphic features, muscle tone abnormalities	*S*-sulfocysteine and taurine (B,U); low cystine (B,U)

TABLE 58-2 Clinical and Laboratory Characteristics of Disorders of Amino Acid Metabolism—cont'd

Common Name	OMIM* No.	Inheritance	Enzyme/Transport Defect	Incidence (USA)	Major Clinical Features	Major Biochemical Marker(s)
Molybdenum cofactor deficiency	252150	AR	Sulfite oxidase, xanthine dehydrogenase, aldehyde oxidase	<1:100,000	Mental retardation, seizures, ectopia lentis, dysmorphic features, muscle tone abnormalities	*S*-sulfocysteine and taurine (B,U); low cystine (B,U); elevated hypoxanthine and xanthine (U); low uric acid (B)
Urea Cycle Disorders						
N-Acetylglutamate synthase deficiency	237310	AR	*N*-Acetylglutamate synthase	<1:100,000	Hyperammonemia, lethargy, hypothermia, apnea, brain edema, coma	Glutamine, alanine (B), low citrulline and arginine (B)
CPS-I deficiency	237300	AR	Carbamoylphosphate I synthetase	<1:100,000	Hyperammonemia, lethargy, hypothermia, apnea, brain edema, coma	Glutamine, alanine (B), low citrulline and arginine (B)
OTC deficiency	311250	X-linked	Ornithine transcarbamylase	>1:50,000	Hyperammonemia, lethargy, hypothermia, apnea, brain edema, coma	Orotic (U), glutamine, alanine (B), low citrulline, arginine (B)
Citrullinemia	603470	AR	Argininosuccinate synthase	>1:75,000	Hyperammonemia, lethargy, hypothermia, apnea, brain edema, coma	Citrulline (B), orotic (U)
Citrullinemia type II (citrin deficiency)	603471 (adult onset); 605814 (neonatal onset)	AR	Aspartate/glutamate mitochondrial exchanger	<1:100,000	Cholestatic jaundice, hepatocellular dysfunction, episodic hyperammonemia, neurologic/ psychiatric symptoms	Citrulline, methionine, lysine (B), orotic (U), elevated galactose (B) in neonatal onset
Argininosuccinic acidemia	207900	AR	Argininosuccinate lyase	<1:100,000	Hyperammonemia, lethargy, hypothermia, apnea, brain edema, coma, trichorrhexis nodosa	Argininosuccinic (B,U), citrulline (B), low arginine (B)
Argininemia	207800	AR	Arginase	<1:100,000	Progressive spasticity, mental retardation	Arginine (B, CSF), orotic acid (U)

HHH syndrome	238970	AR	Mitochondrial ornithine transporter	<1:100,000	Mental retardation, seizures, pyramidal signs, compromised sense of vibration, episodic hyperammonemia	Ornithine (B,U), homocitrulline (U)
Miscellaneous Disorders of Amino Acid Metabolism						
Nonketotic hyperglycinemia	605899	AR	Glycine cleavage system (P, H, T, L proteins)	<1:100,000	Lethargy, seizures, myoclonic jerks, hypotonia, hiccups	Glycine (B,CSF,U), CSF Gly/Plasma Gly ratio >0.09
Gyrate atrophy of the choroid and retina	258870	AR	Ornithine aminotransferase	<1:100,000	Myopia, night blindness, progressive loss of peripheral vision	Ornithine (B)
Hyperprolinemia type I	239500	AR	Proline oxidase	<1:100,000	Clinically benign (most likely); renal disease, neurologic manifestations (disputed)	Proline (B,U), Hydroxyproline, glycine (U)
Hyperprolinemia type II	239510	AR	Delta 1-pryrroline-5-carboxylate dehydrogenase	<1:100,000	Mental retardation, pyridoxine-responsive seizures	Proline (B,U), pyrroline 5-carboxylic (U)
Disorders of Amino Acid Membrane Transport						
Cystinuria	220100	AR	Absorption of cystine and dibasic amino acids in renal tubule and GI tract	>1:25,000	Nephrolithiasis	Cystine, lysine, ornithine, arginine (U)
Lysinuric protein intolerance (LPI)	222700	AR	Cationic amino acid transporter (SLC7A7)	<1:100,000	Failure to thrive, alveolar proteinosis, hepatosplenomegaly, pancreatitis, diarrhea, osteoporosis, hypotonia, postprandial hyperammonemia	Lysine, arginine, ornithine (U), orotic acid (U)
Hartnup disease	234500	AR	Neutral amino acid transporter 1 (SLC6A19)	>1:50,000	Ataxia, seizures, photodermatitis (pellagra-like)	Hyperexcretion of ALA, SER, THR, VAL, LEU, ILE, PHE, TYR, TRP, HIS, GLN, ASN (U)

Postmortem Screening

Among IEMs, fatty acid oxidation (FAO) disorders are those recognized more often after the diagnosis of an affected sibling or as a cause of sudden death.[5] Early reports attributed up to 5% of cases of sudden death in children younger than 5 years to FAO,[7] and mounting evidence indicates that some of these disorders can cause mortality in adults as well.[38] The postmortem evaluation of unexpected death, independent of age, especially when evidence of acute illness or infection is found, should consider FAO as a cause. This is accomplished by analysis of acylcarnitines in blood and bile spots (Figure 58-2).[52] Reference intervals for acylcarnitines in postmortem blood and bile spots are listed in Table 58-3.

Blood and bile are collected on filter paper identical to the cards used for newborn screening; once properly dried they are shipped to the laboratory at room temperature. In cases with a higher index of suspicion, an effort should be made to collect and freeze a specimen of liver[7] and to collect a skin biopsy for establishing the fibroblast culture to be used, if needed, to confirm a diagnosis. Although fatty infiltration of the liver and/or other organs (e.g., heart, muscle, kidneys) is a common observation in FAO disorders, the finding of macroscopic steatosis should not be used as the only criterion in deciding whether to investigate a possible underlying FAO disorder during postmortem evaluation of a case of sudden death. Sudden death from cardiac arrhythmia can be the only finding in fatty acid oxidation defects, and the absence of obvious physical findings on autopsy does not exclude this, especially in adults. In cases of sudden infant death, if parental permission to perform an autopsy is not granted, any leftover specimens or unused portions of blood spots collected for newborn screening, if still available, could be useful samples in obtaining a diagnosis.

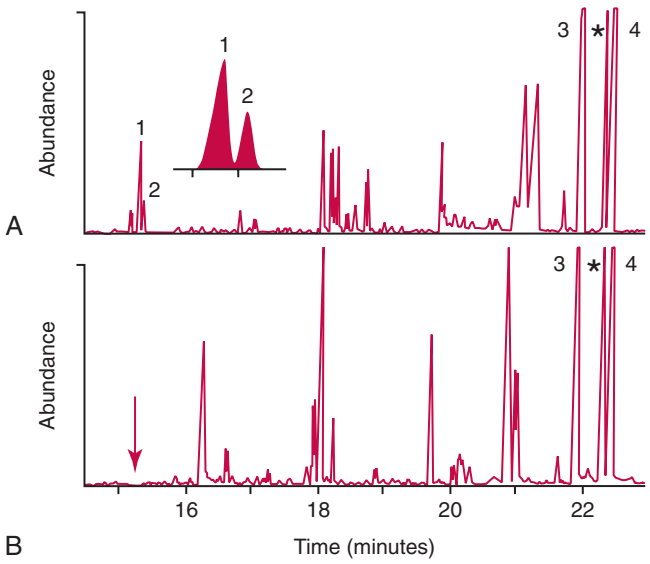

Figure 58-2 Partial urine organic acid profiles. A, Profile of acutely ill patient. Peaks 1 and 2 are derivatives of succinylacetone. B, Reference profile of 15 month old patient. Note * marks the peak of internal standard. *(From Rinaldo P, Matern D, Bennett MJ. Fatty acid oxidation disorders. Ann Rev Physiol 2002;64:477-502.)*

Biochemical Genetics Tests: Analytical Considerations

In addition to clinical presentation and routine laboratory tests, the diagnosis of patients with inborn errors of metabolism relies on specific tests such as ion-exchange chromatography and liquid chromatography with tandem mass spectrometry (LC-MS/MS) for amino acid analysis, gas chromatography/mass spectrometry (GC/MS) for organic acid analysis, tandem mass spectrometry (MS/MS) with (LC-MS/MS) or without liquid chromatographic separation for acylcarnitine profiles, and LC-MS/MS or GC/MS for acylglycine profiles. The combination of these tests, with the use of different specimen types, is the key to biochemical confirmation of metabolic disorders, whose diagnosis is then definitively confirmed using DNA testing or enzyme/transporter assays.

Analysis of (1) plasma amino acids, (2) urine organic acids, and (3) plasma acylcarnitines is the mainstay for the diagnosis of most amino acidopathies, organic acidemias, and disorders of fatty acid oxidation. Because of the early identification of asymptomatic patients by newborn screening, the sensitivity and specificity of these methods need to be very high to detect even low concentrations of diagnostic metabolites. Furthermore, the availability of age-appropriate reference intervals is necessary, because the concentrations of several metabolites (e.g., acylcarnitines) change rapidly with age.

Amino Acid Analysis by Ion-Exchange Chromatography

Several methods have been used in the analysis of amino acids in biological fluids such as plasma, urine, and cerebrospinal fluid. All involve chromatographic separation of amino acids with precolumn [high-performance liquid chromatography (HPLC), GC methods] or postcolumn (ion-exchange chromatography) derivatization, followed by detection by ultraviolet (UV), fluorescence, or mass spectrometry.[1,35,61,65,77,78] The gold standard for analysis of amino acids remains ion-exchange chromatography (IEC), even though recent work using tandem mass spectrometry is showing promising results. The challenge with amino acid analysis includes the need (1) to cover a wide dynamic range, (2) to have a very low detection limit, and (3) to have a high upper limit of linearity. In addition to these analytical requirements, isomers need to be separated and quantified. With ion-exchange chromatography, the sample (plasma/urine/CSF) is deproteinized and injected onto an ion-exchange column (typically a lithium cation-exchange column). Amino acids are separated on the basis of their pK_a by changing the pH and ionic strength of eluting buffers and the temperature of the column. Acidic amino acids are eluted first, followed by neutral then basic amino acids. After their elution from the column, amino acids are mixed with ninhydrin at 135 °C to form a colored adduct. The intensity of their absorbance is proportional to the concentration of the amino acid. Absorbance is read at

TABLE 58-3 Acylcarnitine Reference Intervals in Postmortem Blood and Bile Dried Spots

		Blood (n = 448)		Bile (n = 525)

From Rinaldo P, Hahn S, Matern D. Inborn errors of amino acid, organic acid, and fatty acid metabolism. In: Burtis CA, Ashwood ER, Bruns DE, eds. Tietz textbook of clinical chemistry and molecular diagnostics, 4th edition. St. Louis, Elsevier Saunders, 2006:2241.

two different wavelengths: 570 nm (maximum absorbance for amino acids) and 440 nm (maximum absorbance for imino acids, such as proline and hydroxyproline). The concentration of amino acids is calculated using an internal standard and external calibration. Identification of individual amino acids relies on retention time, ratio of absorbance at the two wavelengths (440/570 nm), and, in case of doubt, spiking of the sample with a standard.

Plasma collected under fasting conditions is the specimen of choice. In infants and small children, the sample should be collected at least 2 hours after the last feeding. Collection of serum should be avoided because of artifacts deriving from the clotting process. Blood should be collected with an anticoagulant (lithium/sodium heparin) and immediately separated and frozen until the time of analysis. Storage of samples at inappropriate temperature, at room temperature, or refrigerated has been known to result in deamination of glutamine and binding of sulfur amino acids to protein. The concentration of most amino acids in red blood cells is very similar to their concentration in plasma; however, some amino acids

(e.g., aspartic acid, taurine, glutamic acid) are present at higher concentrations in red blood cells; therefore, hemolysis will result in an artificially increased concentration of those amino acids. In addition, red blood cells contain the enzyme arginase, which converts arginine to ornithine and urea. Hemolysis may release this enzyme, resulting in decreased concentrations of arginine and increased concentrations of ornithine. Results of plasma amino acid analysis are usually expressed in micromoles/liter.

Urine amino acids are useful only in the investigation of disorders of amino acid transport (e.g., cystinuria, lysinuric protein intolerance, Hartnup disorder) or of prolidase deficiency. A random urine sample, without preservative, is usually sufficient. Specific reabsorption studies may require a timed (24 hour) urine collection. The sample should be collected without preservative and kept refrigerated until the end of the collection. Urine samples, like plasma, should be frozen as soon as possible and kept frozen until analysis. Results are usually normalized to the concentration of creatinine in the specimen.

Analysis of cerebrospinal fluid (CSF) amino acids is performed for very specific cases, such as in the diagnostic investigation of glycine encephalopathy (nonketotic hyperglycinemia) and in disorders of serine metabolism. CSF should be collected while avoiding blood contamination; it should be frozen immediately and kept frozen until the time of analysis. Measurements of CSF amino acids are expressed in micromoles/liter. Amino acid results, independent of specimen type, should be correlated with clinical status, diet, and medications.

Urine Organic Acid Analysis by Gas Chromatography/Mass Spectrometry

The label *organic acids* includes metabolites of almost all pathways of intermediary metabolism and exogenous compounds. Organic acids analyzed by gas chromatography/mass spectrometry (GC/MS) are separated on the basis of their volatility and solubility in the stationary nonpolar liquid phase of the capillary gas chromatography column. Before GC/MS analysis is performed, organic acids must be (1) extracted, usually with an organic solvent; (2) converted to volatile trimethylsilyl (TMS) derivatives; and (3) dissolved in organic solvents.[40,78] With this technique, the mass spectrometer is employed as a detector, thus allowing positive identification of organic acids both by retention time and by their characteristic fragmentation spectrum. A random urine specimen is routinely used for this analysis; however, the most informative samples for the diagnosis of IEM are collected during acute metabolic decompensation. Organic acid analysis in blood or CSF usually is not informative to establish a diagnosis. Their interpretation is challenging because hundreds of compounds will be present in a specimen. Key factors in correct interpretation of results include (1) recognition of abnormal patterns and possible interferences due to dietary or medication artifacts, (2) knowledge about metabolic disorders and their presentation, and (3) information about the clinical status of patients.

Plasma Acylcarnitine Profile

Acylcarnitines derive from conjugation of carnitine with acyl-CoA. Carnitine [3-hydroxy-4-(trimethylazaniumyl) butanoate] is a water-soluble molecule that is essential in the transfer of long-chain fatty acids inside mitochondria for beta-oxidation. In addition, carnitine binds acyl residues accumulating in several organic acidemias and in fatty acid oxidation disorders, to facilitate their excretion. In the presence of a metabolic block (organic acidemia or fatty acid oxidation disorder), specific acylcarnitines, derived from conjugation of carnitine with acyl-CoA upstream of the metabolic block, accumulate, producing a pattern that is characteristic for each disease or group of diseases, so acylcarnitine analysis plays an essential role in the diagnosis of metabolic disorders (see Figure 58-2). Such an analysis is usually performed by tandem mass spectrometry (MS/MS) with or without liquid chromatographic separation prior to MS/MS detection.[39,41] Plasma/serum is the biological fluid of choice, and whole blood spotted on filter paper is used for screening of newborns. Concentrations of acylcarnitines in plasma differ from concentrations in whole blood, especially for long-chain acylcarnitines. This is thought to be due to binding of long-chain acylcarnitines to the membranes of blood cells, resulting in reduced long-chain species in plasma. Plasma for analysis of acylcarnitines should be separated immediately after collection and kept frozen until analysis. Hemolysis has been known to result in elevated long-chain acylcarnitines, misleading the diagnosis. Storage of the sample at room temperature or even refrigerated may result in hydrolysis and, consequently, reduced concentrations of acylcarnitines. Urine acylcarnitine analysis is performed only in the diagnostic work-up of specific disorders, such as glutaric acidemia type I, and only if equivocal results are obtained with other tests. Quantification of acylcarnitines is typically performed using stable isotope dilution. However, some deuterated internal standards are not available for all identified acylcarnitine species. Caution should be taken when acylcarnitine results from different laboratories are compared, because the values may change depending on the internal standards used.[14]

Reference Intervals

Age-appropriate reference intervals should be used in the interpretation of biochemical genetics tests. Reference intervals for urine organic acids, urine acylglycines, plasma, and urine acylcarnitines are listed in Tables 58-4, 58-5, and 58-6.

Enzyme Assay and DNA Testing

Several inborn errors of metabolism produce a characteristic pattern of metabolites that is not observed in other conditions. For most, however, the diagnosis needs to be confirmed by a more specific method involving measurement of the activity of the putatively defective enzyme/transporter and/or DNA testing. This confirmation is very critical, in that for many conditions, specific therapy, if available, needs to be continued for life or is very aggressive (organ or bone marrow transplant). In addition, for some metabolic disorders, genotype-phenotype correlation with specific mutations

affects the overall prognosis. For some diseases, such as phenylketonuria, the mutant enzyme is expressed only in the liver, and it is not practical and is very invasive to obtain diagnostic confirmation by enzyme assay. DNA testing (by sequencing of the whole gene) in this case is often more useful. For several other conditions, the missing enzyme is expressed in blood cells or in fibroblasts obtained by skin biopsy. It must be noted that with decreased costs of DNA testing, this technology is widely used to provide final diagnostic confirmation. The major limitation of DNA sequencing is that for certain conditions, the same biochemical abnormality is caused by deficiency of any of a number of genes (e.g., in methylmalonic acidemia), or multiple genes might be required to encode all subunits of a single enzyme (such as in maple syrup urine disease). Further, DNA sequencing (1) might not identify all mutations causing a disease,

From Rinaldo P, Hahn S, Matern D. Inborn errors of amino acid, organic acid, and fatty acid metabolism. In: Burtis CA, Ashwood ER, Bruns DE, eds. Tietz textbook of clinical chemistry and molecular diagnostics, 4th edition. St. Louis, Elsevier Saunders, 2006:2240.

(2) can miss single exon deletions/duplications, and (3) can identify new variations whose clinical significance is unclear because they have not been reported in other affected patients. For these reasons, biochemical and molecular investigations need to be performed together to confirm or exclude the diagnosis of a metabolic disorder.

DISORDERS OF AMINO ACID METABOLISM

Concentrations of individual amino acids in physiologic fluids reflect a balance between their intake, their release from the catabolism of endogenous proteins, their filtration and reabsorption by the kidney, and their utilization by the

body to synthesize proteins or to produce energy. Changes in any of these processes can affect protein and amino acid metabolism through accumulation or excessive loss of one or more amino acids.

Inborn errors of amino acid metabolism can present at any time in a person's life; most become evident in infancy and early childhood. Affected patients may have failure to thrive, neurologic symptoms, digestive problems, psychomotor retardation, and a wide spectrum of laboratory findings. If not diagnosed promptly and treated properly, these disorders can result in poor growth, mental retardation, and death.

Table 58-2 provides a summary of the most common disorders of amino acid metabolism and transport and their characteristics. Several of these disorders are discussed in the following sections.

Classic Phenylketonuria and Other Hyperphenylalaninemias

Hyperphenylalaninemias result from the impaired conversion of phenylalanine to tyrosine, leading to an increased concentration of phenylalanine in body fluids. They are caused by a primary deficiency of phenylalanine hydroxylase, the enzyme that converts phenylalanine to tyrosine (Figure 58-3), or, in rare cases (<2% of total cases in the United States), by a defect in synthesis (Figure 58-4) or recycling (Figure 58-5) of the essential cofactor tetrahydrobiopterin. The combined incidence of these conditions is about 1 : 10,000 to 1 : 20,000 live births. In PKU, accumulation of phenylalanine and other metabolites such as phenyllactate and phenylpyruvate (phenylketones) occurs. Elevated phenylalanine interferes with neurotransmitter synthesis and uptake, leading to clinical symptoms of phenylketonuria.[63]

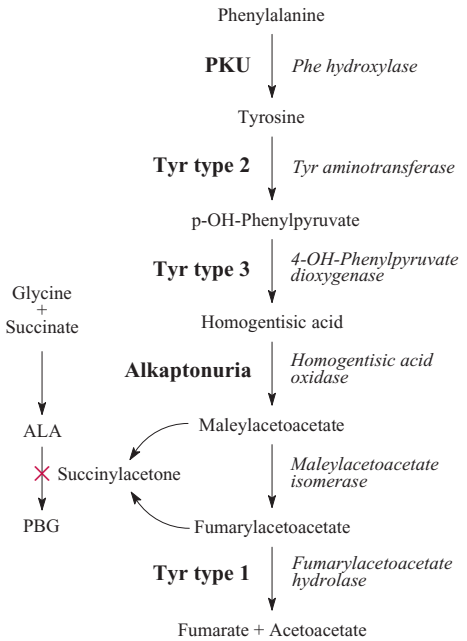

Figure 58-3 Metabolism of phenylalanine and tyrosine. Many different enzymes are required for the conversion of phenylalanine to fumarate and acetoacetate that can be subsequently oxidized to CO_2 and water. The disease caused by deficiency of any of these enzymes is indicated at the left of the arrows representing the function of the enzyme. In humans, no deficiency of maleylacetoacetate isomerase has been reported.

Patients with phenylketonuria appear healthy at birth, apart from an increased incidence of gastroesophageal reflux in patients with very high phenylalanine concentrations. Delays in development, chronic eczema, and acquired microcephaly become evident after a few months of life. Abnormal brain development results in mental retardation. This and all other problems are prevented by a special diet low in phenylalanine that needs to be initiated before 3 weeks of age. Therefore, all infants are screened at birth for this condition. In utero, phenylalanine is removed from the child by the placenta. After birth, phenylalanine accumulates as the child initiates feedings and is exposed to proteins. Therefore, for optimal results, infants should be screened after 24 hours of life, when at least one feeding has occurred, to ensure an adequate rise in phenylalanine concentrations. The diagnosis of phenylketonuria is confirmed by plasma amino acid analysis. In each infant with even minimally elevated serum phenylalanine, cofactor defects need to be excluded by measuring the urine pterin profile and activity of dihydropteridine reductase (DHPR) in blood cells. Hyperphenylalaninemia due to phenylalanine hydroxylase deficiency is biochemically diagnosed when plasma phenylalanine concentrations are above the normal reference interval with a normal urine pterin profile and normal DHPR activity. Phenylalanine hydroxylase is expressed only in the liver, and confirmation of the diagnosis by enzyme assay is not routinely performed. DNA sequencing of the causative gene, however, will definitively confirm the diagnosis, if needed.

In patients with PKU due to phenylalanine hydroxylase deficiency, dietary treatment with a special formula without phenylalanine should be started as soon as possible—ideally before 3 weeks of age.[63] Diet needs to be continued for life. Phenylalanine concentrations are monitored periodically and should remain between 60 and 360 µmol/L (reference interval, 30 to 80 µmol/L) to ensure adequate brain development. If the concentration of phenylalanine is too low, growth of the child is compromised; if it is too high, executive functioning is impaired. High concentrations of phenylalanine in the first years of life lead to mental retardation. Phenylalanine at high concentrations is teratogenic and, depending on the concentration and the period of exposure during pregnancy, will cause (1) increased risk of spontaneous abortion, (2) congenital heart defects, (3) facial dysmorphism, (4) microcephaly, and (5) developmental delay (even in the absence of microcephaly) in the fetuses of women with PKU. Adverse pregnancy outcomes in pregnant women with PKU are minimized by maintaining phenylalanine concentrations less than 360 µmol/L.[37]

In approximately 2% of cases, hyperphenylalaninemia is due to a deficiency of biosynthesis (see Figure 58-4) or recycling (see Figure 58-5) of the cofactor tetrahydrobiopterin (BH_4). BH_4 is also a cofactor for tyrosine and tryptophan

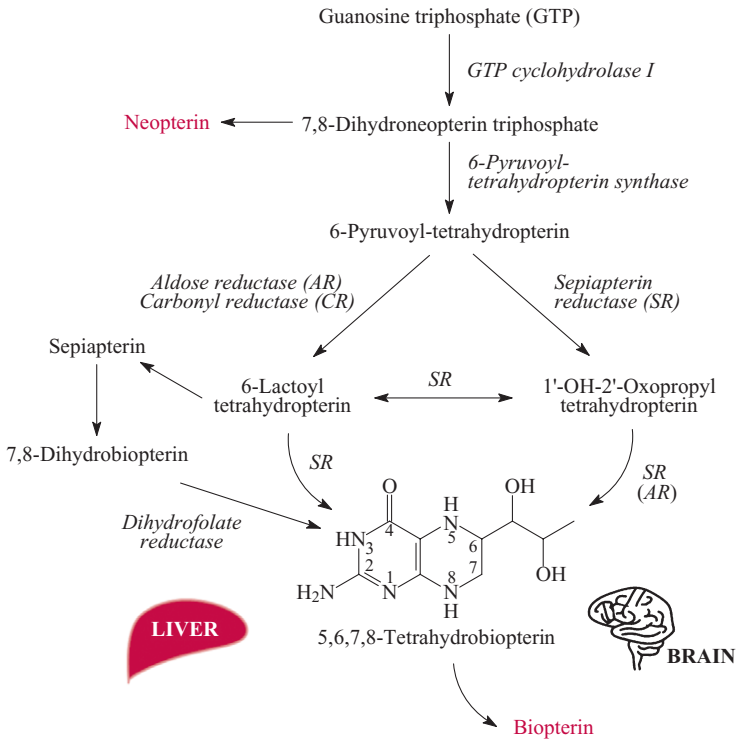

Figure 58-4 Biosynthesis of tetrahydrobiopterin (BH_4). BH_4 synthesis requires three different enzymes: GTP-cyclohydrolase I, 6-pyruvoyltetrahydropterin synthase, and sepiapterin reductase. Some steps can be performed differently in the brain, which is strongly dependent on sepiapterin reductase, as compared with the liver, which can perform the same reaction through the combined action of different enzymes. This leads to tetrahydrohydrobiopterin deficiency only in the brain in sepiapterin reductase deficiency without an increase in plasma phenylalanine, because sufficient synthesis of the cofactor is retained in the liver. The origin of the commonly measured neopterin, biopterin, and sepiapterin is indicated. *(From Longo N. Disorders of biopterin metabolism. J Inherit Metab Dis 2009;32:333-42.)*

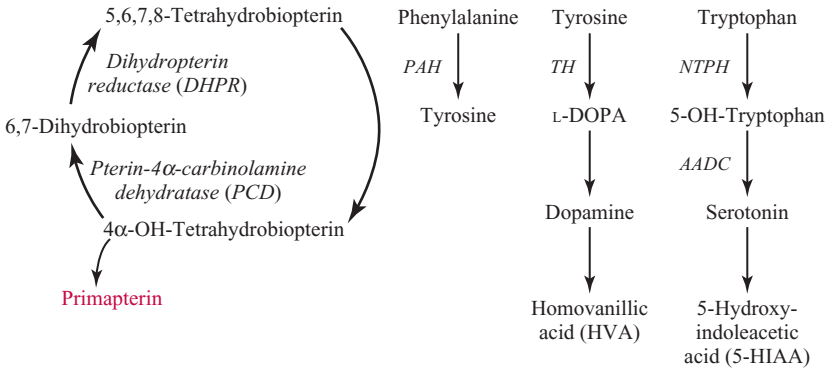

Figure 58-5 Regeneration of tetrahydrobiopterin. Tetrahydrobiopterin provides electrons for the hydroxylation of phenylalanine, tyrosine, and tryptophan by the action of phenylalanine hydroxylase (PAH), tyrosine hydroxylase (TH), and neuronal tryptophan hydroxylase (NTPH), respectively. Reduction of 4α-OH-tetrahydrobiopterin back to the active form requires the sequential action of pterin-4α-carbinolamine dehydratase and dihydropteridine reductase. In the absence of pterin-4α-carbinolamine dehydratase, the substrate is spontaneously converted to primapterin, which can be detected in urine. *(From Longo N. Disorders of biopterin metabolism. J Inherit Metab Dis 2009;32:333-42.)*

hydroxylases (see Figure 58-5).[42] Infants with BH_4 deficiencies show signs of neurologic involvement despite adequate dietary control of phenylalanine concentrations. Impairment of tyrosine and tryptophan hydroxylases reduces the synthesis of the neurotransmitters dopamine and serotonin, with severe neurologic consequences. BH_4 is also a cofactor for nitric oxide synthase, which catalyzes the generation of nitric oxide from arginine, although the clinical consequences of this latter impairment are not known.

Five enzyme deficiencies leading to BH_4 deficiency have been reported (see Table 58-2). One of these, sepiapterin reductase deficiency, impairs BH_4 synthesis only in the brain, because alternative pathways are available for its synthesis in the liver. As a result, patients with this latter condition have normal activity of phenylalanine hydroxylase in the liver and no hyperphenylalaninemia.[21] Among patients with BH_4 deficiencies and elevated phenylalanine, 50% of cases are due to 6-pyruvoyltetrahydropterin synthase (6-PTPS) deficiency. These patients are clinically indistinguishable from those with classic PKU (caused by phenylalanine hydroxylase deficiency), when diagnosed through newborn screening, but they progressively deteriorate with loss of head control, truncal hypotonia with hypertonia of the extremities, drooling, swallowing difficulties, and myoclonic seizures at between 2 and 6 months of age.[42] Treatment of these patients requires BH_4, which usually normalizes the concentration of phenylalanine (except in some cases of DHPR deficiency), and neurotransmitter precursors (L-dopa/carbidopa and 5-OH-tryptophan), which obviate the need for tyrosine and tryptophan hydroxylase.

Infants with benign hyperphenylalaninemia (phenylalanine <300 μmol/L) occasionally are identified by newborn screening because of a moderately elevated blood concentration of phenylalanine. These patients have a partial deficiency of phenylalanine hydroxylase with residual enzyme activity up to 35% of normal. Although detected by neonatal screening, they remain healthy without dietary treatment. The possibility of an underlying cofactor deficiency should be ruled out. Phenylalanine, however, needs to be monitored periodically because, depending on the diet, its concentration can increase to the point where therapy is required.

Tyrosinemia Type I

Hepatorenal tyrosinemia [tyrosinemia type I (TYR-I)] is an autosomal recessive disease caused by deficiency of the enzyme fumarylacetoacetate hydrolase (see Figure 58-3), expressed primarily in the liver and kidney.[62] The incidence of TYR-I is approximately 1 in 100,000, with a clustering of cases in the Lac-St. Jean region of Quebec (Canada). Patients with tyrosinemia type I present before 6 months of age with severe liver involvement, or after 6 months of age with (1) chronic failure to thrive, (2) mild hepatocellular dysfunction, (3) renal involvement, and (4) rickets due to renal Fanconi syndrome.[62] They have extreme irritability caused by peripheral neuropathy mimicking acute intermittent porphyria. This is caused by accumulation of 5-aminolevulinic acid (ALA) as the result of inhibition of ALA dehydratase by succinylacetone,[62] a toxic compound accumulating in tyrosinemia type I. Untreated patients have been known to develop liver cirrhosis and are at very high risk for liver cancer.

Patients with tyrosinemia type I have elevated concentrations of tyrosine in the plasma amino acids, but this elevation usually is not as marked as in patients with other forms of tyrosinemia. Elevated tyrosine is seen in (1) other forms of tyrosinemia (tyrosinemia types II and III), (2) transient tyrosinemia of the newborn, (3) prematurity, (4) hepatocellular dysfunction of almost any cause (including that caused by gluconeogenesis disorders, galactosemia, fructosemia, peroxisomal disorders, or mitochondrial DNA depletion syndrome), and (5) diets very rich in proteins. The biochemical diagnosis is based on the detection in urine organic acids of succinylacetone (4,6-dioxaneheptanoic acid), the byproduct of fumarylacetoacetic acid, which is the intermediate immediately upstream of the enzyme defect.[62] Tyrosinemia type I is identified by newborn screening only when succinylacetone or ALA is used as the primary marker, because tyrosine usually is not elevated in the newborn period in these patients.[60]

Therapy consists of a diet low in tyrosine and phenylalanine (the precursor of tyrosine) and NTBC [2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione], an inhibitor of 4-hydroxyphenylpyruvate dioxygenase, the enzyme located upstream of fumarylacetoacetate hydrolase (see Figure 58-3). NTBC prevents the synthesis of succinylacetone, which disappears almost immediately from urine organic acids after initiation of treatment. The adequacy of the diet is monitored by plasma amino acids. Measurement of alpha fetoprotein is also used to monitor these patients, because liver cancer is a complication of this condition. Liver transplantation is indicated in patients who progress to liver failure and in those acquiring liver cancer.[62]

Homocystinuria

Homocystinuria, characterized by increased concentrations of the sulfur-containing amino acid homocystine in blood and urine, is caused by at least seven genetically different disorders (Figure 58-6). Methionine, homocysteine, and cysteine are linked by the methylation cycle and the transsulfuration pathway.[49] Conversion of methionine to homocysteine proceeds via the formation of *S*-adenosyl intermediates including *S*-adenosylmethionine, the methyl group donor in several transmethylation reactions. Homocysteine is then condensed with serine by cystathionine β-synthase to form cystathionine. By the action of cystathionase, cysteine is generated and participates in protein, glutathione, or taurine synthesis. Homocysteine is also remethylated back to methionine by the action of methionine synthase, an enzyme that requires methylfolate and methylcobalamin as cofactors. Defects in any of these steps can result in homocystinuria. The most common form, classic homocystinuria, is caused by reduced activity of cystathionine β -synthase. The worldwide incidence is approximately 1:300,000 live births[64] with a very high incidence in Qatar (1:1800).[26] Clinical manifestations are nonspecific at first and may include failure to thrive and

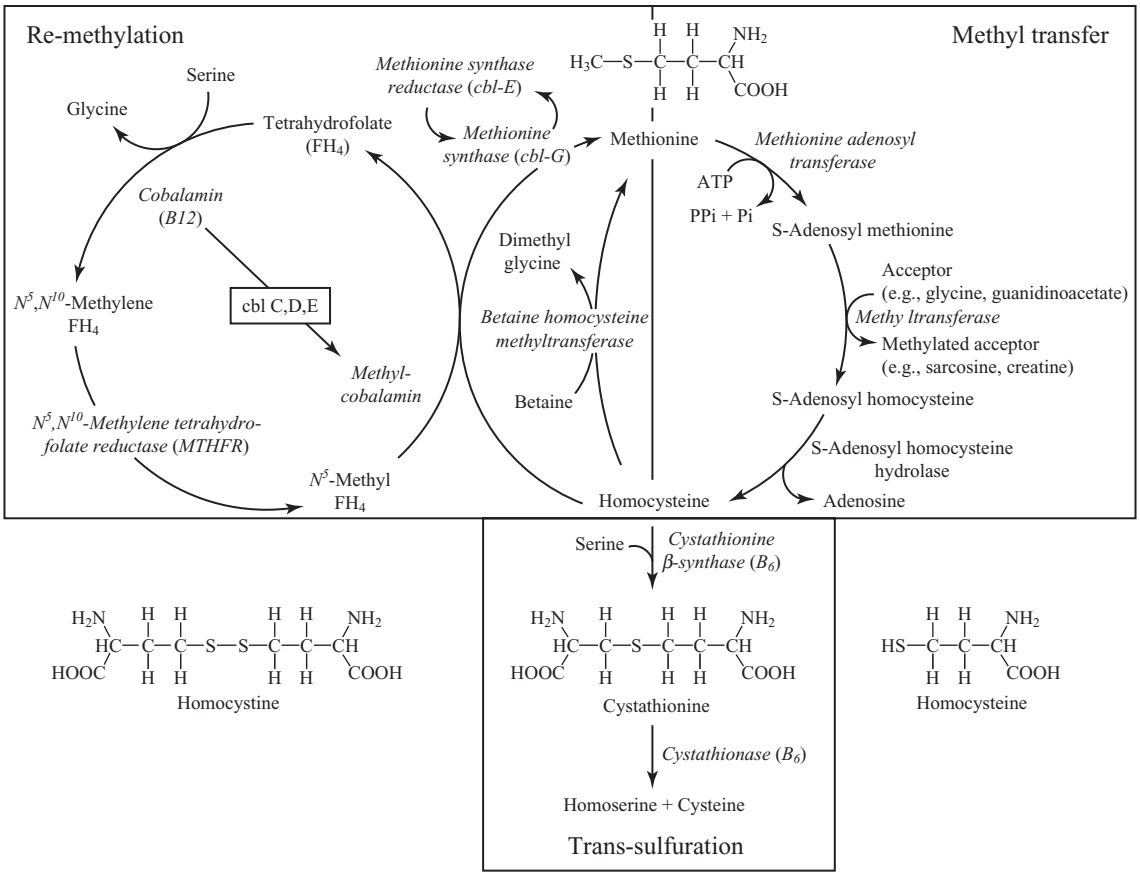

Figure 58-6 Sulfur amino acid metabolism. Methionine transfers a methyl group during its conversion to homocysteine. Defects in methyl transfer or in the subsequent metabolism of homocysteine by the pyridoxal phosphate (vitamin B_6)–dependent cystathionine beta-synthase increase plasma methionine concentrations. Homocysteine is transformed into methionine via remethylation. This occurs through methionine synthase, a reaction requiring methylcobalamin and folic acid. Deficiencies in these enzymes or lack of cofactors is associated with decreased or normal methionine concentrations. In an alternative pathway, homocysteine can be remethylated by betaine:homocysteine methyl transferase. The chemical structures of homocystine (detected by plasma amino acids) and homocysteine (detected by a separate test) are also shown.

developmental delay. Patients present during childhood or adolescence with (1) ophthalmologic problems such as downward dislocation of the lens and myopia, (2) bone abnormalities with marfanoid habitus and pectus excavatum, (3) osteoporosis, (4) mental retardation, and (5) psychiatric disturbances. Thromboembolic episodes have been seen even in children and are a major cause of morbidity and mortality.

The biochemical diagnosis is obtained by plasma amino acid analysis showing increased plasma concentrations of methionine (especially in children) and the presence of the disulfide homocystine. Total plasma homocysteine (measured after reduction of all disulfide bonds and release of homocysteine from proteins) is also markedly increased in this condition; this is measured by immunoassays, by high-performance liquid chromatography, or by tandem mass spectrometry. Increased homocystine and elevated total plasma homocysteine are observed in defects of homocysteine remethylation such as deficiency of (1) 5,10-methylene-tetrahydrofolate reductase, (2) methionine synthase *(cblG)* and methionine synthase reductase *(cblE),* (3) 5-methyl-tetrahydrofolate-homocysteine-methyltransferase, and (4) vitamin B_{12}, and in disorders of cobalamin metabolism (*cblC, cblD,* and *cblF*). Patients with *cblC* and *cblF* and some with *cblD* defects have methylmalonic aciduria, in addition to homocystinuria, because the synthesis of adenosylcobalamin (the cofactor of methylmalonyl CoA mutase) is impaired, as is the synthesis of methylcobalamin (the cofactor of methionine synthase).[25]

Classic homocystinuria is detected in newborn screening by elevated methionine concentration. Methionine is also increased in liver disease, in diets rich in proteins, and in other more rare disorders of sulfur amino acid metabolism such as deficiency of (1) *S*-adenosylhomocysteine hydrolase,

(2) glycine *N*-methyltransferase, and (3) methionine adenosyltransferase (MAT). In these cases, homocystine is absent and total plasma homocysteine is within the reference interval or is only mildly increased. Defects in remethylation of homocysteine could potentially be identified during newborn screening by very low concentrations of methionine. In the severe form of these latter conditions, plasma amino acids show the presence of homocystine, but the concentration of methionine is low. Definitive confirmation of the diagnosis requires DNA testing for most of these conditions. Complementation studies in fibroblasts may be required to identify the specific cause of a cobalamin synthetic defect.

Therapy for classic homocystinuria requires (1) high doses of pyridoxine (the cofactor of cystathionine β-synthase), (2) a special diet low in methionine, and (3) administration of betaine that donates a methyl group to homocysteine to generate methionine. Defects of vitamin B_{12} metabolism require high doses of intramuscular hydroxycobalamin and oral betaine.[49] Mild genetic variations in the methylenetetrahydrofolate reductase gene are frequent in the general population and are responsible for mild elevations of total plasma homocysteine, a risk factor for vascular disease[16] and neural tube defects.[69]

Maple Syrup Urine Disease

Leucine, isoleucine, and valine are essential branched-chain amino acids. After transamination, they undergo decarboxylation by branched-chain α-keto acid dehydrogenase (BCKD), a complex enzyme that requires thiamine pyrophosphate as a cofactor.[17] This complex is composed of four subunits: $E_1\alpha$, $E_1\beta$, E_2, and E_3. The E_3 subunit is shared by two other dehydrogenases: pyruvate dehydrogenase and 2-oxoglutarate dehydrogenase.[17] A defect of any component of the complex causes maple syrup urine disease (MSUD), an autosomal recessive disorder with an incidence of approximately 1:250,000 live births. Several forms of this disease may occur, depending on the severity of the mutations: (1) the classic form, which is the most severe, is characterized by very high plasma concentrations of branched-chain amino acids; (2) some forms that are responsive to pharmacologic amounts of thiamine (thiamine-responsive MSUD)[23]; (3) intermediate or intermittent forms that are triggered by high consumption of proteins or a catabolic state (in which endogenous proteins released mostly by the muscle are degraded to produce energy); and (4) E_3 deficiency which is seen with combined deficiency of pyruvate and 2-oxoglutarate dehydrogenase.[15]

Classic MSUD presents with poor feeding and vomiting during the first week of life followed by lethargy and coma within a few days. This usually follows a normal birth and an uneventful first few days of life, during which branched-chain amino acids, especially leucine, increase to toxic concentrations. Leucine accumulates within the brain, causing cerebral edema, which is responsible for the progressive worsening of neurologic symptoms. Routine laboratory work is mostly unremarkable except for the presence of ketones in urine.

Some patients with significant residual enzyme activity have recurrent episodes of vomiting or a neurologic presentation (developmental delays, seizures) even after 1 year of age with no acute event. Other patients have intermittent episodes of acute decompensation with vomiting, ataxia, and lethargy progressing to coma. Once they recover, patients return to a healthy status with no obvious sequelae, or they have persistent neurologic deficits with seizures.[15]

MSUD is suspected on the basis of clinical presentation. The odor of maple syrup is not always present or appreciated in the newborn period and is better appreciated by smelling ear wax following otoscopic examination. The presence of ketones in urine analysis further suggests the diagnosis, in that the rapid urine test with 2,4-dinitrophenylhydrazine (DNPH) forms a characteristic precipitate. Newborn screening will identify elevated concentrations of leucine/isoleucine with normal concentrations of other amino acids (such as phenylalanine), whose metabolism is not affected. Patients with milder forms of the disease have been missed by screening.[6] Initial biochemical confirmation is performed by plasma amino acid analysis that shows marked elevation of leucine (usually the prominent amino acid), isoleucine, and valine, in addition to the pathognomonic presence of L-alloisoleucine (Figure 58-7). Alloisoleucine is a stereoisomer derived through stepwise racemization and keto-enol tautomerization of (2*S*) 2-oxo-3-methylvaleric acid to its (2*R*) enantiomer, followed by transamination.[58] The 2-oxo acids, the substrates immediately upstream of the enzyme block, are responsible for the positive DNPH test; their respective hydroxy analogs are detectable by urine organic acid analysis after stabilization of the 2-oxo groups via oximation. Urine organic acids show the presence of characteristic branched-chain oxoacids and increased excretion of 2-hydroxyisovaleric acid during episodes of decompensation (see Figure 58-7).

Cornerstones of treatment include dietary restriction of branched-chain amino acids, high-dose thiamine (in responsive cases), valine, and isoleucine supplements. Acute episodes are life threatening and require aggressive treatment of brain edema with intravenous mannitol, careful maintenance of sodium concentrations at above 135 mmol/L with administration of 3% sodium chloride, administration of sufficient calories with intravenous glucose, and use of lipids to block catabolism. Dialysis is sometimes necessary to rapidly remove excess leucine.[47]

Urea Cycle Defects

The urea cycle disposes of the nitrogen groups of amino acids before their carbon skeleton is metabolized to gluconeogenic (most amino acids) or ketogenic precursors (leucine and lysine), or both (isoleucine, phenylalanine, tyrosine, and tryptophan). This cycle requires the combined action of different enzymes and mitochondrial transporters (Figure 58-8). Ornithine enters mitochondria through a specific transporter, ORC1; there it combines with carbamyl phosphate by the action of ornithine transcarbamylase (OTC). Synthesis of carbamyl phosphate requires the ammonia generated from the nitrogen group of amino acids, CO_2, two molecules of ATP,

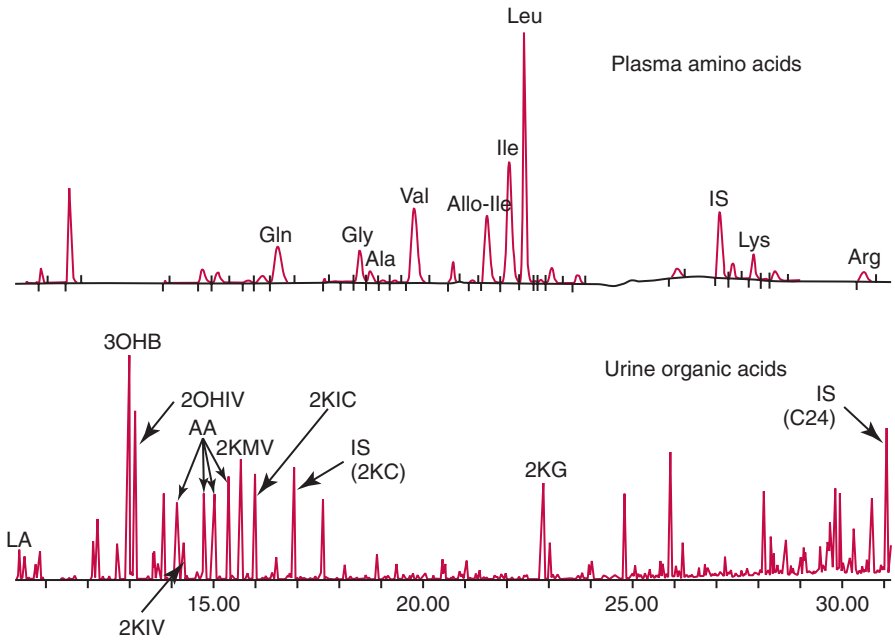

Figure 58-7 Plasma amino acids (by ion-exchange chromatography) and urine organic acids (by gas chromatography/mass spectrometry) in maple syrup urine disease (branched-chain ketoacid dehydrogenase deficiency). *Top,* All three branched-chain amino acids (leucine, valine, and isoleucine) become elevated in maple syrup urine disease. Alloisoleucine, an amino acid not normally present, is also seen in this condition. *Bottom,* Urine organic acids show the presence of the characteristic metabolites 2-OH-isovaleric acid (2OHIV), 2-ketoisovaleric acid (2KIV), 2-ketomethylvaleric acid (2KMV), and 2-ketoisocaproic (2KIC). Lactic acid (LA) and ketones [3-OH-butyric acid (3OHB) and acetoacetate (AA)] are also increased in the catabolic state. 2-Ketocaproic acid (2KC) and tetracosane (C24) are used as internal standards (IS).

and the action of carbamyl phosphate synthase 1 (CPS-1). The activity of this enzyme is dependent on an allosteric activator, *N*-acetylglutamate, which is synthesized by *N*-acetylglutamate synthase (NAGS). The reaction between ornithine and carbamyl phosphate generates citrulline, which exits mitochondria through the ornithine/citrulline exchanger (ORC1).[50] In the cytoplasm, citrulline combines with aspartate that is exported from mitochondria by the citrin transporter (aspartate/glutamate exchanger) through the action of argininosuccinate synthase (ASS). Argininosuccinate is cleaved by a lyase (ASL) into arginine and fumarate. Finally, arginase (ARG) generates urea and ornithine to restart the cycle. Deficiency of any of these enzymes or transporters will impair the function of the urea cycle, causing hyperammonemia. Newborn screening identifies elevated citrulline in citrullinemia type 1 (ASS deficiency) or 2 (citrin deficiency) and, in addition to argininosuccinate, in argininosuccinate lyase deficiency (ASL deficiency). Elevated ornithine and homocitrulline theoretically are the markers for hyperammonemia, hyperornithinemia, and homocitrullinuria syndrome (ORC1 deficiency/HHH syndrome), but it is unclear whether newborns with this condition show elevations of these amino acids. Low concentrations of citrulline with elevated glutamine have been found in NAGS, CPS-1, and OTC deficiency, although appropriate cutoffs have not yet been established for consistent identification of these conditions.

Patients with urea cycle defects may present at any age.[66] In the neonatal period, there is usually a brief interval between birth and clinical manifestations, with the most severe cases presenting before the results of newborn screening are available.[48] Hyperammonemia and the accumulation of glutamine in the brain lead to (1) poor feeding, (2) vomiting, (3) lethargy, or (4) irritability progressing to coma and death. This is caused by the toxic effects of ammonia and by the brain edema caused by glutamine/glutamate accumulation. Milder cases, in which the enzymatic block is not complete, present later in life, many times triggered by excess protein intake or a catabolic state secondary to fasting/infection. In infancy, the symptoms are similar to the neonatal period, but less severe and more variable. Neurologic abnormalities also include ataxia and irritability. Patients are often misdiagnosed as having gastrointestinal disorders, food allergies, behavioral problems, or nonspecific hepatitis. In children and adults, chronic neurologic problems are characterized by (1) learning difficulties, (2) mental retardation, (3) behavioral problems, and (4) recurrent vomiting, which occasionally deteriorates to acute decompensation with severe encephalopathy.[66] Arginase deficiency differs by the usually milder

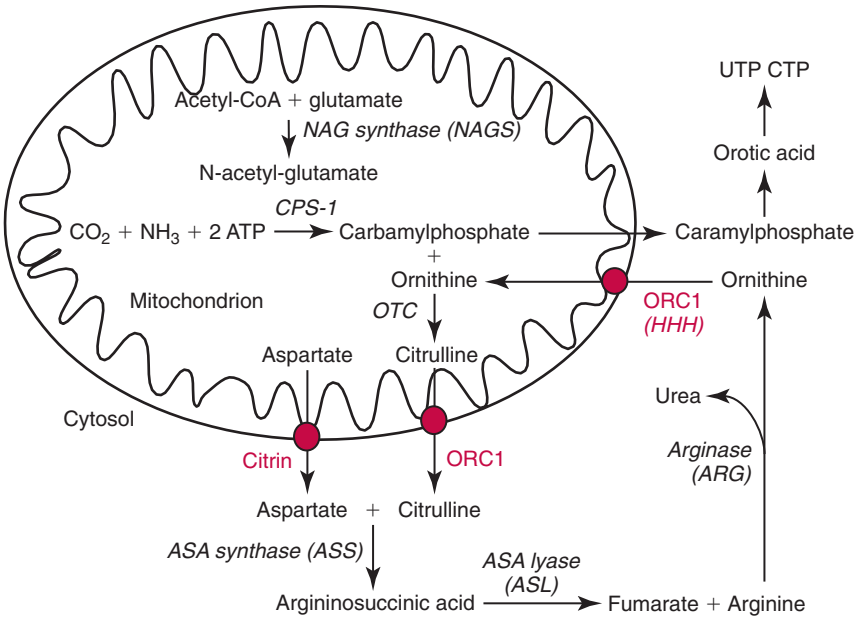

Figure 58-8 The urea cycle leads to the formation of urea starting from ammonia (NH_3). It requires many enzymes and mitochondrial transporters, any of which can be defective and may impair the function of the urea cycle. *ASL,* Arginino succinate lyase; *ASS,* argininosuccinate synthase; *ARG,* arginase; *citrin,* aspartate/glutamate exchanger; *CP,* carbamylphosphate; *CPS-1,* carbamyl phosphate synthase 1; *CTP,* cytidine triphosphate; *NAGS, N*-acetylglutamate synthase; *ORC1,* ornithine/citrulline mitochondrial transporter; *OTC,* ornithine transcarbamylase; *UTP,* uridine triphosphate.

hyperammonemia and by a clinical picture of spastic diplegia, frequently diagnosed as cerebral palsy.[56]

Dominant laboratory findings in urea cycle defects include hyperammonemia and abnormalities of liver function, with variably elevated transaminases and an abnormal prothrombin time (PT)/partial thromboplastin time (PTT) ratio. Plasma amino acids, urine orotic acid, and, in some cases, urine amino acids are necessary for the diagnosis of these disorders. Other conditions that cause hyperammonemia, such as organic acidemias and fatty acid oxidation defects, are excluded by measuring urine organic acid concentrations and observing a plasma acylcarnitine profile. Elevated concentrations of glutamine and alanine, seen when plasma amino acid analysis is performed, are a common finding in all urea cycle defects. Citrulline is the amino acid key to the diagnosis of specific defects. Citrulline is low or undetectable in proximal defects of the urea cycle (NAGS, CPS-1, or OTC deficiency). The concentration of urine orotic acid is elevated in OTC deficiency, but it is within the reference interval or low in NAGS and CPS-1 deficiency. A marked increase in the concentration of plasma citrulline is found in argininosuccinic acid synthase deficiency, a condition commonly known as citrullinemia type 1. A twofold to fivefold elevation of the concentration of plasma citrulline in the presence of argininosuccinic acid is indicative of argininosuccinic acid lyase deficiency. Mild elevation of the concentration of plasma citrulline without elevation of argininosuccinic acid concentration is also seen in citrin deficiency (citrullinemia type 2) or, with other biochemical abnormalities and a severe clinical picture, in the neonatal variant of pyruvate carboxylase deficiency.

Acute hyperammonemia should be treated promptly as a medical emergency. Calories should be provided as intravenous glucose and lipids, with insulin used if possible to reverse the catabolic state. A variety of conjugating agents (benzoate, phenylacetate, phenylbutyrate) are used to deplete the nitrogen pool via excretion of their glycine and glutamine conjugates. Citrulline and/or arginine supplementation provides substrates of the urea cycle downstream to the specific block to allow protein synthesis to resume. If these therapies along with reversal of catabolism fail to effectively reduce blood ammonia within hours, hemodialysis must be instituted. Long-term therapy consists of a diet low in proteins supplemented with citrulline (in OTC, or CPS-1, deficiency) or arginine (ASS; ASL deficiency) and the oral administration of ammonia scavengers (phenylbutyrate, benzoate).[48,66] NAGS deficiency responds to therapy with oral *N*-carbamylglutamate, a precursor of *N*-acetylglutamate.[27]

Glycine Encephalopathy (Nonketotic Hyperglycinemia)

Glycine, the simplest amino acid, is metabolized by several different pathways. The major catabolic pathway for glycine is through the glycine cleavage system, a four peptide complex (protein P, H, T, and L) attached to the inner mitochondrial membrane in liver, brain, kidney, and placenta.[4,36] One carbon

is converted to carbon dioxide, and the other is transferred to tetrahydrofolate to form hydroxymethyltetrahydrofolate, which may react with another mole of glycine to produce serine or to form methyltetrahydrofolate, which serves as a methyl donor.[4,20,36]

Glycine encephalopathy or nonketotic hyperglycinemia (NKHG) is a severe condition caused, in most cases, by a defect in P, T, and H proteins of the glycine cleavage system.[20] Patients with the classic form of the disease present within the first days of life with (1) lethargy, (2) poor sucking, (3) severe hypotonia, (4) hiccups, (5) seizures, and (6) apnea. Most of these patients die in the first few months of life or survive with profound developmental delays. Few patients have been described with transient NKHG that disappears within the first 6 months of life. Atypical variants of NKHG have been diagnosed in patients with rather disparate manifestations who have in common in most cases seizures and delays of different degrees of severity.[20]

Patients with these conditions have no defined abnormalities on routine laboratory testing. Newborn screening is not reliable in identifying patients affected by this condition. The disease is characterized by elevated concentrations of plasma (Figure 58-9) and CSF glycine with no other notable abnormalities, and by unremarkable concentrations of urine organic acids and plasma acylcarnitine profile (to exclude ketotic hyperglycinemia, caused by organic acidemias such as propionic or methylmalonic acidemia). The concentration of glycine will vary in plasma from mildly to markedly elevated, but it is always elevated in the CSF (>30 µmol/L). The calculated CSF:plasma glycine concentration ratio (>0.08, reference interval <0.04) is critical in the diagnosis of this condition,[4] but caution should be used in interpreting the ratio when plasma and CSF specimens are not collected simultaneously or no more than 1 hour apart. Individuals with organic acidemias, such as propionic and methylmalonic acidemia, have been known to present with elevated plasma and CSF glycine in the concentrations observed in NKHG. In this case, analysis of urine organic acids should reveal the metabolites characteristic of the organic acidemia. Contamination of CSF with blood results in increased concentrations of glycine; however, when this occurs, other unrelated amino acids are also elevated. Seizure medications, such as valproate, inhibit the glycine cleavage system, resulting in elevated plasma and CSF glycine. The diagnosis of NKHG is confirmed by enzyme assay or molecular analysis,[4] although some atypical, late-onset cases might have no identifiable mutations in the P, H, or T gene.[20]

No effective treatment is known. Sodium benzoate binds glycine and decreases its concentration. It might help in milder forms of the disease. Treatment of seizures is indicated, although there is no treatment to prevent progression of the disease in severe cases.

ORGANIC ACIDEMIAS

Organic acidemias are inborn errors of metabolism characterized by the accumulation of intermediates in the catabolic pathways of amino acids. These intermediates are water-soluble compounds containing one or more carboxyl groups (organic acids) and other functional groups (-keto, -hydroxy). They may be physiologic metabolites present in excessive amounts, or metabolites not normally present but derived

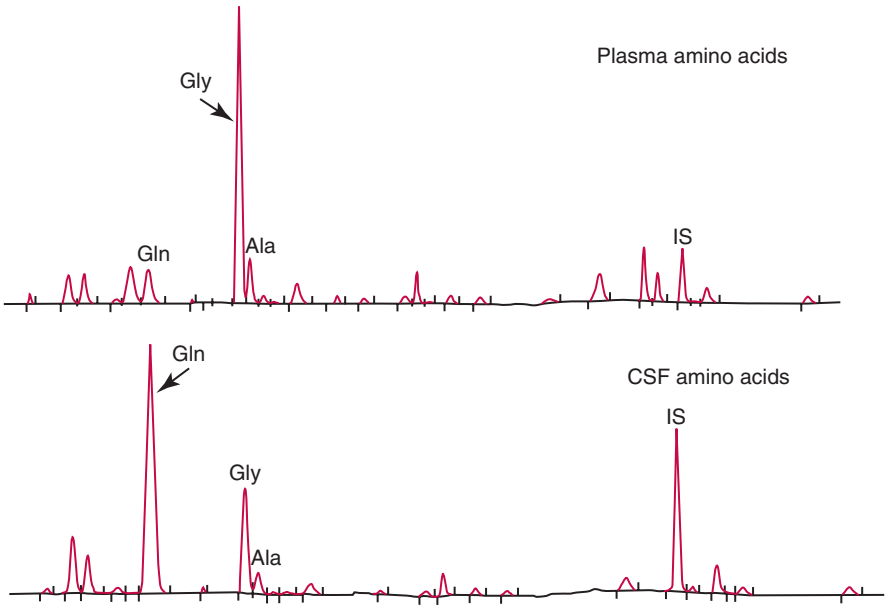

Figure 58-9 Plasma *(top)* and cerebrospinal fluid (CSF) *(bottom)* amino acids (by ion-exchange chromatography) in glycine encephalopathy. Glycine becomes the predominant amino acid in the plasma amino acids *(top)* and is much higher than normal in the cerebrospinal fluid *(bottom)* as compared with glutamine, which physiologically is the predominant amino acid.

from activation of alternative pathways in response to a specific metabolic block. They have heterogeneous clinical presentations, with many of them causing the accumulation of organic compounds resulting in metabolic acidosis (pH = 6.85 to 7.3) with low bicarbonate (<5 to 15 mmol/L) and sometimes hyperammonemia. They differ from renal tubular acidosis by the presence of a significant anion gap, represented by organic anions not measured in routine chemistry panels. The biochemical diagnosis of organic acidemia is accomplished via urine organic acid analysis by gas chromatography-mass spectrometry (GC/MS), in addition to plasma amino acid and plasma acylcarnitine analysis.

Table 58-7 summarizes the most common organic acidemias. Several of these are discussed later.

Disorders of Propionate Metabolism

Propionyl-CoA is an intermediate in the catabolism of isoleucine, valine, threonine, methionine, pyrimidines (uracil and thymine), and cholesterol, and is the final product of the β-oxidation of odd-chain fatty acids. Propionyl-CoA is converted by a biotin-dependent carboxylase (propionyl-CoA carboxylase) to methylmalonyl-CoA, which is converted to succinyl-CoA by an adenosylcobalamin-dependent mutase (methylmalonyl-CoA mutase) for oxidation in the tricarboxylic acid cycle.[18] Primary or secondary defects of these two enzymes were among the first organic acidurias to be discovered; their natural history has been characterized in greater detail than any other inborn error of organic acid metabolism.[18]

The combined incidence of propionic acidemia (PA) and methylmalonic acidemia (MMA) varies considerably, with estimates ranging from 1:2000 to 1:5000 (Saudi Arabia and Greenland)[51] to 1:100,000. Patients with PA and MMA typically are born at term with no pregnancy complications and present with an intoxication type of picture several hours to days after birth. Prominent manifestations include (1) vomiting, (2) hypotonia or hypertonia, (3) lethargy, (4) apnea, (5) hypothermia, and (6) rapid onset of coma. Routine laboratory investigations show severe metabolic acidosis and ketonuria (a finding of critical significance never to be overlooked in the newborn period); lactic acidemia and hyperammonemia are often present[18] with the latter being extremely severe, as in defects of the urea cycle. Similarly, neutropenia and thrombocytopenia caused by bone marrow suppression have been observed. Complications of these disorders include (1) cardiomyopathy (mostly in propionic acidemia), (2) acute and chronic pancreatitis, and (3) progressive renal failure (in methylmalonic acidemia).[18] Patients who survive the initial event have developmental delay, hypotonia or hypertonia, and variable cognitive and neurologic sequelae that are linked to the number and severity of acute episodes.

Newborn screening identifies elevated concentrations of C3 carnitine in both propionic and methylmalonic acidemias, with higher concentrations usually seen in PA. Second-tier methods,[46] performed on the same blood spot used for the initial newborn screening, are available for measurement of methylmalonic and methylcitric acids. Mildly elevated C3 carnitine concentrations have been observed in patients with vitamin B_{12} deficiency and sometimes with hyperbilirubinemia. Diagnosis is confirmed by measurement of urine organic acids showing elevated concentrations of 2-methylcitric acid and other propionate metabolites in propionic acidemia and markedly elevated concentrations of methylmalonic acid in methylmalonic acidemia (Figure 58-10). Variant forms of propionic acidemia, in which the presentation is neurologic, without ketosis or acidosis, are known. In these cases, the only abnormal metabolite is 2-methylcitric acid. With plasma amino acid analysis, hyperglycinemia is observed, although patients with PA in the neonatal period may have normal concentrations of glycine. Acylcarnitine analysis reveals elevated concentrations of propionylcarnitine in both PA and MMA, sometimes associated with carnitine deficiency. Treatment is based on restriction of precursor amino acids and supplementation with carnitine and cofactors—biotin or hydroxycobalamin—as indicated.

Isovaleric Acidemia

Isovaleric acidemia (IVA) is a disorder of leucine catabolism caused by deficiency of isovaleryl-CoA dehydrogenase.[75] Clinical presentation includes both severe metabolic acidosis and hyperammonemia leading to death shortly after birth. Milder variants present with vomiting and failure to thrive, evolving into acute presentation triggered by fever or other illnesses. One revealing feature of this IEM is the characteristic odor of "sweaty feet." Newborn screening by MS/MS reveals elevated concentrations of C5-carnitine (Figure 58-11). The diagnosis is confirmed by urine organic acid analysis showing elevated concentrations of isovalerylglycine as the major byproduct and 3-hydroxyisovaleric acid (see Figure 58-11). Elevated concentrations of C5-carnitine also reflect 2-methyl-butyryl-CoA dehydrogenase deficiency, an inherited disorder of isoleucine metabolism characterized by variable excretion of 2-methylbutyrylglycine. In these patients, analysis of urine organic acids may not detect 2-methylbutyrylglycine; therefore acylglycine analysis should also be performed in the investigation of elevated concentrations of C5-carnitine with normal concentrations of urine organic acids. In several patients identified by newborn screening, excretion of isovalerylglycine is only moderately elevated, possibly caused by a milder form of the disease.[75] Treatment with a low-protein diet, glycine (250 mg/kg/d), and carnitine (50 to 100 mg/kg/d) supplements allows a good prognosis, but acute episodes of metabolic decompensation could be life threatening at any age.

Glutaric Acidemia Type 1

Glutaric acidemia type 1 (GA-1) results from an inherited defect in glutaryl-CoA dehydrogenase, an enzyme involved in the degradation of lysine, hydroxylysine, and tryptophan. Affected individuals may have macrocephaly at birth or may develop it in the first year of life.[30] They can have mild hypotonia, and some develop acute dystonia and spasticity, with metabolic decompensation usually triggered by fever

or other illnesses. Brain imaging of affected individuals demonstrates frontotemporal atrophy and, after a crisis, the characteristic sequelae of acute striatal degeneration and shrinkage of the caudate and putamen.[30] Hypotonia followed by spasticity, abnormal movement, seizures, mild hypoglycemia, and metabolic acidosis has been associated with acute events.

Diagnosis of this condition is confirmed by analysis for urine organic acids indicating excretion of massive quantities of glutaric and 3-hydroxyglutaric acids. This is associated with increased concentrations of glutarylcarnitine in plasma. Some patients, referred to as low excretors, show a more subtle biochemical phenotype with normal or mildly elevated glutaric acid and mildly increased excretion of 3-hydroxyglutaric acid.[30] In these patients, the concentration of plasma glutarylcarnitine is sometimes normal, although they tend to have elevated urinary excretion of glutarylcarnitine.[73] Infants with GA-1 usually have elevated concentrations of glutarylcarnitine identifiable by newborn screening, although low excretors are sometimes missed. Concentrations of glutarylcarnitine are also elevated in patients with kidney failure, but usually in association with other acylcarnitine species.

Treatment consists of a diet restricted in lysine and tryptophan and carnitine supplementation. Prompt treatment of infection or other illness and prevention of metabolic decompensation are critical components in the treatment of this disease.

DISORDERS OF THE CARNITINE CYCLE AND FATTY ACID OXIDATION

Carnitine [3-hydroxy-4-(trimethylazaniumyl)butanoate] plays an essential role in the transport of long-chain fatty acids inside mitochondria for β-oxidation. During periods of fasting or high energy demand, the main substrates for energy production in the liver, cardiac muscle, and skeletal muscle are fatty acids, which are released by adipose tissue. The brain is unable to utilize fatty acids because they cannot cross the blood-brain barrier; however, it is capable of oxidizing ketone bodies derived from β-oxidation of fatty acids in the liver.[44] If fatty acid oxidation is impaired, fatty acids

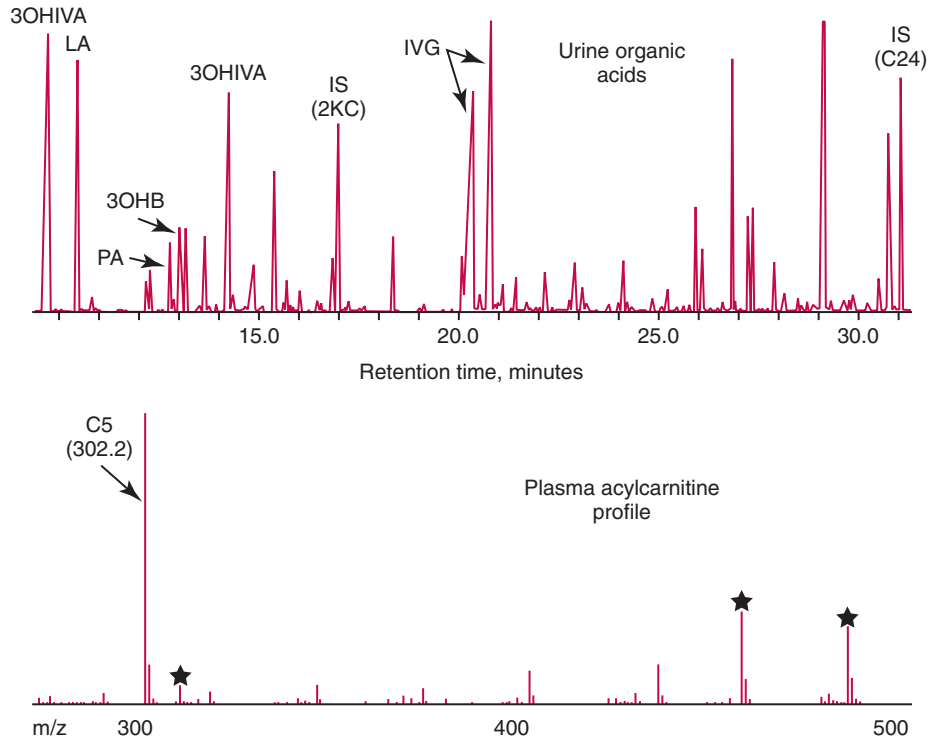

Figure 58-11 Urine organic acids (by gas chromatography/mass spectrometry) *(top)* and plasma acylcarnitine profile (by tandem mass spectrometry) *(bottom)* in isovaleric acidemia. *Top,* 3-OH-isovaleric acid (3OHIVA) and isovalerylglycine (IVG) are the characteristic metabolites of isovaleric acidemia. In this sample, lactic acid (LA), propionic acid (PA), and 3-OH-butyric acid (3OHB) were also increased. *IS,* Internal standard. *Bottom,* C5 (Isovaleryl)-carnitine is markedly increased in patients with classic isovaleric acidemia. will still be released by adipose tissue during fasting or high energy demands, but they accumulate in the liver, heart, and skeletal muscle. In the liver, impaired oxidation of fatty acids will result in steatosis and decreased production of ketones. Ketones are used by the heart, skeletal muscle, and brain as energy sources sparing glucose; in the liver, increased acetyl-CoA, derived from β-oxidation of fatty acids, stimulates gluconeogenesis (production of glucose), mostly from the carbon skeleton of amino acids released from the muscle. Excessive utilization of glucose and lack of gluconeogenesis cause hypoglycemia, which, in addition to decreased availability of ketones, decreases the energy supply to the brain, causing loss of consciousness, seizures, and coma. Fats also accumulate in the heart and skeletal muscle, causing cardiomyopathy and myopathy, in addition to fatal arrhythmias.

Long-chain fatty acids, released from adipose tissue, enter mitochondria for subsequent β-oxidation through the carnitine cycle (Figure 58-12). This cycle requires enzymes and transporters that (1) accumulate carnitine within the cell (OCTN2 carnitine transporter), (2) conjugate it with long-chain fatty acids to form long-chain acylcarnitines [carnitine palmitoyl transferase 1 (CPT-1)], (3) transfer acylcarnitines across the inner plasma membrane [carnitine-acylcarnitine translocase (CACT)], and (4) conjugate fatty acids back to coenzyme A for subsequent β-oxidation [carnitine palmitoyl transferase 2 (CPT-2)]. Medium- and short-chain fatty acids also cross the mitochondrial membrane independent of the carnitine cycle. In the mitochondrial matrix, long-chain fatty acids undergo a series of enzymatic reactions to progressively shorten their chain by two carbon units (acetyl-CoA). Several dehydrogenases are present, each with different carbon chain length specificity from C18 to C4. These enzymes introduce a double bond between carbons C2 and C3 of a given fatty acid (Figure 58-13) and include (1) very long-chain acyl CoA dehydrogenase (VLCAD), (2) long-chain acyl CoA dehydrogenase (LCAD), (3) medium-chain acyl CoA dehydrogenase (MCAD), and (4) short-chain acyl CoA dehydrogenase (SCAD). A trifunctional protein (TFP) adds water and cleaves two carbon atoms from the long-chain fatty acid. This is done through the sequential action of a hydratase (enoyl-CoA hydratase), a β-hydroxyacyl-CoA dehydrogenase [long-chain 3-OH-acyl-CoA dehydrogenase (LCHAD)], and a thiolase (acyl-CoA acetyltransferase). The two-carbon units generated are completely oxidized in the muscle to CO_2 or generate ketone bodies in the liver that are transported to other organs, where they serve as an energy source.

Deficiency in any of these steps leads to impaired energy production, in most cases aggravated by fasting or a catabolic state. Characteristics of disorders of the carnitine cycle and

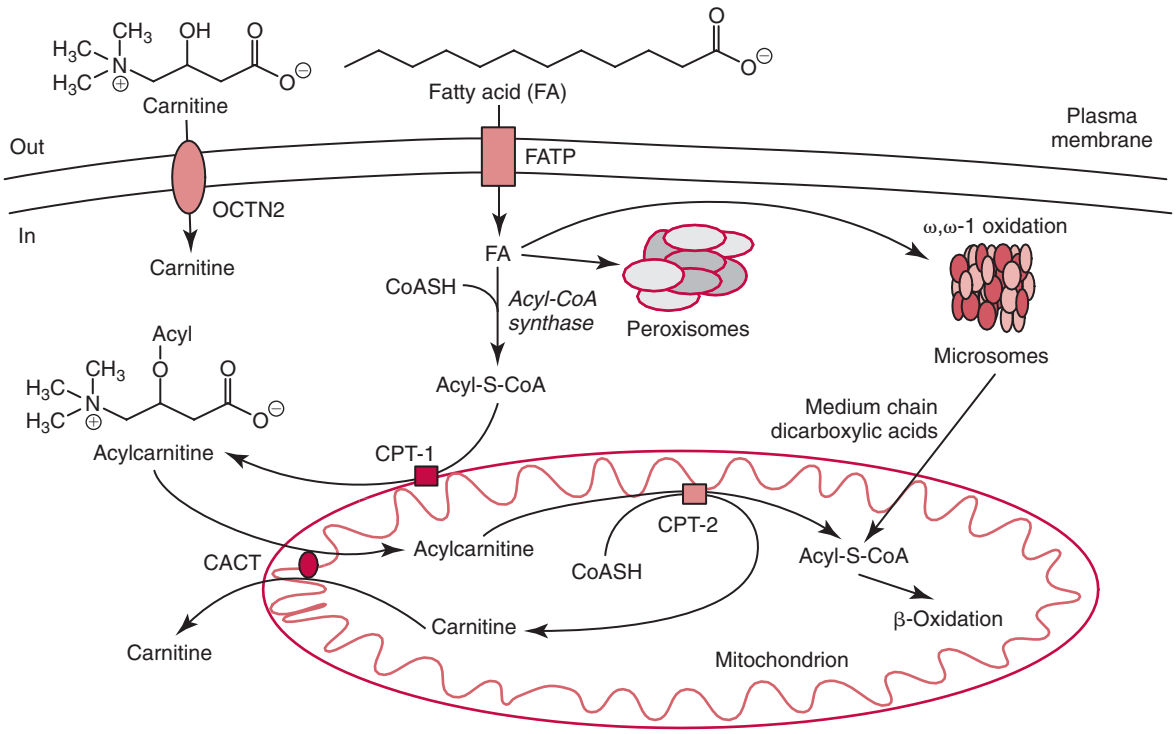

Figure 58-12 The carnitine cycle in fatty acid oxidation. The carnitine cycle is responsible for delivering long-chain fatty acid to the mitochondrial matrix for subsequent beta oxidation. *CACT,* Carnitine acyl carnitine translocase; *CPT-1,* carnitine palmitoyl transferase 1; *CPT-2,* carnitine palmitoyl transferase 2; *FA,* fatty acid; *FATP,* fatty acid transporter protein. *(Modified from Longo N, Amat di San Filippo C, Pasquali M. of fatty acid oxidation are summarized in Table 58-8 and are discussed in greater detail in the following sections.

Carnitine Uptake Defect

Carnitine uptake defect (CUD), or primary carnitine deficiency (OMIM 212140), is an autosomal recessive disorder of the carnitine cycle affecting fatty acid oxidation. It is caused by lack of functional OCTN2 carnitine transporter. Primary carnitine deficiency has a frequency of about 1:40,000 newborns in the general population, but a much higher incidence in the Faroe Islands (1:720).[45] Lack of the plasma membrane carnitine transporter results in urinary carnitine wasting, low serum carnitine concentrations (0 to 9 µmol/L, reference interval 25 to 50 µmol/L), and decreased intracellular carnitine accumulation. Patients with primary carnitine deficiency lose significant amounts (50 to 95%) of filtered carnitine in urine, and their heterozygous parents lose two to three times the normal amount, which explains their mildly reduced plasma carnitine concentrations.[57] Patients typically present with hepatic encephalopathy or cardiomyopathy triggered by fasting or infection. Routine laboratory studies show hypoglycemia with minimal or no ketones in urine, hyperammonemia with variably elevated liver transaminase activities, and, occasionally, elevated creatine kinase activity. Some patients have been completely asymptomatic all of their life and are diagnosed only following the birth of an affected child.[59] Other children, diagnosed because of an affected sibling, had only mild developmental delays. Newborn screening is used to identify reduced concentrations of free carnitine in blood spots. Low carnitine concentrations are also seen in the newborn blood spots of infants of mothers with low carnitine due to a carnitine uptake defect or secondary to an undiagnosed organic acidemia or fatty acid oxidation defect. Diagnosis is further suspected with the finding of extremely reduced concentrations of free, total, and acylated carnitine (free carnitine <9 µmol/L, reference interval 25 to 50 µmol/L) with unremarkable concentrations of urine organic acids. In symptomatic patients, urine organic acid concentrations may reveal a nonspecific dicarboxylic aciduria. Diagnosis is confirmed by demonstrating reduced carnitine transport (<15% of normal) in skin fibroblasts and/or by performing DNA testing, which, however, can fail to identify some of the causative mutations. Therapy consists of lifelong carnitine (100 to 300 mg/kg/d) supplementation.

Carnitine Palmitoyl Transferase 1 Deficiency

Carnitine palmitoyl transferase 1 (CPT-1) conjugates fatty acids to carnitine, allowing their subsequent mitochondrial import (see Figure 58-12). Three different isoforms of CPT-1 have tissue-specific expression encoded by different genes:

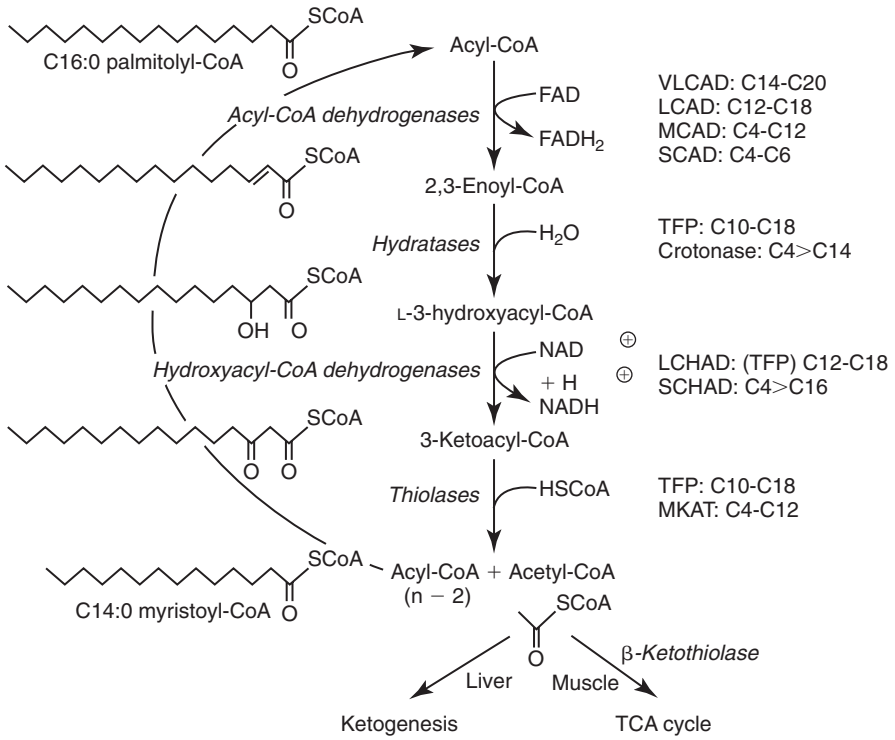

Figure 58-13 Beta oxidation of fatty acids. In the mitochondrial matrix, long-chain fatty acids undergo a series of steps to progressively shorten the fatty acids of two carbon units (acetyl-CoA) through a series of enzymatic reactions. Dehydrogenases with different carbon chain length specificity (*LCAD,* long-chain acyl-CoA dehydrogenase; *MCAD,* medium-chain acyl-CoA dehydrogenase; *SCAD,* short-chain acyl-CoA dehydrogenase; *VLCAD,* very long-chain acyl-CoA dehydrogenase) introduce a double bond between C2 and C3. A trifunctional protein (TFP) adds water and cleaves two carbon atoms from the long-chain fatty acid. This is done through sequential action of a hydratase (enoyl-CoA hydratase), a L-3-hydroxyacyl-CoA dehydrogenase (*LCHAD,* long-chain 3-OH-acyl-CoA dehydrogenase), and a thiolase (acyl-CoA acetyltransferase). The two carbon units generated can be completely oxidized in the muscle to CO_2 or can generate ketone bodies in the liver that may be exported to provide energy to other organs.

liver type (CPT-1A), encoded by a gene on 11q13; muscle type (CPT-1B), encoded by a gene on 22q13; and brain type (CPT-1C), whose gene maps to 19q13.[9] Only deficiency of the liver type, CPT-1A, has been demonstrated in humans. CPT-1 deficiency (OMIM* 255120) is usually triggered by fasting or viral illness. Affected children present, usually between birth and 18 months of age, with altered mental status and hepatomegaly. Routine laboratory evaluation indicates nonketotic hypoglycemia, mild hyperammonemia, elevated liver function tests, and elevated concentrations of free fatty acids. Newborn screening is used to identify elevated concentrations of free carnitine with low concentrations of long-chain acylcarnitines (C16 and C18) and an elevated free carnitine/(C16+C18) ratio. This latter ratio allows discrimination of elevated free carnitine caused by carnitine supplements from CPT-1 deficiency.[24] Plasma carnitine concentrations are usually increased in classic cases, but they generally fall within the reference intervals in milder cases. In these cases, DNA testing or assay of CPT-1 activity in fibroblasts is required to confirm or exclude the diagnosis. Therapy consists of avoidance of fasting, benefitting from night-time feeds with uncooked cornstarch and a low-fat diet rich in medium-chain triglycerides, which do not need the carnitine cycle for β-oxidation in liver mitochondria.

*Online Mendelian Inheritance in Man. OMIM is a comprehensive, authoritative, and timely compendium of human genes and genetic phenotypes (http://www.ncbi.nlm.nih.gov/omim/accessed September 29, 2011).

Carnitine-Acylcarnitine Translocase Deficiency

Carnitine-acylcarnitine translocase (CACT) is responsible for transporting both carnitine and carnitine-fatty acid complexes across the inner mitochondrial membrane (see Figure 58-12). CACT deficiency (OMIM 212138) presents most often in the neonatal period with (1) seizures, (2) irregular heartbeat, and (3) apnea. Frequently, these episodes are triggered by fasting or by the physiologic stress of birth. Patients

TABLE 58-8 Clinical and Laboratory Characteristics of Fatty Acid Oxidation Disorders

Common Name	OMIM* No.	Inheritance	Enzyme/ Transport Defect	Incidence (USA)	Major Clinical Features	Major Biochemical Marker(s)
Carnitine uptake defect	212140	AR	Carnitine transporter	1:40,000	Hypoglycemia, cardiomyopathy, fasting intolerance, hypoketotic hypoglycemia, sudden death	Low free carnitine (B), low long-chain acylcarnitines (B), decreased urinary carnitine reabsorption
CPT-1A deficiency (liver)	255120	AR	Carnitine palmitoyl transferase I	<1:100,000	Liver disease, hypotonia, renal tubular acidosis, fasting intolerance, hypoketotic hypoglycemia	High free carnitine (B), low long-chain acylcarnitines (B)
Translocase deficiency	212138	AR	Carnitine acylcarnitine translocase	<1:100,000	Cardiomyopathy, liver disease, fasting intolerance, hypoketotic hypoglycemia	C16/C18 acylcarnitines (B)

with milder cases present in childhood with attacks triggered by fever, infection, and fasting as other fatty acid oxidation defects. Fasting hypoglycemia and seizures have been reported in these patients.

In neonatal cases and during acute attacks, routine laboratory testing reveals nonketotic hypoglycemia and hyperammonemia with elevated activities of creatine kinase (CK) and abnormal liver function tests. This disease is identified upon newborn screening by elevated concentrations of C16- and C18:1-carnitine, often in addition to low concentrations of free carnitine. Diagnosis is confirmed by a plasma acylcarnitine profile demonstrating a marked increase in concentrations of long-chain acylcarnitines and decreased concentrations of free carnitine. This abnormal profile, however, is not distinguishable from that of neonatal CPT-2 deficiency and direct assay of carnitine-acylcarnitine translocase in fibroblasts or DNA analysis is needed for diagnostic confirmation. Therapy consists of frequent feedings of a diet (1) rich in carbohydrates, (2) low in fat, most of which should be medium-chain triglycerides, and (3) supplemented

with carnitine. This therapy improves the acylcarnitine profile and prevents additional attacks of hypoglycemia and arrhythmia.[32]

Carnitine Palmitoyl Transferase 2 Deficiency

Carnitine palmitoyl transferase 2 (CPT-2) deficiency presents most frequently in adolescents and young adults (OMIM 255110) with muscle pain with or (in most cases) without myoglobinuria, accompanied by elevated activities of serum creatine kinase precipitated by strenuous exercise, cold, fever, or prolonged fasting. Myoglobinuria can cause kidney failure and death. CPT-2 deficiency also presents in infancy (OMIM 600649) and in the neonatal period (OMIM 608836).[9] The neonatal form, which is rapidly fatal, presents shortly after birth (a few hours to 4 days) with (1) respiratory distress, (2) seizures, (3) hepatomegaly, (4) cardiomegaly, (5) cardiac arrhythmia, and, in many cases, (6) dysmorphic features, (7) renal dysgenesis, and (8) neuronal migration defects. The infantile variety usually presents between 6 and 24 months of age with recurrent attacks of hypoketotic hypoglycemia causing loss of consciousness and seizures, liver failure, and transient hepatomegaly. Some children have heart involvement with cardiomyopathy and arrhythmia. Episodes are triggered by infection, fever, and fasting.

Routine laboratory testing usually indicates hyperammonemia, metabolic acidosis, and hypoketotic hypoglycemia with elevated activities of creatine kinase. Newborn screening reveals the same elevation of long-chain acylcarnitines (C16, C18:1) seen in CACT deficiency, with carnitine deficiency being absent in patients with milder forms. Diagnosis is confirmed by an abnormal plasma acylcarnitine profile and by enzyme assay in fibroblasts and/or DNA analysis to differentiate from CACT deficiency. Late-onset CPT-2 deficiency responds to exercise limitation, restriction of fat and long-chain fatty acids with increased dietary carbohydrates, and avoidance of fasting.

Very Long-Chain Acyl-CoA Dehydrogenase Deficiency

Very long-chain acyl-CoA dehydrogenase (VLCAD) catalyzes the first step of the fatty acid β-oxidation spiral (see Figure 58-13). In the mid 1980s, patients with VLCAD deficiency were initially described as having long-chain acyl-CoA dehydrogenase (LCAD) deficiency.[29] However, affected patients were subsequently shown to have VLCAD deficiency.[67] The severity of the phenotype correlates with the genotype[3] with earlier and more severe presentation observed in patients with the most severe deficiency. Patients with VLCAD deficiency present in infancy with (1) cardiomyopathy, (2) cardiac arrest, (3) hypoglycemia, and (4) other hepatic symptoms. This form is rapidly fatal. Older children present with hypoketotic hypoglycemia, and hepatomegaly with or without cardiomyopathy. The milder form presents in adolescents or adults with muscle weakness and pain without cardiac and hepatic involvement.[28]

Routine laboratory testing during acute episodes reveals hypoketotic hypoglycemia and elevated activities of creatine kinase and transaminases. Elevated concentration of C14:1-carnitine in the first newborn screen blood spot is often the only abnormality detected, and it may no longer be present in subsequent screens or diagnostic tests (plasma acylcarnitine profile). For this reason, in all infants with elevated concentrations of C14:1-carnitine on newborn screening, the diagnosis of VLCAD deficiency needs to be confirmed or excluded by specific enzyme assay or fatty acid oxidation studies in vitro, and/or by molecular genetic analysis of the VLCAD gene.[8] Therapy for this condition consists of avoidance of fasting, prompt treatment of infection, and a low-fat diet with medium-chain triglycerides providing most of the calories from lipids. Low-dose carnitine supplements (25 mg/kg/d) are sometimes given. Figure 58-14 shows a characteristic plasma acylcarnitine profile of VLCAD deficiency.

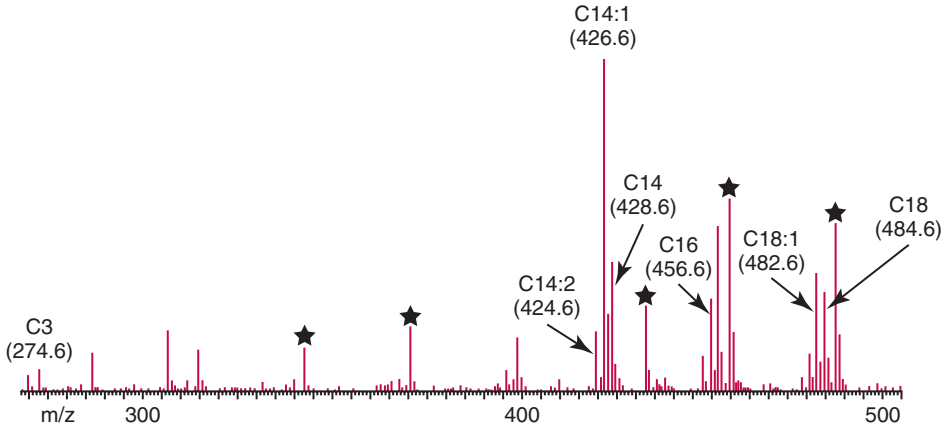

Figure 58-14 Plasma acylcarnitine profile (by tandem mass spectrometry) in very long-chain acyl-CoA dehydrogenase (VLCAD) deficiency. C14:1-carnitine is the diagnostic metabolite in VLCAD deficiency with elevation of other long-chain acylcarnitines (C14-, C16-, C18-, C14:2-, and C18:1-carnitine). Internal standards are indicated with a star.

Trifunctional Protein and Long-Chain 3-Hydroxy-Acyl-CoA Dehydrogenase Deficiencies

The trifunctional protein (TFP) is a hetero-octamer containing four α- and four β-subunits encoded by two different genes.[11] The α-subunit harbors the activities of the second and third steps of fatty acid β-oxidation, long-chain enoyl-CoA hydratase (LCEH), and long-chain 3-hydroxy-acyl-CoA dehydrogenase (LCHAD). The β-subunit harbors the activity of long-chain 3-oxoacyl-CoA dehydrogenase (LCKAT), which catalyzes the last step in β-oxidation of long-chain fatty acids. Mutations in either gene may cause complete TFP deficiency, and a prevalent mutation in the *HADHA* gene encoding the α-subunit (c.G1528C, p.E474Q) causes isolated LCHAD deficiency.[68] A genotype-phenotype correlation has emerged for TFP deficiency, with residual enzyme activity being associated with a milder, later-onset phenotype. Three clinical phenotypes are known: (1) a severe neonatal presentation with cardiomyopathy, Reye-like symptoms, and early death; (2) a hepatic form with recurrent hypoketotic hypoglycemia; and (3) a milder, later-onset neuromyopathic phenotype with episodic myoglobinuria. Patients with LCHAD/TFP deficiencies may also develop pigmentary retinopathy and peripheral neuropathy, whose pathophysiology remains obscure. In addition, mothers of these patients can have significant complications with acute fatty liver of pregnancy or hemolysis, elevated liver enzymes, and low platelet (HELLP) syndrome,[70] possibly due to the transplacental passage of 3-OH-fatty acids and related acylcarnitines.[22] This complication occurs in mothers independently of the fetal phenotype.[68]

Newborn screening identifies elevated concentrations of C16:OH- and C18:1-OH-carnitines in blood spots of infants with LCHAD/TFP deficiency. An abnormal plasma acylcarnitine profile identifies the same abnormalities with elevation of additional long-chain acylcarnitines (Figure 58-15). Urine organic acids collected at the time of an acute episode show hypoketotic C6-C10-dicarboxylic aciduria and C6-C14-3-hydroxydicarboxylic aciduria with prominent unsaturated species. Concentrations of urine organic acids rapidly normalize with therapy and fall within the reference interval in asymptomatic patients. Therapy for these conditions consists of avoidance of fasting, prompt treatment of infection, and a low-fat diet with medium-chain triglycerides providing most of the calories from lipids. Low-dose carnitine supplements (25 mg/kg/d) may be given.

Medium-chain Acyl-CoA Dehydrogenase Deficiency

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency is the most common disorder of fatty acid oxidation, with an estimated frequency of 1:6000 to 1:10,000 Caucasian births.[19,31] Symptoms of the disease are variable, from completely asymptomatic patients to those with hypoglycemia, lethargy, coma, or sudden death. Symptoms usually are triggered by prolonged fasting or illness. Although most patients present in the first year of life, clinical symptoms have been known to occur at any time, and as many as 20% of patients die before diagnosis.[33]

Patients with MCAD deficiency are identified by MS/MS newborn screening because of their characteristic acylcarnitine profile, with increased concentrations of C6- (hexanoyl), C8- (octanoyl), and C10:1-(decenoyl) carnitine, and elevated C8/C2 and C8/C10 ratios (Figure 58-16). Urine organic acid and urine acylglycine analyses during metabolic crisis show (1) increased excretion of dicarboxylic acids (adipic, suberic, sebacic)—saturated and unsaturated, (2) few or absent ketones, and (3) increased excretion of hexanoylglycine and suberylglycine. Phenylpropionylglycine may be present, although usually in older patients. When patients are metabolically stable, the urinary concentration of these analytes is greatly reduced, although concentrations of hexanoylglycine and suberylglycine remain detectable. The abnormal plasma

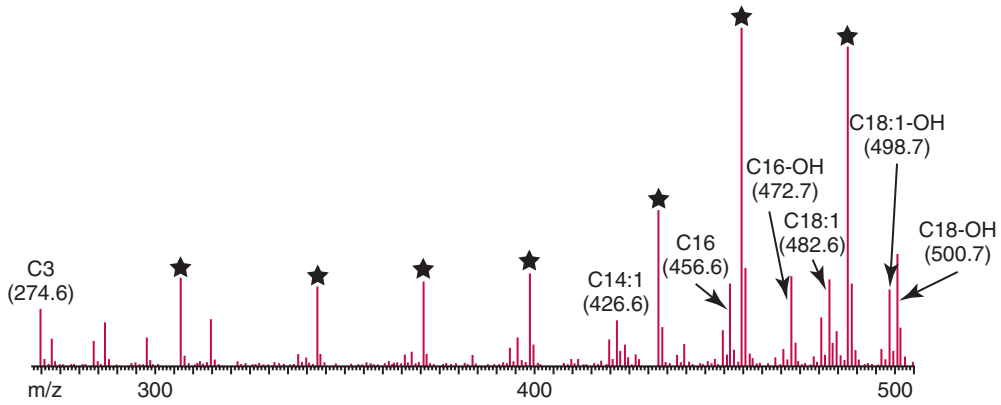

Figure 58-15 Plasma acylcarnitine profile (by tandem mass spectrometry) in trifunctional protein (TFP)/long-chain 3-OH-acyl-CoA dehydrogenase (LCHAD) deficiency. 3-OH-long-chain acylcarnitines (C16-OH-, C18-OH-, and C18:1-OH-carnitine), in addition to long-chain acylcarnitines, become elevated in both TFP and LCHAD deficiency. Internal standards are indicated by a star.

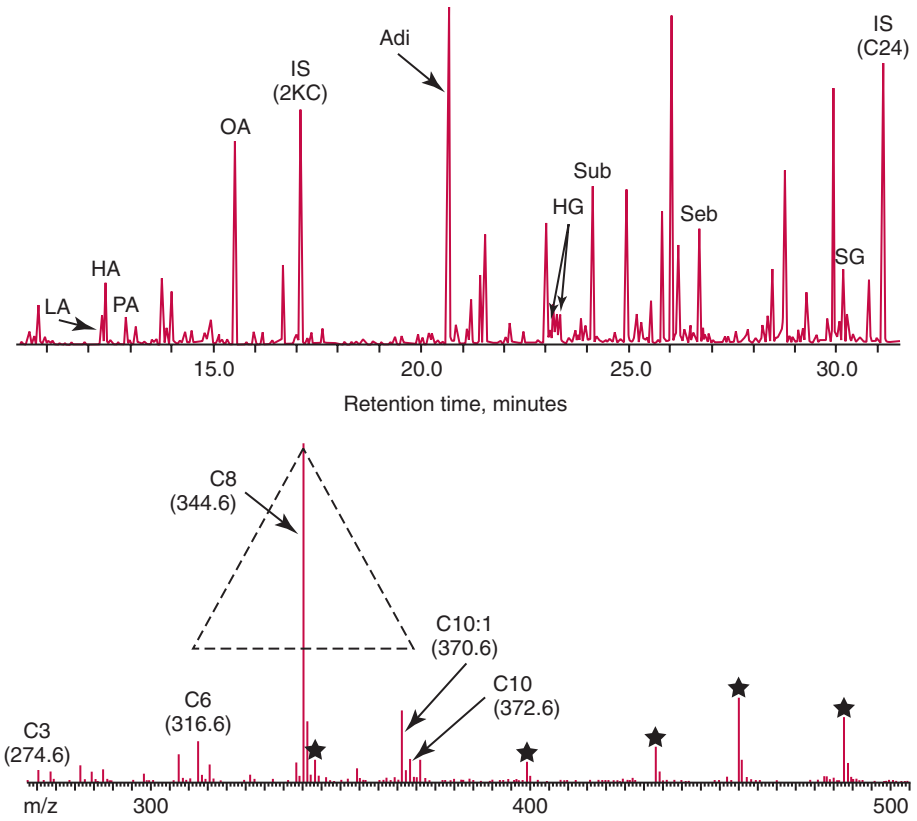

Figure 58-16 Urine organic acids (by gas chromatography/mass spectrometry) *(top)* and plasma acylcarnitine profile (by tandem mass spectrometry) *(bottom)* in medium-chain acyl-CoA dehydrogenase (MCAD) deficiency. Patients with MCAD deficiency can have dicarboxylic aciduria [increased excretion of adipic (Adi), suberic (Sub), and sebacic (Seb) acids, usually in a descending pattern, with adipic being the most increased] during episodes of decompensation or fasting. Hexanoic acid (HA) and octanoic acid (OA) can also be present during decompensation. Hexanoylglycine (HG) and suberylglycine (SG) are the diagnostic metabolites that usually remain present even when the patient is well compensated. Phenylpropionylglycine can appear in older patients as well. Urine acylglycine analysis is more effective than urine organic acid analysis for their quantification. *IS,* Internal standard; *LA,* lactic acid; *PA,* pyruvic acid. *Bottom,* The plasma acylcarnitine profile is characterized by elevated C8-, C6-, and C10:1-carnitine, with the C8-carnitine peak at the vertex of a triangle over the other two elevated species *(indicated by the dashed lines).* In carriers for this condition, C8-carnitine can be elevated, but it is not usually the highest peak on visual inspection. Internal standards are indicated with a star.

acylcarnitine profile is almost always present. Follow-up of an abnormal newborn screening for MCAD deficiency should include analysis of urine organic acids, urine acylglycines, and the plasma acylcarnitine profile. Diagnosis is confirmed by DNA analysis. Among patients presenting with clinical symptoms, 98% carry at least one copy of the common *p.K304E* mutation, with 80% being homozygous for this mutation.[2] In newborns detected prospectively by newborn screening, the *p.Y42H* mutation has been found frequently in association with the common *p.K304E* mutation.[2] The *p.Y42H* mutation has not yet been reported in patients with clinical symptoms[2] and is associated with lower concentrations of diagnostic metabolites in blood and urine.[76]

Treatment consists of avoidance of fasting, low-fat diet, carnitine supplementation, and institution of an emergency plan in case of illness or other metabolic stress. Early diagnosis through newborn screening and early initiation of treatment lead to improved outcomes.

Short-Chain Acyl-CoA Dehydrogenase Deficiency

Short-chain acyl-CoA dehydrogenase (SCAD) deficiency has been associated with a variety of clinical phenotypes, ranging from catastrophic illness in the neonatal period, to hypotonia, developmental delay, seizures, myopathy, and others.[34,74] Lack of a consistent phenotype and the large number of infants

identified with mild variants of this condition led to a re-evaluation of this condition, with the conclusion that SCAD deficiency lacks clinical significance.[74] With this condition, butyryl-CoA is subjected to alternative metabolism with carboxylation to ethylmalonic acid (EMA) mediated by propionyl-CoA carboxylase and conjugation with carnitine and glycine. The most useful biochemical markers of SCAD deficiency include the presence of EMA and butyrylglycine in urine, and butyrylcarnitine (C4) in plasma. This is detected by newborn screening, although several programs in Europe no longer screen for this condition.[74] In practice, SCAD deficiency needs to be differentiated from ethylmalonic encephalopathy, a fatal mitochondrial disorder that impairs the ability to remove sulfide,[71,72] and multiple acyl-CoA dehydrogenase deficiency (in which ethylmalonic acid may accumulate). Analysis of urine organic acids and urine acylglycines and completion of a plasma acylcarnitine profile will allow differentiation among these conditions. In doubtful cases, DNA analysis identifies common and rare variants of the SCAD gene. No treatment is required for SCAD deficiency.

CHAPTER 59

Hemostasis

Russell A. Higgins, M.D., Steve Kitchen, Ph.D., and John D. Olson, M.D., Ph.D.

Hemostasis is the mechanism by which animals with a vascular system protect themselves from exsanguination following an injury. The mechanism is designed to form the hemostatic plug at the site of an injury. It is well recognized that the process may hypofunction, leading to a bleeding diathesis (i.e., predisposition or tendency to bleed), or it may hyperfunction, leading to intravascular coagulation or formation of a potentially life-threatening blood clot in a blood vessel (thrombosis). For purposes of discussion, normal hemostasis is often divided into three parts: (1) vascular, (2) platelet (cellular), and (3) plasma coagulation components. It is important to remember that these three contributors **do not act** separately, but are simultaneously activated and are mutually dependent upon one another.

VASCULAR

At the time of an injury, small and medium vessels contract in response to mechanical, neural, and chemical (platelet secretory products) stimuli, in a remarkably successful effort to prevent blood loss. In addition, the endothelial cell plays a key role in the procoagulant and anticoagulant regulation of platelet function and plasma coagulation. Endothelial cells support platelet function through the synthesis and secretion of von Willebrand factor (VWF) and down regulates function by secretion of the potent inhibitor, prostacyclin (PgI_2). Anticoagulant functions occurring at the endothelial surface include (1) binding of thrombin to thrombomodulin (TM); (2) conversion of protein C to activated protein C; and (3) clearance of activated coagulation factors by antithrombin (AT). The endothelium also contributes to activation and regulation of fibrinolysis by secretion of tissue plasminogen activator (tPA) and plasminogen activator inhibitors.[93] Tissue factor (TF) is found in many tissues in the body, but of particular interest is its presence in the vascular smooth muscle and pericytes that surround the vessel. This vascular distribution of TF has been referred to as the hemostatic envelope.[34,39] Figure 59-1 depicts the procoagulant and regulatory roles of the endothelium in hemostasis.

PLATELETS

Platelets are key cellular elements in the hemostatic process.[77] They are anuclear fragments of the megakaryocyte, produced in the bone marrow and released into the bone marrow sinusoids. They normally circulate for approximately ten days. The functions of the platelet include (Table 59-1): *(1). adhesion* of the platelet to surfaces at the site of injury—the platelet recognizes non-endothelial surfaces and adheres to those surfaces in an initial step in the hemostatic process; *(2). aggregation* of platelets at the site of an injury—platelets recognize one another and aggregate, building a structure of platelets at the site of injury; *(3) secretion* of the two types of granules, alpha granules (contain such proteins as fibrinogen and von Willebrand factor) and dense bodies (contain non-protein components like epinephrine, adenine nucleotides, serotonin and others)—upon platelet activation, granule contents are secreted into the microenvironment, contributing to vascular smooth muscle contraction, further platelet activation and support of plasma coagulation; *(4) support of plasma coagulation* at the site of the injury—macromolecular enzyme complexes are assembled on the surface of the platelet, greatly accelerating the production of thrombin and, consequently, fibrin; *(5) clot retraction* may be thought of as the in vivo suture—the platelet contains contractile proteins that shrink the clot by drawing the edges of small injuries closer together, a function that may be an early step in the healing process; *(6) support of the injured endothelial cell* occurs with the fusion of platelets to damaged endothelium—the platelet becomes a part of the endothelium, helping to support its function.[5] Platelet function testing parallels these activities of the platelet.

COAGULATION

Blood coagulation is a complex biological process that occurs as conversion of the soluble molecule, fibrinogen, to the insoluble molecule, fibrin. The cascade of enzymatic reactions leading to the formation of fibrin allows for amplification of the initial signal from injury and regulation of the process.

The process of coagulation has three pathways: extrinsic, intrinsic, and common. The extrinsic pathway (also known

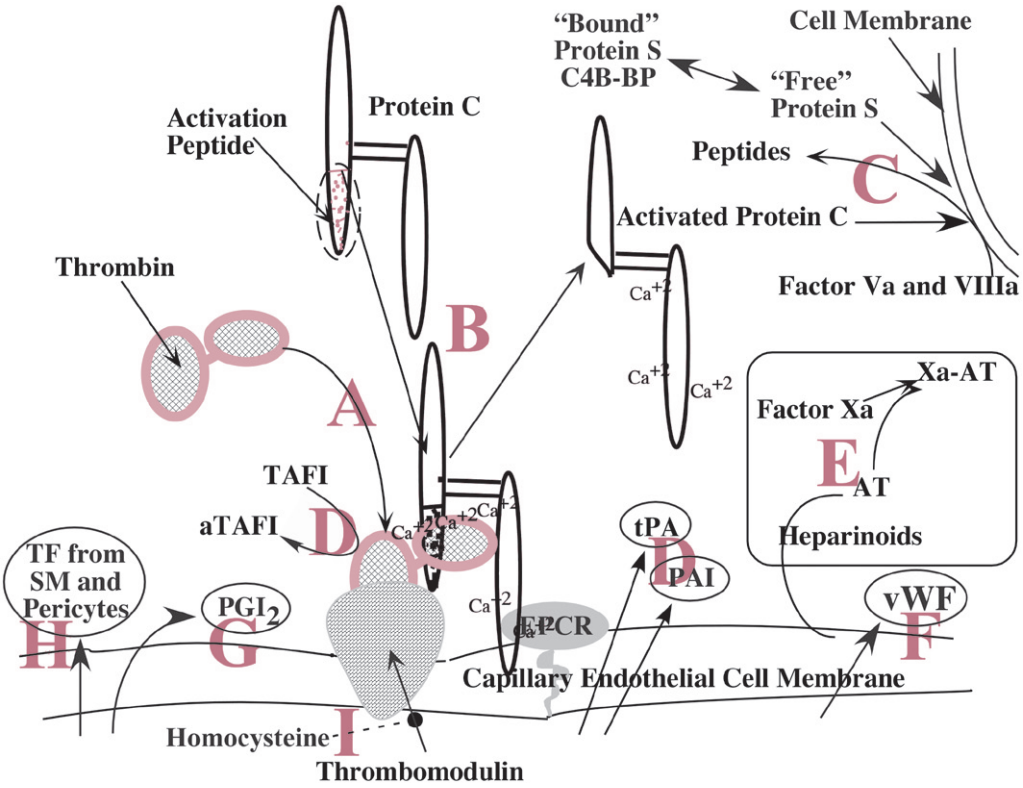

Figure 59-1 Role of the Endothelium in Hemostasis. [A] Thrombin released into the circulation at the site of an injury binds to thrombomodulin (TM), an endothelial cell membrane protein. Bound to TM, thrombin does not cleave fibrinogen. [B] Protein C, bound to the endothelium by endothelial cell protein C receptor (EPCR), is cleaved by thrombin bound to thrombomodulin; the activation peptide is removed and activated protein C (APC) released. [C] At a distant site of coagulation, APC with its cofactor, the free form of protein S, cleaves factors Va and VIIIa, inactivating them and downregulating coagulation at the site. [D] Fibrinolysis is also regulated by actions at the surface of the endothelium by the release of tissue plasminogen activator (tPA) and plasminogen activator inhibitors (PAI), as well as the activation of thrombin-activatable fibrinolysis inhibitor by thrombin bound to TM. [E] Antithrombin (AT) associated with heparin-like compounds in the endothelial cell membrane binds to activated serine proteases such as factor Xa, inhibiting their function through covalent linkage, allowing clearance from the circulation by the liver. [F] VWF, a key molecule in platelet adhesion, is synthesized by the endothelial cell and secreted both into the blood and abluminally into the subendothelial basement membrane. [G] Prostaglandin synthesis in the endothelial cells produces PGI_2, a potent platelet inhibitor, and secretes it into the blood. [H] Tissue factor (TF) is synthesized in the smooth muscle and pericytes of small vessels forming the hemostatic envelope. [I] Homocysteine in the endothelial cell inhibits the expression of TM in the endothelial cell membrane.

as the tissue factor pathway) is initiated by release of TF and F is measured by the prothrombin time (PT). The intrinsic pathway (also known as the contact activation pathway) is initiated by activation of the "contact factors" of plasma and is measured by the activated partial thromboplastin time (aPTT) test. The common pathway results from merging of the extrinsic and intrinsic pathways and includes the final steps before a clot is formed. The individual pathways and their interactions are shown in Figure 59-2 and will be discussed later in the chapter.

The process of coagulation in vivo proceeds through stages of initiation, amplification, and propagation (Figure 59-3). The initial action of TF and factor VIIa generates small amounts of thrombin, which serve to amplify the reaction through (1) activation of platelets, (2) activation of platelet membrane-bound factors V and VIII, and (3) assembly of macromolecular enzyme complexes on the platelet surface. This leads to amplified generation of thrombin that will feed back to activate factors XI, VIII, and V, propagating the reaction.[84] Thrombin plays two key roles in these final

TABLE 59-1 Platelet Functions

Function	Description
Adhesion	Upon activation, the platelet recognizes surfaces other than normal endothelium and adheres to those surfaces.
Aggregation	Upon activation, the platelet recognizes and attaches (aggregates) to other platelets.
Secretion	Upon activation, the platelet secretes the contents of the alpha granules and dense bodies (delta granules).
Support of plasma coagulation	At the site of injury, the platelet serves as a surface upon which macromolecular enzyme complexes form and plasma coagulation is accelerated.
Clot retraction	Following clot formation, the filapodia of platelets attach to the fibrin strands and, through contraction, reduce clot size and express serum in vitro and juxtapose edges of the injury in vivo.
Support of damaged endothelium	Platelets adhere to damaged endothelium, fuse with the membrane, and become incorporated with the endothelial cytoplasm.

steps in the formation of fibrin. First, it is the procoagulant enzyme that cleaves fibrinogen, forming fibrin monomer; second, following fibrin monomer polymerization, thrombin activates factor XIII. Activated factor XIII is a transglutaminase that cross-links the polymer via formation of bonds between lysine and glutamine near the carboxyl end of the γγ chains (within the strands) and bonding between the αγ chains. It is important to keep the process localized to the site of injury, a process that involves regulation of reactions at the site, as well as inactivation of any circulating activated factors on the endothelial surface in the downstream capillary bed. Localization of the process is facilitated by the platelet serving as the template for reactions and by the presence of natural inhibitors like tissue factor pathway inhibitor that neutralize excess enzyme.[40,106] Thrombin that is released also binds to TM in the endothelial cell membrane in the capillary bed and activates protein C, which, with cofactor protein S, inhibits excess enzyme generation through inactivation of factors Va and VIIIa. As fibrin is formed at the site of injury, platelets contract, drawing fibrin strands closer together and helping to stabilize the clot and juxtaposing edges of the wound in anticipation of healing. Note: The in

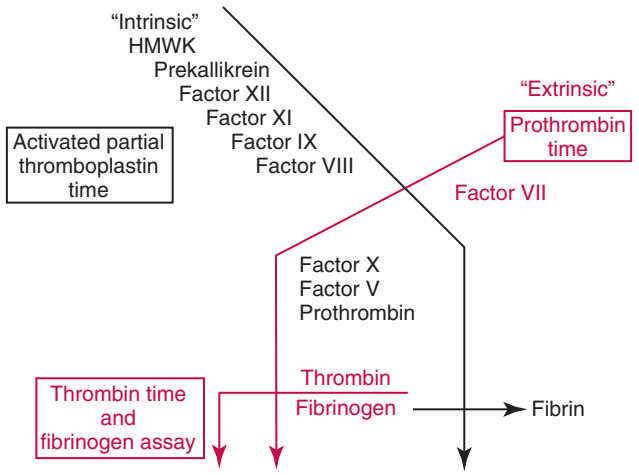

Figure 59-2 Extrinsic, intrinsic, and common pathways of coagulation. (See text for details.)

vitro (Figure 59-2) and the in vivo (Figure 59-3) coagulation mechanisms are not identical. In vitro, high molecular weight kininogen, prekallikreln and factor XII play a key role in coagulation activation, while these same factors play no role in coagulation in vivo.

Fibrinolysis is the process of converting insoluble fibrin to soluble products that are then cleared from the circulation by the liver. The zymogen plasminogen, which is closely associated with fibrin in the clot via molecular sites of recognition, is converted to the enzyme plasmin by urokinase or tPA (Figure 59-4). Plasmin cleaves fibrin to form fibrin degradation products, most commonly measured in the plasma as D-dimer.[11,25A]

When some procoagulant factors are increased, or regulatory proteins are decreased, patients are at increased risk for the development of thrombosis. Thus, acquired or inherited disorders affecting one or more of the many elements involved in hemostasis can lead to an increased risk of thrombosis.

This chapter describes the tests that are most commonly used in evaluating the hemostatic process, along with a brief description of disorders as they relate to those tests.

PRIMARY HEMOSTASIS

Primary hemostasis is characterized by vascular contraction, platelet adhesion, and formation of a platelet thrombus. It begins immediately after endothelial disruption with platelets being a key cellular component in the hemostatic process.[77] Platelets are anuclear fragments of the megakaryocyte cytoplasm, produced in the bone marrow and released into the bone marrow sinusoids. They normally circulate for approximately 10 days. Functions of the platelet are listed in Table 59-1.[63] Platelet function testing parallels these activities of the platelet.

Clinical testing is used to evaluate key aspects of platelets, including (1) number of platelets in a volume of blood, (2) microscopic structure of platelets, (3) global function of platelets, (4) platelet adhesion, (5) platelet aggregation

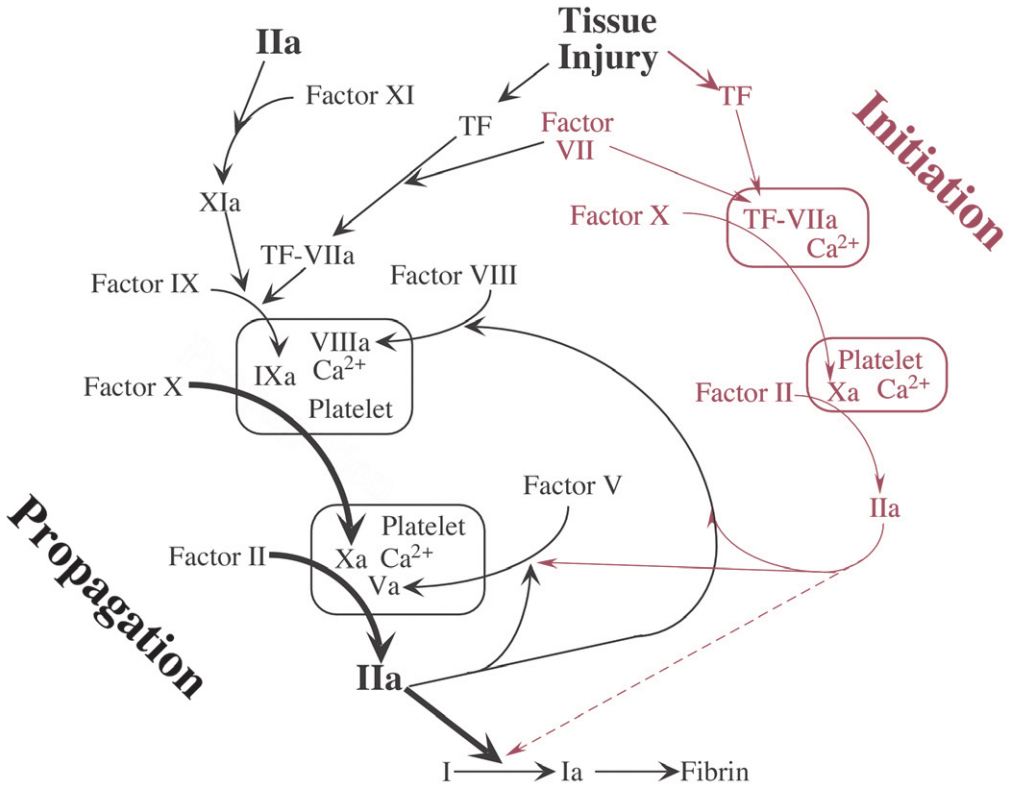

Figure 59-3 Model of the In Vivo Activation of Coagulation. At the site of injury, tissue factor (TF) is released and binds to and activates factor VII. In the presence of calcium (Ca^{2+}), the complex activates factor X. A macromolecular complex is formed on phospholipid (surface of the platelet) with the cofactor, factor V, and initial limited quantities of thrombin (IIa) are produced from prothrombin. This process has been called *extrinsic coagulation* and is the initiation of the coagulation process. This small amount of thrombin serves to activate platelets at the site, activate factor V, activate factor VIII, and activate factor XI. This feedback activation leads to acceleration of the cascading activation of enzymes on the surface of the activated platelet with a resulting burst of IIa generation and the formation of fibrin. The activities enclosed in the boxes depict the formation of macromolecular enzyme complexes that involve vitamin K–dependent coagulation factors (II, VII, IX, and X) and their cofactors (VIIIa and Va), joining with Ca^{2+} on the surface of the platelet.

and secretion, (6) platelet support of plasma coagulation, (7) platelet retraction, and (8) molecules on the platelet surface that are observable by flow cytometry.

Evaluating Platelet Number

The number of platelets in a whole blood sample is counted using automated or manual techniques. The number is usually expressed as thousands of platelet per microliter of blood.

Automated Platelet Counting

Automated methods are effective in counting normal numbers of platelets in a background of normal blood cells. Initial platelet counts are nearly always performed using automated methods.[10] The specimen that is used is whole blood that has been collected into a tube containing ethylenediaminetetraacetic acid (EDTA). In addition to preventing coagulation, the high affinity of EDTA for calcium inhibits platelet activation. Automated cell counters rely on two basic methods to count platelets in whole blood, both of which exploit the small size of the cell in comparison with other normal cells. In the first of these methods, diluted cells are aspirated through a small aperture across which there is an electrical potential. The lipid envelope of the cell causes a change in the potential when it passes the aperture. Thus, the cell is counted by measuring this change in potential, with the magnitude of the change being proportional to the volume of the cell. Platelets are distinguished from other cells on the basis of their small size. For samples with high platelet counts, statistical adjustments are made to the raw count to adjust for the coincidence of more than one cell passing the aperture simultaneously.

In a second automated method, diluted cell suspensions are passed through a cuvette that is slightly larger than a capillary. Laminar flow within the cuvette causes cells to pass through single file. A laser beam passes through the cuvette to a detector. As each cell passes through the path of the laser,

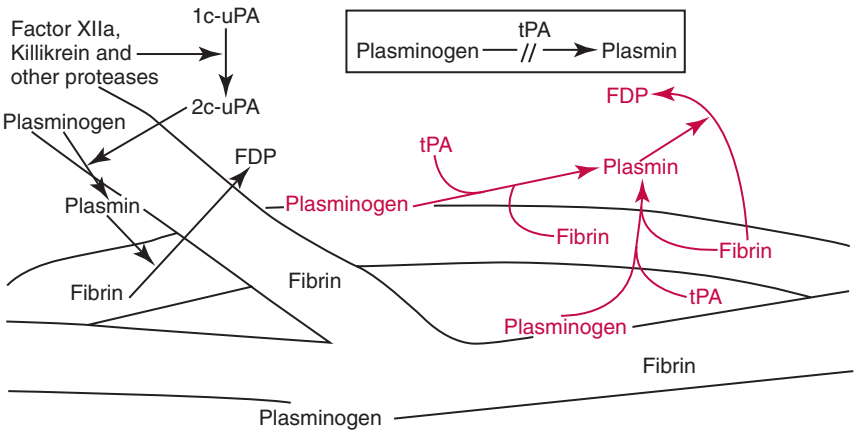

Figure 59-4 Activation of Plasminogen and Fibrinolysis. In vivo, plasminogen is activated to the plasmin (a serine protease) by two pathways. First, *(shown in black)* single-change urokinase (1c-uPA) is converted to active two-chain urokinase (2c-uPA) by contact activation factors and other proteases. Then 2c-uPA cleaves plasminogen to form plasmin. Second, tissue plasminogen activator (tPA) *(shown in red)* converts plasminogen to plasmin only in the presence of its cofactor, fibrin. Fibrin as a cofactor for this reaction is of interest because it is also the substrate for the enzyme being generated. Without fibrin, conversion of plasminogen to plasmin is too inefficient to be physiologically relevant.

the event is counted, and the size and complexity of the cell cytoplasm is determined by the degree of forward and side light scatter, respectively. As varying types of cells pass the laser, they are distinguished from one another on the basis of size and cytoplasmic complexity.

Manual Platelet Counting

At extremes of platelet count and in conditions with red blood cell or white blood cell cytoplasmic fragmentation, the platelets in a specimen are counted manually. This requires manual dilution of the blood and visual counting of the cells in a hemocytometer chamber that holds a defined volume of blood. Alternatively, the proportion of platelets to red blood cells is determined on a blood film using a method similar to that used to count reticulocytes. The platelet count is then determined by using the ratio of platelets to red blood cells and calculating from the red blood cell count which can be determined by manual or automated counting.

Evaluating Platelet Structure

Platelet structures that are morphologically evaluated for their role in hemostasis include alpha particles and dense bodies.

Evaluating Alpha Granules

The alpha secretory granule, the most common organelle of the platelet, contains a number of proteins (von Willebrand factor, fibrinogen, and many others) that are secreted when the platelet is activated. These granules (proteins) are a deep purple color when stained with Wright-Giemsa stain and give the platelets their delicate granular structure when a routine blood film is examined. Figure 59-5 demonstrates the light microscopic appearance of alpha granules.

Evaluating Dense Bodies (Delta Granules)

The dense secretory granule of the platelet contains nonprotein molecules (adenine and guanine nucleotides, vasoactive amines, and many others) that are secreted upon activation. These granules have a high content of calcium ion, making them electron dense (see Figure 59-5). Platelets in platelet-rich plasma adhere when placed on a transmission electron microscopy (TEM) grid, where they are then visualized using TEM.[144] The method, called *whole mount TEM,* is rapid and reliably demonstrates the 5 to 10 delta granules seen normally in platelets. Figure 59-5 demonstrates whole mount and thin-section electron microscopy of a normal platelet.

Thin-section TEM, although used less frequently than whole mount TEM, provides greater detail of platelet structure and may be helpful in determining the cause of hemorrhage related to abnormal platelet activity.[143]

Evaluating Global Platelet and Vascular Function

Various techniques are used to evaluate platelet and vascular function, including bleeding time and the PFA-100 analyzer (Siemens Healthcare Diagnostics, Deerfield, Ill).

Bleeding Time

Over the past century, many iterations of bleeding time have been employed. Currently, the test is performed on the volar aspect (the surface of the arm on the same side as the palm) of the forearm. A blood pressure cuff is applied at 40 mm Hg to provide uniform intravascular pressure at the site of the incision. A small incision (≈1 cm long and 1 mm deep) is made using a disposable template that provides a uniform incision from test to test. The result is influenced by the

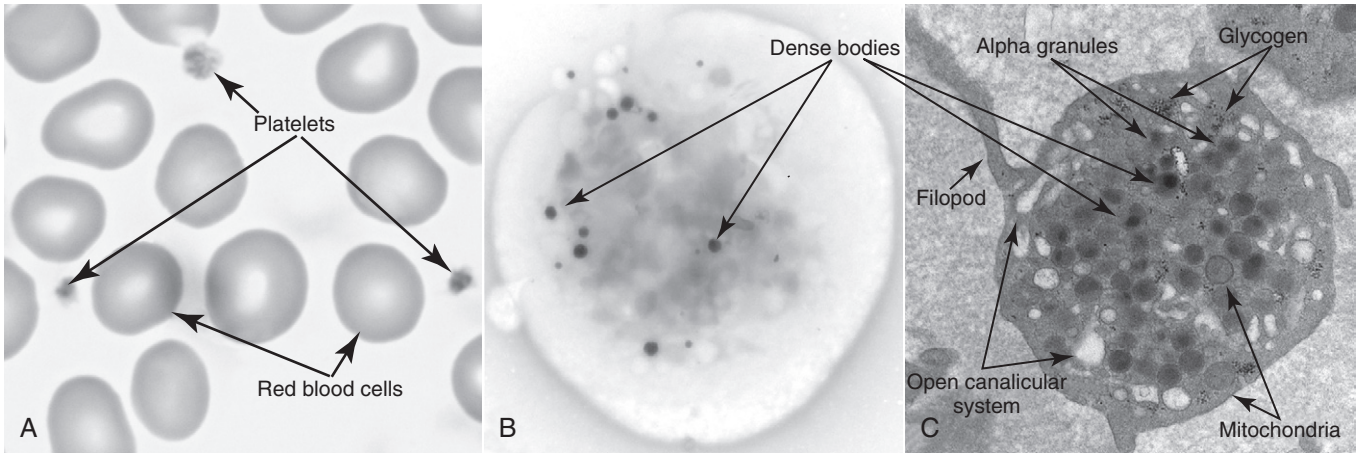

Figure 59-5 Platelet Morphology. A is a photo of a Wright-Giemsa–stained blood film with several red blood cells and three platelets. Normally, the platelets demonstrate some variation in size and shape, as seen here. Variable staining of the cytoplasm of the platelet is due to the alpha granules, the proteins of which stain deep purple. B is an electron micrograph of a whole mount of a platelet. The purpose of the preparation is to demonstrate the dense bodies (electron dense because of the high concentration of calcium). Visualization of other organelles requires thin-section preparation. C is a thin-section electron micrograph demonstrating many of the platelet organelles.

direction of incision, with a shorter time obtained if the incision is parallel to the sides of the forearm compared with a perpendicular incision. Blood at the site of injury is gently blotted with a filter paper every 30 seconds until no blood is detectable on the paper (time required ≈4 to 8 minutes). The test is not very sensitive, exhibits high intertechnologist imprecision, and has fallen out of favor, being replaced with other global tests of platelet function like the PFA-100. This may be appropriate for testing of platelet function; but, in most laboratories, bleeding time remains the only method by which to assess the vascular contribution to hemostasis and may continue to be useful for this purpose.[19,82] In the United States, many institutions no longer perform the test.

Platelet Function Analyzer (PFA-100 and PFA-200)

Platelets exposed to shear stress, such as occurs at the site of injury, are activated. This characteristic is exploited in the PFA-100 analyzer, a global test of platelet function. The analyzer utilizes a whole blood specimen containing 109 mmol/L trisodium citrate as an anticoagulant. After blood is drawn through a capillary tube, platelets pass through a small perforation in a membrane with embedded activators [collagen/epinephrine and collagen/adenosine diphosphate (ADP)]. The time required for adhering and aggregating platelets to close the perforation is measured (the closure time) (Figure 59-6). The collagen/epinephrine test is sensitive, and if it is found to be normal, the collagen/ADP test usually is not performed. If the collagen/epinephrine test is abnormal, it is followed by the collagen/ADP test. If the collagen/ADP test is normal, the problem is likely related to aspirin or another medication that affects platelet function. If the collagen/ADP test is abnormal, the problem is likely related to an inherited or acquired disorder of platelet function (Table 59-2). The test is affected by anemia and thrombocytopenia (any disorder in which there is an abnormally low number of platelets) and is not performed if the patient has either or both of those conditions. Similar to the test for bleeding time, the test is not sensitive.[54] The PFA-200 also provides a method to evaluate the effect of the platelet function-inhibiting thienopyridine drugs on platelets.

TABLE 59-2 Expected Results of the PFA-100 Analyzer

Condition	Collagen/Epinephrine Cartridge Closure Time	Collagen/ADP Cartridge Closure Time
Normal	Normal	Normal
Medication (aspirin effect)	Prolonged	Normal
Platelet function defect	Prolonged	Prolonged

PFA-100 Platelet Function Analyzer, Siemens Healthcare Diagnostics, Deerfield, Ill.
ADP, Adenosine diphosphate.

Evaluating Platelet Adhesion

Various assays are used to evaluate platelet adhesion. They include assays for (1) ristocetin-induced platelet aggregation (RIPA), (2) von Willebrand factor–ristocetin cofactor, (3) von Willebrand factor–collagen binding, (4) von Willebrand factor immunoactivity, (5) von Willebrand antigen, (6) VWF multimer, and (7) ADAMTS13.

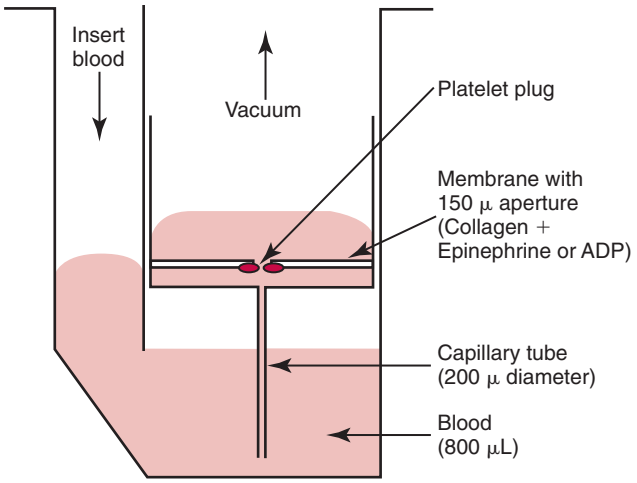

Figure 59-6 Schematic of the PFA-100 Analyzer. The PFA-100 analyzer provides a global measure of platelet function in a whole blood specimen. Blood anticoagulated with citrate is pipetted into the cuvette with a reaction membrane with collagen/epinephrine or collagen/ADP. Using a vacuum (syringe suction), blood is aspirated through the capillary tube at a rate sufficient to produce a wall shear rate of 1000 seconds^{-1}. Blood containing shear stress–activated platelets enters a small chamber and passes through the aperture of the membrane. At the aperture, the platelets adhere and aggregate until the aperture is closed and flow is obstructed. The time to achieve closure is referred to as *closure time*.

Ristocetin-Induced Platelet Aggregation Assay

Ristocetin is an antibiotic that was originally derived from cultures of *Norcardia lurida*. It was found to cause in vivo and in vitro aggregation of platelets. Aggregation induced by ristocetin is mediated by VWF. When aggregation is induced by ristocetin, the test will reflect both the activity of VWF in the plasma and function of the receptor for VWF in the platelet membrane (GP Ib-V-IX complex). The methods used to detect aggregation of the platelets are the same as those described in the section on platelet aggregation (see later). Testing is done at a high concentration of ristocetin to detect VWF ristocetin cofactor (VWF:RCo) activity, and at low concentration to detect possible increased affinity of VWF:RCo for its receptor on the platelet. The value of this is discussed later.[45,79]

von Willebrand Factor–Ristocetin Cofactor Assay (VWF:RCo)

The most common of the assays for VWF, it exploits the binding of VWF to platelets in the presence of ristocetin.[99] Platelets are prepared free of VWF using gel filtration or washing. Platelets are used fresh for the assay or, as is done for commercial assays, are lyophilized for longer storage and then are reconstituted with a buffer for the assay. Platelets are used in an agglutination reaction with ristocetin as the agonist. The specimen used is platelet-poor plasma (PPP) harvested from whole blood anticoagulated with 109 mmol/L trisodium citrate. Using dilutions of normal pooled plasma, a calibration curve is developed based on the rate or extent of agglutination. The rate or extent of agglutination of the patient's specimen is then compared with the calibration curve, and the value extrapolated. This original method for determining the activity of VWF is very labor intense, but despite difficulty with imprecision, it remains the gold standard for the development and validation of other methods.

von Willebrand Factor–Collagen-Binding Assay (VWF:CB)

The binding of VWF to collagen matrix initiates the process of platelet adhesion and the hemostatic process. VWF activity is quantified using the collagen-binding function.[43] The specimen used is PPP harvested from whole blood containing 109 mmol/L trisodium citrate as an anticoagulant. The methods available are primarily enzyme-linked immunosorbent assay (ELISA)-type assays in which VWF binds to stationary phase collagen (collagen types I and III—alone or in combination—derived from human, equine, or bovine tendon), followed by quantification of the bound VWF. The concentration of VWF:CB tends to parallel that of VWF:RCo in most settings. Some assays of VWF:CB are more sensitive to high molecular weight VWF multimers and may detect type 2 VWD (see later) more readily.

von Willebrand Factor Immunoactivity Assay (VWF:IA)

Monoclonal antibodies to functional epitopes in the VWF (e.g., GP Ib-binding site) have been developed. A homogeneous immunoturbidometric assay with antibody-coated latex beads shows a direct correlation of the degree of agglutination with VWF activity in the plasma.[122] These assays have been correlated with other functional assays of VWF. For additional details regarding this type of immunoassay, see Chapter 16.

von Willebrand Antigen Assays (VWF:Ag)

The specimen used is PPP harvested from whole blood anticoagulated with 109 mmol/L trisodium citrate. The original assay for VWF:Ag was the immunoelectrophoretic method of Laurell (referred to as Laurell rocket assay).[81] With this method, polyclonal monospecific antibody to VWF is uniformly distributed in a porous agarose gel. Controls and patient specimens are electrophoresed into the gel, the distance of a precipitin "rocket" from the sample well being proportional to the quantity of VWF protein. This method is labor-intensive and time-consuming and has been replaced by classic ELISA assays (see Chapter 16 for description of enzyme-linked immunosorbent and related assays). To simplify the assay and allow for easier automation, currently popular microparticle agglutination assays were developed and are most commonly used. Monoclonal antibody to VWF is coated on microparticles [latex immunoassay (LIA)]. VWF directly agglutinates the microparticles with the end point measured by turbidometric or nephelometric methods. Acceptable correlation of the classic ELISA with the LIA has been noted, and although LIA assays may give higher results

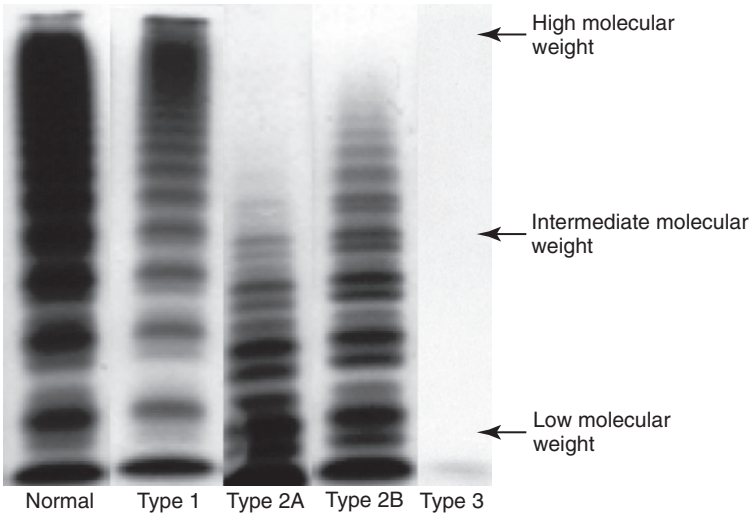

Figure 59-7 Multimeric Analysis of VWF-Ag. Plasma is electrophoresed into a porous gel of agarose or agarose and acrylamide, the multimers are separated, and the VWF:Ag multimers are radiolabeled with antibody to VWF:Ag. Typical patterns of normal and VWD types 1, 2A, 2B, and 3 are shown in the autoradiograph. The pattern seen in type 2M is like that of type 1. *(Image courtesy M. R. Ledford-Kraemer.)*

than the ELISA, good agreement among results is currently obtained with different methods in proficiency testing exercises.[44]

VWF:Multimer Assay

In megakaryocytes and endothelial cells, the *VWF* gene codes for a subunit protein of approximately 220 kDa. Post-ribosomally, carbohydrate is added to the subunit, dimers of the subunits are formed, and the dimers undergo polymerization. The VWF secreted is a population of molecules varying in size from 500 kDa to as large as 20,000 kDa or more. The size of these VWF multimers is controlled in the plasma by a metalloprotease, ADAMTS13 (see later), the size of the multimers being related to the function of the molecule. These multimers are qualitatively detected in the plasma using electrophoresis in a porous gel, followed by visualization with a radiolabeled or enzymatically labeled antibody to VWF.[42,117] Analysis of the multimer patterns is subjective (Figure 59-7). The specimen used is PPP harvested from whole blood containing 109 mmol/L trisodium citrate as an anticoagulant. Loss of the high molecular weight multimers is associated with reduced function (type 2A or 2B VWD), as described later.

ADAMTS13 Assay

ADAMTS13 is **a** **d**isintegrin **a**nd **m**etalloproteinase with a **t**hrombo**s**pondin type 1 motif, member **13**. It also is known as the VWF-cleaving protease and is the enzyme that depolymerizes VWF after secretion from the endothelial cell. When ADAMTS13 is absent or inhibited by autoantibody, thrombotic thrombocytopenic purpura (TTP) can result. The available functional assay for this molecule is based on the ability of the patient's plasma to cleave the high molecular weight multimers of VWF. It requires lengthy incubation followed by VWF multimer analysis, taking up to 2 days. TTP is a condition of clinical urgency; the current assay is not timely enough for diagnostic purposes, being used only for confirmation after treatment has begun. New assays have become available, including the fluorescence resonance energy transfer (FRET) assay[74] and the ELISA,[146] which are proving to be of greater diagnostic usefulness.

Evaluating Platelet Aggregation and Secretion

Platelet aggregation and secretion is evaluated by using aggregation and secretion studies.

Platelet Aggregation Studies

The original platelet aggregation studies were described more than 40 years ago. In the presence of agonist, platelets will stick to each other in a reaction that is mediated primarily by fibrinogen. After more than 45 years, light transmission aggregometry (LTA), with minimal modification, remains the "gold standard" method for evaluating platelet aggregation.[12] For LTA, the specimen used is platelet-rich plasma (PRP) harvested from whole blood containing 109 mmol/L trisodium citrate as an anticoagulant. It is also necessary to harvest PPP because the limit of detection of the aggregometer is adjusted with the patient's own PPP for maximum light transmission, and PRP for minimum light transmission. LTA is a simple turbidometric measurement, the PRP is placed in the light path (37 °C, continuous stirring), and, after the agonist is added, increased transmission of light is recorded over time as the platelets aggregate (Figure 59-8). An alternative method has been developed that allows the use of anticoagulated whole blood. In this case, an electric probe is placed in the specimen and an alternating current passed through the blood. Upon activation, platelets are attracted to the electrodes to which they attach. As more platelets

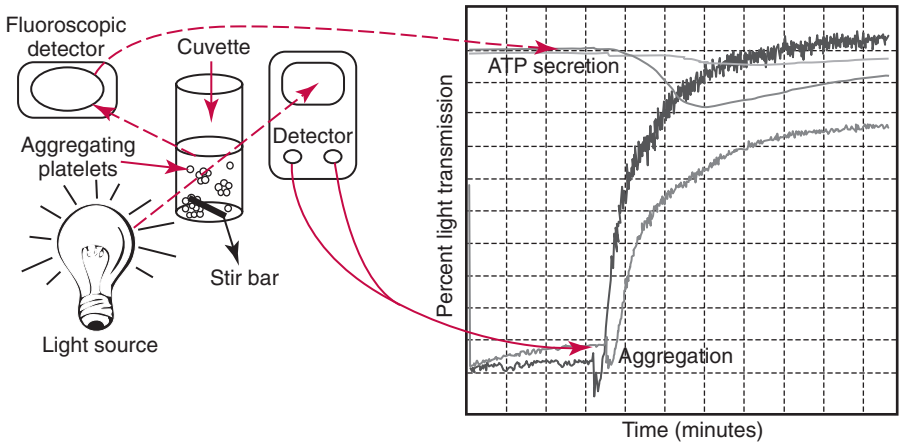

Figure 59-8 Platelet Aggregation. Platelet-rich plasma harvested from whole blood collected in citrate anticoagulant is stirred continuously at a constant rate at 37 °C. Increasing absorbance (loss of turbidity) following addition of an agonist is measured. The gain of the detector is set using the patient's platelet-rich plasma and platelet-poor plasma. The reaction may be quantified by measuring its rate or extent. Measuring secreted adenosine triphosphate (ATP) reflects secretion of platelet-dense bodies from the platelet. Luciferin and luciferase are added to the aggregation reaction. Luciferase converts luciferin to its product in a reaction that is absolutely dependent on ATP and emits photons. Fluorescence is measured, and secretion is quantified as a function of the quantity of ATP released.

TABLE 59-3 Commonly Used Platelet Aggregation Agonists

Collagen	Activates receptor GP VI
ADP	Activates receptors P_2Y_1 and P_2Y_{12}

attach, the flow of current is impeded—a change that is plotted over time. Although LTA remains the "gold standard" for platelet aggregation, advantages of the impedance method include (1) testing in the presence of other blood cells, (2) reduced artifact from preparation, and (3) a smaller sample size requirement.[89] Regardless of the method used to measure the end point, the agonists used to assess aggregation function are the same. The commonly used agonists are summarized in Table 59-3.

Platelet Secretion

Platelets secrete a wide variety of products into the microenvironment following activation. These products are stored in the platelet delta granules (dense bodies) and alpha granules (Table 59-4). Initial evaluation of platelet secretory function requires a morphologic evaluation (see earlier) to determine whether these granules are present and morphologically adequate. The function of secretion was originally evaluated by exploiting the ability of platelets to take up radioactively labeled serotonin in the laboratory and then measuring release of the label following stimulation of the platelets. The method is very labor-intensive and requires the use of radioisotopes. However it remains the method of choice for evaluation of heparin-induced thrombocytopenia (see later). This method has been replaced in all other clinical settings with the use of the lumi-aggregometer, in which luciferin and luciferase are added to the patient specimen before the agonist is added.[145] Conversion of luciferin to its product by luciferase is dependent on adenosine triphosphate (ATP), the only source of which is release from the platelets. In the conversion of luciferin to its product, photons are emitted and are detected by a fluorometer in a quantity that correlates with the ATP released. This method allows for the simultaneous assessment of aggregation and secretion in the same reaction. The method

tahir99-VRG & vip.persianss.ir

is conducted using LTA or impedance aggregometry. In addition to in vitro demonstration of secretion, surrogate markers of in vivo release can be detected in the plasma. Platelet factor 4 and beta-thromboglobulin are products that are unique to the platelet; when elevated in the plasma, they provide evidence of in vivo secretion. Immunochemical assays (see Chapter 16) are available for both of these analytes.

Evaluating Platelet Support of Plasma Coagulation

Platelet support of plasma coagulation is evaluated by measuring the amount of residual prothrombin in a serum specimen after coagulation in the test tube is complete.

When normal whole blood is allowed to clot in a nonsiliconized glass tube, the combined function of platelets and plasma coagulation will efficiently convert nearly all of the available prothrombin to thrombin (prothrombin consumption). Abnormality of any of the coagulation factors or platelets will reduce the efficiency of this process, and some prothrombin will be left in the serum. This prothrombin is then quantified and compared with the starting plasma prothrombin, allowing an assessment of the percentage of prothrombin that is consumed. If the patient's prothrombin time and activated partial thromboplastin time are normal, prothrombin consumption reflects the contribution of the platelet to fibrin generation. The test suffers from lack of reproducibility and is not in widespread use, but it can provide information on platelet support of plasma coagulation. It is most frequently abnormal in acquired platelet function disorders such as paraproteinemias and uremia.[13]

Evaluating Platelet Contractile Function

Platelet contractile function is evaluated by determining clot retraction.

Upon activation, platelets form filapodia, slender projections from the surface of the cell that attach to fibrin strands. Platelet actin tethers to membrane receptors and organizes with cytoplasmic myosin within these filapodia, forming a rudimentary muscle that contracts at the conclusion of the hemostatic process. This has been described as the in vivo suture, drawing the edges of the injury closer together as healing is initiated. This phenomenon is seen (and is measured qualitatively) by observing the formation of serum in a tube without anticoagulant; the clot shrinks (an active process that depends on the platelet), expressing the serum. This clot retraction is dependent on the contractile function of the platelet, and methods have been described to quantify it. Although not widely used, the technique remains useful, particularly if the more specific information provided by platelet aggregometry is not available.[13,125]

Evaluation of Platelets Using Flow Cytometry

Flow cytometry is a useful adjunct in evaluating platelet function in selected situations. Agonist receptors and other membrane proteins are detected on the resting platelet. Study of a specific receptor to determine whether it is present and to assess its surface density is used to identify some of the inherited platelet function disorders. Upon activation, the platelet expresses new antigens on the surface or modifies existing receptors. Detecting these modifications is helpful in documenting activation or lack thereof in patients with suspected platelet function disorders. Detection of these surface or activation antigens has been made possible by the development of specific monoclonal antibodies that are labeled with a fluorophor, enabling flow cytometric analysis.[92]

Evaluation of Antiplatelet Medication

Evaluation of the effects of medications that affect platelet function is of interest to clinicians for two reasons. First, it is important to know whether the medication is actually inhibiting the platelet functions as intended for the patient to receive the desired reduced risk of thrombosis. Second, many patients who are taking antiplatelet medications need emergency or elective procedures and may be at increased risk for hemorrhage during those procedures. Increased risk of hemorrhage in patients taking antiplatelet medications has been demonstrated but is widely variable among patients. Unfortunately, tests of the medication effect on platelet function do not accurately predict whether there will be a hemorrhagic outcome.

Several techniques are used to measure the effects that medications have on platelet function. They include the PFA-100 and PFA-200 analyzers and the Verify Now and platelet aggregation assays.

PFA-100

The PFA-100 was described earlier in the chapter. It has been shown to be effective in detecting aspirin resistance in many cases and may detect the reduced platelet function caused by aspirin. It is not useful in the evaluation of other antiplatelet medications, but the PFA-200 offers a method to evaluate the thienopyridines.

Verify Now

Verify Now (Accumetrics, San Diego, Calif) is a rapid turbidometric assay that exploits the affinity of activated platelets for fibrinogen. With it, a whole blood specimen is pipetted into a disposable cartridge containing fibrinogen-coated microparticles. By using cartridges with different agonists, the effect of antiplatelet medication is assessed: (1) for glycoprotein IIb/IIIa (GP IIb/IIIa) antagonist drugs, (2) for activation with thrombin receptor activation peptide (TRAP); (3) for aspirin, activation with arachidonic acid; and (4) for thienopyridine drugs, activation with ADP.[88] The specimen used is whole blood containing 109 mmol/L trisodium citrate as an anticoagulant, collected into a special plastic 2 mL vacutainer tube. Currently, this method is used only for evaluation of medication effect.[76]

Platelet Aggregation

The "gold standard" for medication effect on platelet function is platelet aggregation using LTA or impedance with the appropriate agonist for the medication (ADP for the thienopyridines; arachidonic acid or collagen for aspirin). Other

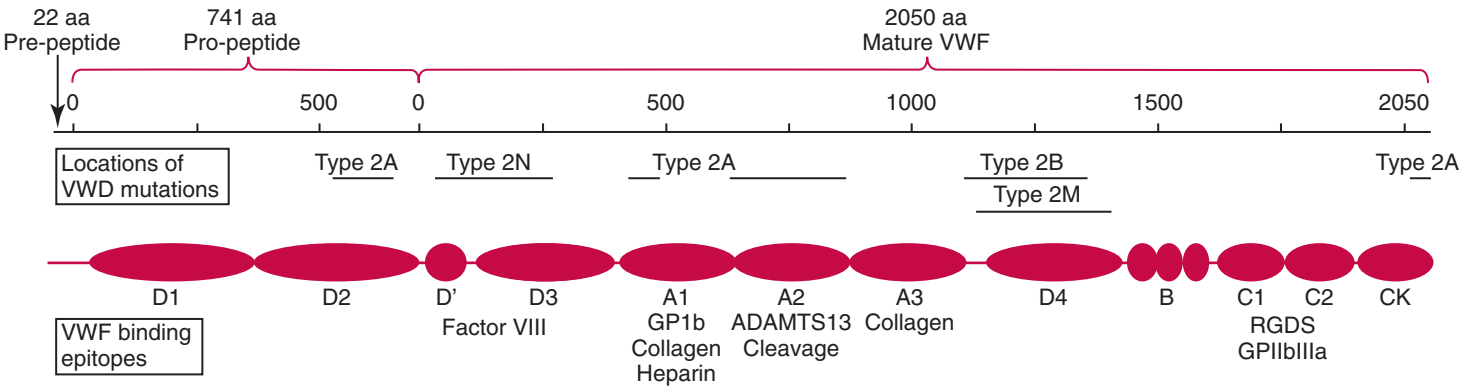

Figure 59-9 VWF Protein. The VWF gene, residing in chromosome 12p13.2, is approximately 178 kilobases with 52 exons. The product of the gene is a protein of 2813 amino acids. There is a 22 amino acid pre-peptide and a larger 741 amino acid pro-peptide, both of which are cleaved from the molecule leaving the mature VWF (2050 amino acids). VWF contains four types of repeated molecular domains. The figure depicts the domains, the locations of functional epitopes, and the locations of the most common mutations in the types of VWD. The protein forms dimers by linkage of the amino terminal end with subsequent formation of multimers via polymerization of the dimers.

methods can be compared against this reference method. LTA and impedance are cumbersome, labor-intense methods that do not lend themselves well to urgent or routine testing, leading to the development of Verify Now and PFA-100. Of interest, agreement is still lacking regarding the appropriate concentrations of agonists to be used when evaluating medication effects.[76]

Clinical Use of Laboratory Tests for Platelet Disorders

The assays and devices discussed earlier are used to detect both inherited and acquired platelet disorders.

Inherited Disorders

Inherited disorders of platelet function include (1) von Willebrand disease, (2) the Bernard-Soulier syndrome, (3) Glanzmann thrombasthenia, and (4) other disorders.

von Willebrand Disease

VWD is the most common of the inherited bleeding disorders. Its exact frequency is not accurately defined. Some have estimated the prevalence to be as high as 1:100; however, in clinical practice it does not appear that high. This is a disorder of platelet function that is caused by the absence or abnormality of a plasma protein, VWF. The function of the platelet itself is normal. A second important role for VWF is the binding and stabilizing of coagulation factor VIII in the circulation. The *VWF* gene, residing in chromosome 12p13.2, is approximately 178 kilobases with 52 exons. The product of the gene is a protein of 2813 amino acids. There is a 22 amino acid pre-peptide and a larger 741 amino acid pro-peptide, both of which are cleaved from the molecule, leaving the mature VWF (2050 amino acids). VWF contains four types of repeated molecular domains.[50] Figure 59-9 shows a schematic of the VWF domains and their related functional epitopes. Currently, 526 mutations have been catalogued (http://www.vwf.group.shef.ac.uk/). Analysis of the mutations associated with VWD was initially undertaken to understand the structure and function of the *VWF* gene, the mRNA, and VWF protein; however, some mutation analysis has now become a part of clinical diagnosis. Details of the mutations are beyond the scope of this chapter. For more information, the reader is referred to Sadler and Blinder.[119] The classification of VWD is defined by (1) the quantity of VWF, (2) the relationship of the VWF activity:antigen ratio, (3) the concentration of factor VIII, and (4) the multimeric structure of the VWF:Ag.[120] Types 1 and 3 represent quantitative reductions in the factor, and type 2 (2A, 2B, 2M, 2N) represents dysfunctional factor. Table 59-5 summarizes the classification.

Type 3 VWD is the most severe form of the disorder and the least common, occurring in approximately 0.5 to 5:1,000,000 in the population. VWF activity and antigen are usually undetectable, and factor VIII is commonly 0.05 U/mL or less. Patients manifest a severe bleeding disorder and often require treatment with VWF-containing products. Multimeric analysis is not performed because VWAg is essentially absent. The condition is inherited as a recessive trait in which patients are homozygous or doubly heterozygous. Mutations, mostly deletions, do not occur in a localized portion of the gene, but are distributed between exons 3 and 52. Because VWF is essentially absent, the amount of factor VIII will also be severely reduced, because factor VIII needs VWF to stabilize it in the circulation. As in all types of VWD, management is focused on replacement of VWF; however, platelet transfusion may also play a role. Alpha granules of platelets of patients with type 3 VWD contain no VWF, the secretion of which is important in adhesion. Thus, in contrast to all other types of VWD, these patients may benefit from platelet transfusion.[120]

tahir99-VRG & vip.persianss.ir

TABLE 59-5 Classification of Von Willebrand Disease (VWD)

Type of VWD	Incidence	Description
Type 1	70-80%	Mild to moderate VWD with corresponding reduction of VWF:RCo, VWF:CB, and VWF:Ag, and factor VIII of variable magnitude
Type 3	<1%	Severe VWD with near absence of VWF and factor VIII
Type 2A	10-15%	Dysfunctional VWF with reduced high molecular weight VWF:Ag multimers
Type 2B	5%	Dysfunctional VWF with reduced high molecular weight VWF:Ag multimers and increased affinity of VWF for the GP Ib-IX-V receptor on the platelet
Type 2M	<1%	Dysfunctional VWF with normal distribution of VWF:Ag multimers
Type 2N	<1%	Dysfunctional VWF with reduced binding of factor VIII manifesting as reduced circulating factor VIII and normal platelet function

Type 2 VWD occurs as the result of an abnormal or dysfunctional VWF and, as a group, accounts for 20 to 30% of cases of VWD. As might be expected, with a multifunctional, large protein, mutations have led to a number of variations in the dysfunction of the molecule. The classification requires analysis of the VWF multimers because the loss of high molecular weight multimers is associated with dysfunction in two of the subtypes of VWD—2A and 2B. Current subtypes of the dysfunction of the molecule are listed in Table 59-5, and each are discussed below.

Type 2 VWD is suspected when there is a discrepancy between VWF activity and the VWF antigen. Ratios of $\frac{\text{VWF:RCo}}{\text{VWF:Ag}}$ of 0.5 to 0.6 or less indicate a dysfunctional molecule and serve as an indication to test further, as described later, to subtype the disorder. In general, the ratio $\frac{\text{VWF:CB}}{\text{VWF:Ag}}$ will be lower than the ratio $\frac{\text{VWF:RCo}}{\text{VWF:Ag}}$ in type 2A and 2B, but the reverse is true in type 2M.[120]

Type 2A VWD is associated with abnormal multimer analysis and loss of high molecular weight multimers. It is the most common of the type 2 subtypes, accounting for 10 to 15% of cases of VWD. High molecular weight multimers are critical for the platelet adhesion event, and their loss reduces adhesion, leading to a mild to moderate bleeding diathesis. Molecular lesions are most frequently identified in the exon 28 region of the gene (the A2 domain); however, mutations have been described in other domains. Inheritance is generally dominant, especially if the mutation is located in the A2 domain. If inheritance is recessive, there may be value in analyzing other domains of the gene. The severity of the bleeding diathesis tends to be related to VWF:RCo activity in the plasma. As with type 2M, treatment of type 2A VWD with desamino-D-arginine vasopressin (DDAVP) is variable, and management generally requires the infusion of VWF-containing products. Platelet transfusion is not recommended.[120]

Type 2B VWD is associated with loss of the high molecular weight multimers of VWF:Ag; however, the proportion of those multimers that are missing is often less than that seen in type 2A. Type 2B VWD is uncommon, accounting for less than 5% of cases of VWD. The mutations that have been described are also in exon 28 (the A2 domain), at or near the GP Ib binding epitope of the mature protein. The abnormality gives the VWF protein a higher affinity for the GP Ib receptor on the platelet surface. This increased affinity is detected in the laboratory by demonstrating RIPA at a low concentration of ristocetin (usually ≤0.5 mg/mL)—a concentration that will not induce aggregation in the presence of normal VWF. This testing is indicated whenever multimeric analysis shows loss of the high molecular weight VWF:Ag multimers and is the method used to distinguish type 2A from type 2B VWD. In type 2B VWD, binding of VWF to platelets in vivo may occur spontaneously or with minimal stimulus, causing in vivo aggregation and clearance of the platelets. Thus, thrombocytopenia is a common finding in patients with this disorder, and consumption of VWF in this manner contributes to decreased amounts of VWF. Patients with type 2B VWD present with a mild to moderate bleeding diathesis. Management is generally limited to infusion of VWF-containing products. Use of DDAVP is not recommended because of the possibility that the release of VWF may induce in vivo platelet agglutination and precipitate a thrombotic complication. Platelet transfusion is not recommended.[120] Platelet-type VWD (pseudo-VWD) is a syndrome with reduced high molecular weight multimers due to increased affinity in the receptor for VWF on the platelet. VWD type 2B and platelet-type VWD are difficult to distinguish clinically. See the discussion of the Bernard Soulier syndrome, later.

Type 2M VWD comprises those patients in whom the VWF activity-to-antigen ratio is low and multimeric analysis of the VWF:Ag shows a normal distribution of the multimers (with M indicating normal multimers). This type of VWD is rare and the prevalence has not been well characterized. Mutations of the gene are most frequently found in exon 28 (the A2 domain of the gene). The tendency to bleed is generally mild to moderate. Management generally consists of infusion with VWF-containing products. The response to DDAVP is variable, and a trial with DDAVP may be useful. Platelet transfusion is not recommended.

tahir99-VRG & vip.persianss.ir

Type 2N VWD results in a decrease in plasma factor VIII but normal VWF-mediated platelet function. Thus, the phenotype of the disorder is similar to that of hemophilia but shows autosomal inheritance. All testing of VWF functions and antigen is normal. Mutations in the *VWF* gene occur in exons 20 to 28 (the D′ domain), which code for the epitope in the VWF protein that binds to factor VIII. A few specialty laboratories are able to measure the binding of factor VIII to patient VWF, confirming the diagnosis. Distinguishing type 2N VWD from hemophilia is important because treatment of the disorders requires the infusion of different products.[120]

Type 1 VWD is the most prevalent form of VWD, accounting for approximately 70 to 80% of cases.[101] Inheritance of type 1 VWD is autosomal; however, the phenotype of the associated bleeding tendency is quite variable, with many patients manifesting a mild to moderate bleeding disorder, while others with similar laboratory values do not manifest a bleeding tendency. With laboratory analysis, one generally finds a concomitant reduction in VWF activity, VWF antigen, and factor VIII. Values vary from below 0.2 IU/mL to as high as 0.5 IU/mL. Genetic analysis of patients is complex. European and Canadian reports of the molecular analysis of patients with type 1 VWD show that of those patients with clearly normal multimer analysis, only 55 to 63% had an identifiable mutation, and that those mutations were not localized in the gene.[21,52] There is a relationship between the concentration of VWF in the plasma and the probability of detecting a mutation in the gene. Of those with 0.15 IU/mL or less VWF protein, 95% had a mutation, while only 50% of those with 0.45 IU/mL or greater VWF protein had mutations. Among those who have mutations, 10 to 15% have more than one mutation identified.[50] What of those patients with reduced VWF and no identifiable mutation? Carboxylation of the VWF protein is closely associated with the ABO blood group of normal individuals. Those with blood group O have lower circulating VWF than those who have the A and/or B antigen. It is thought that carboxylation may influence the half-life of the molecule.[49] Analysis of the blood groups of patients with type 1 VWD shows a significantly higher number of patients with blood group O. Thus, changes in the postribosomal carboxylation of VWF may account for VWD without mutations in the *VWF* gene. Management of bleeding in type 1 VWD depends on the severity and expected duration of the hemorrhagic challenge. Those with a mild challenge of short duration can receive DDAVP, while those with more extensive challenge require infusion with VWF-containing products.[119]

Bernard-Soulier Syndrome

The Bernard-Soulier syndrome (BSS) is a disorder of platelet function that is related to the function of VWF; however, in this condition, the amount of VWF protein is normal, with the lesion being in the VWF receptor on the surface of the platelet, GP Ib/V/IX. The disorder is inherited as an autosomal recessive trait with bleeding seen only in homozygotes, and it is seen most frequently in consanguineous relations. It is a rare disorder, with a prevalence of less than 1:1,000,000 in the general population. Mutations have been reported in the genes coding for GP Iba (gene symbol *GP1BA*) and GP IX *(GP9),* but not GP V *(GP5).* For further details, see http://www.bernard-soulier.org/mutations. It is one of the giant platelet syndromes with concurrent thrombocytopenia and is associated with moderate to severe bleeding. Bleeding episodes are managed with platelet transfusions. While discussing mutations of the GP Ib/V/IX receptor, it is useful to mention platelet-type or pseudo-VWD. This is also an inherited bleeding syndrome in which there is a normal *VWF* gene and protein, but a lesion in the platelet receptor causes an increased affinity with VWF. This disorder is difficult to distinguish from type 2B VWD. The diagnosis relies on demonstration that the VWF is normal in the plasma and that the platelets are abnormal (complex mixing studies are done in some laboratories), or the differential diagnosis is made with mutation analysis. The distinction is important because the condition is managed with platelet transfusion.[78]

Glanzmann Thrombasthenia

Absence or abnormality of the platelet integrin, GP IIb/IIIa, the receptor for fibrinogen in aggregation, is the cause of Glanzmann thrombasthenia (GT). Mutations (deletions or other mutations) in the genes for GP IIb or GP IIIa membrane proteins have been identified. The disorder is inherited as an autosomal recessive trait that leads to a mild to moderate bleeding diathesis. It is a rare disorder, affecting approximately 1:1,000,000 in the general population; however, it may be more prevalent in populations with consanguineous relations. Platelet count is normal; however, platelet aggregation with all agonists except ristocetin is abnormal. In addition, the bleeding time is prolonged, the PFA-100 value is prolonged, and clot retraction is abnormal. Bleeding episodes are treated with platelet transfusion.[98]

Other Disorders

Many other functions of the platelet such as those related to (1) binding of collagen, (2) formation of secretory granules, (3) mechanisms of secretion, and (4) others have rare inherited disorders that affect these specific functions. Only a small number of laboratories are capable of evaluating these rare disorders, and the ability to make diagnoses of this type is often complicated by the need to evaluate fresh platelets to evaluate function. Molecular approaches have not yet been documented sufficiently to be of clinical diagnostic usefulness.

Acquired Disorders

Factors that affect acquired disorders include medications, degree of renal failure, paraproteinemia, and primary bone marrow disorder.

Medication

Many medications affect platelet function. For example, drugs such as aspirin, thienopyridines, and monoclonal inhibitors of GP IIb/IIIa are used specifically to reduce function when inhibition of thrombosis, particularly arterial thrombosis, is

tahir99-VRG & vip.persianss.ir

TABLE 59-6 Examples of Medications Affecting Platelet Function

Class of Medication	Examples
Nonsteroidal anti-inflamatory	Aspirin, naproxen, ibuprofen, indomethacin
GP IIb/IIIa antagonists (antibodies)	Abciximab, eptifibatide, tirofiban
Thienopyridines	Clopidogrel, ticlopidine
Increase cAMP and/or cGMP	Iloprost, dipyridamole, prostacyclin
Cardiovascular medications	Many
Volume expanders	Dextran, hydroxyethyl starch
Chemotherapeutic agents	Mitomycin, daunorubicin, BCNU
Psychotropic medications	Many
Others	Antihistamines, clofibrate, rad contrast agents

desired. In other cases, the effects on platelet function are adverse complications of the medication. These effects generally are not enough to lead to a bleeding complication; however, if the medication is used in patients with inherited or acquired platelet disorders or other disorders of hemostasis, the effect may increase bleeding. Examples of medications that affect platelet function are listed in Table 59-6.[8]

Renal Failure

In patients with renal failure, organic acids such as guanidinosuccinic and phenolic acids are abnormally retained in the blood. These acids have a deleterious effect on all platelet functions and are often associated with a bleeding diathesis. Neither creatinine nor urea has a significant effect on platelet function, but they provide a useful surrogate marker for other retained products. Platelet functions tend to be affected at urea nitrogen of ≈60 mg/dL or greater and creatinine of 3 to 4 mg/dL. In vitro studies have confirmed the deleterious effects of organic acids and the rapid rate at which normal platelets demonstrate loss of function. For this reason, the use of platelet transfusion in managing hemorrhage in uremic patients is ineffective. Management is difficult; however, treatment with dialysis to reduce retained acids is often effective. In addition, the use of DDAVP has proven of some value.[139] Treatment of anemia by keeping the hemoglobin above 10 g/dL using erythropoietin and transfusion has a beneficial effect in managing bleeding.[95]

Paraproteinemia

Patients with multiple myeloma or Waldenström macroglobulinemia often have remarkably elevated concentrations of immunoglobulins. These immunoglobulins are associated with hemorrhage via two basic mechanisms. First, the paraproteins interfere with fibrin-monomer polymerization, which is reflected in prolonged thrombin time. Second, the proteins adsorb nonspecifically to the surface of the platelet, masking the receptors on the surface of the platelet and reducing platelet activity. These problems are managed by reducing the concentration of the protein through management of the underlying malignancy. In acute situations, plasmapheresis is effective in reducing paraprotein concentrations, but only for short-term management.[38]

Primary Bone Marrow Disorder

In myeloproliferative and myelodysplasplastic syndromes, the megakaryocyte, similar to other cell lines, is affected by malignant transformation. The effects of malignant megakaryocyte production of platelets on platelet function are widely variable. These effects may include but are not limited to (1) increased or decreased platelet counts, (2) reduced granules, (3) reduced or abnormal membrane receptors, (4) adsorption of high molecular weight VWF multimers, causing an acquired type 2 von Willebrand disease (VWD), or (5) abnormal signal transduction mechanisms. As a result of these variable effects, patients may manifest abnormal bleeding or, paradoxically, thrombosis. Bleeding episodes may be managed with platelet transfusion; however, in patients with thrombocytosis, it is difficult to determine whether the risk to the patient is bleeding or thrombosis. Patients at thrombotic risk may benefit from treatment with antiplatelet medication.[109]

GENERAL CONSIDERATIONS IN COAGULATION TESTING

Special considerations in coagulation testing include (1) preanalytical variables, (2) optical versus mechanical end point detection, and (3) chromogenic assays.

Preanalytical Variables for Coagulation-Based Assays

Control of preanalytical issues in coagulation testing is paramount to good laboratory performance. In addition to the common issues of hemolyzed, icteric, or lipemic samples, some preanalytical factors of particular importance in coagulation testing include (1) clotted specimens, (2) improper blood-to-anticoagulant ratio, and (3) contamination with heparin or other anticoagulants. Traumatic venipuncture, activation of blood within the collection device, or improper mixing of the anticoagulant with blood may result in clotting, which consumes coagulation factors, making testing unreliable. Blood for coagulation testing should be collected by standard venipuncture techniques into 109 mmol/L (3.2%) trisodium citrate, such that the final ratio of blood to anticoagulant is 9:1. Blood is commonly collected into commercially available tubes with prealiquoted trisodium citrate and a line indicating the appropriate volume of blood to be drawn. Collection of a volume of specimen less than the recommended volume ("a short draw") will result in excess anticoagulant and prolonged clotting times. Likewise, samples with high hematocrit (>55%) will require a decreased volume of

tahir99-VRG & vip.persianss.ir

anticoagulant because of a lower plasma volume. Some coagulation testing, such as activated clotting time, may be performed on whole blood; however, most routine clot-based assays are performed on platelet-poor plasma. To avoid interference from phospholipid and other platelet-derived substances such as platelet factor 4, platelet-poor plasma is prepared by centrifugation, typically at 1500 g for at least 15 minutes. Phospholipids are important for the spatial orientation of coagulation molecules and have a significant impact on the activated partial thromboplastin time. Platelet factor 4 binds heparin and may alter clot-based tests. Centrifugation and testing should occur as soon as possible, usually within 24 hours for prothrombin time (PT), or within 4 hours for aPTT. Centrifuged samples may be stored at 18 to 24 °C, whereas colder temperatures should be avoided because of possible activation of factor VII. When testing is delayed, the plasma should be separated from the cells and kept below −20 °C or at −70 °C for longer storage.[25] Household grade freezers with autodefrost cycles are not suitable.

Optical versus Mechanical End Point Detection

Clot-based tests, among which PT/international normalized ratio (INR) and aPTT are common, are based on detecting the time interval from initiation of coagulation to clot formation. Detection of clot formation as an end point has been accomplished in a number of ways. Early methods used a tilt-tube technique that depended on visually identifying clot formation in plasma samples. A water bath was necessary to keep the temperature at 37 °C. Currently, this time-intensive manual method is used only to develop international standards for thromboplastin.

As a result of high-volume testing, most coagulation testing is now performed on automated instruments that control the temperature of the reaction and detect end points by use of any one of several methods. Most methods detect a change in physical/mechanical properties or a change in the light transmission produced by polymerized fibrin. Numerous approaches for mechanical end point detection have been developed. One mechanical method consists of a metal ball at the bottom of a sample cuvette that is sent into a back-and-forth motion by a magnet; the end point is detected when fibrin monomers polymerize into fibrin strands and impede the motion of the ball. Another mechanical detection system uses a magnet to hold a ball to the side of a rotating cuvette until fibrin strands physically displace the ball. Optical detection (usually nephelometric but occasionally turbidometric, Chapter 10, Optical Techniques) is the most commonly employed method, detecting a decrease in light transmission or increased light scatter as fibrin monomers are polymerized into fibrin strands.[124] Optical end points may occur at preset thresholds; however, other instruments use the kinetics, such as maximum acceleration of fibrin polymerization, to define end points. Light sources have traditionally been halogen lamps or lasers, but newer instruments may use light-emitting diodes (LEDs) that increase longevity and allow measurement at wavelengths that have less overlap with interfering substances. Differences are expected between end point detection systems. An advantage of mechanical over optical end point detection is the ability to measure clots in the presence of substances such as hemoglobin, bilirubin or lipid that interfere with optical methods.

Chromogenic Assays

Chromogenic assays have been used to bypass the complexity of the clotting cascade, including the effects of elevated coagulation factors, anticoagulant medications, and lupus anticoagulants (discussed later). In these assays, serine proteases (such as thrombin, factor Xa, factor IXa, factor XIa, and factor XIIa) of the clotting cascade cleave oligopeptide substrates, releasing chromogens that are then detected optically at 405 nm:

$$\text{Serine Protease} + \text{Chromogenic Substrate} \rightarrow p\text{-nitroaniline (detected at 405 nm)}$$

The chromogenic method is commonly applied to assays that measure (1) factor VIII, (2) factor X, (2) protein C, (3) antithrombin, and (4) heparin concentration (anti-Xa method). However, numerous other applications are possible. The 405-nm wavelength is advantageous because of less spectral overlap with common interfering substances.

SECONDARY HEMOSTASIS

As opposed to primary hemostasis, which involves the processes of vascular contraction and platelet function, secondary hemostasis is defined as "the formation of fibrin through the coagulation cascade" (http://ahdc.vet.cornell.edu/clinpath/modules/coags/second.htm).

Vitamin K–Dependent Factors

Activity of coagulation factors II, VII, IX, and X and natural anticoagulants, protein C, and protein S, is dependent on the action of vitamin K (see Chapter 31). Vitamin K–dependent carboxylases convert glutamic acid residues to gamma-carboxyglutamic acid residues on vitamin K–dependent coagulation factors, imparting calcium binding function to these factors. Reduced vitamin K is regenerated through the action of a vitamin K epoxide reductase. Deficiencies of vitamin K result in inactive coagulation factors as the result of inadequate gamma carboxylation with resultant loss of calcium binding capability. Vitamin K deficiency, therefore, may lead to an acquired bleeding disorder.

Oral vitamin K antagonists (VKAs), such as warfarin, are used for individuals who require sustained anticoagulation. VKA inhibits vitamin K epoxide reductase that is responsible for regenerating the active vitamin K cofactor necessary for gamma carboxylation. Because protein C is a vitamin K–dependent natural anticoagulant with a short half-life, patients treated with VKA alone have an initial risk of thrombosis until the other vitamin K–dependent procoagulants are also reduced. For this reason, anticoagulant effect is first achieved with heparin, and then oral VKA is overlapped with

tahir99-VRG & vip.persianss.ir

heparin therapy for 3 to 5 days. A study comparing combined VKA and heparin therapy against VKA therapy alone for proximal vein thrombosis was terminated early because of an increased rate of symptomatic extension or recurrence of venous thromboembolism in the group treated with VKA alone.[15]

Evaluation of Secondary Hemostasis

Tests used to evaluate secondary hemostasis include (1) prothrombin time and international normalized ratio, (2) activated partial thromboplastin time, (3) fibrinogen assays (Clauss and derived), (4) mixing studies, (5) factor assays, (6) inhibitor assays, (7) factor XIII assays, and (8) thrombin time.

Prothrombin Time/International Normalized Ratio (PT/INR)

The PT is a clot-based assay that reflects the activity of *extrinsic and common pathway* factors of the coagulation cascade. The PT is initiated by the addition of a thromboplastin reagent containing tissue factor, calcium, and phospholipid. The PT cannot be compared among different laboratories because the specific thromboplastin/instrument combination determines the responsiveness of the test. The INR, which is derived mathematically from the PT, allows harmonization of PT across laboratories for the purpose of monitoring VKA. All results are standardized using the international sensitivity index (ISI) for the particular thromboplastin/instrument combination used to perform the test.[127] ISI is based on the slope of the relationship between log PT values obtained with a test thromboplastin reagent and a reference thromboplastin, using samples from normal individuals and patients on VKA. The INR is then calculated as follows:

$$INR = \left[\frac{\text{PT (patient)}}{\text{PT (geometric mean of normal)}}\right]^{ISI}$$

The PT/INR is performed on platelet-poor plasma at 37 °C. The tissue factor in the reagent initiates the extrinsic pathway of the coagulation cascade (see Figure 59-2), the phospholipids provide a surface for assembly of coagulation factors, and the calcium chloride counteracts the binding of plasma calcium by citrate, making calcium available for the coagulation process. The timer is started when reagent is added, and the end point occurs when fibrin monomer polymerization is detected.

$$\text{Patient plasma} + \text{Thromboplastin (Tissue factor and Phospholipid)} + CaCl_2 \rightarrow \text{Fibrin clot}$$

The addition of tissue factor activates the extrinsic pathway much like the natural process; however, clotting occurs before the intrinsic pathway is significantly propagated, as occurs with in vivo coagulation. Consequently, the PT/INR is not sensitive to factor VIII or other intrinsic coagulation factors, and PT/INR could be considered a test of the initiation phase of coagulation.

The PT/INR is used to identify deficiencies or inhibitors of factors VII, X, V, and II and fibrinogen. Expected results of clotting assays, including PT/INR, are shown in Table 59-7 for key inherited and acquired disorders.

The sensitivity of PT/INR reagents to the deficiency of coagulation factors varies with the specific reagent and instrument combination. Therefore, it is useful for laboratories to determine the sensitivity of a given PT/INR system to factors VII, X, V, and II. This is accomplished by measuring the PT/INR in a dilutional series of factor-deficient plasma with normal pooled plasma. The activity at which the PT/INR is prolonged beyond the upper limit of the reference interval signifies the sensitivity of the assay to the factor being tested (Figure 59-10; for illustration, this example uses the aPTT test rather than PT/INR). If a reagent is overly sensitive to decreases in a factor (e.g., 0.5 IU/mL factor VII), the laboratory may detect clinically insignificant prolongations of the PT/INR. Needless laboratory evaluations and delays in surgical interventions may be avoided if reagents are selected carefully.

The PT/INR has been used to monitor vitamin K antagonist therapy because it is sensitive to vitamin K–dependent factors, II, VII, IX, and X. Monitoring during bridging or conversion of patients from heparin therapy to therapy with VKAs is made possible by the addition of heparin-neutralizing substances. Vitamin K antagonist therapy and its monitoring are addressed in greater detail later.

Activated Partial Thromboplastin Time (aPTT)

The aPTT is a clot-based assay that is initiated by activation of contact factors and reflects the activity of the intrinsic and common coagulation pathways (see Figure 59-2). Activation of contact factors [high molecular weight kininogen (HMWK), prekallikrein, and factors XII, and XI] is achieved by the addition of one of a wide variety of activators, most having in common a negatively charged surface. Activators including kaolin, celite, and micronized silica have been used extensively when mechanical end points are determined by coagulometers (see earlier); however, if an optical detection is used, micronized silica or the soluble chemical activator, ellagic acid, is used because they do not interfere with light transmission.

The aPTT is carried out in two stages. First, reagent containing an activator and phospholipids is added and incubated with the citrated plasma at 37 °C for several minutes (varies with the method). Second, the plasma is recalcified with calcium chloride, which is required for subsequent activation of downstream coagulation factors, and the timer is started. The timer is stopped when the end point is detected.

$$\text{Patient plasma} + \text{Activator} + \text{Phospholipid} \rightarrow \text{Factor XIIa} + \text{Factor XIa (stage 1)}$$

$$CaCl_2 + \text{Factor XIIa} + \text{Factor XIa} + \text{Other Coagulation Factors} \rightarrow \text{Fibrin Clot (stage 2)}$$

The aPTT is sensitive to activities of the intrinsic and common pathway factors (1) HMWK, (2) prekallikrein, (3) XII, (4) XI, (5) IX, (6) VIII, (7) X, (8) V, (9) II, and (10) fibrinogen.[14] Common uses of the aPTT include monitoring of heparin therapy and screening for deficiencies or

inhibitors of intrinsic and common pathway factors. The use of aPTT for monitoring heparin therapy is discussed later. The response of aPTT reagents to (1) heparin,[71] (2) factor deficiency, (3) specific factor inhibitors, and (4) lupus anticoagulants[16] varies widely. If a clinical laboratory intends to use aPTT to detect factor deficiencies, it is important to know the threshold of factor deficiency that prolongs the aPTT. The response of aPTT to factor VIII and factor IX is particularly important because of the prevalence of hemophilias A and B. Determining this responsiveness is accomplished by measuring the aPTT in a dilutional series of factor-deficient plasma with normal pooled plasma. The activity at which the aPTT is prolonged beyond the upper limit of the reference interval signifies the sensitivity of the assay to the factor being tested (see Figure 59-10). In general, the desired response to factors VIII, IX, and XI should be approximately 0.3 IU/mL. Very sensitive or insensitive reagents may create problems.

The aPTT is prolonged in a variety of clinically significant and insignificant scenarios. Table 59-7 summarizes some causes of prolonged aPTT and/or PT/INR. Seven general potential causes of isolated prolongation of aPTT include (1) a procoagulant deficiency that may be associated with a bleeding history—may include multiple factor deficiencies; (2) a contact factor deficiency without bleeding risk (XII, prekallikrein, HMWK); (3) a specific inhibitor acquired as an alloimmune or autoimmune phenomenon (e.g., factor VIII inhibitor); (4) a nonspecific inhibitor such as a lupus anticoagulant; (5) a medication effect or contamination (e.g.,

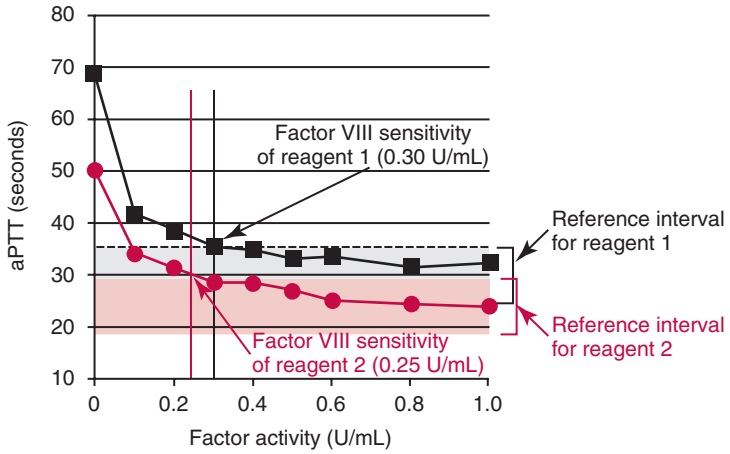

Figure 59-10 Relationship of aPTT to Factor VIII Activity. The graph demonstrates typical relationships of factor activity to clotting time. Response curves are shown for two aPTT reagents. Reference intervals for the reagents are represented as gray and red shaded areas for reagent 1 and reagent 2, respectively. The factor activity at which aPTT prolongs above the reference interval is the limit of detection of the reagent *(shown as black or red arrows)*. The graph demonstrates that aPTT reagents vary in their response to coagulation factors. Reagent 2 has a lower sensitivity than reagent 1 for factor VIII and may be less useful in detecting mild hemophilia A. PT reagents (and instrument combinations) also vary in their responses to extrinsic and common pathway factors and are assessed in a similar manner.

heparin, direct thrombin inhibitor); (6) a spurious result; and (7) an extreme of the population in which the aPTT may be minimally increased outside the upper limit of the reference interval, usually defined by two standard deviations, which includes only 95% of the population.

Although activated partial *thromboplastin* time implies the addition of thromboplastin, this is not the case. This ambiguity is a result of use of the term "partial" thromboplastin by Langdell and associates[80] to describe a group of reagents that produced clotting that was less rapid in hemophiliac plasma than in normal plasma. This was contrasted with "complete" thromboplastin reagents used in the prothrombin time assay, which did not discriminate normal and hemophiliac plasmas. Partial thromboplastin activity was achieved by replacing thromboplastin with cephalin or diluting thromboplastin; however, the overall effect of the dilutions was to remove the thromboplastin activity, making the contribution of the intrinsic pathway measurable. Subsequently, the addition of activators led to the aPTT that we recognize.

aPTT may be prolonged in patients who are not at risk for bleeding, such as those with deficiency of factor XII, prekallikrein, or HMWK. In fact, the intrinsic pathway is best considered a laboratory phenomenon, and in vivo coagulation is better considered in terms of initiation, amplification, and propagation (see Figures 59-2 and 59-3). In vivo, the initiation phase of coagulation is rapidly inhibited by tissue factor pathway inhibitor, with accompanying feedback by thrombin that initiates the propagation phase of coagulation. The aPTT reflects clinically significant deficiencies of factors in the propagation phase (factors XI, IX, and VIII) of in vivo coagulation and is an important test for identifying these deficiencies.

Fibrinogen (Clauss and Derived)

Coagulation ultimately depends on the conversion of fibrinogen to fibrin monomer by thrombin (see Figure 59-2). The Clauss method[24] is the most common method used to measure fibrinogen concentration. Initial dilution of plasma (usually 1:10) to dilute fibrinogen with addition of excess thrombin results in a clotting assay that is dependent on the functional fibrinogen concentration. Thrombin (final concentration 30 to 100 U/mL) is added to the diluted plasma. With the enzyme (thrombin) at saturation, and the substrate (fibrinogen) at limiting concentration, the rate of fibrin formation depends on the concentration of fibrinogen:

Citrated patient plasma (diluted) +
Thrombin (30 to 100 U/mL) → Fibrin clot

The fibrin end point is used to determine fibrinogen concentration from a calibration curve. The calibration curve is generated using plasma with a known fibrinogen concentration. Five dilutions of the calibrator are made, and a calibration curve is generated by plotting fibrinogen concentration against the rate of fibrin clot formation.

Another method of fibrinogen determination is PT-derived fibrinogen, or PT-fibrinogen. The fibrinogen concentration is proportional to the change in absorbance in an optical PT/INR measurement. A calibrator is used to create a calibration curve relating the change of absorbance of PT/INR to the fibrinogen concentration. The PT-fibrinogen assay may overestimate fibrinogen concentration in (1) patients with disseminated intravascular coagulation, (2) patients on fibrinolytic therapy, and (3) many patients with dysfibrinogenemia. In addition, some fibrinogen calibrators contribute more turbidity and may not be optimal for PT-fibrinogen

tahir99-VRG & vip.persianss.ir

measurements. The Clauss method is considered by many to provide a more meaningful fibrinogen measurement because fibrinogen degradation products are not detected, whereas PT-fibrinogen methods are more sensitive to fibrinogen degradation products. Fibrinogen degradation products prolong some clot-based tests by interfering with fibrin monomer polymerization but may also clinically act as anticoagulants and may contribute to hemorrhage in disseminated intravascular coagulation (see later).[86]

Mixing Studies

Mixing studies are performed on abnormally prolonged clot-based assays such as aPTT and PT. The purpose of mixing studies is to determine whether prolonged clotting times are due to factor deficiency or inhibitor activity. Mixing studies are useful for guiding the coagulation work-up, but they lack clinical sensitivity and specificity. Hence, the results of mixing studies are followed up with (1) lupus anticoagulant tests, (2) factor assays, and (3) possibly functional inhibitor studies for confirmation. Inhibitors are categorized as nonspecific or specific types. Nonspecific inhibitors (e.g., heparin, lupus anticoagulant) have activity against multiple procoagulants, while specific inhibitors are directed at a single factor. Lupus anticoagulants are a heterogeneous group of immunoglobulins with phospholipid-dependent activity against coagulation factors; they are discussed in greater detail later. Acquired factor VIII inhibitors are specific inhibitors that prolong the aPTT and clinically manifest as bleeding. These are usually seen as alloantibodies in the setting of hemophilia A treated with factor VIII concentrates, but they may be seen in nonhemophiliac patients as an autoantibody. Although rare, specific inhibitors may occur against any factor, and a high degree of clinical suspicion is needed when bleeding is otherwise unexplained.

Mixing studies are useful when clotting time (e.g., aPTT, PT) is unexpectedly prolonged outside of the reference interval. They are also recommended for lupus anticoagulant testing (see section on DRVVT and lupus anticoagulant studies later) to confirm the inhibitor effect. Citrate-anticoagulated patient plasma is mixed in a 1:1 ratio with normal pooled plasma, and then the clotting assay is repeated *immediately*. Normal pooled plasma should be derived from a sufficient number of apparently healthy individuals to ensure a quantity of 1 IU/mL of all factors. If a factor deficiency in the patient plasma exists, the resulting 1:1 mix supplies the factors needed to correct the clotting time back into the reference interval. If an inhibitor is present, the mixed specimen will not correct the clotting time into the reference interval.

The utility of mixing studies largely depends on the patient population and the clinical setting. For example, aPTT mixing studies are performed more frequently than PT/INR mixing studies because lupus anticoagulants, which are common, affect aPTT much more frequently than PT. When aPTT is prolonged and mixing studies fail to adequately correct into the reference interval, an inhibitor is suspected. If the patient is asymptomatic or has a history of thrombosis, the next step should be to look for lupus anticoagulant rather than to measure factor VIII, IX, and XI concentrations. Conversely, if the patient has a bleeding presentation, a specific inhibitor may be suspected and factor concentrations should be measured. PT/INR mixing studies may be helpful at times. Inhibitors and deficiencies of factor VII and the common pathway factors are rare and can be investigated with PT/INR or aPTT mixing studies.

Immediate aPTT mixing studies that correct to the reference interval require incubated mixing to assess for *time-dependent inhibitors*. In such studies, the patient's plasma is mixed with normal pooled plasma and they are incubated *together* for 1 or 2 hours at 37 °C. The aPTT is then repeated and compared with a control. The control consists of patient plasma and normal pooled plasma incubated at 37 °C *separately,* followed by mixing and aPTT. This step is important because it controls for loss of labile factors during the incubation process (Figure 59-11). One approach to interpretation is to consider a 10% difference between the test and the control to indicate a time-dependent inhibitor. Acquired alloantibodies to factor VIII are frequently time dependent; however, up to 15% of lupus anticoagulant measurements are also time dependent.[26] Considering the high prevalence of lupus anticoagulant relative to the low prevalence of acquired factor VIII inhibitors in hemophilia patients (1 to 2 per million of population per year), laboratories are more likely to encounter time-dependent lupus anticoagulants than time-dependent acquired factor VIII inhibitors (Table 59-8).

The performance characteristics of mixing studies as tests to detect lupus anticoagulants depend on the (1) phospholipid content of reagents; (2) factor and phospholipid content of normal pooled plasma (NPP); (3) titer and strength of the lupus anticoagulant; (4) presence of multiple factor deficiencies; (5) heparin contamination; and (6) criteria for interpretation. Weak inhibitors or very sensitive aPTT reagents

TABLE 59-8 Prevalence of Time-Dependent Inhibitors in a Population of 300 Million*

Inhibitor Type	Population	Prevalence of Inhibitor	% Time Dependence	Number of Time-Dependent Inhibitors
Lupus anticoagulants	300×10^6	3%	10%	900,000
Factor VIII inhibitor in hemophilia A	30,000	15%	90%	4050

*Time-dependent inhibitors are 222 times more likely to be due to LA than to specific factor VIII inhibitor.

tahir99-VRG & vip.persianss.ir

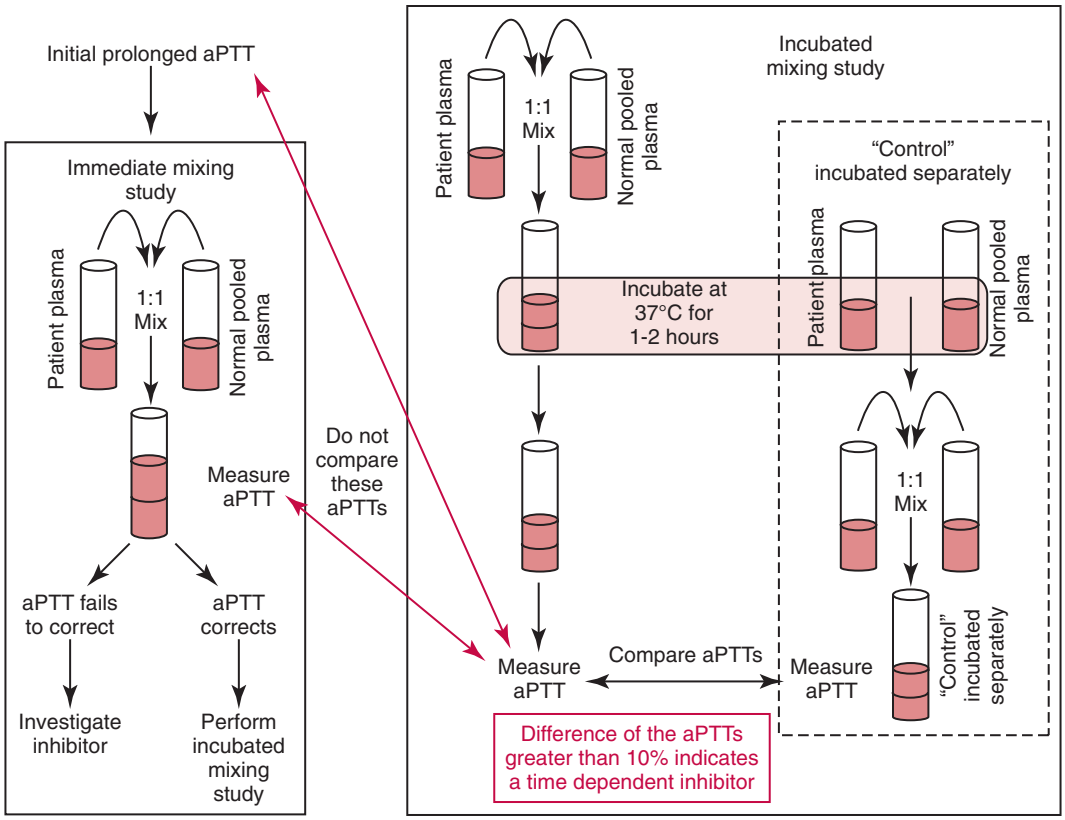

Figure 59-11 Sequence for the Performance of Mixing Studies. In this example, a 1:1 mixing study is used. An immediate mixing study is shown on the left. Equal volumes of patient plasma and normal pooled plasma are mixed, and then the aPTT is measured. If aPTT fails to correct (e.g., into the reference interval), then there is evidence of an inhibitor and the mixing study is complete. If the immediate mixing study corrects, then an incubated mixing study is needed to exclude a time-dependent inhibitor. The incubated mixing study starts with mixing equal volumes of patient plasma and normal pooled plasma. The 1:1 mix is incubated for 37 °C for 1 to 2 hours, and then an aPTT is performed. Interpretation of the incubated mixing study relies on the control shown in the *dashed black box,* in which patient plasma and normal pooled plasma are incubated separately (i.e., mixed after incubation) to control for loss of labile factors. The control aPTT is used for comparison with the incubated mixing study; neither the initial aPTT nor the aPTT of the immediate mix should be used for comparison.

may cause substantial difficulties. Phospholipid-poor assay reagents are more sensitive to lupus anticoagulants, so perhaps weaker lupus anticoagulants are detected before mixing, but they are rapidly diluted out by 1:1 mixing. *If the aPTT is only minimally elevated (e.g., <5 seconds above the reference interval), then 1:1 mixing studies are not useful, because the clotting times may correct despite the presence of an inhibitor.* Some laboratories use an alternative mixing study with four parts patient and one part NPP to improve sensitivity for these weak inhibitors.[23] Mixing studies certainly are not quantitative, and the clinical significance of these "weak" inhibitors is not known. NPP should be prepared from at least 20 apparently healthy individuals to ensure 1.0 IU/mL of all factors. It is also important that NPP be platelet poor because contamination, especially in frozen aliquots, may contribute to phospholipid content that will neutralize lupus anticoagulants. In some instances, 1:1 mixing may not correct when multiple factors are deficient. Heparin or direct thrombin inhibitors may confound interpretation and should be suspected with prolonged or unmeasurable thrombin time.

Interpretation of mixing studies is not always straightforward, and criteria for interpretation may vary somewhat from laboratory to laboratory. Although we have considered correction of the immediate 1:1 mix to be into the reference interval (+2 standard deviations), many variations are used (e.g., +3 standard deviations of the mean aPTT). Rosner and colleagues[116] suggested an index, and Chang and coworkers demonstrated improved performance when using a percent correction and a 4:1 mix.[23] In summary, there is no uniformity in the performance of mixing studies, nor are there uniform criteria for interpretation; ultimately, the laboratory director must decide the appropriate approach and each result should be accompanied with an interpretation.

Factor Assays

The most commonly performed factor assay is the one-stage factor assay. One-stage assays are based on the aPTT or the PT, depending on which factor is being measured. The assay is performed on dilutions of patient plasma into factor-deficient plasma. Factor-deficient plasma is deficient in a single factor but contains essentially 1.0 IU/mL of all other factors. Plasma from severe hemophiliacs has been used historically; factor-deficient plasmas manufactured by immunodepletion methods are now commercially available. Dilution of patient plasma into deficient plasma ensures that clotting times are dependent on the factor being measured. aPTT-based one-stage assays are used to measure factor activity of intrinsic factors, and PT/INR-based assays are used to measure factor activity of factor VII. aPTT- or PT/INR-based assays have been used to measure the activity of common pathway factors (factor II, V, or X). Factor activity is then determined from a calibration curve created by plotting the clotting time (PT or aPTT) in seconds versus the concentration of factor (Figure 59-12).

The aPTT-based one-stage factor VIII assay consists of a dilutional series of patient plasma into factor VIII–deficient plasma, starting with a 1:10 dilution. The initial dilution serves to prolong the aPTT into a steeper part of the relationship between clotting time and factor activity (see Figure 59-12). The aPTTs of the dilutional series are used to extrapolate factor VIII activity from the calibration line. The 1:10 dilution is considered the starting point for comparison with the calibration line, which also starts with a 1:10 dilution. Each subsequent dilution in the series needs to be multiplied by a dilution factor to achieve the equivalent of the 1:10 dilution. This procedure also is used to measure the intrinsic and common pathway factors by substituting the appropriate factor-deficient plasma.

Various mathematical transformations, most commonly log transformation, are employed to create a straight calibration line. Factor activity should be determined with at least three dilutions to enhance accuracy and allow for the detection of inhibitors by assessing parallelism. Because one-stage assays are aPTT or PT in INR dependent, they may be affected

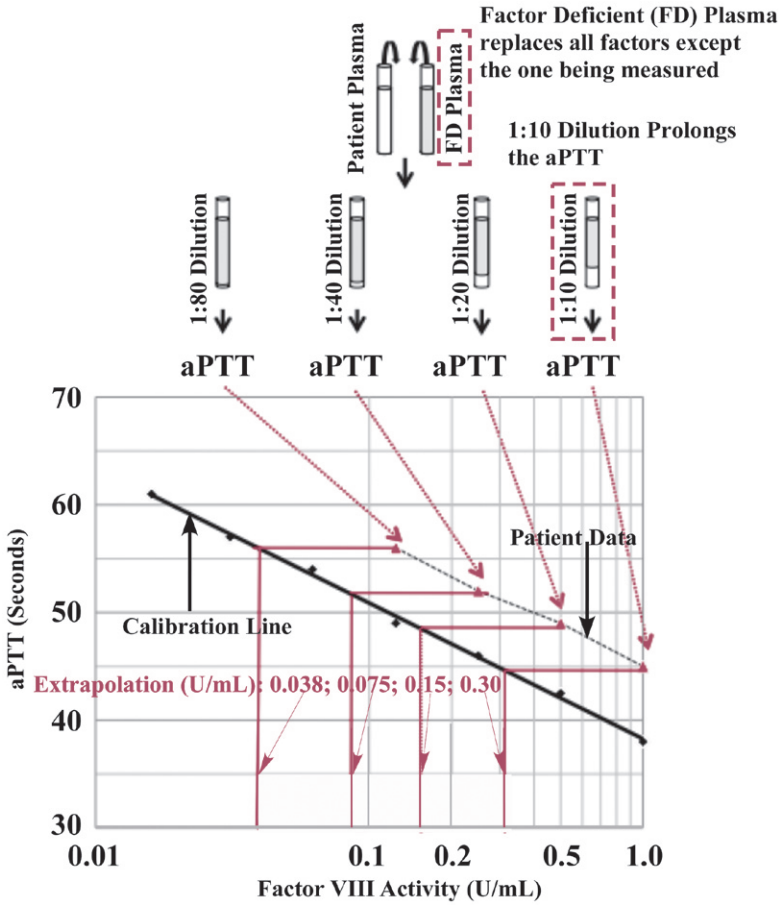

Figure 59-12 aPTT-Based One-Stage Factor VIII Assay. Dilutions of patient plasma into factor VIII–deficient plasma are made by starting with a 1:10 dilution. The aPTT of diluted plasmas is used to extrapolate factor VIII activity from the calibration curve. The 1:10 dilution is considered the starting point for comparison with the calibration line, which also starts with a 1:10 dilution. Each subsequent dilution in the series needs to be multiplied by a dilution factor to achieve the equivalent of the 1:10 dilution.

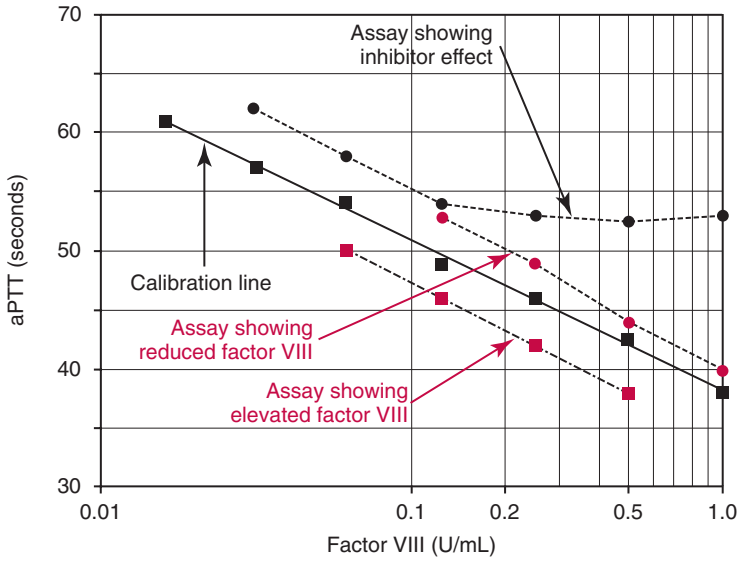

Figure 59-13 Factor VIII Assay Demonstrating the Effect of an Inhibitor. Parallelism should be demonstrated to ensure accurate measurement of factor activity. The dilutional series of three separate patient plasmas are shown. Parallelism between the calibration curve and the patient plasma dilutions is seen in two of the factor VIII assays *(red boxes and red circles)*. A third patient plasma containing lupus anticoagulant shows a nonparallel series *(black circles)*. The first three dilutions of the nonparallel series recover increasing amounts of factor activity (after correction for dilution). However, the last three dilutions show that the line becomes parallel to the calibration curve as the lupus anticoagulant is diluted out. The first two dilutions that become parallel are used to acquire an accurate factor VIII activity, by averaging factor activity after correction for dilution.

by inhibitors present n the patient's plasma including lupus anticoagulant, heparin, or direct thrombin inhibitors. Multiple determinations at increasing dilutions (e.g., 1:10, 1:20, 1:40) allow assessment of parallelism between patient data and the calibration curve (see Figure 59-13). Serial dilutions, when parallel, should return the same activities after multiplying by the dilution factors. If increasing activity is obtained as dilutions increase, the patient's curve will be nonparallel to the calibration curve, and an inhibitor is suspected. Additional higher dilutions can be used in an attempt to dilute the inhibitor. When at least two consecutive dilutions produce similar activities, the inhibitor effect has been diluted out; the activity is then reported using the average of these activities, after correction for dilution. It may not be possible to dilute out strong or high titer inhibitors. The one-stage factor assay depicting elevated, reduced, and inhibited assays is shown in Figure 59-13.

The two-stage assay is not widely used but offers specialized laboratories an alternative method to measure factor VIII activity. The first stage contributes exogenous coagulation factors needed for formation of the prothrombinase complex, except for factor VIII. In this first stage, the formation of Xa depends on the amount of factor VIII in the patient's plasma. In the second stage, normal pooled plasma is added to the reaction (now containing factor Xa) as a source of prothrombin and fibrinogen so that fibrin clotting will occur. The clotting time in the second step is proportional to the amount of factor VIII in the patient sample. A calibration curve is then used to determine the factor VIII activity.[5]

Chromogenic factor VIII assays are based on the two-stage assay (Figure 59-14). Similar to the two-stage assay, the first stage allows for the generation of factor Xa. Calcium, phospholipid, excess purified factor IXa, and factor X are added such that the amount of factor Xa generated during this first stage depends on the amount of factor VIII received from the patient sample. The second stage measures the absorbance developed from the enzymatic release of *p*-nitroaniline from a chromogenic substrate of Xa. A direct thrombin inhibitor is often added to the second stage to decrease cleavage of the chromogenic substrate by IIa. A calibration curve relates the change in absorbance at 405 nm to factor VIII activity in the specimen.[70]

$$[\text{Patient plasma} + \text{Buffer (1:50)}] + [\text{IXa and X (in excess)}] + CaCl_2 + \text{Phospholipid} \rightarrow \text{Xa}$$

$$\text{Xa} + \text{Substrate} + \text{Direct thrombin inhibitor} \rightarrow p\text{-nitroaniline (detected at 405 nm)}$$

Important differences have been observed in factor VIII activity depending on the method used. Two-stage assays and chromogenic assays are less sensitive to lupus anticoagulants[32] because of the higher initial plasma dilutions employed. Some chromogenic assays include thrombin to fully activate factor VIII to VIIIa; others rely on feedback activation of factor VIII by thrombin generation analogous to the in vivo propagation phase of coagulation. One-stage assays sometimes will

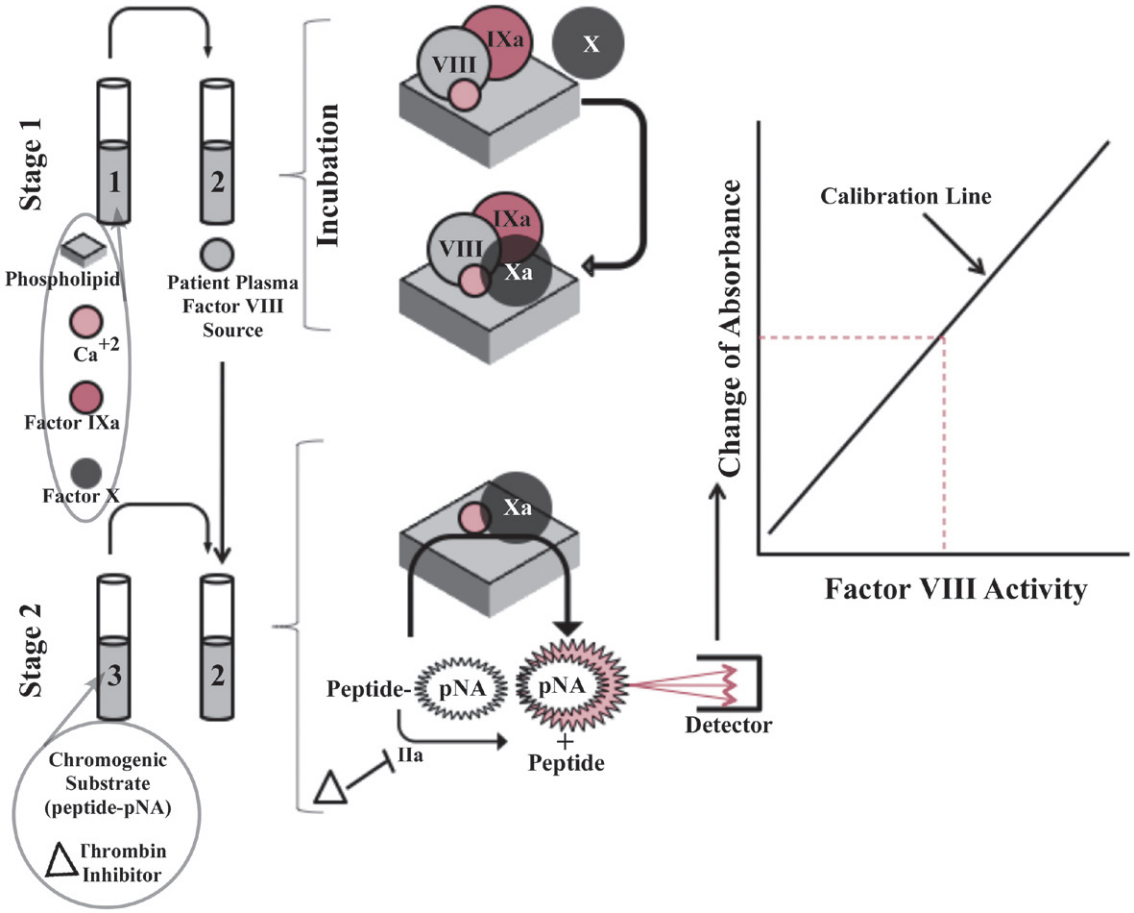

Figure 59-14 Schematic of the Chromogenic Assay for Factor VIII. The chromogenic factor VIII assay is modeled after the classic two-stage factor VIII assay. The patient sample *(tube 2)* is highly diluted with buffer, allowing measurement in the presence of lupus anticoagulant. During the first stage, substrates *(tube 1)* are added to the diluted patient plasma to allow formation of the tenase complex and subsequent conversion of factor X to factor Xa. Conversion of factor X to factor Xa is dependent on factor VIII activity supplied by patient plasma. The second stage starts when chromogenic substrate is added to tube 2. Factor Xa generated during the first stage hydrolyzes the chromogenic peptide substrate and releases para-nitroaniline. A thrombin inhibitor prevents nonspecific hydrolysis of the chromogenic substrate by thrombin. Absorbance resulting from the release of para-nitroaniline is detected at 405 nm and is used to extrapolate factor VIII activity from the calibration curve. *pNA,* Para-nitroaniline.

overestimate factor VIII activity when compared with two-stage or chromogenic assays.[36,100] It is important to keep this in mind because a one-stage assay may not exclude a mild hemophilia A, and clinical correlation with bleeding symptoms and family history may be needed. Less frequently, two-stage assays will recover more factor VIII activity.

Factor Inhibitor Assays

Inhibitors are quantified by using a functional inhibitor assay. The Bethesda assay established the framework for functional inhibitor assays and defined the Bethesda unit.[65] The primary focus of this assay and unit was to create uniformity in the measurement of factor VIII inhibitors in patients with hemophilia A. This is accomplished by creating an incubated mix of patient plasma (containing the inhibitor) with NPP (containing approximately 1.0 IU/mL factor VIII activity) and then measuring the remaining factor VIII activity. Strong inhibitors reduce the resultant factor VIII activity more than weak inhibitors do. Titration of this effect is possible by using serial dilutions of patient plasma before mixing.

The Bethesda assay begins with undiluted patient plasma or dilutions of patient plasma with imidazole buffer. The patient sample is then mixed with NPP. The mixed sample is incubated for 2 hours at 37 °C, and then factor VIII is assayed. A reference mix, consisting of a 1:1 incubated mix of imidazole buffer and NPP, is crucial to control for loss of labile factors. The residual factor activity is calculated as follows:

$$\text{Residual Factor Activity (IU/mL)} = \frac{\text{Patient Mix Factor Activity (IU/mL)}}{\text{Reference Mix Factor Activity (IU/mL)}}$$

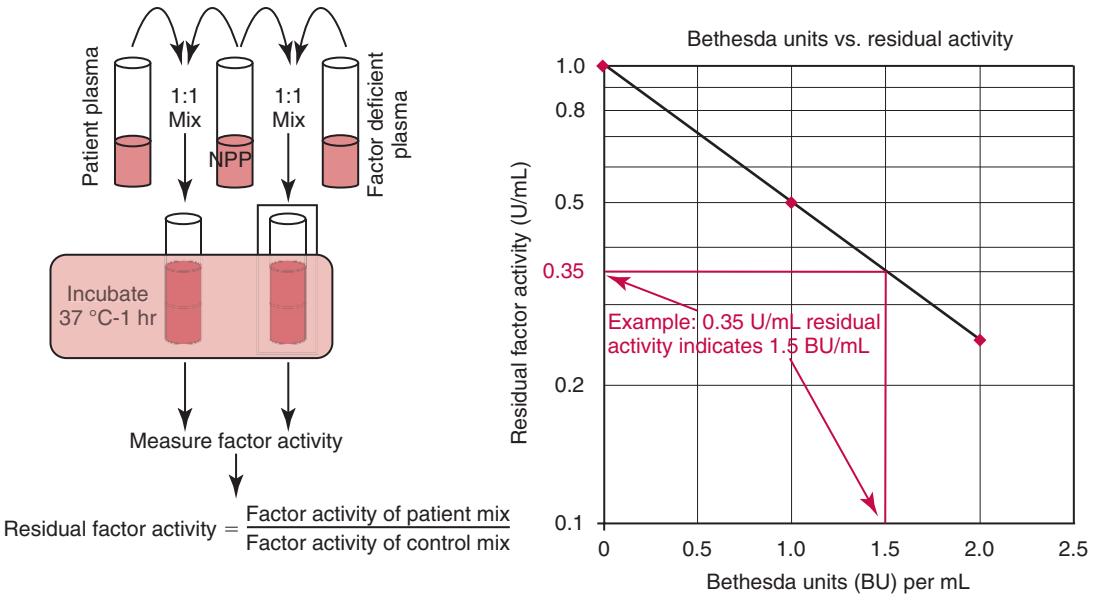

Figure 59-15 Schematic of the Functional Inhibitor Assay. Patient plasma is the source of inhibitor, and buffered normal pooled plasma is the source of coagulation factors. Patient plasma is mixed with an equal volume of buffered normal pooled plasma. The mix is then incubated for 1 to 2 hours at 37 °C, allowing time-dependent inhibitors to work. A control mix consists of an incubated mix of equal volumes of factor (e.g., factor VIII)-deficient plasma (without inhibitor) and buffered normal pooled plasma. One-stage factor assays are used to determine the factor activities of the patient mix and the control mix. Residual factor activity is then calculated. The definition of a Bethesda unit provides a calibration line, and residual factor activity is used to extrapolate the titer in Bethesda units/mL. When high titers of inhibitor are present, initial dilutions of the patient plasma into factor-deficient plasma are required *(not shown)*.

Finally the residual factor activity is translated into Bethesda units. One Bethesda unit (BU) per milliliter is defined as the inhibitor activity producing a residual factor activity of 0.5 IU/mL. A value of 2 BU/mL is then the inhibitor activity producing a residual factor activity of 0.25 IU/mL. A log-linear graph of factor activity and BU/mL is drawn according to this definition (Figure 59-15). For ease of use, a chart relating residual factor to BU/mL is constructed. Parallelism of dilutions should be expected to confirm the precision of the result. To assay other factor inhibitors, the factor VIII–deficient plasma used in the assay is replaced with the corresponding factor-deficient plasma.

Nijmejen modifications of the Bethesda assay improve specificity near the low analytical limit of detection.[137] The Nijmejen modifications are that (1) factor-deficient plasma is used for dilutions instead of imidazole buffer and (2) NPP is buffered at pH 7.4. Both of these changes reduce loss of factor VIII during incubation. Buffering the NPP prevents increasing pH, and diluting with factor-deficient plasma normalizes protein concentrations in the reference plasma. Many laboratories in the North American Specialized Coagulation Laboratory (NASCOLA) survey were found to be using a hybrid of the classic Bethesda and Nijmejen procedures in which a commercially available buffered NPP was used but imidazole buffer was used for dilutions of patient plasma. The high coefficient of variation (CV) and the variation in laboratory procedures make standard treatment guidelines based on BU/mL difficult.[102]

The behaviors of inhibitors in laboratory tests are not uniform. Although most inhibitors demonstrate an expected increase in residual factor VIII activity with increasing dilutions (type I inhibitor), some inhibitors (type II inhibitors) lack this relationship. Type II inhibitors lack parallelism to the calibration curve and may be difficult to titer. In these cases, dilutions of patient plasma corresponding to approximately 0.5 IU/mL residual activity are used to estimate BU/mL.[136] In addition, some factor VIII inhibitors increase factor VIII clearance but do not affect factor VIII activity. These non-neutralizing factor VIII inhibitors cannot be detected with a mixing study, nor can they be titered with a functional inhibitor assay. ELISA assays for detecting factor VIII antibodies would be a more appropriate alternative for non-neutralizing types of inhibitors.

Factor XIII Assays

Plasma factor XIII is a zymogen that is activated by thrombin in a calcium-dependent reaction. The active enzyme catalyzes the covalent cross-linking of fibrin molecules and polymers, producing a stable clot (Figure 59-16). Factor XIIIa is a transglutaminase that links glutamine residues to lysine residues via the transfer of an acyl group and the release of ammonia. Factor XIIIa activity is not reflected in clot-based assays such

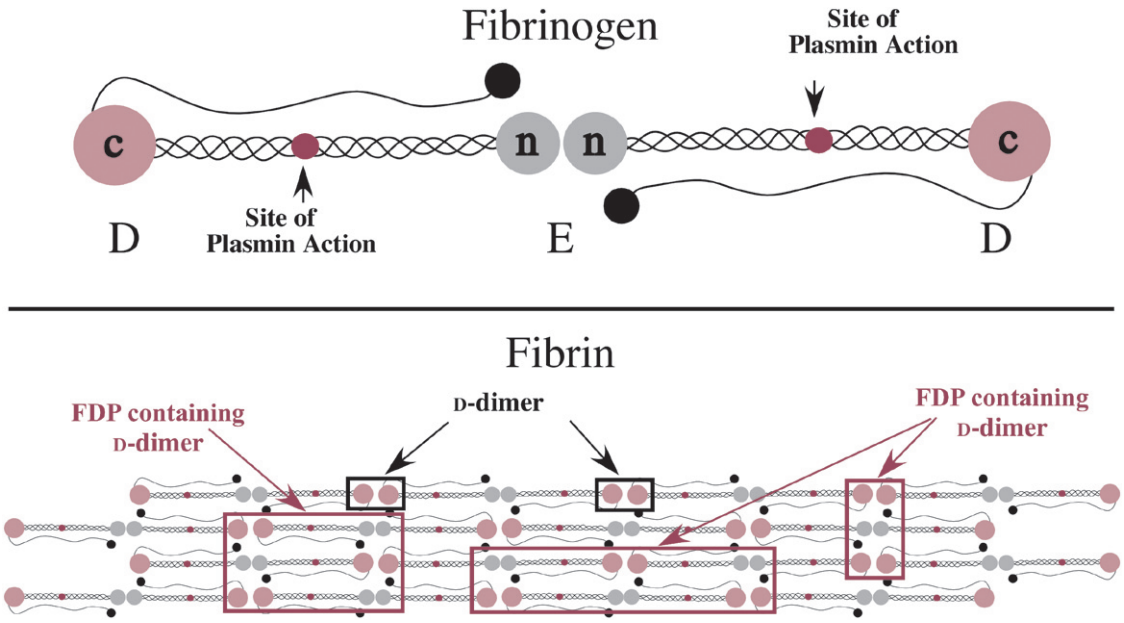

Figure 59-16 **Fibrinogen, Fibrin and the Formation of D-dimer. The primary substrate for the enzyme thrombin is fibrinogen (340kDa). When activated by thrombin, an N terminus peptide is cleaved from the Aα and Bβ, fibrinopeptides A and B, forming fibrin monomer. Fibrin monomer polymerizes end to end and side to side forming a fiber, fibrin, in a process that is not enzymatically driven. As depicted, the polymerization of fibrin monomer occurs with the association of the *D* domains of two fibrin monomers (referred to as D-dimer) with the *E* domain of a third. Crosslinking occurs with the action of a transamidase, factor XIIIa, forming the stable fibrin clot. Fibrinolysis occurs upon the activation of plasminogen to plasmin, a serine protease the initially cleaves the fibrin molecule between the *D* and *E* domains. Soluble fragments of fibrin (fibrin degradation products) that contain variable numbers of the *D-D* domains (D-dimer) are produced.**

as aPTT and PT/INR, which depend on fibrin polymerization as an end point, because non–covalently linked, polymerized fibrin monomer is sufficiently stable to support the mechanical end point in the tests.

The urea solubility screen, or a variation thereof, is the most common screening method for factor XIII deficiency. Before the actions of factor XIIIa take place, fibrin polymer structure is held together by hydrogen bonds and is soluble when subjected to weak alkalis and acids[114] or to high concentrations of solute such as urea. This is the basis of factor XIII screening methods. In the urea solubility screen, fibrin clot is formed from citrated patient plasma and then is suspended in 6 mol/L urea. The clot is visually observed at intervals for dissolution. Covalently linked fibrin clots do not dissolve. Non–covalently linked fibrin clots are dissolved after 1 to 3 hours in severe factor XIII–deficient plasmas. A fibrin clot prepared from NPP serves as the control. This method detects only very severe factor deficiency; very little factor XIIIa activity is required to stabilize a fibrin clot.

Data from U.K. National External Quality Assessment Scheme (NEQUAS) Surveys demonstrated variability in screening methods.[62] Fibrin clots were achieved with calcium alone, calcium and thrombin, or thrombin alone; moreover, when thrombin was used, the concentration was not uniform. Acetic acid, urea, and monochloroacetic acid were used as solvents. Altogether 15 different combinations of solvents and clot preparations were used, contributing to variable responses. Further evaluation of plasmas spiked with factor XIII confirmed that a combination of thrombin and acetic acid provided the best sensitivity, which was in the interval of 0.01 to 0.05 IU/mL factor XIII. Positive solubility screens for factor XIII need confirmation by quantitative methods that may be factor XIII antigen assays or factor XIII activity assays. For a full description of quantitative assays, see Reference 64.

Thrombin Time

Thrombin time (TT) is a clot-based assay reflecting two steps: (1) conversion of fibrinogen to fibrin monomer by thrombin, and (2) polymerization of fibrin monomers. A low concentration of thrombin (final concentration of 0.1 to 0.3 U/mL; concentration depends on the source of thrombin) is added to citrated plasma, fibrin is generated, and the time it takes to form the clot is measured.

Citrated patient plasma (undiluted)
+ Thrombin (low concentration) → Fibrin clot

Note that TT is different from the Clauss fibrinogen measurement because, in the Clauss fibrinogen method, the patient plasma is diluted and a higher concentration of thrombin is

used. Although thrombin time is still sensitive to low fibrinogen concentrations, these differences contribute to the greater responsiveness of thrombin time to (1) thrombin inhibitors, (2) abnormal fibrinogen (dysfibrinogen), and (3) substances that interfere with fibrin polymerization compared with the Clauss fibrinogen assay. Thrombin inhibitors prolong thrombin times and are commonly encountered as therapeutic anticoagulants, including heparin and direct thrombin inhibitors. Because these inhibitors may interfere with other clot-based tests, some laboratories use thrombin time as a tool to detect the unexpected presence of these therapeutic agents. If thrombin time is used for this purpose, then the laboratory should determine the responsiveness of its thrombin time assay to direct thrombin inhibitors and heparin.

Inhibitors to bovine thrombin and/or factor V occur in some individuals exposed to topical bovine thrombin during surgical procedures. Bovine thrombin combined with a source of fibrinogen, such as cryoprecipitate, is an effective hemostatic agent. However, topical bovine thrombin preparations also contain bovine factor V, so inhibitors to both bovine II and V can be produced. Bovine factor V inhibitors may cross-react with human factor V to produce bleeding, but cross-reactivity of bovine thrombin inhibitors with human thrombin is rare. There is, however, prolongation of the thrombin time if bovine thrombin is used for thrombin time assays instead of human thrombin; this will be confirmed by a normal thrombin time using human thrombin.

Thrombin time may be prolonged in the presence of structurally abnormal fibrinogens, called *dysfibrinogens.* Congenital dysfibrinogenemia occurs only rarely, and it is much more common to see acquired dysfibrinogenemia. Individuals with dysfibrinogenemia are typically asymptomatic, but some may be at risk for bleeding or thrombosis. Both bleeding and thrombosis may occur in the same patient. Liver and biliary diseases are common causes of acquired dysfibrinogenemia and produce fibrinogen molecules with increased sialylation of carbohydrate moieties. As a result, an increase in negative charge retards fibrin polymerization[31] and prolongs the thrombin time. Thrombin time and the closely related reptilase time are considered initial screening tests for dysfibrinogenemia. The final laboratory diagnosis of dysfibrinogenemia is confirmed by finding a discrepancy in the ratio of fibrinogen clotting activity to the fibrinogen antigen concentration.[28]

Prolonged thrombin times occur in a wide variety of settings and are not specific for dysfibrinogenemia (Table 59-9). For example, substances that prolong TT include (1) paraproteins, (2) fibrin(ogen) degradation products, and (3) high fibrinogen concentrations. Paraproteins affecting thrombin times may be of any heavy chain and are seen in the clinical setting of Waldenström macroglobulinemia or multiple myeloma. Paraproteins may affect other tests of hemostasis, including aPTT and bleeding time.[104] These patients may even have clinical symptoms of bleeding, but it is not possible to predict bleeding based on any laboratory test. Increased fibrin degradation products and increased fibrinogen, by virtue of their structural similarities to fibrin, may prolong the thrombin time by competing with normal fibrin monomers in the polymerization process. High concentrations of

TABLE 59-9 Thrombin Time in Various Clinical Settings

Clinical Settings	Thrombin Time	Mechanism
Inherited dysfibrinogenemia	Prolonged	Inhibition of fibrinopeptide A and B Inhibition of fibrin monomer polymerization
Acquired dysfibrinogenemia	Prolonged*	Inhibition of fibrin monomer polymerization
AL amyloidosis	Prolonged	Unknown
Monoclonal immunoglobulins	Prolonged	Inhibition of thrombin Inhibition of fibrin monomer polymerization
Fibrin degradation products	Prolonged	Inhibition of fibrin monomer polymerization
Low fibrinogen	Prolonged	Decreased fibrinogen substrate
Elevated fibrinogen	Prolonged	Interference with fibrin-monomer polymerization
Medications/Iatrogenic Settings		
Argatroban	Prolonged	Inhibition of thrombin
Hirudin and related medications	Prolonged	Inhibition of thrombin
Unfractionated heparin	Prolonged	Inhibition of thrombin
Fractionated heparin	Prolonged	Inhibition of thrombin
Bovine thrombin, topical	Prolonged	Development of alloantibodies to thrombin*
Dextran	Shortened	Increased rate of fibrin monomer polymerization
Hydroxyethyl starch	Shortened	Unknown
Thrombolytics (urokinase, tissue plasminogen activator)	Prolonged	Inhibition of fibrin monomer polymerization due to fibrin degradation products
Radiocontrast agents	Prolonged	Inhibition of fibrin monomer generation and polymerization

*Thrombin time is most commonly affected when bovine thrombin is used as a reagent.

Modified after Cunningham MT, Brandt JT, Laposata M, Olson JD. Laboratory diagnosis of dysfibrinogenemia. Arch Pathol Lab Med 2002;126:499-505.

fibrin degradation products are seen in disseminated intravascular coagulation and after fibrinolytic therapy. High concentrations of fibrinogen are commonly encountered as part of an acute-phase reaction in hospitalized patients. Thus fibrinogen assays are useful in the evaluation of prolonged thrombin time.

Clinical Use of Laboratory Tests for Disorders of Secondary Hemostasis

Laboratory tests described earlier are used in the diagnosis and evaluation of inherited and acquired disorders of secondary hemostasis.

Inherited Disorders

The most common inheritable bleeding disorders due to coagulation factor deficiencies include (1) hemophilia A (factor VIII deficiency), (2) hemophilia B (factor IX deficiency), and (3) factor XI deficiency (historically referred to as hemophilia C). The pathophysiologic consequence of these deficiencies is a defect in the propagation phase of coagulation. As discussed earlier, the clot-based tests, aPTT and PT artificially separate coagulation into intrinsic, extrinsic, and common pathways (see Figure 59-2) that only loosely resemble physiologic coagulation, wherein the pathways do not operate independently. In the laboratory, deficiencies of the intrinsic pathway produce isolated prolongation of aPTT. Mixing studies are indicated to help guide further laboratory evaluation toward factor deficiency or the presence of inhibition. Together, correction of the immediate aPTT mixing study and lack of prolongation after incubation suggest factor deficiency. Measurement of intrinsic factor activities is then indicated, usually starting with factor VIII, factor IX, and factor XI, because of their clinical association with bleeding. Measurement of factor XII, prekallikrein, and HMWK is helpful in explaining prolonged aPTT in the absence of deficiency of factor VIII, factor IX, or factor XI, particularly if there is no clinical bleeding history.

Inherited deficiencies of factors VII, X, V, and II and fibrinogen are rare but present with bleeding phenotypes. Factor VII deficiency causes isolated prolongation in PT/INR without prolongation of the aPTT. A mixing study of the PT/INR indicates a deficiency, and factor VII activity is low, usually in the 0 to 20% range in significant deficiency. Inherited deficiencies of X, V, and II and fibrinogen prolong PT and aPTT. aPTT mixing studies show a factor deficiency, and factor activity is markedly decreased. Inherited afibrinogenemia or hypofibrinogenemia causes prolongation of PT/INR and aPTT, which correct with mixing studies. A functional fibrinogen assay shows markedly decreased fibrinogen. In all cases of inherited deficiency, clinical correlation with a bleeding and family history is needed to make a diagnosis.

Factor XIII deficiency is a rare disorder of secondary hemostasis with a bleeding phenotype and normal PT/INR, aPTT, TT, and fibrinogen. A urea solubility test demonstrates dissolution of fibrin clot in 1 to 2 hours. Low factor XIII can be confirmed with antigen or activity assays. Platelet function and studies of fibrinolysis are normal.

Factor VIII Deficiency (Hemophilia A)

Factor VIII deficiency is an X-linked recessive genetic disorder with an incidence of 1 in 5000 live male births. Because one third of mutations occur spontaneously, a family history is not always present. Severity of bleeding correlates with the amount of factor VIII with activities of (1) less than 0.01 IU/mL, (2) 0.01 to 0.05 IU/mL, and (3) 0.05 to 0.40 IU/mL associated with severe, moderate, and mild hemophilia A, respectively.[142]

Laboratory studies of individuals with factor VIII deficiency show isolated prolongation of aPTT and normal PT. A normal thrombin time is helpful to exclude heparin contamination as a cause for prolonged aPTT. Mixing studies should help identify a factor deficiency. Factor activities of the intrinsic pathway should be measured to confirm suspicion of an intrinsic pathway deficiency. In a male patient, factor VIII, IX, and XI activity should be measured. Female carriers may have mildly reduced factor VIII activity and mild bleeding symptoms, but investigation of factor XI deficiency and VWD is probably best considered first in females. Decreased factor VIII activity with normal activity of factors IX and XI is expected in hemophilia A. Patients with *von Willebrand disease also present with an isolated prolonged aPTT and low factor VIII activity, so evaluation of von Willebrand disease is warranted in some cases before a diagnosis is rendered.* Correlation with the family and clinical history completes the diagnosis of factor VIII deficiency. The distinction of hemophilia A from type 2N VWD is difficult. Type 2N VWD is caused by decreased affinity of VWF for Factor VIII. The patients thus have decreased factor VIII because it is not protected by binding to VWF. The distinction of type 2N VWD and hemophilia A can be accomplished with a careful family history and a VWF:VIII binding assay, which is performed only at very specialized laboratories. A family history of hemophilia may be absent in up to 30% of infant males with hemophilia A due to spontaneous mutations. Genetic testing to identify a specific factor VIII mutation may be useful in prenatal testing of carrier females.

Factor VIII activity is used to follow factor VIII replacement therapy—the mainstay of prophylaxis and of management of an acute bleed. When postinfusion recovery of factor VIII activity is lower than anticipated or the patient fails to respond clinically, a factor VIII inhibitor is suspected. The aPTT is prolonged, but in this case, mixing studies suggest an inhibitor. Most factor VIII inhibitors are time dependent; thus, an immediate aPTT mixing study may correct the prolonged aPTT. However, an incubated aPTT mixing study reveals prolongation compared with the appropriate control. Factor VIII inhibitor is quantified in BU/mL with a Bethesda assay or a variation thereof. The titer is used to guide therapeutic decisions. An inhibitor titer of less than 5 BU/mL may respond to high doses of factor replacement, although higher titers are not likely to respond and require alternative treatment. Anamnestic responses may occur, in which low or undetectable inhibitor titers rise 4 to 7 days after re-exposure to factor VIII. Inhibitors have been reported in 10 to 25% of patients and are associated with certain molecular defects in

the *F8* (for factor VIII) gene. Inhibitors may occur in mild disease. Alternative treatments for patients with inhibitors have included replacement with porcine factor VIII (previously available as a plasma-derived concentrate and currently in trials as a recombinant product) or products with factor VIII-bypassing activity such as recombinant activated factor VIIa concentrate or activated prothrombin complex concentrates.[67] These latter two products activate factor X without factor VIII or IX.

Factor IX Deficiency (Hemophilia B)

Factor IX deficiency, also known as hemophilia B or Christmas disease, is a heritable X-linked recessive bleeding disorder. The incidence is approximately 1 in 30,000 males. Clinically, the bleeding manifestations relate closely to the amount of factor IX. This is similar to hemophilia A, but a lower proportion of these patients inherit severe deficiency.

The laboratory approach to diagnosis is similar to that for hemophilia A. When an isolated prolonged aPTT is present, investigation with mixing studies helps identify a factor deficiency. Measured factor IX activity is low with normal factor VIII and XI activity.

The mainstay of treatment for bleeding episodes with these patients is infusion of factor IX concentrates. The amount infused depends on (1) the severity of bleeding, (2) the site of the bleeding, and (3) the size of the patient. In susceptible individuals, infusion may induce the development of alloantibodies to factor IX. The incidence of inhibitor formation in hemophilia B is approximately 1 to 3%—much lower than that in hemophilia A. The development of inhibitors can be preceded or accompanied by an allergic or anaphylactic reaction. Bleeding episodes with a factor IX inhibitor titer less than 5 BU/mL in low responders and those that do not produce a significant anamnestic reaction are treated with factor IX concentrates. Higher inhibitor titers (≥5 BU/mL) and high responders require infusion of products that bypass factor IX (e.g., recombinant factor VIIa).

Factor XI Deficiency (Hemophilia C)

Factor XI deficiency is a rare autosomal recessive disorder with a high incidence in the Ashkenazi Jewish population. Terms for this disorder include (1) plasma thromboplastin antecedent (PTA) deficiency, (2) Rosenthal syndrome, and (3) hemophilia C. More recently, autosomal dominant forms have been described. The bleeding symptoms are heterogeneous, and, in contrast to factor VIII or IX deficiency, bleeding severity does not correlate well with plasma factor concentration. Bleeding at mucosal sites or after surgical challenges is common, so deficiency is not discovered until adulthood in some cases.

aPTT is prolonged and factor XI activity is low. Two mutations are responsible for most (88%) of the classic autosomal recessive disease in the Ashkenazi Jewish population; combinations of these mutations produce factor XI activities in the 0.01 to 0.1 IU/mL interval.[53] Mixing studies of aPTT suggest a deficiency. Inhibitors may occur after treatment with plasma and may be titered with functional inhibitor assays. Inhibitors occur frequently in patients with low factor XI concentrations when exposed to plasma as replacement therapy.[123] Plasma concentrates and recombinant products are not available.

Factor XIII Deficiency

Inherited deficiency of factor XIII is rare with an estimated prevalence of 1 to 2 per million.[3] The classic presentation of (1) umbilical stump bleeding, (2) excessive bleeding after trauma, and (3) abnormal scar formation was described in 1960.[35] Severe factor XIII deficiency is associated with recurrent spontaneous abortion.[58] Bleeding risk is expected when factor XIII activity falls below 0.03 IU/mL. Severe factor XIII deficiency is treated with fresh frozen plasma (FFP) or cryoprecipitate.

A limited number of clinical settings may warrant detection of factor XIII above 0.05 to 0.1 IU/mL. Monitoring with quantitative assays may be helpful in demonstrating recovery and in timing doses. Monitoring may also be helpful during pregnancy in women with factor XIII deficiency because a factor XIII concentration of 0.1 IU/mL has been suggested to support pregnancy.[3,58] Rarely, acquired deficiencies or inhibitors of factor XIII have been encountered that may be associated with amounts of factor XIII greater than that of classic factor XIII deficiency. Some less sensitive solubility-based screening methods may not detect these mild to moderate factor XIII deficiencies, so quantitative methods may be desirable when these clinical scenarios are evaluated. Overall experience with quantitative assays is still somewhat limited.

Acquired Disorders

Many conditions cause acquired disorders of secondary hemostasis that manifest as hemorrhage (see Table 59-7). Lupus anticoagulants are associated with thrombosis and will be discussed later. Specific factor inhibitors, except for factor XII inhibitor, cause a bleeding phenotype. Specific factor inhibitors prolong PT, aPTT, or both, depending on the targeted factor. The work-up includes demonstration of an inhibitor with mixing studies, demonstration of decreased factor, measurement of the inhibitor titer, and clinical correlation with a bleeding phenotype.

Unfractionated heparin, low molecular weight heparin, and direct thrombin inhibitors are examples of pharmacologic inhibitors that prolong PT and aPTT. Unfractionated heparin below 1.0 IU/mL does not affect many commercially available PT reagents because a heparin neutralizing substance is added. Mixing studies typically demonstrate an inhibitor. A complication of anticoagulant therapy is hemorrhage. Monitoring is required for some anticoagulants to ensure that coagulation is within a therapeutic interval. See the later section on monitoring anticoagulation therapy for a detailed discussion.

Acquired factor deficiencies usually involve deficiency of multiple coagulation factors. A notable exception is the rare association of AL amyloidosis with factor X deficiency. Vitamin K deficiency and VKA therapy (discussed earlier) decrease activities of factors II, VII, IX, and X. Disseminated

intravascular coagulation (DIC; discussed in greater detail later under "Fibrinolysis") is a pathologic disorder that consumes fibrinogen and multiple coagulation factors. Because many coagulation factors are synthesized in the hepatocytes, liver disease is associated with multiple factor deficiencies.[132] Dilutional coagulopathy in patients receiving aggressive fluid replacement or massive transfusions of cellular components without sufficient plasma replacement is another example of acquired deficiency of multiple coagulation factors. These acquired deficiencies of multiple coagulation factors can cause isolated prolongation of PT/INR or prolongation of both PT/INR and aPTT. aPTT mixing studies can be difficult to interpret in multiple factor deficiency because a 1:1 mix may not correct the aPTT to the reference interval. In these cases, clinical correlation and additional laboratory tests, including TT and measurements of D-dimer, fibrinogen, and specific factors, are often helpful.

Liver Disease

Traditionally, severe chronic liver disease was thought to be associated with impairment of secondary hemostasis resulting in a bleeding phenotype. Because procoagulants are synthesized in the liver, cirrhosis is associated with prolongation of clotting tests. A notable exception is factor VIII, an acute-phase reactant that is increased in liver disease. PT/INR and aPTT are indeed prolonged in cirrhosis, and PT/INR in particular has been used to assess bleeding risk and to guide therapy with FFP before procedures are undertaken. Unfortunately, PT/INR does not reliably predict bleeding risk in severe liver disease.

It has been suggested that bleeding risk in cirrhosis may be partially attributed to hyperfibrinolysis due to deficiencies of naturally occurring fibrinolysis inhibitors that are produced in the liver such as (1) thrombin-activatable fibrinolysis inhibitor (TAFI), (2) α_2-antiplasmin, and (3) plasminogen activator inhibitor-1 (PAI-1). Similarly, thrombotic complications in cirrhosis have been attributed to deficiencies of natural anticoagulants (e.g., protein C, protein S) or plasminogen, all of which are produced by the liver. Clotting assays do not reflect the contributions of these liver-derived molecules to in vivo hemostasis. Likewise, measurement of individual components of fibrinolysis or secondary hemostasis may not be informative in isolation. More recent models of hemostasis in severe liver disease suggest that it is the summative balance of secondary hemostasis and fibrinolysis that determines risk.[135]

Moderate to severe thrombocytopenia associated with cirrhosis also may contribute to bleeding risk. Following platelet count is an important part of assessing bleeding risk in cirrhotic patients.

INR is used in the model for end-stage liver disease (MELD) score, an index of severity of liver disease used to prioritize liver transplantation. The current INR system was designed to monitor patients on VKA therapy. As a consequence, the ISI does not harmonize INRs among laboratories for the purpose of monitoring liver disease. Interlaboratory variation in PT/INR systems contributes to variation in MELD scores. Harmonizing results with liver-specific ISIs is effective,[7,133] but currently, laboratories are poorly equipped to handle two INR systems, and commercial thromboplastins do not have an assigned ISI for liver disease.

Vitamin K Deficiency

Vitamin K deficiency may manifest with bleeding or may be identified incidentally with an isolated prolonged PT/INR or prolonged PT/INR and aPTT in a nonbleeding patient. TT and fibrinogen are normal. Measuring vitamin K–dependent factors can help confirm the diagnosis. It is helpful to measure several vitamin K–dependent factors along with at least one non–vitamin K–dependent factor for comparison. Mixing studies can potentially be useful, but multiple-factor deficiency may not correct after mixing. The utility of PT/INR mixing studies or factor assays is also limited because vitamin K deficiency is very common and may be investigated clinically by treating with vitamin K. If vitamin K therapy fails to restore the PT/INR, then mixing studies and factor assays are performed to evaluate for possible inherited deficiency or acquired inhibitor.

Without vitamin K prophylaxis, neonates are at risk for vitamin K deficiency. Neonatal risk of vitamin K deficiency is due to a combination of inadequate vitamin K intake and lack of intestinal flora—an important source of vitamin K. Bleeding from neonatal vitamin K deficiency is easily avoided by treating neonates with vitamin K, but this problem is still encountered in developing countries. Adult vitamin K deficiency may be due to drugs that affect vitamin K metabolism, inadequate intake, liver or biliary disease, or inadequate intestinal adsorption. Postsurgical patients receiving parenteral nutrition are at risk of acquired deficiency because the vitamin K stored in the liver can be depleted in a short time. Antibiotic therapy that alters the intestinal flora may lead to deficiency of vitamin K.

FIBRINOLYSIS

Fibrinolysis is a regulated mechanism for the enzymatic degradation of existing cross-linked fibrin clots (see Figure 59-4). Plasmin, a key enzyme of fibrinolysis, cleaves the insoluble, cross-linked fibrin clot into soluble fibrin degradation products (See Figure 59-16 and further description below under the heading *D-Dimer Assays*) of varying molecular weights and compositions. Fibrinolysis serves to balance the activity of coagulation. Perturbations in coagulation or fibrinolysis disrupt the balance and create risk for thrombosis or hemorrhage.

Fibrinolysis is limited to the site of injury/thrombosis by the local production of tPA by endothelial cells and by circulating inhibitors in the plasma. Fibrinolysis is downregulated by (1) PAI-1, (2) α_2-antiplasmin, and (3) thrombin activatable fibrinolysis inhibition (TAFI). PAI-1 irreversibly binds and inhibits tPA. α_2-Antiplasmin is found free in the circulating plasma or covalently bound to fibrin, through the action of factor XIIIa. α_2-Antiplasmin binds to and then cleaves plasmin, resulting in an inactivated plasmin/α_2-antiplasmin

complex. Circulating plasmin is more rapidly neutralized than fibrin-bound plasmin, further contributing to the localization of fibrinolysis.

TAFI provides a regulatory link between coagulation and fibrinolysis. In the presence of thrombomodulin, thrombin converts TAFI to TAFIa. TAFIa cleaves C-terminal lysines on fibrin at potential binding sites of plasminogen. Consequently, plasminogen is less available for plasmin generation, thus delaying fibrinolysis.[113]

Evaluation of Fibrinolytic Activity

Various tests are used to evaluate fibrinolytic activity, including (1) thrombin time, (2) fibrin(ogen) degradation product (FDP) assays, (3) D-dimer assays, (4) PAI-1 assays, (5) α_2-antiplasmin assays, and (6) plasminogen assays.

Thrombin Time

Thrombin time was discussed in detail earlier in relation to secondary hemostasis testing. However, thrombin time also is used in evaluation of fibrinolytic activity. Thrombin time may be prolonged by increased fibrin degradation products in settings of increased fibrinolysis such as disseminated intravascular coagulation and thrombolytic therapy.

FDP Assays

Under normal physiologic conditions, plasmin cleaves cross-linked fibrin into soluble fibrin degradation products of various molecular weights and compositions. If plasmin activity exceeds the capacity of antiplasmin activity in the circulation, fibrinogen may be cleaved into fibrinogen degradation products. Fibrinogen is cleaved into high molecular weight fragments, known as X and Y fragments. Further enzymatic degradation yields lower molecular weight D and E fragments.[85] Collectively, fibrin and fibrinogen products are referred to as FDP. FDP titers are determined by immunoassays, usually manual semiquantitative latex-agglutination immunoassays using monoclonal antibodies raised against FDP. Serum is tested in assays that employ antibodies that are reactive against fibrinogen; plasma or serum may be used in assays employing antibodies without fibrinogen reactivity.

When increased plasmin activity (e.g., from increased urokinase after prostate surgery) is the prevailing pathology, the process is referred to as *primary fibrin(ogen)olysis* and may be associated with bleeding. The clinical utility of FDP assays is limited because of their poor low end sensitivity compared to many current quantitative D-dimer assays.

D-Dimer Assays

D-Dimer moieties are formed specifically by the cross-linkage of D-domain subunits of fibrin strands by factor XIIIa (see Figure 59-16). D-Dimers are detected in plasma after plasmin has enzymatically cleaved cross-linked fibrin clot. Therefore, detection of D-dimer in plasma signifies cleavage of cross-linked fibrin, but not cleavage of fibrinogen, fibrin monomers, or non–cross-linked fibrin strands. D-Dimer assays are useful for the evaluation of disseminated intravascular coagulation and, if the assay has sufficient negative predictive value and diagnostic sensitivity, for the evaluation of patients in whom deep vein thrombosis or thromboembolism is suspected.

Immunoassays used to measure concentrations of D-dimer include (1) ELISA, (2) immunoturbidometric assay, (3) latex immunoassay techniques, and (4) luminescence immunoassay. Fragments of fibrin degradation containing D-dimer moieties are not uniform, and various dimer, trimer, and tetramer species of fragments occur. Also, monoclonal antibodies vary in their ability to recognize the wide variety of D-dimer species, and calibrators vary in their content of these D-dimer species. This variability has led to considerable difficulty in standardizing D-dimer assays. Therefore, rather than standardization, international efforts have focused on harmonization of D-dimer testing. Further difficulty has arisen from inconsistency in reported D-dimer units. It is imperative that both the unit type and the unit of concentration are reported correctly. D-Dimer units may be D-dimer units (D-DU) or fibrinogen equivalent units (FEU). D-DU (185 kDa) is approximately one half the weight of FEU (340 kDa). The appropriate unit type (D-DU vs. FEU) and unit of concentration (e.g., ng/mL; µg/L; etc.) are determined by the calibrator used in the assay and should be available in the package insert. Using the wrong units may result in poor interlaboratory accuracy (failed proficiency testing) and, more important, improper laboratory thresholds for excluding deep vein thrombosis (DVT) and pulmonary embolism (PE).

Quantitative D-dimer is widely used to exclude DVT and PE. Clinicians use the D-dimer concentration combined with the degree of clinical suspicion of DVT or PE (low, moderate, or high pretest probability) to decide whether diagnostic imaging is indicated. The value of the D-dimer assay for this purpose derives from its high sensitivity and negative predictive value. A D-dimer concentration below the established threshold, in a patient with low or moderate pretest probability, strongly suggests that DVT or PE is not present, and imaging studies are not pursued. Patients with high pretest probability require diagnostic imaging, and D-dimer should not be measured. Only quantitative D-dimer assays meeting criteria for negative predictive value and sensitivity, established in large clinical studies for evaluation of DVT and PE, should be used to exclude thromboembolism. The minimum performance criteria at the threshold D-dimer value for excluding thromboembolism are as follows: (1) 0.98 negative predictive value with the one-sided lower confidence interval at 0.95, and (2) 0.98 sensitivity with the one-sided lower confidence interval at 0.90. In most instances, laboratories cannot establish their own threshold values and must rely on clinical studies performed by manufacturers of commercial D-dimer kits. Semiquantitative tests by latex agglutination generally lack sensitivity and are inappropriate for evaluation of thromboembolism.

Plasminogen Activator Inhibitor Type 1 Assays

PAI-1 deficiency has been reported as a congenital defect but may be acquired as well. Congenital PAI-1 deficiency is associated with bleeding risk, but experience is limited and the

prevalence is unknown. High concentrations of PAI-1 have been associated with risk of arterial thrombosis. PAI-1 assays are not widely performed in clinical laboratories but may be useful after common causes of bleeding have been conclusively ruled out. As with other enzymes of coagulation and fibrinolysis, qualitative and quantitative defects of PAI-1 have been reported, and a functional assay for screening purposes is desirable.

A specific chromogenic substrate for plasmin simplifies functional assays for PAI-1, plasminogen, and α_2-antiplasmin. A general scheme for PAI-1 functional assays is to add a known amount of plasminogen activator (tPA or urokinase) to citrated patient plasma, followed by excess plasminogen. Plasmin activity is measured by its cleavage of a chromogenic substrate. Residual plasmin activity is inversely proportional to the PAI-1 of the subject plasma. Inhibitors of α_2-antiplasmin and other plasmin inhibitors are added to prevent interference.[27]

PAI-1 activity assays were developed to detect increased PAI-1, and the available assays do not perform acceptably at low concentrations. Zero activity has been included in the reference interval with this strategy. Agren and associates[1] modified a PAI-1 activity assay by adding calibration points to the low end of the calibration curve. The same group has suggested that the reference cutoff for PAI-1 activity for this method is around 1U/mL.

PAI-1 deficiency is an important consideration in patients with convincing bleeding histories because antifibrinolytic therapies may be beneficial. PAI-1 deficiency is a difficult diagnosis to make and requires exclusion of more common hemorrhagic diatheses before it is entertained. Data on PAI-1 are difficult to interpret because of their diurnal variation and their elevation as an acute-phase reactant. PAI-1 activity may be combined with PAI-1 antigen assays to assist interpretation of results. Strict clinical correlation and sometimes studies of family members are needed to make a diagnosis.

α_2-Antiplasmin

Congenital α_2-antiplasmin deficiency is a rare disorder associated with bleeding. Bleeding symptoms may be delayed, reminiscent of other deficiencies affecting clot stability, such as factor XIII deficiency or PAI-1 deficiency. Acquired deficiencies also occur with liver disease. Similar to other rare disorders of fibrinolysis, careful clinical and laboratory exclusion of more common bleeding disorders is required before a diagnosis of α_2-antiplasmin deficiency is pursued. Quantitative and qualitative types of α_2-antiplasmin deficiency have been reported.[20]

For functional α_2-antiplasmin assays, excess plasmin is added to citrated patient plasma. α_2-Antiplasmin from the patient sample will form inactive plasmin-antiplasmin complexes. Residual plasmin activity is measured by the addition of a chromogenic substrate. Residual plasmin is inversely proportional to antiplasmin in the patient plasma. A calibration curve relates the absorbance change due to plasmin activity to α_2-antiplasmin activity of the test plasma. Antigen assays may be considered in individuals with decreased functional activity to substantiate findings or to define qualitative deficiency.

Plasminogen Assay

Plasminogen deficiency is a rare congenital disorder. Originally, plasminogen deficiency was reported to be associated with thrombosis, but other reports challenge its importance as an independent risk factor. More important, severe congenital plasminogen deficiency can result in the unusual clinical finding of fibrin pseudomembranes at various mucosal surfaces. The most common site of pseudomembrane deposition is the eye, referred to as *ligneous conjunctivitis.* Quantitative and qualitative deficiencies have been identified, but pseudomembrane deposition is thought to be associated with quantitative deficiencies. Acquired plasminogen deficiency (e.g., in liver disease) may occur, but the clinical importance is not clear.[91]

Excess tissue plasminogen activator is added to citrated patient plasma. Plasmin activity is then measured chromogenically, and the plasminogen is extrapolated from a calibration curve. Antigenic assays are also available.

Clinical Use of Laboratory Tests for Disorders of Fibrinolysis—Disseminated Intravascular Coagulation

Overt disseminated intravascular coagulation (DIC) is an excessive uncontrolled thrombin generation and fibrinolysis, exceeding the regulatory capacity of the endothelium and plasma inhibitors. Fibrin thrombi are formed in the microvasculature, trapping platelets and shearing red blood cells (RBCs) into schistocytes as they pass through the fibrin strands. Ultimately DIC consumes (1) coagulation factors, (2) inhibitors, (3) platelets, and (4) RBCs. Clinically, patients with DIC present with bleeding and thrombosis, although thrombosis may not be as readily apparent because these clots primarily occur in the microvasculature. Ecchymosis, petechiae, and oozing from intravenous access sites or surgical incisions are frequent hemorrhagic presentations. In addition, occlusion of small vessels leads to end-organ damage. DIC is not a disease, but rather a manifestation of a wide variety of possible underlying disorders (Table 59-10). The clinical diagnosis begins with recognizing the thrombohemorrhagic picture, which should then trigger a search for the underlying disease process. Compensated DIC, or nonovert DIC, may precede overt DIC or may occur in isolation. In nonovert DIC, the regulatory mechanisms are not completely overwhelmed, and consumption of RBCs, platelets, and hemostatic factors is not complete. Nonovert DIC can also occur in chronic clinical conditions such as cancer, often with predominantly prothrombotic manifestations. Treatment is supportive and relies on clinical management of the underlying cause.

Stereotypical laboratory data for overt DIC include (1) prolonged clotting times (aPTT, PT, and TT), (2) low fibrinogen, (3) elevated FDP, (4) elevated D-dimer, (5) thrombocytopenia, and (6) anemia, often with schistocytes on a peripheral smear. Clotting times may be prolonged because

TABLE 59-10 International Society of Thrombosis and Hemostasis Criteria for Diagnosis of Overt Disseminated Intravascular Coagulation (DIC)

Clinical Conditions Associated With DIC	Diagnostic Algorithm for the Diagnosis of Overt DIC
Sepsis/severe infection Trauma/burns/surgery Organ destruction Malignancy Obstetric calamities Vascular abnormalities Severe hepatic failure Severe toxic or immunologic reactions	1. Risk assessment: Does the patient have an underlying disorder known to be associated with overt DIC (from column to left)? If yes: Proceed to 2. If no: Do not use this algorithm. 2. Order global coagulation tests (PLT count, PT, fibrinogen, soluble fibrin monomers or fibrin degradation products). 3. Score global coagulation test results. PLT count (>100 = 0; <100 = 1; <50 = 2) Elevated fibrin-related marker (e.g., FDP, D-dimer) (no increase = 0; moderate increase = 2; strong increase = 3) Prolonged PT (<3 s = 0; >3 s but <6 s = 1; >6 s = 2) Fibrinogen level (>1 g/L = 0; <1 g/L = 1) 4. Calculate score. 5. If ≥5: Compatible with overt DIC; repeat score daily. If <5: Suggestive (not affirmative) for nonovert DIC; repeat score next 1 to 2 days.

Modified after Taylor FB Jr, Toh CH, Hoots WK, Wada H, Levi M. Towards definition, clinical and laboratory criteria, and a scoring system for disseminated intravascular coagulation. Thromb Haemost 2001;86:1327-30.

of hypofibrinogenemia, interference from FDPs, or consumption of coagulation factors. Prolongation of clotting assays, however, is not always present in DIC because circulating activated factors partially degrade fibrinogen and shorten clotting times. Fibrinogen concentrations may be low from consumption but are not low in every case. Likewise, platelet count varies significantly in DIC patients, and schistocytes are not always present. Nonetheless, clotting assays, fibrinogen assays, platelet counts, and reviews of peripheral smears are important tests for evaluating DIC.

The International Society on Thrombosis and Haemostasis (ISTH) has published a scoring system for the diagnosis of overt DIC (see Table 59-10).[130] This scoring system subsequently was prospectively validated. The ISTH has also provided an approach to nonovert DIC. The diagnosis of nonovert DIC is more difficult, relying on the daily trend of laboratory test results, not on a single set of laboratory data.

THROMBOSIS

Thrombosis is defined as "the formation or presence of a blood clot in a blood vessel." The vessel may be any vein or artery as, for example, in deep vein thrombosis or coronary (artery) thrombosis. The clot itself is termed a *thrombus.* If the clot breaks loose and travels through the bloodstream, it is a thromboembolism (http://www.medterms.com).

Regulation

Fibrin generation is controlled by several mechanisms involving a number of different inhibitors and pathways, including (1) control over the initiation phase, whereby tissue factor/factor VII (TF/FVII) drives the generation of factor Xa; (2) inhibition of several activated clotting factors principally by antithrombin; and (3) control of cofactor functions of factors V and VIII through the protein C pathway.

Initiation of coagulation is controlled by tissue factor pathway inhibitor (TFPI), which inhibits factor Xa and also the TF-FVIIa-phospholipid complex in a two-step process. First, TFPI binds to factor Xa, whose action is then inhibited. The TFPI-Xa complex then binds to TF/VIIa through a different part of the TFPI molecule. Both factor Xa and factor VIIa are inactive in this quaternary complex. TFPI therefore shuts down the initiation stage, and only if sufficient activation of factor X overcomes this inhibition does the process of coagulation proceed. About 80% of TFPI is associated with the endothethial cell membranes and is not normally available in plasma for measurement in laboratory assays. The remainder circulates in plasma, but about ¾ of plasma TFPI is bound to low-density lipoproteins, and perhaps half of the free TFPI is inactive. Protein S facilitates the effect of TFPI by enhancing the formation of the TFPI-FXa complex.[51] This anticoagulant effect of protein S is a more recent discovery than the identification of protein S as an anticoagulant component of the protein C pathway (see later). Determination of TFPI in plasma does not currently have a role beyond continuing research, and available assays are probably too crude in view of the complex relationships involved, although genetic knockout of the gene *TFPI* (which codes for TFPI) in mice is lethal, so this is undoubtedly a physiologically important protein.

As was discussed earlier, when coagulation is initiated, various enzyme reactions (nearly all serine proteases) lead to

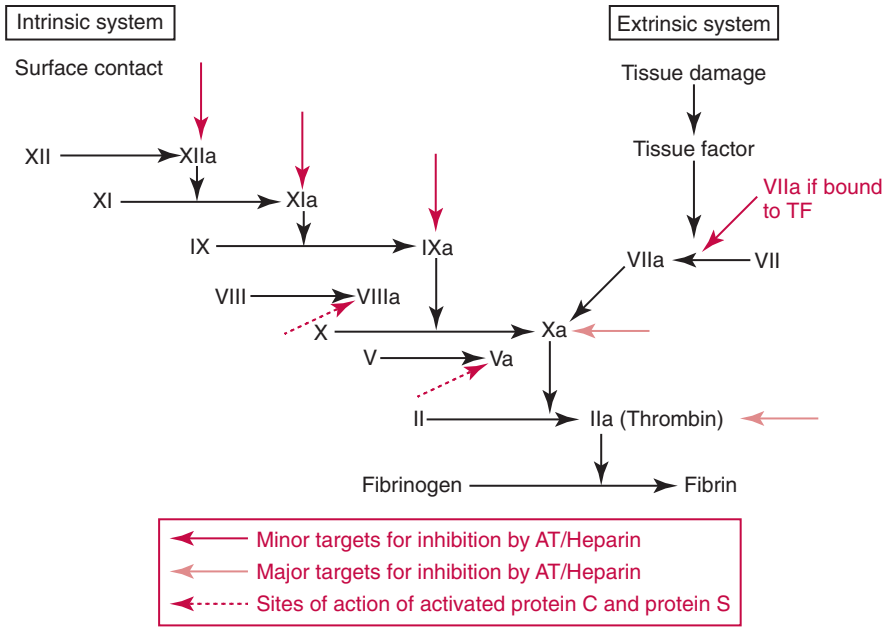

Figure 59-17 Points at Which Natural Inhibitors Affect the Coagulation Cascade. AT inhibits the activity of serine proteases. The primary effect is inhibition of factor Xa and thrombin (IIa); however, other factors are also inhibited, including plasmin *(not shown)*. Factor XIII is not a serine protease; it is a transglutaminase and is not inhibited by AT. Protein C and protein S inhibit coagulation through cleavage of the activated forms of factors V and VIII.

a cascading activation of coagulation factors to generate thrombin. These are subject to control by the serine protease inhibitors collectively termed *serpins,* the most important of which is AT. Activated clotting factors inhibited by AT are shown in Figure 59-17. Serpins, including AT, first bind to their target and form a final covalent complex, whereby the protease is irreversibly trapped in an inactive state. AT predominantly inhibits thrombin, factor Xa, and factor IXa, but it also inhibits other coagulation proteases. The anticoagulant action of AT is dependent on its cofactor, heparin. In vivo, several types of heparin-like glycosaminoglycans function as cofactors for AT; these include heparan sulfate on the endothelial cell surface. It is the interaction with AT and this heparan sulfate that localizes the activity of AT to the vessel wall. When the vessel wall is lost or damaged, this reaction does not occur, allowing thrombin to accelerate coagulation unchecked. Thrombin that is bound to fibrin in the clot is protected from inhibition by AT, which is synthesized in the liver and circulates with a half-life of approximately 3 days. A second serpin, whose action is enhanced by the presence of heparan or dermatan sulfate, is named heparin cofactor II (HC II). In contrast to AT, HC II inhibits thrombin whether clot bound or not. It has no action against other coagulation serine proteases. About a quarter of thrombin inhibition occurs via HC II. AT deficiency is highly associated with thrombophilia, but HC II deficiency is not. The primary function of HC II may relate to the role of thrombin outside of hemostasis. For a review of AT and HC II, see Rau and colleagues.[110]

The critical complexes that lead to generation of factor Xa and of thrombin have several features in common. Both are formed by calcium-mediated assembly of clotting factor complexes on the surface of phospholipid. Both complexes require a cofactor for reaction rates to be sufficiently enhanced for enzyme generation to overcome the control mechanisms ranged against them. Factor VIII after its conversion to factor VIIIa is the cofactor that facilitates activation of factor X; factor V after conversion to factor Va performs a similar function, leading to the formation of thrombin. Both factor Va and factor VIIIa are regulated by the protein C pathway (see Figure 59-1).

Protein C is a vitamin K–dependent protein produced in the liver. Activation of PC to activated protein C (aPC) is driven by thrombin in complex with thrombomodulin, a protein located in the endothelial cell surface. This process is mediated through PC binding to an endothelial cell PC receptor (EPCR) that presents PC to the thrombin-thrombomodulin complex. When thrombin is complexed with thrombomodulin, it loses its normal procoagulant functions and takes on an anticoagulant role via activation of PC, because aPC then inactivates factor Va and factor VIIIa through proteolytic degradation in the presence of calcium, phospholipid, and its cofactor protein S. Similar to protein C, protein S is a vitamin K–dependent factor. It is produced in the liver, endothelial cells, and megakaryocytes. Approximately 60 to 70% of plasma protein S is bound to C4b binding protein (C4bBP) and has no significant role in hemostasis. The remainder is termed free protein S and functions as a cofactor for the

degradation of factor Va and factor VIIIa by aPC. For a review of the protein C pathway, see Castellino and Ploplis.[22]

Tests for the Evaluation of Natural Anticoagulants

Anticoagulants are substances that prevent coagulation. Various pharmaceuticals are used in vivo as medication for thrombotic disorders. They include intravenous heparin and oral anticoagulants such as warfarin and dicumarol. Assays used to measure anticoagulants include (1) activated protein C resistance, (2) factor V Leiden mutation detection, (3) protein C, (4) protein S, and (5) antithrombin assays.

Activated Protein C Resistance Assays

Addition of activated protein C (aPC) to plasma leads to an anticoagulant effect, because aPC degrades the activated forms of factor V (FVa) and factor VIII (FVIIIa), thus slowing the clotting process. Activated protein C resistance (aPCR), which was first described by Dahlback and coworkers,[29] is defined as impairment of this anticoagulant response to aPC. These authors reported that aPCR was associated with a predisposition to thrombosis. Activated protein C cleaves factor Va, and a vast majority of patients with familial aPCR have a point mutation at the cleavage site.[9] This abnormal factor V protein, in which the arginine at position 506 is replaced with a glutamine (Arg506Gln or R506Q), has been named factor V Leiden (FVL).[9]

The first assay established for determination of aPCR measured aPTT with and without purified human aPC in the calcium chloride reagent. The aPTT with aPC is divided by the baseline aPTT and the quotient is called the aPCR ratio. A low ratio indicates the presence of aPCR. A number of tests are now available to detect the abnormal phenotype or the presence of the genetic defect.

Because phenotypic aPCR tests may be influenced by in vitro platelet activation and platelet contamination, plasma should be double-centrifuged at 2000 ×g for 15 minutes to reduce the residual platelet count to a minimum. Other factors that affect the test include reduced concentrations of clotting factor II or factor X (decreased ratio) and increased quantities of factor VIII (increased ratio). The presence of lupus anticoagulant (LAC) has been known to increase aPCR. The original aPCR test[115] should not be used during VKA anticoagulant therapy and is unreliable if the patient has a prolonged PT/INR or aPTT for other reasons. Increased aPCR has been observed to occur in the absence of FVL and has been reported to increase the risk of thrombosis.[33] The original test detects both FVL- and non–FVL-related causes of aPCR, but many centers use a modified version that is more sensitive and more specific for the presence of FVL. This involves the dilution of patient plasma in factor V–depleted plasma. A normal result in this modified aPCR test result excludes the presence of FVL and is not affected by clotting factor concentrations.

Good separations of aPCR results are often noted in (1) normal subjects, (2) patients with heterozygous deficiency of FVL, and (3) homozygous individuals. Thus, a very low aPCR test (with or without plasma dilution in factor V–depleted plasma) result may be suggestive of homozygous FVL. Although rarely observed, this may be due to compound heterozygosity for FVL and factor V deficiency. In these cases, only FVL is present in plasma, and such patients are described as pseudohomozygous for FVL. Misdiagnosis of homozygous FVL could have serious consequences in terms of genetic counseling, so suspicion of FVL based on phenotypic tests is best confirmed by genetic analysis.

Several so-called global screening tests are variations of the original aPCR test and may detect deficiencies of protein C and protein S, as well as aPCR and FVL. Several of these tests utilize a protein C activator from the venom of the Southern Copperhead viper *(Agkistrodon contortrix contortrix)*. The venom contains an enzyme that converts protein C to aPC in the sample. The aPC, catalyzed by protein S, greatly prolongs the clotting time, unless aPCR and FVL are present. Results of currently available global screening tests may be normal in the presence of mild deficiency of protein C and protein S[48]; thus, a normal result cannot be used to exclude a deficiency of these factors.

Factor V Leiden Mutation Detection

FVL is the most common cause of inherited thrombophilia in many countries in Western Europe and in North America, and some variability among different populations has been noted. Heterozygous FVL has a prevalence of around 3% in Caucasians but is more prevalent still in the area of Sweden where the defect was first identified. It is practically absent from some Eastern populations and the black populations of Africa.

FVL was originally detected using amplification of *F5* gene DNA by use of the polymerase chain reaction, where DNA fragments were amplified before digestion with a restriction enzyme.[9] Such assays using restriction enzyme digestion of DNA are labor-intensive compared with other methods and may include hazardous components. Alternative methods include the allele-refractory mutation system (ARMS) and real-time polymerase chain reaction with melting analysis of the products. Details of molecular methods are found in Section IV of this book, "Molecular Diagnostics and Genetics."

External quality assurance is available for FVL and prothrombin G20210A analysis with an error rate of 3 to 6% among approximately 50 centers performing such tests.[108] Errors identified include sample mismatching, equipment malfunction, and transcription errors. Similar results have been reported in other programs. Genetic tests are generally considered to be definitive, and mistakes are serious errors. It is prudent to confirm FVL homozygous genotypes on a separate sample.

Protein C Assays

Heritable protein C deficiency has a prevalence of about 1 in 700 in the general population and of 2 to 4% in selected subjects with a personal history of venous thrombosis. Protein C deficiency is associated with a fivefold to 10-fold increased

risk of venous thromboembolism, although some kindreds appear to have no such increased risk. Combined defects with coinheritance of protein C deficiency and FVL markedly increase thrombotic risk, beyond that caused by inheritance of either defect alone.[72]

Protein C concentration is very low in the newborn. Protein C concentrations may only reach adult values at 16 years of age, with further increases occurring up until about 30 years of age.[129] Protein C concentrations may be reduced in patients with (1) liver disease and (2) vitamin K deficiency, and (3) by vitamin K antagonists such as warfarin. In vitamin K deficiency, the protein C assay result depends on the measurement system. When a low concentration of protein C is detected, physiologic, clinical, and pharmacologic causes should be excluded. PT/INR should be performed as an indication of normal liver function. Not all cases with genetic defects of protein C have reduced activity by protein C assay. Some carriers have protein C concentrations within the normal reference interval.

On initiation of warfarin therapy, protein C concentrations fall with a half-life of around 4 to 6 hours, similar to factor VII, but much shorter than other vitamin K–dependent clotting factors such as IX, X, and II. It should be noted that it is not possible to diagnose protein C deficiency in subjects who are in the induction phase of warfarin therapy and testing is not recommended in patients on stable VKA therapy.

Clotting, chromogenic, and antigenic assays are available for measuring protein C concentrations. Clotting-based protein C assays require the addition of test sample to protein C–depleted plasma, then Southern Copperhead viper activator converts protein C to aPC, which prolongs clotting time through destruction of factors Va and VIIIa. The clotting end point is based on aPTT, PT/INR, or the addition of snake vemons. Assays based on aPTT may be influenced by the phospholipid composition of the reagent and by the concentration of factor VIII.

Protein C assays based on aPTT may underestimate protein C in samples with high concentrations of factor VIII. The presence of FVL, particularly homozygous FVL, may falsely reduce concentrations of protein C reported by clotting-based assays because FVL is resistant to destruction by aPC, and clotting time does not fully reflect aPC activity. Predilution of patient plasma in protein C–depleted plasma may reduce or remove the influence of FVL.[61] Protein C can be overestimated through the anticoagulant influence of LAC. The advantage of clotting-based assays is that they may detect rare heritable functional defects that remain undetected by other techniques.

Chromogenic assays of protein C generally utilize Southern Copperhead viper activator conversion of protein C to aPC. However, currently available chromogenic substrates for protein C measurement lack complete specificity and are cleaved by a variety of proteases. Partially clotted samples and serum may give falsely high chromogenic protein C activity results because of background protease activity. Some Southern Copperhead viper activator-based chromogenic assays are unable to detect all patients with type II protein C deficiency, where there is disparity between antigen and functional activity.

Protein C antigen is now typically determined by ELISA-based assays, which are relatively precise and very sensitive to low concentrations of protein C. These have been used to differentiate type I and II deficiency. About ¾ of patients recorded as having protein C deficiency have type I deficiency (low antigen and function), with most of the rest having type II deficiency which is characterized by normal concentrations of protein but low protein C as measured by both clotting and chromogenic assays.

Protein S

Protein S is a glycoprotein whose amino acid sequence is coded by the *PROS1* gene. Deficiency of protein S is associated with a fivefold increased risk of venous thrombosis, and the combination of the FV Leiden mutation and the protein S deficiency is associated with a high risk for thrombosis.[73] The incidence of familial protein S deficiency is around 1 in 700 to 1 in 3000 of the general population in the United Kingdom.[37]

Heritable protein S deficiency is classified as type I, II, or III. Type I is defined by reduced concentrations of total protein S antigen (total PS) and free protein S antigen (free PS) and reduced protein S activity. Type II deficiency is characterized by isolated deficiency of protein S activity. Type III deficiency displays normal concentrations of total PS, but a reduced concentration of free PS and reduced activity of PS. Type III protein S deficiency, however, may not be a separate disorder because it has occurred with some of the same gene mutations that cause type I deficiency in other family members. Protein S concentrations are lower in women than in men and may be further decreased by certain oral contraceptives; its quantities are particularly low in the newborn. Gender-specific reference intervals are therefore useful. Low total protein S with normal concentrations of free protein S occur in patients with low concentrations of C4bBP. Pregnancy, acute phase reactions, oral contraceptives, and hormone replacement therapy may reduce concentrations of total protein S, but not free protein S. Again similar to protein C, protein S concentrations are reduced in (1) liver disease, (2) vitamin K deficiency, and (3) VKA therapy. Testing of patients while they are anticoagulated is problematic. Measurement of total protein S antigen probably is not helpful in most cases, and an assay that measures the concentration of free protein S is preferred. In normal subjects, the free protein S antigen concentration reflects the functional protein S activity in plasma. Free protein S has been measured by ELISA but is increasingly measured using latex-based assays in automated analyzers. Many of these methods have removed the need to first separate free PS from that bound to C4bBP, usually by precipitation of bound PS using polyethylene glycol. Measurement of free PS has been shown to be better at detecting protein S deficiency in subjects with *PROS1* gene defects than measurement of total protein S.[83]

Functional assays of protein S are based on the ability of protein S to act as cofactor in aPC-mediated destruction of activated V and/or VIII. This anticoagulant activity may be detected through PT, aPTT, or venom-based clotting time. Functional assays of protein S may be sensitive to type II defects, which are missed by antigenic assay. However, problems arise when many functional assays are used. Some patients were incorrectly diagnosed as having type II protein S deficiency when aPC resistance resulted in underestimation of protein S by functional assay.[41] Results obtained in proficiency testing surveys indicate that even in normal subjects, activity results determined using different assays are not interchangeable. As with protein C, protein S can be overestimated through the additive anticoagulant influence of LAC. Consequently, many laboratories currently avoid use of functional assays because of these problems.

Antithrombin Assays

Antithrombin deficiency may be inherited as the result of a molecular defect, but it may also be acquired (1) through decreased production (e.g., liver disease), (2) through increased turnover (e.g., consumption, heparin therapy), or (3) by renal loss in nephrotic syndrome. The in vivo half-life of plasma antithrombin is around 65 hours, although it may be shorter for antithrombin infused as replacement therapy.

Two main categories of antithrombin deficiency are known: type I, which is characterized by parallel reduction in activity and antigen concentration, and type II, in which activity and antigen concentration are discordant. Three types of qualitative functional defects have been identified, including (1) those in the heparin-binding site (HBS), (2) those in the reactive site, and (3) pleiotropic/multiple effects. Heritable antithrombin deficiency has a prevalence of around 1 in 3000 of the population and is associated with a 10- to 50-fold increased risk of venous thrombosis. Not all defects are equally thrombotic, and individuals with heterozygous HBS defects may have no increased risk.

Because antigen concentrations are normal in many type 2 defects, a functional antithrombin assay is essential. Most experts prefer an assay sensitive to all type II defects. The reference interval for antithrombin concentration is narrow, and accurate assays are required to distinguish normal from abnormal. Suitable chromogenic assays are available based on the ability of the sample to inhibit generation of color by the action of either thrombin or factor Xa (in the reagent) on a chromogenic substrate specific for the protease (thrombin or Xa).

Antithrombin variants may react poorly with one enzyme (thrombin or Xa) and normally with another; this pattern may vary in the presence and absence of heparin. Heparin cofactor II, whose activity is enhanced by heparin, is an additional protein that neutralizes human thrombin. The presence of heparin cofactor II in plasma may reduce the specificity of antithrombin assays, particularly those utilizing human thrombin, where there is an assay incubation time with thrombin of longer than 30 seconds.[131] This problem is partially solved by using bovine thrombin or factor Xa. Thrombin-based antithrombin assays should not be used in patients receiving direct thrombin inhibitors when concentrations can be substantially overestimated.

Results obtained with different assays vary, so that in some defects normal results occur in one assay type, whereas activity is low in another. Many variant AT defects have been described when these problems occur, so results should be interpreted only with knowledge about the assay characteristics.

Chromogenic substrate assays are preferred for measurement of antithrombin concentration. These generally involve the incubation of enzyme (thrombin or factor Xa) with diluted plasma in the presence of heparin before a chromogenic substrate is added; para-nitroaniline (pNA) release from the substrate is monitored at 405 nm. Antithrombin inhibits the enzyme, and the decrease in absorbance at 405 nm with sample compared with no sample is proportional to the antithrombin concentration. Precision varies among different assays. For example, bovine-thrombin–based assays typically show a CV of approximately 1.5%, whereas factor Xa–based assays tend to have a CV of about 2.5%. The determination of the reference interval (to include the 2.5 to 97.5 percentile) for antithrombin should use non-parametric methods because the distribution of results is not Gaussian. Factors such as (1) age, (2) sex, (3) oral contraceptive use, and (4) circadian rhythm influence antithrombin concentrations to varying degrees. However, for practical purposes, it is acceptable to use a single (adult) reference interval that includes similar numbers of men and women. Antithrombin concentrations are low in neonates. Antithrombin is consumed during clotting, and artificially low concentrations are found in clotted samples, whereas genuinely low concentrations may occur as a consequence of recent massive thrombosis. Because liver disease and heparin therapy will reduce AT concentrations, a PT/INR should be performed on specimens with low antithrombin concentration to assess whether the sample is clotted or the patient has liver disease.

When a congenital deficiency is suspected, antithrombin antigen is measured to differentiate type I from type II antithrombin deficiency. Antithrombin antigen is measured by immunoassays such as ELISA, immunoelectrophoresis (IEP), radial immunodiffusion (RID), and immunoturbidometry (ITB). Genetic analysis is useful to identify the defect at a molecular level because different defects are associated with different thrombotic risk.

Evaluating Excess Procoagulants

Many substances are precursors of the various blood factors that promote coagulation of blood. They are known as procoagulants and include substances such as (1) prothrombin 20210, (2) factor VIII and von Willebrand factor, (3) fibrinogen, and (4) factor XIII.

Prothrombin *G20210A* Detection

The prothrombin *G20210A* mutation is a genetic defect that leads to an increase in the concentration of factor II in plasma and confers an increased risk of venous thrombosis.

This defect *(PT G20210A)* occurs in around 2 to 3% of Caucasians and leads to a twofold to threefold increased risk of venous thromboembolism (VTE).[107] Increased prothrombin concentration alone will not reliably identify carriers of the genetic defect. Details of molecular methods are found in Section IV of this book, "Molecular Diagnostics and Genetics."

Factor VIII and von Willebrand Factor

It has been reported that elevated activity of factor VIII is an independent risk factor for venous thrombosis.[75] For example, elevated activities of factor VIII are found in approximately 20% of subjects with VTE. The elevation is independent of the acute-phase response (which causes transient but marked increases in factor VIII). The risk increases as factor VIII rises above 150 IU/dL, with an eightfold increase in risk above 270 IU/dL. Elevated activities of factor VIII, however, do occur in a number of other situations, and activities above 150 IU/dL are found in 10 to 30% of apparently healthy subjects. For this reason, many laboratories do not routinely include factor VIII determination in the standard panel of tests used to investigate patients for heritable thrombophilia; it is not recommended in some countries, such as the United Kingdom.[4]

It has been reported that risk of VTE is increased as the activity of von Willebrand factor is increased.[96] One function of VWF is to transport factor VIII in plasma, forming a relationship between the two molecules. Higher quantities of VWF lead to greater quantities of factor VIII, and when multivariate analysis is performed, factor VIII is shown to be an independent risk factor, whereas VWF is not; increased risk of thrombosis is a consequence of the increased quantities of factor VIII.[75]

Fibrinogen

Numerous studies have shown that the concentration of fibrinogen is associated with risk of coronary heart disease and stroke, and a meta-analysis of 31 such studies has confirmed this.[30] It remains unclear, however, whether higher fibrinogen causes coronary heart disease, and no consensus has been reached on whether measurement of the concentration of fibrinogen is clinically useful for assessing risk in individual patients. Currently it seems likely that the independent effect of fibrinogen is small. At present most experts would suggest that it is not cost-effective to consider population-wide screening of fibrinogen concentrations.

Factor XIII

As discussed earlier, factor XIII is a tetrameric transglutaminase consisting of two A subunits, which form the active site, and two B subunits, which protect the A subunits from degradation. Once activated by thrombin to factor XIIIa, the A subunits dissociate from the B subunits in the presence of calcium, revealing the active site. Factor XIIIa then covalently cross-links fibrin to produce a clot with high mechanical strength and increased resistance to fibrinolysis. There is a molecular defect of factor XIII in which a G-to-T transition leads to a leucine in place of a valine at amino acid 34.[128,140] This factor XIII *Val34Leu* variant behaves differently than wild-type factor XIII and is activated two to three times more quickly. The resulting clot has a different structure from that which occurs in the presence of wild-type factor XIIIa. A meta-analysis of 12 studies (which included more than 3000 objectively diagnosed VTE cases) has confirmed that the presence of this factor XIII Leu allele confers a small but significant protective effect against VTE (about a 15% reduction in risk among heterozygotes).[140] More studies related to arterial thrombosis are available, and a meta-analysis of more than 200 publications has confirmed that the risk of acute myocardial infarction is reduced by about 20% in patients heterozygous for this defect.[128]

Monitoring Anticoagulant Therapy

Several guidelines are available from the American College of Chest Physicians on the monitoring of anticoagulant therapy. They address anticoagulants such as (1) argatroban, (2) bivalirudin, (3) fondaparinux, (4) hirudin, (5) low molecular weight heparin, (6) unfractionated heparin,[55,56] and (7) vitamin K antagonists.[2] Details of several of these substances are discussed in the following sections.

Unfractionated Heparin

Heparin is a highly sulfated polysaccharide used as an anticoagulant for the treatment and prevention of thromboembolic disease. For many years, clinical preparations were unfractionated, containing mixtures of polysaccharide chains of different lengths. Such unfractionated materials typically have average molecular weights of 12,000 to 15,000 Da.

The anticoagulant effect of unfractionated heparin (UFH) is exerted after binding to a cofactor, AT, referred to in the older literature as antithrombin III. After binding to heparin, the AT undergoes a conformational change, facilitating very rapid inactivation of thrombin and several other activated clotting factors, which, like thrombin, have serine in their active site (so-called serine proteases). These include factor Xa, factor IXa, factor XIa, and factor XIIa. The number of saccharide units in the polysaccharide chain of heparin influences these reactions. At least 5 saccharide units are required for some anticoagulant activity. Polymers measuring less than 5 saccharide units in length have no anticoagulant activity. For inhibition of thrombin, heparin chains must bind to both AT and thrombin and thus need to be 18 or more units in length. Simultaneous binding is not required for neutralization of factor Xa, and chains between 5 and 17 units long catalyze neutralization of Xa without affecting thrombin directly. So-called low molecular weight heparins (LMWHs), containing a more uniform population of these shorter polysaccharides, are manufactured from UFH by controlled depolymerization. LMWH is discussed later. Laboratory monitoring of treatment doses of UFH therapy is compulsory because the dose needed for protection from thrombosis varies between subjects, and overdose is associated with hemorrhagic risk.

aPTT for Monitoring UFH

The most widely used test for monitoring UFH is the aPTT (discussed above). In an early study, it was demonstrated that the risk of VTE was reduced when the aPTT ratio (patient/control value) was greater than 1.5, and a therapeutic reference interval of 1.5 to 2.5 was suggested.[6] However, several subsequent studies have shown marked differences among aPTT reagents and methods in terms of heparin responsiveness.[18] Thus, a specific reference interval of 1.5 to 2.5 is not appropriate for all reagents. For each aPTT method, it is necessary to establish a therapeutic reference interval by measurement of aPTT and heparin concentration by protamine titration or anti-Xa assay. For example, for the early studies,[6] an aPTT reference interval of 1.5 to 2.5 was found to be equivalent to 0.2 to 0.4 International Units (IU) of heparin/mL by protamine titration assay or 0.3 to 0.7 IU/mL by anti-Xa assay.[55] (Note that IU of heparin are completely distinct from the saccharide units that make up the molecules of heparin. The IU are based on anticlotting activity, whereas the saccharide units are structures.) Titration or heparin assay, regression analysis is used to calculate the reference intervals of aPTT ratios equivalent to the above heparin concentrations.[18] This should not be done using plasmas spiked with heparin in vitro because the reference interval established may be different from that determined using ex vivo samples. (*Note:* Such a reference interval should be established using between 30 and 60 such samples, although some have suggested that several hundred specimens may be needed.)

If the aPTT ratio is used, it should be calculated using the midpoint of the normal reference interval as the denominator. It should be noted that there is a poor correlation between aPTT and heparin concentration, possibly reflecting the poor specificity of aPTT for heparin effect. The aPTT is influenced by the concentrations of other clotting factors, including those affected (1) by warfarin (see later) or (2) by factor XII, or (3) especially by the quantity of factor VIII, which will change dramatically as a patient with acute thrombosis recovers, that is, as the acute-phase response changes. Because of variability in the process, the therapeutic reference interval should be checked for all new lot numbers of aPTT reagent. In practice, laboratories often sequester large amounts of a single reagent lot to avoid the labor-intensive process of calibrating the aPTT assay for new lots. Preanalytical variables dramatically affect the results of aPTT in samples containing UFH. For example, when citrate is used as anticoagulant, platelets in the blood sample are activated, leading to release of a granule constituent, platelet factor 4, which neutralizes heparin. The aPTT therefore decreases over time by perhaps 30% within 4 to 5 hours, depending on the reagent. Therefore, citrate samples should be analyzed within 2 to 3 hours to minimize this problem. The problem with citrated samples is particularly marked if a blood sample has a large air space within the tube, with much more rapid and marked loss of heparin.[112] The problem is avoided if blood samples are collected into an anticoagulant cocktail comprising citrate, theophylline, adenosine, and dipyridamole (CTAD) that is commercially available and that inhibits platelets, thereby avoiding this problem. Such samples are stable with respect to aPTT for much longer than 4 hours.

If UFH is given by intravenous infusion or by subcutaneous injection, the sample should be collected 4 to 6 hours after initiation of therapy or after any dose adjustment, to allow steady state to be reached.

On various occasions, the aPTT is inappropriate for monitoring UFH because of lack of specificity. Thus, the aPTT may be within the therapeutic reference interval despite suboptimal heparin concentrations because of (1) the presence of lupus anticoagulant (LA); (2) combined UFH and VKA; (3) combined UFH and thrombolytic therapy; and (4) congenital or acquired factor deficiency. The effect of UFH is rapidly reversed by infusion of protamine sulfate.

Heparin Assays for Monitoring UFH

Historically, a heparin assay based on protamine titration was used in North America to establish the therapeutic reference interval for UFH therapy (see aPTT section earlier). However, this assay was (1) poorly standardized, (2) not commercially available, (3) not well suited to automation, and (4) practically obsolete in terms of current usage. Currently, the most popular assays used to measure heparin activity are based on the ability of heparin to neutralize factor Xa that has been added to the test sample. They are known as anti-Xa assays and measure the ability of heparin-accelerated AT to inhibit Xa with residual Xa activity measured through its ability to clot plasma or more often by the amidolytic cleavage of a small chromogenic substrate. In the latter assay, a peptide substrate is cleaved to release para-nitroaniline with the change in absorbance being inversely proportional to heparin concentration. Some anti-Xa assays include the addition of exogenous AT to the test sample, ensuring an excess of AT. Other heparin assays do not add exogenous AT, the rationale being that the assay should reflect the ability of heparin to exert an anticoagulant effect, regardless of the quantity of AT present in the patient's plasma. Therefore, these assays may be more likely to correlate with clinical efficacy. This is especially important in that infusion of UFH could lead to a reduction in the quantity of the patient's AT through increased clearance and a shorter half-life. Similar available assays employ thrombin (FIIa) in place of factor Xa; they are therefore anti-IIa assays. Both anti-Xa and anti-IIa assays for UFH need to be calibrated with a heparin that has itself been calibrated against a World Health Organization (WHO) international standard.

Thrombin Time for Monitoring UFH

Thrombin-clotting time (TCT) is prolonged by UFH, the magnitude of which depends on the reagents, the method, and the concentration of heparin. Although it has been proposed as suitable for monitoring therapy, the test is rarely selected for this purpose. One problem is that for many methods, the TCT becomes difficult to measure at doses of heparin within or just above the upper limit of the therapeutic reference interval. This problem is removed by the use of

higher concentrations of thrombin, or by the inclusion of calcium in the thrombin time reagent, which may improve the correlation between TCT and concentration of UFH. However, some versions of TCT methods are useful even at low concentrations of heparin. Such methods are useful in the detection/exclusion of heparin as a cause of prolonged aPTT, where clinical information is lacking, or where contamination of heparin in a sample is suspected.

Activated Clotting Time for Monitoring UFH

UFH is used in high doses during cardiopulmonary bypass at concentrations of 3 to 10 U/mL or more; this causes aPTT and TCT to be unmeasurable by all available conventional methods. The test of choice for monitoring in this setting is activated clotting time (ACT). A variety of instruments and methods are available for this purpose, and currently no consensus has been reached on whether one particular method should be recommended. It is important to keep in mind that results obtained using different methods are not interchangeable,[141] despite the fact that there are similarities in the terminology used for reporting results. With most techniques, the ACT employs an activator such as celite or kaolin to accelerate clotting during the operative and perioperative periods. The activator affects the ACT; however, celite-activated ACT is prolonged relative to an ACT determined using kaolin. In addition, ACT may be prolonged by the hypothermia and hemodilution that may accompany cardiopulmonary bypass procedures. Thus, a poor correlation has been noted between heparin concentration as measured in specific assays and results obtained by ACT. Aprotinin prolongs celite-activated ACT in a dose-dependent way independently of heparin, and if aprotinin is used, ACT should be maintained at a higher result to ensure adequate heparinization, perhaps with twofold higher ACT results. When all factors are taken into account, management protocols often need to be device and anticoagulant specific.

ACT results are affected by the quantities of several clotting factors. For example, if the patient has severe deficiency of factor XII, HMWK, or prekallikrein, then the contact phase is compromised and the baseline value is grossly prolonged to similar values as those achieved by the high-dose heparin used for anticoagulation during cardiopulmonary bypass and other procedures. In these cases, the test cannot be used safely, so tests specific for the action of heparin such as anti-Xa assay must be considered. Therefore, a preheparinization baseline ACT is needed to exclude the presence of such an abnormality.

Low Molecular Weight Heparin

Evidence-based practice guidelines for anticoagulant therapy were published in 2008.[55] As mentioned previously, LMWHs are derived from UFH by depolymerization of the polysaccharide chains. The ratio of activity against factor Xa to activity against thrombin is high but varies among different preparations. LMWHs are favored over UFH as the treatment of choice in a number of clinical situations for several reasons, including (1) a better benefit-to-risk ratio, (2) more predictable dose response with reduced requirement for monitoring, and (3) a lower incidence of heparin-induced thrombocytopenia. Most LMWHs have an average molecular weight below 5000 Da, and their bioavailability is approximately 90% after subcutaneous injection, with a half-life of between 3 and 6 hours. Prophylactic doses are given as fixed doses or weight-adjusted doses; therapeutic doses are weight-based. For most patients, monitoring is not necessary, but some experts recommend monitoring in special populations including (1) obese patients (less reliable dose-response relationship), (2) pediatric patients, (3) patients with renal insufficiency (LMWHs are cleared by the kidney), and (4) pregnant women. When creatinine clearance is less than 30 mL/min, 50% of the normal recommended dose of LMWH has been recommended.[55] The test of choice if monitoring is performed is the anti-Xa assay. If twice-daily doses of enoxaparin are used, the target for therapy is a peak concentration of 0.6 to 1.0 IU/mL for samples taken 4 hours after injection.[55] For once-daily treatment doses, anti-Xa activity 4 hours after injection is often more than 1 U/mL and may be closer to 2 U/mL. Evidence-based guidance on expected concentrations in such patients is lacking. Anti-Xa assays should be calibrated with an LMWH preparation that has itself been calibrated against a WHO international standard for LMWH; even then differences between results of different assays are noted. Clotting-based anti-Xa assays are unsuitable for monitoring LMWH. The anti-Xa activity of LMWH is poorly reversed by protamine sulfate.

Fondaparinux

Fondaparinux (trade name Arixtra) is a synthetic pentasaccharide with a molecular weight of ≈1700 Da that binds AT with higher affinity than does heparin. It has a half-life of ≈17 hours after subcutaneous injection. A predictable anticoagulant response allows once-daily subcutaneous injection in fixed doses without the need for laboratory monitoring. It is contraindicated in renal insufficiency. In circumstances where it may be useful to determine the activity of fondaparinux, the assay of choice is anti-Xa, but in this case, the assay must be calibrated using fondaparinux in the standard plasma—not LMWH. Expected concentrations following 2.5 mg and 7.5 mg daily doses are 0.2 to 0.4 μg/mL and 0.5 to 1.5 μg/mL, respectively, although the therapeutic reference interval has not been established.[55] Fondaparinux is not reversed by protamine sulfate.

Direct Thrombin Inhibitors

The most widely used oral and parenteral anticoagulants including VKA, UFH, and LMWH have a number of limitations that have led to the development of newer alternatives. Several direct thrombin inhibitors have now been licensed for use in particular clinical settings. For example, recombinant hirudin is licensed for treatment of arterial or venous thrombosis where heparin-induced thrombocytopenia (HIT) is present (see later discussion of HIT), and for use in cardiopulmonary bypass. In most studies, increased bleeding compared with alternatives has restricted its use somewhat. A

synthetic hirudin analog named bivalirudin is also available and may be useful in certain settings.

New Anticoagulants

Rivaroxaban and dabigatran are two new anticoagulant drugs that have been released for clinical use.

Rivaroxaban **(Xarelto)** is an oral direct factor Xa inhibitor already licensed in Europe and Canada for VTE prophylaxis in adults undergoing elective hip or knee replacement surgery.[118] Laboratory monitoring is not required. The half-life is 7 to 11 hours. Bioavailability is 80 to 100% for oral doses with predictable pharmacokinetics and pharmacodynamics. Excretion is about ⅔ via the renal route, primarily as an unchanged drug. Rivaroxaban has been shown to be more effective than enoxaparin in preventing VTE after knee replacement.[57]

Dabigatran extexilate (Pradaxa in Australia, Europe and USA; Pradax in Canada; Prazaxa in Japan) is a new anticoagulant at an advanced stage of clinical development.[126] This oral prodrug is converted to dabigatran. The plasma half-life of dabigatran is 14 to 17 hours, with excretion largely through the kidneys. It was found to be equivalent to enoxaparin therapy after hip or knee replacement, with similar efficacy and safety.[57] In 2009, it was shown to be equivalent to warfarin over a 6 month treatment course in the prevention of recurrent VTE, when dabigatran etexilate was given in fixed doses with no monitoring; however, warfarin was dose-adjusted to achieve and maintain an INR of 2 to 3.[126]

Satifactory assays for rivaroxaban and dabigatran are not yet available. Despite the fact the monitoring is not required for these anticoagulants, there are many clinical circumstances in which the clinician will want to know if the drug is at an appropriate level, as in the patient with bleeding complication or recurrent thrombosis. Efforts to develop assays are underway at the time of this writing.

Hepatic toxicity was a concern in relation to a recently withdrawn, newly developed anticoagulant, ximelagatran, which is a prodrug of a direct thrombin inhibitor, melagatran. Such problems are more likely to occur with longer-term use.[90] Currently available data suggest that the type of hepatotoxicity seen with ximelagatran may not occur with rivaroxaban or dabigatran etexilate, but this remains to be fully established.

Most experts predict that use of VKA and widely used parenteral anticoagulants will decline, to be replaced by some of the newer anticoagulants that are given orally, safely, effectively, and without laboratory monitoring. For a review, see Garcia and coworkers.[47]

Therapy With Vitamin K Antagonists

Vitamin K antagonists such as warfarin are used (1) as oral drugs for the treatment of VTE; and (2) as prophylaxis in patients with atrial fibrillation, artificial heart valves, or various thrombophilic states. The number of patients requiring long-term VKA therapy continues to grow and is estimated at 750,000 to 1 million at present in the United Kingdom, with a similar prevalence in many developed Western populations. This number is expected to continue to rise, even though possible new anticoagulant drugs are being investigated in clinical trials.

VKAs function as an anticoagulant by interfering with the vitamin K cycle, which is needed for the postribosomal modification of clotting factors II, VII, IX, and X, as well as the anticoagulant proteins PC, PS, and protein Z. A consequence of VKA therapy is that these factors are no longer fully functional. Typically in the clotting process, several amino acids in these factors are carboxylated in a way that facilitates binding of the factors to calcium and phospholipid surfaces. Without these modifications, binding is reduced and clotting proceeds much more slowly. The problem is that the dose response is variable, so dosage must be very closely monitored to avoid over- or under-anticoagulation.

Many different types of VKA are used; warfarin (also known as Coumadin, Jantoven, Marevan, Lawarin, and Waran) is most common in North America and the United Kingdom. Numerous drugs affect the action of VKA in an unpredictable fashion, making monitoring necessary. Indeed, optimal oral anticoagulant therapy requires regular monitoring to ensure an appropriate balance between antithrombotic effects and unwanted hemorrhagic side effects. As discussed earlier, the test of choice for this monitoring in most countries is measurement of PT. Because of variability in different lots of thromboplastins, a normalization model has been developed that is based on expression of results using the INR.

As discussed in greater detail earlier in this chapter, the INR is based on the source of thromboplastins, and series of international standard thromboplastins are available from the WHO. Commercial thromboplastins are calibrated against the WHO reference thromboplastin by determination of paired prothombin times performed with the reference and commercial thromboplastin on a series of plasma specimens from healthy normal subjects and plasmas from patients stabilized on VKA therapy. The $\log_{10}$ of paired PTs is plotted and a regression line fitted through the data. The slope of the line indicates the responsiveness of the commercial thromboplastin relative to the WHO international standard. This is used to derive the ISI. The ISI is then used to convert PT into INR using the equation presented earlier.

The ISI is influenced by the analyzer used to perform testing; thus a single thromboplastin may have different ISIs when used with different analyzers. The reagent manufacturer, therefore, provides specific ISI values for different models. It has been reported that some analyzers of the same model type vary to the extent that local calibration of the ISI may be needed. For a full review, see Tripodi.[134] When the INR system is used, the same result should be obtained, irrespective of the methods that have been used to derive the value, but on some occasions, this does not occur. For example, this is a particular problem when INRs are elevated substantially above the therapeutic reference interval. It may also occur when patients have LAC where prolongation of PT/INR is a combination of VKA therapy and interference with the test by LAC. Some reagents and certain patients are particularly prone to this problem. To monitor VKA

TABLE 59-11 Some PT/INR-POC Devices

	End Point Detection	Memory Storage	Sample Volume	Quality Control Available	Sample Type	Tests Other Than INR
CoaguChek S (Roche)	Iron oxide particles	60	10 µL	Liquid QC	Capillary/venous native whole blood	No
CoaguChek XS (Roche)	Electrochemical cleavage	100	10 µL	Built-in QC	Capillary/venous native whole blood	No
CoaguChek XS Plus (Roche)	Electrochemical cleavage	500	10 µL	Liquid and built-in QC	Capillary/venous native whole blood	No
Hemochron Signature Series (ITC/Thoratec Corporation)	Blood flow through a restriction channel	200+ basic model 600+ top model	50 µL	Liquid QC	Native or citrated capillary/ venous whole blood	Yes
i-STAT (Abbott Diagnostics)	Electrochemical cleavage	5000	20 µL	Liquid QC	Native whole blood	Yes
INRatio (HemoSense/ Inverness Medical)	Electric impedance	60	15 µL	Built-in QC	Native capillary whole blood	No
ProTime (ITC/Thoratec Corporation)	Photoptic detection of decreased blood flow	50	27 µL	Liquid and built-in QC	Capillary/venous native whole blood	No

therapy when the PT/INR is affected by LAC, it is necessary to select a PT/INR system (perhaps by sending samples to other laboratories) that is not responsive to the LAC effect in that patient (as evidenced by a normal PT/INR before commencement of VKA therapy). For clinical recommendations on targets for INR in VKA therapy, see Ansell and associates.[2]

Point of Care for Monitoring VKA Therapy

Much of the testing for monitoring anticoagulant therapy continues to be performed in core or reference clinical laboratories, but there is a trend toward performing such measurements near the patient.[105] This type of testing is known as point-of-care (POC) testing[68] (see Chapter 20), and POC devices are now available that allow the patient to measure INR at home.[87] Consequently, the patient is able to adjust his or her VKA dose, and guidelines and recommendations have been established for self-testing and self-management of oral anticoagulation.[17,46] However, it should be noted that results from a 2010 study did not support the superiority of self-testing over clinic testing in reducing the risk of stroke, major bleeding episodes, and death among patients taking warfarin therapy.[87]

Determination of INR with POC instruments involves insertion of an individual test strip or cartridge into the monitor, followed by addition of the patient's blood sample. The blood reconstitutes dried thromboplastin reagent and initiates clotting reactions in the presence of calcium, leading to clot formation, which is detected as an end point. Within POC-INR devices are many types of end-point detection systems. For some systems, electronic quality control (QC) is available, whereby an electronic device is inserted into the monitor in place of the test strip, and an electronic signal is produced that tests the electronic system within the POC monitor. Table 59-11 provides a list of currently used POC-INR systems.

Some manufacturers of POC-INR systems produce test strips for INR determination with built-in quality control. For example, the CoaguChek XS and CoaguChek XS Plus devices (Roche Diagnostics Corp., Indianapolis, Ind) have a test strip integrity check. With these devices, a test strip containing a compound (Resazurin) that is sensitive to factors such as light, humidity, and temperature is analyzed. Chemical changes that occur are measured electrochemically, and the patient INR is displayed only if the test strip integrity check is acceptable. In addition to internal QC checks, external quality assurance (QA) is available for POC-INR testing in the United States and Europe.[69]

It should be noted that POC-INR results may not agree with those generated in local clinical laboratories, particularly when values are beyond the therapeutic interval. As part of the quality control process, a venous sample is collected at the same time as the POC test and is analyzed in an appropriate laboratory. Some patients show discrepancies between INRs determined by two different techniques, despite being stabilized on oral anticoagulant therapy. One cause of this is the presence of LAC, although discrepancies also occur without an LAC.

In a 2008 study, Murray and colleagues[97] concluded that patients could successfully participate in a formal external quality assurance (EQA) program utilizing the same freeze-dried test samples as are used in conventional laboratory EQA programs. The same study demonstrated that comparing the patient POC device with a reference device was an effective form of EQA.

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is a serious complication of heparin therapy because patients with HIT have a substantially increased thrombotic risk. HIT is thought to be caused by the development of antibodies that recognize neoantigens formed from complexes of platelet factor 4 and heparin. Thrombocytopenia or thrombosis without the presence of heparin-dependent antibodies is not HIT, nor is the isolated presence of such antibodies without thrombocytopenia or thrombosis. The diagnosis of HIT is therefore based on both clinical and laboratory features. The frequency of HIT is greater in surgical than medical patients and is greater with UFH than LMWH. In orthopedic patients given prophylactic subcutaneous heparin, the incidence is around 5%, which is approximately 10-fold higher than the incidence with LMWH in this group. For medical patients on therapeutic UFH, the incidence is around 0.5 to 1%. When HIT develops, the platelet count decreases 5 to 14 days following initiation of therapy in patients who were not previously exposed to heparin therapy. If patients have had heparin in the previous 3 months, preexisting antibodies may appear as soon as heparin is used. Because the platelet count decreases by more than 50%, it must be checked regularly to identify those at risk of HIT with associated thombosis. Severe thrombocytopenia ($<15 \times 10^9$ cells/L) is rare. Approximately half of patients who develop HIT will have associated thrombosis. The initial assessment is clinical and is based on a system that has been termed the 4 T's system (**t**hrombocytopenia; **t**iming of fall in platelets; **t**hrombosis; o**t**her causes of thrombocytopenia not evident). This system generates a pretest probability score. If the score is high, then heparin therapy must be terminated and alternative anticoagulants used.

It is important to remember that diagnosis and management of HIT are clinical, with the laboratory used only for confirmatory purposes. Several laboratory tests available for these purposes are based on platelet activation (functional) or immunologic assays using PF4-heparin complexes as an antigen. Platelet activation assays require a healthy subject as a source of donor platelets, and not all subjects are suitable because responsiveness to HIT antibodies varies. Such assays are improved by washing of platelets, but overall these assays are technically difficult and are not widely used. Alternatively, commercial ELISA assays are available from several manufacturers, as are rapid gel agglutination techniques. Antigen assays available at the time of this writing have clinical sensitivity in the range of 80 to 100% but low specificity. False positives are common. The degree of positivity is important in that strong positivity is associated with thrombosis. Some experts believe that only immunoglobulin (Ig)G antibodies cause the clinical disorder. Many commercial antigen assays detect IgM and IgA antibodies, as well as IgG. For full reviews and guidance, see Warkentin and coworkers[138] and Keeling and associates.[66]

Antiphospholipid Antibodies and Lupus Anticoagulant

Antiphospholipid antibodies (APAs), including lupus anticoagulant antibodies, anticardiolipin antibodies, and β_2 glycoprotein-1 antibodies, occur in the antiphospholipid syndrome (APS). This is a disorder of the immune system that is characterized by excessive clotting of blood and/or certain complications of pregnancy [i.e., premature miscarriage, unexplained fetal death, or premature birth (http://www.medicinenet.com)]. It is an acquired problem with immune pathogenesis that has been known to cause thrombosis and pregnancy loss. APS is diagnosed when particular clinical symptoms coincide with the presence of APA in laboratory tests. Some antibodies are transient; thus a diagnosis of APS requires repeat testing for confirmation after 12 weeks. The most common thrombotic symptoms are venous thromboembolism and ischemic stroke, with some patients having thrombocytopenia. Types of pregnancy failure that are consistent with APS include (1) three or more unexplained consecutive abortions before 10 weeks, (2) unexplained death of a morphologically normal fetus at or after 10 weeks, and (3) premature birth before 34 weeks due to severe preeclampsia or placental insufficiency. Internationally, classification criteria have been published.[94]

At present the degree of standardization of tests for APA is poor, and the limitations of such tests must be kept in mind when patients are assessed for possible APS. Several types of APA are undoubtedly linked to thrombosis and pregnancy loss. These include (1) anti-β_2-glycoprotein-1(anti-β_2-GP-1), (2) lupus anticoagulant (LA), and (3) anticardiolipin antibodies (ACAs). Other types of APA have been reported to be linked to APS, but currently no consensus has been reached on their clinical relevance.

It has long been recognized that some individuals with systemic lupus erythematosus (SLE) have prolonged aPTTs. This was shown to be due to the presence of an in vitro inhibitor called lupus anticoagulant (LAC). These inhibitors previously were thought to work against phospholipid but were found to be active against proteins that bind to lipids; these proteins include β_2-glycoprotein-1, prothrombin, annexin V, and others.[59,111,121] Antibodies that prolong phospholipid-dependent clotting tests are collectively termed LAC. This group is very heterogeneous in relation to clinical picture and laboratory features. It should be noted that although some SLE individuals are positive for LAC, most cases of LAC are not associated with SLE, even though the term *lupus anticoagulant* has continued to be used. In addition, it should be noted that not all antiphospholipid antibodies prolong these clotting tests. Some cases with detectable LA do not have clinical features and therefore are not classified as APS. The aPTT, however, is not prolonged in all cases where LA is present, and most cases with LA and prolonged

aPTT have no bleeding symptoms but may have thrombosis as described previously. Only rarely is LA associated with bleeding, usually when acquired prothrombin deficiency is a consequence of high concentrations of antiprothrombin antibody.

The guidelines for LAC detection were updated by the Scientific and Standardization Committee (SSC) of the ISTH in 2009.[103] This update addresses a number of important aspects of standardization. For example, the quality of the sample affects results of LA tests, and if there are residual platelets, they can rupture during the testing, leading to loss of antibody and false-negative results. This is a particular problem if plasmas are frozen before testing; therefore, double centrifugation is required before deep freezing. Filtering to remove residual platelets, however, is not recommended. The guidelines also recommend that the dilute Russell's viper venom time (DRVVT) should be the first test performed, and the second test should be a sensitive aPTT-based test. The DRVVT is a clot-based test that is initiated by the addition of a Russell viper venom that directly activates factor X, thereby bypassing effects of extrinsic and intrinsic pathways. For an aPTT test to be sensitive to the presence of LAC, the aPTT reagent should have a low phospholipid concentration. Only the DRVVT or the aPTT test needs to be positive to be considered evidence of LAC, although in most cases, both will be positive. In addition, a confirmatory step is required for each individual LAC test to confirm the phospholipid-dependent nature of the inhibitor. This confirmation is achieved by repeating the test with a higher phospholipid concentration to neutralize the phospholipid-dependent inhibitors. There is also a role for performing a mixing study of LAC tests to help differentiate between a clotting factor deficiency (which may be associated with bleeding) and a lupus inhibitor (more likely associated with thrombosis than bleeding).

As a consequence of thrombosis, many patients with LAC require VKA therapy. Interpretation of LAC tests is difficult during VKA therapy because reductions in the quantities of various coagulation factors during VKA therapy will affect the DRVVT and aPTT tests. The SSC LAC guideline recommends that such testing should be done 1 to 2 weeks after discontinuation of VKA therapy.[103] If testing is necessary at the time of VKA therapy, it is recommended that (1) the DRVVT should be performed when the INR is less than 1.5, (2) testing should not be done when the INR is greater than 3.5, and (3) a mix of test and normal plasma should be considered when the INR is between these limits. In addition, the SSC guideline does not recommend use of (1) dilute prothrombin time, (2) assays based on snake venoms, or (3) kaolin-clotting time for LAC detection.

Various solid-phase ELISA tests are available for the detection of APA. These include tests for ACA for which commercial kits have been available for many years. Standardization of such kits, however, is rather poor, and comparisons consistently demonstrate that even concordance as to whether a sample is positive or negative is frequently absent when testing is done with two or more different kits.[60] Both IgG and IgM forms of ACA occur. Evidence that the IgM isotype is of clinical relevance is weak, and many laboratories test only for IgG. Some but not all ACA assays incorporate β_2-glycoprotein-1 in the reagents so that cardiolipin bound to the surface of a microtiter plate will be associated with β_2-glycoprotein-1. Some ACA kits detect only β_2-glycoprotein-1–dependent antibodies, whereas others detect non–β_2-glycoprotein-1–dependent antibodies. Evidence suggests that it is the β_2-glycoprotein-1–dependent antibodies that have the greatest clinical significance in APS, and a number of specific anti-β_2-glycoprotein-1 antibody kits are in use. As for ACA kits, standardization of APS kits is poor, and there will be patients with APS who are negative by one kit and positive by another.[60]

TABLE 60-1 Reference Intervals and Values

Results of laboratory tests have little practical utility until clinical studies have ascribed various states of health and disease to intervals of values. Reference intervals are useful because they attempt to describe the typical results found in a defined population of apparently healthy people. Different methods may yield different values, depending on calibration and other technical considerations. Hence, different reference intervals and results may be obtained in different laboratories. Variability among methods is particularly characteristic of methods that use antibodies to detect the material of interest, and when results are reported as relative units of activity. Values from apparently "healthy" and diseased people may overlap significantly. Therefore reference intervals, although useful as a guide for clinicians, should not be used as absolute indicators of health and disease (see Chapter 5). The reference intervals presented in this chapter are for **general informational purposes only.** Guidelines for defining and determining reference intervals have been discussed in Chapter 5 and published in the 2010 CLSI C28-A3 guideline ("How to Define and Determine Reference Intervals in the Clinical Laboratory; Approved Guideline—Third Edition"). As stated in several chapters in this textbook, each individual laboratory should generate its own set of reference intervals.

Where both exist, reference intervals are listed in both conventional and international units and are for use in adults in the fasting state unless otherwise stated. Values for other age groups, when included, are clearly identified. Most of the values listed were obtained from chapters in this book. Some were extracted, however, from WU Alan H. B. *Tietz clinical guide to laboratory tests,* 4th edition. Philadelphia, WB Saunders, 2006; and Burtis CA, Ashwood ER, Bruns DE. *Tietz textbook of clinical chemistry and molecular diagnostics,* 4th edition. Philadelphia, WB Saunders, 2006. For several of the specific proteins, reference intervals—obtained after calibration of the analytical system with the international protein reference RPPHS/CRM-470—are listed in Chapter 21.

A valuable source for reference intervals for older methods is http://cclnprod.cc.nih.gov/dlm/testguide.nsf/ (accessed August 18, 2011).

For convenience and to preserve space, we have used standard abbreviations commonly used in laboratory medicine. Less common abbreviations and some nonstandard abbreviations are given below:

TABLE 60-2 Therapeutic and Toxic Levels of Drugs

Therapeutic drug monitoring and detection of drug overdose have become increasingly important aspects of the role of the laboratory in patient care. The information given for drugs in this table has been gathered from published sources. These examples are intended to complement Chapter 34 of this book, and do not represent all drugs for which drug testing may be useful. In addition, knowledge and drug measurement methodologies are continuously improving; therefore it may be necessary to supplement the information given here with information obtained from other sources as it becomes available for these and other drugs. Reliable drug analysis information depends on a well-coordinated sample collection, assay methodology characteristics, and patient-associated considerations such as age, disease state, concomitant drug administration, and clinical procedures that the patient may have undergone. In practice, each organization should have its own set of therapeutic and toxic levels for the drugs it measures.

Many tests for therapeutic drugs require careful timing between administration and sample collection if the measured drug level is to be of optimal use clinically. Drugs are listed by their chemical or generic name, followed by an example of a commercial brand name for the drug (where appropriate). Unless otherwise indicated, target concentrations reflect steady-state, predose (trough) sampling. These targets, as well as toxic thresholds provided, are intended to serve as guidelines and should not be used to optimize drug dosing independently of clinical factors. See Chapter 34 for detailed information about therapeutic drug monitoring regarding these and additional drugs.

Conversion factors provided represent the free-base form of the parent drug only—not metabolites, unless otherwise indicated. Active metabolites are indicated for many drugs as "+," but therapeutic or toxic concentrations are not routinely provided. Note that calculated conversions to SI units are rounded, unless the value is less than 1.0. For convenience and to preserve space, standard abbreviations commonly used in laboratory medicine are used. Less common abbreviations and some nonstandard abbreviations are given in the following paragraph. Whenever plasma or whole blood is indicated, the recommended preservative is presumed to be EDTA, although heparin may be acceptable. Separator gel blood collection tubes for serum or plasma are not recommended for drug testing because of possible adsorption of drugs and/or drug metabolites to the gel itself, contributing to the risk of falsely low drug concentrations. Some drugs (e.g., busulfan, olanzapine) are labile and require special handling. Consult laboratory validation data and current literature sources for specific handling recommendations and anticipated stability guidelines.

TABLE 60-2 Therapeutic and Toxic Levels of Drugs—cont'd

Drug	Specimen	Status	Reference Values: Conventional Units	Conversion Factor	SI Units
Lamivudine (Epivir, 3TC)	S or P		µg/mL	4.36	µmol/L
		Therap	>0.4		>2
Lamotrigine (Lamictal)	S or P		µg/mL	3.91	µmol/L
		Therap	2.5-15		10-59
Levetiracetam (Keppra)	S or P		µg/mL	5.88	µmol/L
		Therap	12-46		71-270
Lidocaine (Xylocaine)	S or P		µg/mL	4.27	µmol/L
	≥45 min following bolus dose	Therap	1.5-5		6-21
		Toxic	>6		>26
Lithium (Eskalith)	S or P		mEq/L	1.0	mmol/L
		Therap	0.5-1.2		0.5-1
		Toxic	>2		>2
Lorazepam (Ativan)	S or P		ng/mL	3.11	nmol/L
		Therap dose	50-240		156-746
Maprotiline (Ludiomil)	S or P		ng/mL	3.60	nmol/L
		Therap	125-200		450-720
		Toxic	>300		>1080
Meperidine (Demerol)	S or P		ng/mL	4.04	nmol/L
		Therap	70-500		283-2020
		Toxic	>1000		>4004
Mephobarbital (Mebaral)	S or P		µg/mL	4.06	µmol/L
		Therap	1-7		4-28
		Toxic	>15		>61
Meprobamate (Equanil)	S or P		µg/mL	4.58	µmol/L
		Therap	6-12		28-55
		Toxic	>60		>275
Methadone (Dolophine)	S or P		ng/mL	3.23	nmol/L
		Therap	100-400		320-1280
		Toxic	>2000		>6460
Methamphetamine (Desoxyn)	S or P		µg/mL	6.70	µmol/L
		Therap	0.01-0.05		0.07-0.34
		Toxic	>0.5		>3
Methaqualone (Quaalude)	S or P		µg/mL	4.00	µmol/L
		Therap	2-3		8-12
		Toxic	>10		>40
Methotrexate (Trexall, Rheumatrex)	S or P		µmol/L	2.20	µmol/L
		Toxic			
		24 h after high-dose therapy	≥10		≥22
		48 h after high-dose therapy	≥1		≥2
		72 h after high-dose therapy	≥0.1		≥0.2
Methsuximide (Celontin) as normethsuximide	S or P		µg/mL	5.29	µmol/L
		Therap	10-40		53-212
		Toxic	>40		>212

TABLE 60-2 Therapeutic and Toxic Levels of Drugs—cont'd

Drug	Specimen	Status	Reference Values: Conventional Units	Conversion Factor	Reference Values: SI Units
Methyldopa (Aldomet)	S or P		µg/mL	4.73	µmol/L
		Therap	1-5		5-24
		Toxic	>7		>33
Methyprylon (Noludar)	S or P		µg/mL	5.46	µmol/L
		Therap	8-10		43-55
		Toxic	>50		273
Mexiletine (Mexitil)	S or P		µg/mL	5.58	µmol/L
		Therap	0.5-2		3-11
		Toxic	>2.0		>11
Morphine	S or P		ng/mL	3.50	nmol/L
		Therap	10-80		35-280
		Toxic	>200		>700
Mycophenolate mofetil (CellCept) as mycophenolic acid	S or P		µg/mL	3.12	µmol/L
		Therap	1.3-3.5		4-11
		Toxic	>12		>38
Nefazodone (Serzone)	S or P		ng/mL	2.13	nmol/L
		Therap	25-2500		53-5325
		Toxic	>2500		>5325
Nelfinavir (Viracept)	S or P		µg/mL	1.76	µmol/L
		Therap	>1		>2
		Toxic	>6		>11
Netilmicin (Netromycin)	S or P		µg/mL	2.10	µmol/L
		Therap			
		Peak			
		Less severe infection	5-8		10-17
		Severe infection	8-10		17-21
		Trough			
		Less severe infection	<1		<2
		Moderate infection	<2		<4
		Severe infection	<4		<8
		Toxic			
		Peak	>10		>21
		Trough	>2		>4
Nevirapine (Viramune)	S or P		µg/mL	3.76	µmol/L
		Therap	>3.5		<13.2
		Toxic	>12		>45.1
Nordiazepine, active metabolite of several benzodiazepines	S or P		ng/mL	3.76	nmol/L
	S or P	Therap	100-500		376-1880
		Toxic	>500		>1880
Nortriptyline (Aventyl)	S or P		ng/mL	3.80	nmol/L
		Therap	70-170		266-646
		Toxic	>500		>1900
Olanzapine (Zyprexa)	S or P		ng/mL	3.20	nmol/L
		Therap	20-80		64-256
		Toxic	>1000		>3200
Oxazepam (Serax)	S or P		µg/mL	3.49	µmol/L
		Therap	0.2-1.4		0.7-5

TABLE 60-2 Therapeutic and Toxic Levels of Drugs—cont'd

Drug	Specimen	Status	Reference Values		
			Conventional Units	Conversion Factor	SI Units
Oxcarbazepine (Trileptal) as monohydroxyoxcarbazepine (MHD)	S or P		µg/mL	3.97	µmol/L
	S or P	Therap	3-35		12-139
		Toxic	>40		>159
Oxycodone (Percodan)	S or P		ng/mL	3.17	nmol/L
		Therap	10-100		32-317
		Toxic	>200		>634
Paraldehyde (Paral)	S or P		µg/mL	7.57	µmol/L
		Therap			
		Sedation	10-100		76-757
		Anesthesia	>200		>1514
		Toxic	>200		>1514
		Lethal	>500		>3785
Paroxetine (Paxil)	S or P		ng/mL	3.04	nmol/L
		Therap	70-120		213-365
Pentazocine (Talwin)	S or P		µg/mL	3.5	µmol/L
		Therap	0.05-0.2		0.2-0.7
		Toxic	>1.0		>4
Pentobarbital (Nembutal)	S or P		µg/mL	4.42	µmol/L
		Therap			
		Hypnotic	1-5		4-22
		Therap coma	20-50		88-221
		Toxic	>10		>44
Perphenazine (Apo-Perphenazine)	S or P		µg/mL	2.48	µmol/L
		Therap	0.6-2.4		2-6
		Toxic	>12		>30
Phenacetin	S or P		µg/mL	5.58	µmol/L
		Therap	1-30		6-167
		Toxic	50-250		279-1395
Phenobarbital (Luminal)	S or P		µg/mL	4.31	µmol/L
		Therap	10-40		43-173
		Toxic			
		Slowness, ataxia, nystagmus	35-80		151-345
		Coma, with reflexes	65-117		280-504
		Coma, without reflexes	>100		>431
Phensuximide (Milontin) + norphensuximide	S or P		µg/mL	5.29	µmol/L
		Therap	40-60		212-317
Phenylbutazone (Butazolidin)	S or P		µg/mL	3.24	µmol/L
		Therap	50-100		162-324
		Toxic	>100		>324
Phenytoin (Dilantin)	S or P		µg/mL	3.96	µmol/L
		Therap	10-20		40-79
		Free	1.0-2.0		4-8
		Toxic	>20		>79
Posaconazole (Noxafil)	S or P		µg/mL	1.43	µmol/L
		Therap	>1.25		>2

TABLE 60-2 Therapeutic and Toxic Levels of Drugs—cont'd

Drug	Specimen	Status	Reference Values: Conventional Units	Conversion Factor	Reference Values: SI Units
Primidone (Mysoline) + phenobarbital	S or P		µg/mL	4.58	µmol/L
		Therap	5-10		23-46
		Toxic	>15		>69
Procainamide (Pronestyl) + *N*-acetylprocainamide (NAPA)	S or P		µg/mL	4.25	µmol/L
		Therap	4-10		17-42
			12-18 (NAPA)	3.61	43-65
		Toxic	>12		>51
			>40 (NAPA)		>144
Propafenone (Rythmol)	S or P		µg/mL	2.93	µmol/L
		Therap	0.5-2.0		1.5-6
		Toxic	>2		>6
Propoxyphene (Darvon)	S or P		µg/mL	2.95	µmol/L
		Therap	0.1-0.4		0.3-1
		Toxic	>0.5		>2
Propranolol (Inderal)	S or P		ng/mL	3.86	nmol/L
		Therap	20-100		77-386
Protriptyline (Vivactil)	S or P		ng/mL	3.80	nmol/L
		Therap	70-260		266-988
		Toxic	>500		>1900
Quetiapine (Seroquel)	S or P		mg/L	2.58	µmol/L
		Therap	0.7-1.7		2-4
		Toxic	>200		>516
Quinidine (BioQuin)	S or P		µg/mL	3.08	µmol/L
		Therap	2-5		6-15
		Toxic	>6		>19
Risperidone (Risperdal) + 9-hydroxyrisperidone	S or P		ng/mL	2.44	nmol/L
		Therap	20-60		49-146
Ritonavir (Norvir)	S or P		µg/mL	1.39	µmol/L
		Therap	>2		>3
		Toxic	>22		>31
Salicylates as salicylic acid	S or P		µg/mL	0.00727	mmol/L
		Therap			
		Analgesia, antipyresis	<100		<0.7
		Anti-inflammatory	150-300		1-2
		Toxic	>100		>0.7
		Lethal, 24+ h after a dose or with chronic ingestion	>500		>4
Saquinavir (Fortovase, Invirase)	S or P		µg/mL	1.49	µmol/L
		Therap	>0.25		>0.4
		Toxic	>6.0		>9
Secobarbital (Seconal)	S or P		µg/mL	4.20	µmol/L
		Therap	1-2		4.2-8.4
		Toxic	>5		>21.0

TABLE 60-2 Therapeutic and Toxic Levels of Drugs—cont'd

Drug	Specimen	Status	Reference Values: Conventional Units	Reference Values: Conversion Factor	Reference Values: SI Units
Sertraline (Zoloft)	S or P		ng/mL	3.27	nmol/L
		Therap	10-50		33-164
		Toxic	>300		>981
Sirolimus (Rapamune, Rapamycin)	WB		ng/mL	1.10	nmol/L
		Therap	4-20		4-22
		Toxic	>20		>22
Sotalol (Betapace, Sorine)	S or P		µg/mL	3.67	µmol/L
		Therap	1-3		4-11
Streptomycin	S or P		µg/mL	1.72	
		Therap			
		Trough	<5		<9
		Peak	20-30		34-52
		Peak/MIC	>10		>17.2
		Toxic	>50		>86
Sulfonamides as sulfanilamide	S or P		mg/mL	5.81	mmol/L
		Therap	5-15		29-87
		Toxic	>20		>116
Tacrolimus (FK 506, Prograf)	WB		ng/mL	1.24	nmol/L
		Therap	3-20		4-25
		Toxic	>20		>25
Teicoplanin (Targocid)	S or P		µg/mL	0.53	µmol/L
		Peak	>10		>5
Theophylline (Uniphyl)	S or P		µg/mL	5.55	µmol/L
		Therap			
		Bronchodilator	8-20		44-111
		Prem apnea	6-13		33-72
		Toxic	>20		>111
Thiopental (Pentothal)	S or P		µg/mL	4.13	µmol/L
		Hypnotic	1-5		4-21
		Coma	30-100		124-413
		Anesthesia	7-130		29-536
		Toxic	>10		>41
Thioridazine (Mellaril)	S or P		µg/mL	2.70	µmol/L
		Therap	0.2-2.0		0.5-5
		Toxic	>10		>27
Tiagabine (Gabitril)	S or P		ng/mL	2.66	nmol/L
		Therap	20-200		53-532
		Toxic	>520		>1383
Tobramycin (Nebcin)	S or P		µg/mL	2.14	µmol/L
		Therap			
		Peak			
		Less severe infection	5-8		11-17
		Severe infection	8-10		17-21
		Trough			
		Less severe infection	<1		<2
		Moderate infection	<2		<4
		Severe infection	<4		<9

Drug	Specimen	Status	Reference Values: Conventional Units	Reference Values: Conversion Factor	Reference Values: SI Units
Tobramycin (Nebcin)—*cont'd*		Toxic			
		Peak	>10		>21
		Trough	>2		>4
		Peak/MIC	>10		>21
Tocainide (Tonocard)	S or P		µg/mL	5.20	µmol/L
		Therap	6-15		31-78
		Toxic	>15		>78
Tolbutamide (Orinase)	S or P		µg/mL	3.70	µmol/L
		Therap	90-240		333-888
		Toxic	>640		>2368
Topiramate (Topamax)	S or P		µg/mL	2.95	µmol/L
		Therap	5-20		15-59
		Toxic	>12		>36
Trazodone (Desyrel)	S or P		ng/mL	2.68	nmol/L
		Therap	650-1500		1748-4020
		Toxic	>4000		>10,720
Trimipramine (Surmontil)	S or P		ng/mL	3.40	nmol/L
		Therap	150-350		510-1190
		Toxic	>500		>1700
Valproic acid (Depakene)	S or P		µg/mL	6.93	µmol/L
		Therap	50-100		346-693
		Toxic	>100		>693
Vancomycin (Vancocin)	S or P		µg/mL	0.69	µmol/L
		Therap			
		Peak	20-40		14-28
		Trough	>10		>7
		Toxic	>80		>55
Venlafaxine (Effexor) + desmethylvenlafaxine	S or P		ng/mL	3.61	nmol/L
		Therap	195-400		704-1444
		Toxic	>1000 (sum)		>3610
Vigabatrin (Sabril)	S or P		µg/mL	7.74	µmol/L
		Therap	0.8-36		6-279
Voriconazole (Vfend)	S or P		µg/mL	2.86	µmol/L
		Therap	1-6		3-17
		Toxic	>6		>17
Warfarin (Coumadin)	S or P		µg/mL	3.24	µmol/L
		Therap	1-10		3-32
		Toxic	>10		>32
Zidovudine (AZT, Retrovir)	S or P		µg/mL	3.74	µmol/L
		Therap	>0.2		>0.8
Zonisamide (Zonegran)	S or P		µg/mL	4.71	µmol/L
		Therap	10-40		47-188

TABLE 60-3 Critical Values

Critical values, also known as panic or alert values, are laboratory results that indicate a life-threatening situation for the patient. Because of their critical nature, urgent notification of a critical value to the appropriate healthcare professional is necessary. Table 60-3 has been adapted from extensive national surveys. The median or average critical limit determined by these surveys is shown. In practice, each organization should have its own set of critical limits and physician notification policy.

Test	Units	Lower Limit	Upper Limit	Comments
Blood Gases				
pH		7.2	7.6	Arterial, capillary
PCO_2	mm Hg	20	70	Arterial, capillary
PO_2	mm Hg	40	—	Arterial
PO_2 (children)	mm Hg	45	125	Arterial
PO_2 (newborn)	mm Hg	35	90	Arterial
Chemistry				
Albumin (children)	g/dL	1.7	6.8	Serum or plasma
Ammonia (children)	µmol/L	—	109	Plasma
Bilirubin (newborn)	mg/dL	—	15	Serum or plasma
Calcium	mg/dL	6.0	13	Serum or plasma
Calcium (children)	mg/dL	6.5	12.7	Serum or plasma
Calcium, ionized	mmol/L	0.75	1.6	Plasma
Carbon dioxide, total	mmol/L	10	40	Serum or plasma
Chloride	mmol/L	80	120	Serum or plasma
Creatinine	mg/dL	—	5.0	Serum or plasma
Creatinine (children)	mg/dL	—	3.8	Serum or plasma
Glucose	mg/dL	40	450	Serum or plasma
Glucose (children)	mg/dL	46	445	Serum or plasma
Glucose (newborn)	mg/dL	30	325	Serum or plasma
Glucose, CSF	mg/dL	40	200	CSF
Glucose, CSF (children)	mg/dL	31	—	CSF
Lactate	mmol/L	—	3.4	Plasma
Lactate (children)	mmol/L	—	4.1	Plasma
Magnesium	mg/dL	1.0	4.7	Serum or plasma
Osmolality	mOsm/kg	250	325	Serum or plasma
Phosphorus	mg/dL	1.0	8.9	Serum or plasma
Potassium	mmol/L	2.8	6.2	Serum or plasma
Potassium (newborn)	mmol/L	2.8	7.8	Serum or plasma
Protein (children)	g/dL	3.4	9.5	Serum or plasma
Protein, CSF (children)	mg/dL	—	188	CSF
Sodium	mmol/L	120	160	Serum or plasma
Urea nitrogen	mg/dL	—	80	Serum or plasma
Urea nitrogen (children)	mg/dL	—	55	Serum or plasma
Uric acid	mg/dL	—	13	Serum or plasma
Uric acid (children)	mg/dL	—	12	Serum or plasma
Hematology				
Hematocrit				
Adult	%	20	60	First report only
Newborn	%	33	71	
Hemoglobin				
Adult	g/dL	7	20	First report only
Newborn	g/dL	10	22	
WBC				
Adult	$\infty 10^3/\mu L$	2.0	30	First report only
Children	$\infty 10^3/\mu L$	2.0	43	
Platelets	$\infty 10^3/\mu L$	40	1000	
Blasts	Any seen (first report only)			
Drepanocytes	Presence of sickle cells or aplastic crisis			

Continued

TABLE 60-3 Critical Values—cont'd

Test	Units	Lower Limit	Upper Limit	Comments
Coagulation				
Fibrinogen	mg/dL	100	800	
Prothrombin time	s	—	30	
Partial thromboplastin time	s	—	78	
Urinalysis	Presence of pathological crystals (urate, cysteine, leucine, or tyrosine)			
Microscopic	Strongly positive glucose and ketones			
Chemical				
Cerebrospinal Fluid				
WBC (0-1 y)	Cells per µL	—	>30	
WBC (1-4 y)	Cells per µL	—	>20	
WBC (5-17 y)	Cells per µL	—	>10	
WBC (>17 y)	Cells per µL	—	>5	
Malignant cells, blasts, or microorganisms		Any	Applies to other sterile body fluids

From Wieser ME, Cople T. Atomic weights of the elements 2009 (IUPAC Technical Report). Pure Appl Chem 2011;83:359-96.

[a] Value in parentheses denotes mass number of most stable known isotope.
[b] Name and symbols are not officially accepted. Kurchatovium, Ku, has been proposed by Russian investigators and rutherfordium, Rf, by American investigators for element 104.
