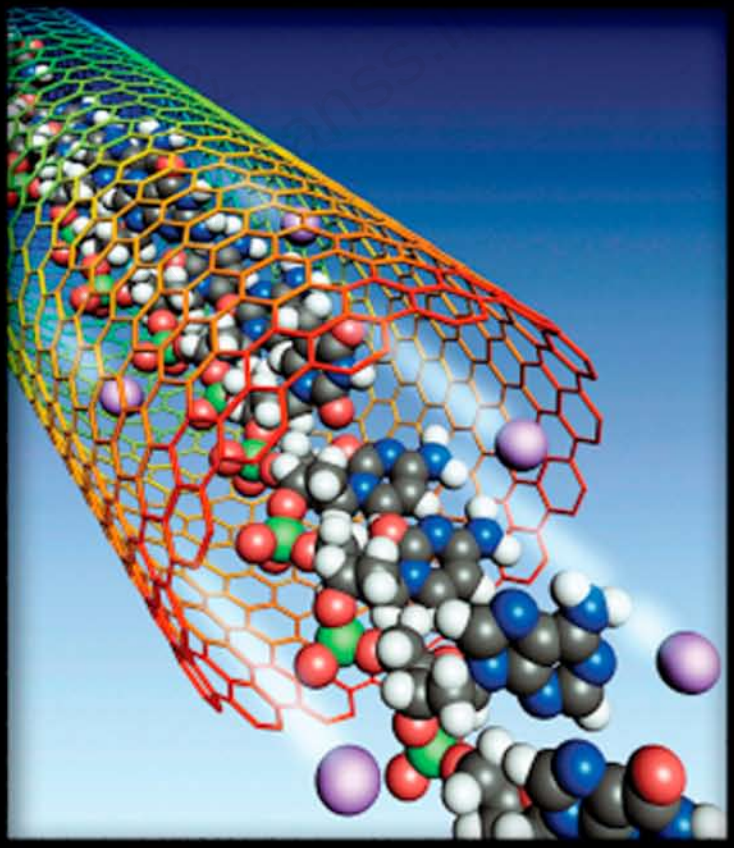
FIFTH EDITION

Tietz Textbook of CLINICAL CHEMISTRY *and* MOLECULAR DIAGNOSTICS



Carl A. Burtis • Edward R. Ashwood • David E. Bruns

ELSEVIER

tahir99-VRG & vip.persianss.ir

Contents

SECTION I PRINCIPLES OF LABORATORY MEDICINE

1 Clinical Chemistry, Molecular Diagnostics, and Laboratory Medicine
2 Selection and Analytical Evaluation of Methods—With Statistical Techniques
3 Clinical Utility of Laboratory Tests
4 Evidence-Based Laboratory Medicine
5 Establishment and Use of Reference Values
6 Preanalytical Variables and Biological Variation
7 Specimen Collection and Processing
8 Quality Management

SECTION II ANALYTICAL TECHNIQUES AND INSTRUMENTATION

9 Principles of Basic Techniques and Laboratory Safety
10 Optical Techniques
11 Electrochemistry and Chemical Sensors
12 Electrophoresis
13 Chromatography and Extraction
14 Mass Spectrometry
15 Enzyme and Rate Analyses
16 Principles of Immunochemical Techniques
17 Nucleic Acid Techniques
18 Microfabrication and Microfluidics and Their Application to Clinical Diagnostics
19 Automation in the Clinical Laboratory
20 Point-of-Care Instrumentation

SECTION III ANALYTES

21 Amino Acids, Peptides, and Proteins
22 Serum Enzymes
23 Enzymes of the Red Blood Cell
24 Tumor Markers
25 Kidney Function Tests
26 Carbohydrates
27 Lipids, Lipoproteins, Apolipoproteins, and Other Cardiac Risk Factors
28 Electrolytes and Blood Gases
29 Hormones
30 Catecholamines and Serotonin
31 Vitamins and Trace Elements
32 Hemoglobin, Iron, and Bilirubin
33 The Porphyrias and Other Disorders of Porphyrin Metabolism
34 Therapeutic Drugs and Their Management
35 Clinical Toxicology
36 Toxic Metals

SECTION IV MOLECULAR DIAGNOSTICS AND GENETICS

37 Principles of Molecular Biology
38 Genomes and Nucleic Acid Alterations
39 Nucleic Acid Isolation
40 Inherited Diseases
41 Identity Assessment
42 Molecular Methods in Diagnosis and Monitoring of Infectious Diseases
43 Pharmacogenetics
44 Hematopoietic Malignancies
45 Plasma Nucleic Acids

SECTION V PATHOPHYSIOLOGY

46 Diabetes Mellitus
47 Cardiac Function
48 Kidney Disease
49 Physiology and Disorders of Water, Electrolyte, and Acid-Base Metabolism
50 Liver Disease
51 Gastric, Pancreatic, and Intestinal Function
52 Bone and Mineral Metabolism
53 Pituitary Function and Pathophysiology
54 The Adrenal Cortex
55 The Thyroid: Pathophysiology and Thyroid Function Testing
56 Reproductive Endocrinology and Related Disorders
57 Pregnancy and Its Disorders
58 Newborn Screening and Inborn Errors of Metabolism
59 Hemostasis

SECTION VI APPENDIX

60 Reference Information for the Clinical Laboratory

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of product liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Health Services Division
Oak Ridge National Laboratory
Oak Ridge, Tennessee
Clinical Professor of Pathology
University of Utah School of Medicine
Salt Lake City, Utah
Introduction to Laboratory Medicine; Reference Information for the Clinical Laboratory

Angela M. Caliendo, M.D., Ph.D.
Professor and Vice Chair
Pathology and Laboratory Medicine
Emory University School of Medicine
Director, Emory Medical Laboratories
Emory University Hospital
Atlanta, Georgia
Molecular Methods in Diagnosis and Monitoring of Infectious Diseases

Daniel W. Chan, Ph.D., D.A.B.C.C., F.A.C.B.
Professor of Pathology, Oncology, Radiology, and Urology
Director, Clinical Chemistry Division & Center for Biomarker Discovery and Translation
Co-Director, Pathology Core Laboratories
Department of Pathology
Johns Hopkins Medical Institutions
Baltimore, Maryland
Tumor Markers

Rossa W. K. Chiu, M.B.B.S., Ph.D., F.H.K.A.M. (Pathology), F.R.C.P.A.
Professor
Department of Chemical Pathology
The Chinese University of Hong Kong
Specialist in Chemical Pathology
Honorary Consultant
Prince of Wales Hospital
Hong Kong SAR, China
Principles of Molecular Biology; Nucleic Acid Isolation; Plasma Nucleic Acids

Allan C. Deacon, Ph.D., F.R.C.Path.
Consultant Clinical Scientist (Retired)
Clinical Biochemistry Department
Bedford Hospital
Bedford, United Kingdom
The Porphyrias and Other Disorders of Porphyrin Metabolism

Michael P. Delaney, B.Sc., M.D., F.R.C.P.
Consultant Nephrologist
East Kent Hospitals University NHS Foundation Trust
Kent and Canterbury Hospital
Canterbury, Kent, United Kingdom
Kidney Disease

Paul D'Orazio, Ph.D.
Director, Critical Care Analytical
Research and Development
Instrumentation Laboratory
Bedford, Massachusetts
Electrochemistry and Chemical Sensors

Basil T. Doumas, Ph.D.
Professor Emeritus
Department of Pathology
Medical College of Wisconsin
Milwaukee, Wisconsin
Hemoglobin, Iron, and Bilirubin

D. Robert Dufour, M.D., F.C.A.P., F.A.C.B.
Consultant, Pathology and Hepatology
Veterans Affairs Medical Center
Emeritus Professor of Pathology
George Washington University Medical Center
Washington, DC
Liver Disease

John H. Eckfeldt, M.D., Ph.D.
Ellis Benson Professor and Vice Chair for Clinical Affairs
Department of Laboratory Medicine & Pathology
University of Minnesota
Minneapolis, Minnesota
Hemoglobin, Iron, and Bilirubin

Graeme Eisenhofer, Ph.D.
Professor
Department of Medicine III
Institute of Clinical Chemistry and Laboratory Medicine
Chief, Division of Clinical Neurochemistry
University Hospital Carl Gustav Carus Dresden at the Dresden University of Technology
Dresden, Germany
Catecholamines and Serotonin

George H. Elder, M.D., F.R.C.P., F.R.C.Path.
Emeritus Professor
Department of Infection, Immunity, & Biochemistry
School of Medicine
Cardiff University
Cardiff, United Kingdom
The Porphyrias and Other Disorders of Porphyrin Metabolism

tahir99-VRG & vip.persianss.ir

Kojo S. J. Elenitoba-Johnson, M.D.
Professor of Pathology
University of Michigan Medical School
University of Michigan Hospital
Ann Arbor, Michigan
Hematopoietic Malignancies

Jens Peter Goetze, M.D., D.M.Sc.
Chief Physician
Department of Clinical Biochemistry
Rigshospitalet
Associate Professor
University of Copenhagen
Copenhagen, Denmark
Cardiac Function

Bruce A. Goldberger, Ph.D.
Professor and Director of Toxicology
Departments of Pathology and Psychiatry
University of Florida College of Medicine
Gainesville, Florida
Chromatography and Extraction

David G. Grenache, Ph.D., M.T.(A.S.C.P.), D.A.B.C.C., F.A.C.B.
Associate Professor of Pathology
University of Utah School of Medicine
Medical Director, Special Chemistry
ARUP Laboratories
Salt Lake City, Utah
Pregnancy and Its Disorders

Ann M. Gronowski, Ph.D.
Professor, Department of Pathology & Immunology
Professor, Department of Obstetrics & Gynecology
Washington University School of Medicine
St. Louis, Missouri
Reproductive Endocrinology and Related Disorders

Amy R. Groszbach, M.ED., M.L.T., M.B.(A.S.C.P.)$^{C.M.}$
Education Specialist II
Molecular Genetics Laboratory, Mayo Clinic
Program Director, Molecular Genetics Technology Internship Program
Mayo School of Health Science, Mayo Clinic
Rochester, Minnesota
Specimen Collection and Processing

Doris M. Haverstick, Ph.D., D.A.B.C.C.
Associate Professor of Pathology
University of Virginia
Charlottesville, Virginia
Specimen Collection and Processing

Charles D. Hawker, Ph.D., M.B.A., F.A.C.B.
Professor (Adjunct) of Pathology
University of Utah School of Medicine
Scientific Director, Automation & Special Projects
ARUP Laboratories
Salt Lake City, Utah
Automation in the Clinical Laboratory

Russell A. Higgins, M.D.
Assistant Professor
Director, Hematology Laboratory
University of Texas Health Science Center San Antonio
San Antonio, Texas
Hemostasis

Trefor Higgins, M.Sc.
Director of Clinical Chemistry
$DynaLIFE_{Dx}$
Clinical Professor
Department of Laboratory Medicine & Pathology
Faculty of Medicine
University of Alberta
Edmonton, Alberta
Hemoglobin, Iron, and Bilirubin

Peter G. Hill, B.Sc., Ph.D., F.R.C.Path, Dip.Hlth.Mgt.
Emeritus Consultant Clinical Biochemist
Royal Derby Hospital
Derby, United Kingdom
Gastric, Pancreatic, and Intestinal Function

Christopher P. Holstege, M.D.
Chief, Division of Medical Toxicology
Associate Professor, Departments of Emergency Medicine and Pediatrics
University of Virginia School of Medicine
Medical Director, Blue Ridge Poison Center
University of Virginia Health System
Charlottesville, Virginia
Clinical Toxicology

Joshua L. Hood, M.D., Ph.D.
Research Instructor
Consortium for Translational Research in Advanced Imaging and Nanomedicine (C-TRAIN)
Washington University
St. Louis, Missouri
Electrolytes and Blood Gases; Physiology and Disorders of Water, Electrolyte, and Acid-Base Metabolism

Gary L. Horowitz, M.D.
Associate Professor of Pathology
Harvard Medical School
Director of Clinical Chemistry
Beth Israel Deaconess Medical Center
Boston, Massachusetts
Establishment and Use of Reference Values

Glen L. Hortin, M.D., Ph.D.
Medical Director
Cincinnati Business Unit
Quest Diagnostics
Cincinnati, Ohio
Chromatography and Extraction; Amino Acids, Peptides, and Proteins

T. Scott Isbell, Ph.D.
Clinical Chemistry Fellow
Department of Pathology & Immunology
Division of Laboratory & Genomic Medicine
Washington University School of Medicine
St. Louis, Missouri
Reproductive Endocrinology and Related Disorders

Allan S. Jaffe, M.D.
Consultant in Cardiology and Laboratory Medicine
Professor of Medicine
Chair, CCLS Division of Laboratory Medicine & Pathology
Mayo Clinic and Medical School
Rochester, Minnesota
Cardiac Function

Ishwarlal Jialal, M.D., Ph.D., F.R.C.Path(London), D.A.B.C.C.
Robert E. Stowell Endowed Chair in Experimental Pathology
Director of the Laboratory for Atherosclerosis and Metabolic Research
Professor of Internal Medicine (Endocrinology, Diabetes, and Metabolism)
University of California Davis Medical Center
Sacramento, California
Pituitary Function and Pathophysiology; The Adrenal Cortex

Emily S. Jungheim, M.D.
Instructor
Washington University
Endocrinologist
Barnes Jewish Hospital
St. Louis, Missouri
Reproductive Endocrinology and Related Disorders

Raymond E. Karcher, Ph.D.
Adjunct Associate Professor
Oakland University
Rochester, Michigan
Clinical Chemist
William Beaumont Hospital
Royal Oak, Michigan
Electrophoresis

Malek Kaumon, M.D., Ph.D.
Professor of Pathology and Laboratory Medicine
University of Pennsylvania School of Medicine
Director, Clinical Immunology & Histocompatibility Laboratory
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Identity Assessment

Steve Kitchen, Ph.D.
Lead Scientist
Department of Coagulation
Sheffield Teaching Hospitals
Sheffield, United Kingdom
Hemostasis

George G. Klee, M.D., Ph.D.
Professor of Laboratory Medicine & Pathology
College of Medicine
Staff Consultant
Department of Laboratory Medicine & Pathology
Mayo Clinic
Rochester, Minnesota
Quality Management

Michael Kleerekoper, M.D., F.A.C.B., F.A.C.P., M.A.C.E.
Clinical Professor of Medicine/Endocrinology
Wayne State University
Detroit, Michigan
Hormones; Bone and Mineral Metabolism

Larry J. Kricka, D.Phil., F.A.C.B., C.Chem., F.R.S.C., F.R.C.Path.
Professor
University of Pennsylvania
Director of General Chemistry
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Optical Techniques; Principles of Immunochemical Techniques

Noriko Kusukawa, Ph.D.
Director, New Technology Assessment & Licensing
ARUP Laboratories
Adjunct Associate Professor of Pathology
University of Utah School of Medicine
Salt Lake City, Utah
Nucleic Acid Techniques; Genomes and Nucleic Acid Alterations

Edmund J. Lamb, Ph.D., F.R.C.Path.
Head, Clinical Biochemistry
East Kent Hospitals University NHS Foundation Trust
Canterbury, Kent, United Kingdom
Kidney Function Tests; Kidney Disease

Geralyn Lambert-Messerlian, Ph.D.
Associate Professor
Department of Pathology & Laboratory Medicine
Alpert Medical School of Brown University
Associate Director
Division of Prenatal & Special Testing
Women and Infants Hospital of Rhode Island
Providence, Rhode Island
Pregnancy and Its Disorders

James P. Landers, Ph.D.
Professor of Chemistry
Professor of Mechanical Engineering
University of Virginia
Associate Professor of Pathology
Member-UVA Cancer Center
University of Virginia School of Medicine
Charlottesville, Virginia
Electrophoresis; Microfabrication and Microfluidics and Their Application to Clinical Diagnostics

Loralie Langman, Ph.D., F.C.A.C.B., D.A.B.C.C. (C.C., M.B., T.C.), D.A.B.F.T.
Director, Toxicology and Drug Monitoring Laboratory
Department of Laboratory Medicine & Pathology
Mayo Clinic
Associate Professor of Laboratory Medicine and Pathology
Mayo Clinic College of Medicine
Rochester, Minnesota
Clinical Toxicology

Vicky A. LeGrys, Ph.D., Dr.A., M.T.(A.S.C.P), C.L.S.(N.C.A.)
Professor
Division of Clinical Laboratory Science
School of Medicine
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina
Electrolytes and Blood Gases

Kristian Linnet, M.D., Ph.D.
Professor, Chief, Section of Forensic Chemistry
Department of Forensic Medicine, Faculty of Health Sciences
University of Copenhagen
Copenhagen, Denmark
Selection and Analytical Evaluation of Methods—With Statistical Techniques

Y. M. Dennis Lo, M.A., D.M., D.Phil., F.R.C.P. (Lond. & Edin.), F.R.C.Path., F.R.S.
Li Ka Shing Professor of Medicine and Professor of Chemical Pathology
Department of Chemical Pathology
The Chinese University of Hong Kong
Honorary Chief of Service
Prince of Wales Hospital
Hong Kong SAR, China
Principles of Molecular Biology; Nucleic Acid Isolation; Plasma Nucleic Acids

Stanley F. Lo, Ph.D., D.A.B.C.C., F.A.C.B
Associate Professor of Pathology
Medical College of Wisconsin
Associate Director, Clinical Laboratories
Children's Hospital of Wisconsin
Milwaukee, Wisconsin
Principles of Basic Techniques and Laboratory Safety

Nicola Longo, M.D., Ph.D.
Professor of Pediatrics and Pathology
Chief, Division of Medical Genetics
Department of Pediatrics
Medical Co-Director, ARUP Biochemical Genetics Laboratory
University of Utah
Salt Lake City, Utah
Newborn Screening and Inborn Errors of Metabolism

Gwendolyn A. McMillin, Ph.D., D.A.B.C.C. (C.C., T.C.)
Clinical Associate Professor of Pathology
University of Utah School of Medicine
Medical Director, Clinical Drug Abuse Testing, Trace Elements
Co-Medical Director, Pharmacogenomics
ARUP Laboratories
Salt Lake City, Utah
Therapeutic Drugs and Their Management; Pharmacogenetics; Reference Information for the Clinical Laboratory

Mark E. Meyerhoff, Ph.D.
Philip J. Elving Professor of Chemistry
The University of Michigan
Department of Chemistry
Ann Arbor, Michigan
Electrochemistry and Chemical Sensors

Thomas P. Moyer, Ph.D.
Professor of Laboratory Medicine
Mayo College of Medicine
Mayo Clinic
Rochester, Minnesota
Therapeutic Drugs and Their Management; Toxic Metals

John D. Olson, M.D., Ph.D.
Professor and Vice Chair for Clinical Affairs
Department of Pathology
University of Texas Health Science Center
Director of Clinical Laboratories
University Health System
San Antonio, Texas
Hemostasis

Mauro Panteghini, M.D.
Professor of Clinical Biochemistry and Clinical Molecular Biology
Department of Clinical Sciences
University of Milan Medical School
Director, Clinical Biochemistry Laboratory
Ospedale "Luigi Sacco"
Milan, Italy
Enzyme and Rate Analyses; Serum Enzymes

Jason Y. Park, M.D., Ph.D., F.A.C.P.
Assistant Professor
Department of Pathology
University of Texas Southwestern Medical Center
Associate Director
Advanced Diagnostics Laboratory
Children's Medical Center
Dallas, Texas
Optical Techniques; Principles of Immunochemical Techniques

Marzia Pasquali, Ph.D., F.A.C.M.G.
Professor of Pathology
University of Utah School of Medicine
Medical Director, Biochemical Genetics & Supplemental Newborn Screening
ARUP Laboratories
Salt Lake City, Utah
Newborn Screening and Inborn Errors of Metabolism

Christopher P. Price, Ph.D., F.R.S.C., F.R.C.Path.
Visiting Professor in Clinical Biochemistry
Department of Primary Care Health Sciences
University of Oxford
Oxford, United Kingdom
Evidence Based Laboratory Medicine; Point-of-Care Testing; Kidney Function Tests; Kidney Disease

Alex J. Rai, Ph.D., D.A.B.C.C., F.A.C.B.
Director, Special Chemistry Laboratory
New York Presbyterian Hospital
Assistant Professor of Pathology
Chief Scientific Officer
Center for Advanced Laboratory Medicine
Department of Pathology & Cell Biology
Columbia University Medical Center
New York, New York
Tumor Markers

Alan T. Remaley, M.D., Ph.D.
Department of Laboratory Medicine
National Institutes of Health
Bethesda, Maryland
Lipids, Lipoproteins, Apolipoproteins, and Other Cardiovascular Risk Factors

Nader Rifai, Ph.D.
Director, Clinical Chemistry
Department of Laboratory Medicine
Children's Hospital Boston
Professor
Harvard Medical School
Boston, Massachusetts
Editor-in-Chief, *Clinical Chemistry*
Washington, D.C.
Lipids, Lipoproteins, Apolipoproteins, and Other Cardiovascular Risk Factors

Juha Risteli, M.D., Ph.D., F.E.B.M.B.
Professor of Clinical Chemistry
Department of Clinical Chemistry
Institute of Diagnostics
University of Oulu
Chief Physician (Part-Time)
Laboratory
Oulu University Hospital
Oulu, Finland
Bone and Mineral Metabolism

Leila Risteli, M.D., Ph.D., M.A., F.E.B.M.B.
Chief Physician
Laboratory
Oulu University Hospital
Adjunct Professor of Medical Biochemistry
University of Oulu
Oulu, Finland
Adjunct Professor of Clinical Chemistry
University of Tampere
Tampere, Finland
Bone and Mineral Metabolism

Norman B. Roberts, M.Sc., Ph.D., C.Chem.
Consultant Clinical Scientist
Department of Clinical Biochemistry
The Royal Liverpool and Broadgreen University Hospitals
Honorary Reader
Clinical Chemistry
The University of Liverpool
Liverpool, United Kingdom
Vitamins and Trace Elements

William L. Roberts, M.D., Ph.D.
Professor of Pathology
University of Utah School of Medicine
Medical Director, Automated Core Laboratory
ARUP Laboratories
Salt Lake City, Utah
Reference Information for the Clinical Laboratory

Alan L. Rockwood, Ph.D., D.A.B.C.C.
Scientific Director for Mass Spectrometry
ARUP Laboratories
Associate Professor (Clinical) of Pathology
University of Utah School of Medicine
Salt Lake City, Utah
Mass Spectrometry

Thomas G. Rosano, Ph.D., D.A.B.C.C., D.A.B.F.T.
Head of Clinical Laboratory Services
Director of Clinical Chemistry & Forensic Toxicology
Professor of Pathology and Laboratory Medicine
Albany Medical Center Hospital & College
Albany, New York
Catecholamines and Serotonin

David B. Sacks, M.B., Ch.B., F.R.C.Path.
Senior Investigator
Chief, Clinical Chemistry
National Institutes of Health
Bethesda, Maryland
Carbohydrates; Diabetes Mellitus

Desmond Schatz, M.D.
Professor and Associate Chairman
Department of Pediatrics
Division of Endocrinology
Medical Director, Diabetes Center
University of Florida
Gainesville, Florida
The Thyroid: Pathophysiology and Thyroid Function Testing

Mitchell G. Scott, Ph.D.
Professor of Pathology and Immunology
Co-Medical Director, Clinical Chemistry
Division of Laboratory & Genomic Medicine
Washington University School of Medicine
St. Louis, Missouri
Electrolytes and Blood Gases; Physiology and Disorders of Water, Electrolyte, and Acid-Base Metabolism

Alan Shenkin, Ph.D.
Professor
Unit of Clinical Chemistry
School of Clinical Sciences
University of Liverpool
Liverpool, England
Vitamins and Trace Elements

Nicholas E. Sherman, Ph.D.
Research Associate Professor
Director of Mass Spectrometry
University of Virginia
Charlottesville, Virginia
Mass Spectrometry

Christine L. H. Snozek, Ph.D.
Assistant Professor
Mayo Clinic College of Medicine
Associate Director, Toxicology and Drug Monitoring Laboratory
Department of Laboratory Medicine & Pathology
Mayo Clinic
Rochester, Minnesota
Therapeutic Drugs and Their Management

Lori J. Sokoll, Ph.D., F.A.C.B.
Associate Professor of Pathology, Oncology, and Urology
Associate Director, Clinical Chemistry Division
Department of Pathology
Johns Hopkins Medical Institutions
Baltimore, Maryland
Tumor Markers

Andrew St. John, Ph.D., M.A.A.C.B.
Consultant
ARC Consulting
Perth, W. Australia
Point-of-Care Testing

Wouter W. van Solinge, Ph.D.
Head of Department and Medical Director, Division Laboratories & Pharmacy
Professor of Clinical Chemistry and Laboratory Medicine
Department of Clinical Chemistry & Haematology
University Medical Center Utrecht
Utrecht University, Faculty of Science
Utrecht Institute for Pharmaceutical Sciences
Division Pharmacoepidemiology & Clinical Pharmacology
Utrecht, The Netherlands
Enzymes of the Red Blood Cell

Richard van Wijk, Ph.D.
Assistant Professor
Laboratory for Red Blood Cell Research
Department of Clinical Chemistry & Haematology
University Medical Center Utrecht
Utrecht, The Netherlands
Enzymes of the Red Blood Cell

Mary Lee Vance, M.D.
University of Virginia School of Medicine Charlottesville, VA
Professor of Medicine and Neurosurgery
Pituitary Function and Pathophysiology; The Adrenal Cortex

Cindy L. Vnencak-Jones, Ph.D., F.A.C.M.G.
Director, Molecular Diagnostics Laboratory
Vanderbilt University Medical Center
Professor, Department of Pathology, Microbiology, & Immunology and Department of Pediatrics
Vanderbilt University School of Medicine
Nashville, Tennessee
Inherited Diseases

G. Russell Warnick, M.S., M.B.A.
Executive Director
Foundation for Health Information and Technology
Chief Science Officer
Health Diagnostic Laboratory
Richmond, Virginia
Lipids, Lipoproteins, Apolipoproteins, and Other Cardiovascular Risk Factors

Foreword

Laboratory medicine is at the center of the multidisciplinary healthcare team. Laboratory medicine specialists have a responsibility to convert data into evidence-based knowledge and added value that is then applied to clinical situations in the interests of improved patient outcomes and experiences. To reach this advanced level of knowledge and practice, the laboratory medicine specialist needs support. In the clinical chemistry specialty, that support is available through the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*.

The 4th edition of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics* published in 2005 enhanced the status of the *Tietz Textbook* as the definitive reference work in the field. In common with so many areas of medicine, clinical chemistry and molecular diagnostics is advancing at a considerable rate, and so this 5th edition is both welcome and important. It brings new knowledge, fresh insights, and a growing appreciation of the central role of laboratory medicine in healthcare.

The 60 chapters in the 5th edition span the full range of clinical chemistry and molecular diagnostics from principles through to pathophysiology and clinical use. Each chapter has been written by international experts, and so the textbook benefits from their many contributions. Their knowledge and expertise have been skillfully blended by the established editorial team of Dr. Carl A. Burtis, Dr. Edward R. Ashwood, and Dr. David E. Bruns, ably assisted by a strong international team of Associate Editors. The result is a text that is comprehensive but easy to read and understand. Whether the reader is a student studying clinical chemistry and molecular diagnostics, an established professional who wants to update knowledge and understanding, or a clinician who wishes to find a specific piece of information, the *Tietz Textbook* will deliver.

This is an important time for clinical chemistry and molecular diagnostics with parallel developments in technology and clinical practice, including the following:

- The advent of a variety of point-of-care testing devices that are sophisticated in design but simple to use, and that bring laboratory medicine to the doctor's office, to the workplace, and to the home
- The impact of automation and robotics in enhancing analytical capacity and throughput in the clinical laboratory
- The impact of DNA sequencing and other genomic technologies that have the potential to rapidly obtain and analyze comprehensive genetic information that will help unravel the mystery of disease causation and will direct targeted therapies
- The appreciation that knowledge acquired from clinical chemistry and other laboratory medicine investigations may be used in evidence-based algorithms and clinical guidelines as part of an integrated approach to healthcare
- The development of personalized medicine, which recognizes that we are all different and uses genetic and other information to predict, prevent, and optimize therapy for the individual person
- The promise of regenerative medicine and living cell–based therapies, which have the potential to repair damaged pathways, rejuvenate the immune system, and restore health to many who now live with chronic disease and tissue damage
- The accessibility of advanced technologies in routine laboratory practice, enabling analysis of the end products of cellular processes and expanding metabolic profiling techniques to the investigation of cancer and metabolic regulatory disorders
- The globalization of healthcare, which facilitates harmonization of practice and assists the rapid development of laboratory medicine services in emerging nations
- The recognition that high quality in the preanalytical, analytical, and postanalytical phases, coupled with demonstrable value for money, is integral to the future of laboratory medicine

These developments all represent subspecialties in their own right, but they are also topics that should be fixed in the mind of every laboratory medicine specialist. True to its reputation and status as the world's leading text, the 5th edition of *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics* addresses all of these issues, in addition to providing the essential foundations from which our discipline has evolved.

Preface

The intertwined disciplines of Clinical Chemistry and Molecular Diagnostics continue to expand in depth and breadth, a process that has blurred traditional boundaries between them and other disciplines of laboratory medicine. As a result of this dynamic and relentless explosion of technical and medical advances, clinical laboratories have entered an era of rapid test growth and menu expansion. The knowledge base that defines the field has expanded exponentially, thus placing additional burdens on laboratory professionals to maintain their technical expertise and consultative skills.

To provide an authoritative textbook that contains a current and comprehensive overview of this knowledge base is a challenging and daunting task that threatened to overwhelm our ability to cover all relevant topics. Consequently, to assist us in the endeavor of producing this 5th edition of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics,* we organized and recruited a board of associate editors comprising senior and experienced laboratorians. These subject matter experts were asked to edit chapters that contained information most familiar to them. Authorities composing this committee were Drs. Ann Gronowski, W. Greg Miller, Michael Oellerich, Francois Rousseau, Mitchell Scott, and Karl Voelkerding. The three of us thank these associate editors for their hard work and dedication. We are confident that readers of the new edition will discover and benefit from their expertise and superb editing skills and the resultant strengthening of chapters in this new edition. In addition to these associate editors, who edited multiple chapters, we asked colleagues to review single chapters, and we wish to thank Drs. Dave Armbruster, Charles Eby, Doris M. Haverstick, and Kristi J. Smock for their help as reviewers.

Another challenge we faced was the mandate from the publisher that the 5th edition be produced in a single volume. Consequently, we spent many hours reviewing and revising the table of contents. This required some cutting and condensing of chapters and topics, but we were able to retain the chapters on molecular diagnostics, which appeared for the first time in the last edition. Also, because we received multiple requests from readers of previous editions for a chapter on coagulation, we added a chapter on that topic and are grateful to Drs. John Olson, Steve Kitchen, and Russell Higgins for producing a comprehensive and readable chapter on hemostasis and thrombosis.

Many new authors have joined our team of core veterans from previous editions. In fact, 40 of the 99 authors represented in the 5th edition are new to the effort. We believe that these knowledgeable and enthusiastic new authors and our expert core of veteran authors, associate editors, and reviewers of specific chapters have produced chapters that are timely and reflect the state of the art of topics addressed. The international flavor of the book and the global nature of the field are more evident than ever before in the list of countries represented by this outstanding group of colleagues.

Information technology continued to have a significant role in the preparation and production of the 5th edition. As with the last edition, each chapter was submitted electronically. A new tool that was utilized in the 5th edition was Elsevier's Electronic Manuscript Submission System (EMSS). With it, each chapter including figures was uploaded into the book's template. Editors accessed and edited chapters as they became available and then uploaded their revised drafts. Once all 60 chapters were submitted and the editing process completed, the entire book was sent to our project manager at Elsevier, and the production process started. As with previous editions of the *Textbook,* many of the figures, especially those that included chemical structures, were drawn or revised by one of us (E.R.A.) using ChemWindows software (http://www.softshell.com; accessed August 26, 2011). This resulted in a uniform representation of chemical structures and facilitated the integration of figures with text while reducing errors.

We greatly appreciate the opportunity provided to us by Elsevier to participate in the preparation of the 5th edition of this textbook. It has been an exciting, challenging, and educational experience. We have endeavored to ensure that this edition will live up to the reputation and success of its distinguished predecessors. We have benefited from and enjoyed working with the Elsevier staff in St. Louis, especially Managing Editor Ellen Wurm-Cutter and Senior Project Manager Rachel McMullen. Their patience, warm cooperation, sound advice, and professional dedication are gratefully acknowledged.

We would be amiss if we didn't thank the individuals who made all of this possible: our readers. Over the years, we have appreciated and enjoyed having many of you approach us to say how much you enjoyed our books and the significant role they have played in your lives and careers. We have heard from a diverse spectrum of laboratory professionals, including practicing clinical chemists and pathologists; medical, graduate, and medical technology students; clinical chemistry fellows; pathology residents; molecular genetics and pathology fellows; recently board-certified clinical chemists, pathologists, and molecular geneticists; medical librarians; medical researchers; and students who are studying for their Boards. In short, nothing makes us happier than hearing that our book has been helpful and useful!

Contents

SECTION I PRINCIPLES OF LABORATORY MEDICINE 1

1 **Clinical Chemistry, Molecular Diagnostics, and Laboratory Medicine 3**
David E. Bruns, M.D., Edward R. Ashwood, M.D., and Carl A. Burtis, Ph.D.

2 **Selection and Analytical Evaluation of Methods—With Statistical Techniques 7**
Kristian Linnet, M.D., Ph.D., and James C. Boyd, M.D.

3 **Clinical Utility of Laboratory Tests 49**
Edward R. Ashwood, M.D., and David E. Bruns, M.D.

4 **Evidence-Based Laboratory Medicine 61**
Christopher P. Price, Ph.D., F.R.S.C., F.R.C.Path., Patrick M. M. Bossuyt, Ph.D., and David E. Bruns, M.D.

5 **Establishment and Use of Reference Values 95**
Gary L. Horowitz, M.D.

6 **Preanalytical Variables and Biological Variation 119**
Donald S. Young, M.B., Ph.D.

7 **Specimen Collection and Processing 145**
Doris M. Haverstick, Ph.D., D.A.B.C.C., and Amy R. Groszbach, M.E.D., M.L.T., M.B.(A.S.C.P.)[C.M.]

8 **Quality Management 163**
George G. Klee, M.D., Ph.D., and James O. Westgard, Ph.D.

SECTION II ANALYTICAL TECHNIQUES AND INSTRUMENTATION 205

9 **Principles of Basic Techniques and Laboratory Safety 207**
Stanley F. Lo, Ph.D., D.A.B.C.C., F.A.C.B.

10 **Optical Techniques 233**
Larry J. Kricka, D.Phil., F.A.C.B., C.Chem., F.R.S.C., F.R.C.Path., and Jason Y. Park, M.D., Ph.D., F.C.A.P.

11 **Electrochemistry and Chemical Sensors 259**
Paul D'Orazio, Ph.D., and Mark E. Meyerhoff, Ph.D.

12 **Electrophoresis 287**
Raymond E. Karcher, Ph.D., and James P. Landers, Ph.D.

13 **Chromatography and Extraction 307**
Glen L. Hortin, M.D., Ph.D., and Bruce A. Goldberger, Ph.D.

14 **Mass Spectrometry 329**
Alan L. Rockwood, Ph.D., D.A.B.C.C., Thomas M. Annesley, Ph.D., and Nicholas E. Sherman, Ph.D.

15 **Enzyme and Rate Analyses 355**
Renze Bais, Ph.D., A.R.C.P.A., and Mauro Panteghini, M.D.

16 **Principles of Immunochemical Techniques 379**
Larry J. Kricka, D.Phil., F.A.C.B., C.Chem., F.R.S.C., F.R.C.Path., and Jason Y. Park, M.D., Ph.D., F.A.C.P.

17 **Nucleic Acid Techniques 401**
Carl T. Wittwer, M.D., Ph.D., and Noriko Kusukawa, Ph.D.

18 **Microfabrication and Microfluidics and Their Application to Clinical Diagnostics 443**
Lindsay A. L. Bazydlo, Ph.D., and James P. Landers, Ph.D.

19 **Automation in the Clinical Laboratory 469**
James C. Boyd, M.D., and Charles D. Hawker, Ph.D., M.B.A., F.A.C.B.

20 **Point-of-Care Testing 487**
Christopher P. Price, Ph.D., F.R.S.C., F.R.C.Path., and Andrew St. John, Ph.D., M.A.A.C.B.

SECTION III ANALYTES 507

21 **Amino Acids, Peptides, and Proteins 509**
Glen L. Hortin, M.D., Ph.D.

22 **Serum Enzymes 565**
Mauro Panteghini, M.D., and Renze Bais, Ph.D., A.R.C.P.A.

23 **Enzymes of the Red Blood Cell 599**

CHAPTER 1

Clinical Chemistry, Molecular Diagnostics, and Laboratory Medicine

David E. Bruns, M.D., Edward R. Ashwood, M.D., and Carl A. Burtis, Ph.D.

Clinical chemists, clinical biochemists, chemical pathologists, medical technologists, molecular biologists, and other clinical laboratory scientists are laboratory professionals who play an important role in the global delivery of quality healthcare and public health.[3]

In this chapter, we begin with a general discussion introducing the field of laboratory medicine and the disciplines of clinical chemistry (or clinical biochemistry) and molecular diagnostics. This will include a discussion of the meaning of the term *laboratory medicine* and the relationships among clinical chemistry, molecular diagnostics, laboratory medicine, and evidence-based laboratory medicine. The concepts introduced in this chapter are developed in the remaining chapters of this book.

We end the chapter with a discussion on the ethical issues that clinical chemists/biochemists face in the practice of their profession and issues they will face in the future.

LABORATORY MEDICINE

The term *laboratory medicine* refers to the discipline involved in the selection, provision, and interpretation of diagnostic testing that uses samples from patients. Those active in the field participate in (1) analytical testing, (2) research, (3) administration, (4) teaching activities, and (5) clinical service to varying degrees.

Testing has many uses in laboratory medicine (Box 1-1). In a hospital setting, its use is vital to establish and monitor the severity of a physiologic disturbance. In hospitalized patients, the latter constitutes the largest volume of testing.

Historically, the clinical laboratory as an entity in providing healthcare services began with the manual measurement of a variety of analytes (now termed *measurands*),[10] including (1) metabolites, (2) proteins, (3) lipids, (4) carbohydrates, (5) enzymes, and (6) drugs. The first laboratory attached to a hospital was established in 1886 in Munich, Germany, by Hugo Wilhelm von Ziemssen.[5,8] In the United States, the first clinical laboratory was The William Pepper Laboratory of Clinical Medicine, established in 1895 at the University of Pennsylvania in Philadelphia (http://hss.sas.upenn.edu/microbio/insts2.html). As the demand for these analytical services increased, analytical processes were mechanized and ultimately automated.[9] Technical and scientific advances and the growing understanding of disease at the biochemical and genetic levels have expanded the need for the clinical laboratory to provide analytical services in a broad and diverse spectrum of disciplines (Box 1-2), with clinical chemistry and molecular diagnostics being particularly dynamic as they have developed and expanded alongside the growing understanding of disease at the biochemical and genetic levels. Most individuals entering these two disciplines have backgrounds in biochemistry, molecular biology, physiology, or another biochemistry-related field, and some have backgrounds in areas such as analytical chemistry.[14] Principles of measurement science and metrology, often adapted from the field of analytical chemistry by clinical chemists, have never been more important than they are now, as quantitative molecular methods such as viral load assays and measurement of the numbers of DNA triplet repeats are replacing numerous qualitative techniques throughout medicine.

CLINICAL CHEMISTRY AND LABORATORY MEDICINE

The ties between clinical chemistry and other areas of laboratory medicine have deep roots. Individuals working primarily in the area of clinical chemistry/biochemistry have developed tools and methods that have become part of the fabric of laboratory medicine beyond the clinical chemistry laboratory. Examples include the (1) theory and practice of reference intervals (see Chapter 5), (2) use of both (internal) quality control and proficiency testing (see Chapter 8), (3) introduction of automation into the clinical laboratory (see Chapter 19), and (4) concepts of diagnostic testing (see

BOX 1-1 Uses of Testing in the Clinical Laboratory

- *Confirming* a clinical suspicion (which could include *making* a diagnosis)
- *Excluding* a diagnosis
- Assisting in the *selection, optimization, and monitoring* of treatment
- Providing a *prognosis*
- *Screening* for disease in the absence of clinical signs or symptoms
- Establishing and monitoring the *severity* of a physiologic disturbance

BOX 1-2 Disciplines of the Modern-Day Clinical Laboratory

- Biochemical Genetics
- Blood Banking (Transfusion Medicine)
- Cancer Diagnostics
- Clinical Chemistry/Biochemistry
- Clinical Hematology
- Clinical Immunology
- Cytogenetics
- Drug Monitoring
- Endocrinology Testing
- Hemostasis/Thrombosis (Coagulation) Testing
- Identity Testing
- Infectious Disease Testing
- Information Technology
- Laboratory Management
- Microbiology
- Molecular Cytogenetics
- Molecular Diagnostics
- Nutrition
- Organ Transplantation
- Organ Function Testing
- Pharmacogenetics
- Proteomics
- Quality Management
- Toxicology
- Trace Elements

Chapters 3 and 4). From the physician's and the patient's perspective, no distinction is evident between these specialties, and invariably the repertoire of more than one specialty will be called upon when a clinical decision is made. Examples of clinical scenarios that require tests from multiple laboratory areas include the diagnosis and management of many diseases and the management of patients in intensive care (see Chapters 46 through 59 ["Pathophysiology" section of this text]).

Boundaries between and among the parts of the clinical laboratory have become more blurred with increasing emphasis on the use of chemical and "molecular" (nucleic acid) testing. Molecular diagnostic testing has evolved beyond human genetic testing, an area in which clinical chemists have long been active. Now, clinical chemists in "molecular" laboratories contribute their expertise in laboratory medicine to infectious disease testing, cancer diagnostics, and identity testing, activities that formerly were associated primarily or solely with, respectively, clinical microbiology, hematology, and blood bank laboratories. Successful contribution by clinical chemists to these areas requires an understanding of the principles of laboratory medicine and close collaboration with clinical microbiologists, hematologists, and others who have specialized expertise in those areas of laboratory medicine.

The relationship between the clinical chemist and laboratory medicine has evolved further with the advent of "core" laboratories. These laboratories provide all of the high-volume and emergency testing in many hospitals. Their efficient and reliable operation depends on automation (see Chapter 19), computers, and high levels of quality control and quality management (see Chapter 8). Clinical chemists, who have long been active in these areas, have assumed increasing responsibility in core laboratories and thus have become more involved in areas such as hematology, coagulation, urinalysis, and even microbiology. Thus a new type of "clinical chemist" has emerged, and again the functions require a broader knowledge of laboratory medicine and greater collaboration with other specialists.

A virtual merger of clinical chemistry and laboratory medicine has been suggested in many ways. For example, journals in the field of clinical chemistry publish papers in all of the areas of laboratory medicine. The current logo of the American Association for Clinical Chemistry reads, "AACC—Improving Healthcare through Laboratory Medicine." Moreover, the international association of clinical chemistry societies is now called the International Federation of Clinical Chemistry and Laboratory Medicine. To be active in the field of laboratory medicine today requires, more often than not, familiarity with core concepts in several if not all of the subdisciplines of the field.

During the past two decades, the field of clinical chemistry has been profoundly influenced by new activities in the fields of clinical epidemiology and evidence-based medicine (EBM). Clinical epidemiologists have developed study designs to quantify the diagnostic accuracy (as opposed to analytical accuracy) of the tests developed in laboratory medicine (see Chapter 3). Moreover, they have introduced methods to evaluate the effects and value of laboratory testing in healthcare (see Chapter 2). These developments are expected to play an increasing role in the selection and interpretation of tests. Thus the fourth chapter of this book is devoted to evidence-based laboratory medicine.

ETHICAL ISSUES IN LABORATORY MEDICINE

As in other branches of medicine, practitioners in laboratory medicine are faced with ethical issues, often on a daily basis; examples are listed in Box 1-3.

Specific issues that challenge laboratory professionals include (1) confidentiality of genetic information and patient

BOX 1-3 Ethical Issues in Clinical Chemistry and Molecular Diagnostics

- Confidentiality of genetic information
- Confidentiality of patient medical information
- Allocation of resources
- Codes of conduct
- Publishing issues
- Conflicts of interest

medical information, (2) allocation of healthcare resources, (3) codes of conduct, (4) publishing issues, and (5) conflict of interest.

Confidentiality of Genetic Information

Prominent in the news in the first and second decades of this millennium has been the issue of confidentiality of genetic information. Legislation was considered necessary to prevent denial of health insurance or employment to people found by DNA testing to be at risk of disease. Less appreciated is the fact that the issue of confidentiality of clinical laboratory data predated DNA testing. In fact, many non-DNA tests, old and new, also carry information about risks of illness and death. Clinical laboratorians have long been responsible for maintaining the confidentiality of all laboratory results, a situation made even more critical with the advent of increasingly powerful genetic testing.

Confidentiality of Patient Medical Information

Because new medical tests are constantly needed, laboratory physicians and scientists spend a great deal of time and effort developing new diagnostic tests or evaluating them for use in a specific setting. This process requires use of patient samples and may involve use of patient medical information.[4] Ethical judgments are required regarding the type of informed consent that is needed from patients for use of their samples and clinical information. Clinical laboratory physicians and scientists often serve on institutional review boards that examine proposed research on human subjects. In these discussions, ethical concepts such as equipoise and confidentiality are central to decisions.

Allocation of Resources

Because resources are finite, clinical laboratorians must make ethically responsible decisions about allocation of resources. When a trade-off exists between cost and quality, ethical issues may need to be considered: What is best for patients generally? How can the most good be done with the available resources? For laboratorians in business, the newly appreciated area of business ethics comes into play. One example, recently epitomized by scandals associated with names such as Madoff and Enron, involves the area of accounting, a human endeavor that in the public mind had not been much associated with concerns about ethics.

Codes of Conduct

Most professional organizations publish a Code of Conduct that requires adherence by their members. For example, the American Association for Clinical Chemistry (AACC) has published Ethical Guidelines (http://www.aacc.org/about/ethics/Pages/default.aspx) that require AACC members to endorse principles of ethical conduct in their professional activities, including (1) selection and performance of clinical procedures, (2) research and development, (3) teaching, (4) management, (5) administration, and (6) other forms of professional service.

Publishing Issues

Publication of documents having high scientific integrity depends on authors, editors, and reviewers all working in concert in an environment governed by high ethical standards.[2]

Authors are responsible for honest and complete reporting of original data produced in ethically conducted research studies. Practices such as fraud, plagiarism, and falsification or fabrication of data are unacceptable! The International Committee of Medical Journal Editors (ICMJE)[12] and the Committee on Publication Ethics (COPE)[7] have published policies that address such behavior. Other practices to be avoided include (1) duplicate publication, (2) redundant publication, and (3) inappropriate authorship credit; in addition, ethical policies require that factors that might influence the interpretation of a study must be revealed.

Most journals now have conflict-of-interest policies for both authors and journal editors. For example, *Clinical Chemistry* requires that authors complete a full disclosure form upon manuscript submission. Annually, the Editor and Associate Editors also are required to provide such a form (http://www.clinchem.org).

Conflict of Interest

Concern has been raised over the interrelationships between practitioners in the medical field and commercial suppliers of drugs, devices, equipment, etc., to the medical profession.[13] These concerns led the National Institutes of Health (NIH) in 1995 to require official institutional review of financial disclosure by researchers and management of situations in which disclosure indicates potential conflicts of interest and/or conflicts of effort in research (http://ethics.od.nih.gov/Topics/finance.htm). In 2009, the Institute of Medicine (IOM) issued a report[11] that questioned inappropriate relationships between pharmaceutical and device companies and physicians and other healthcare professionals.[13] Similarly, the relationships between clinical laboratorians and manufacturers and providers of diagnostic equipment and supplies have been scrutinized.

As a consequence of these concerns and as a result of the enactment of various laws designed to prevent fraud, abuse, and waste in Medicare, Medicaid, and other federal programs, professional organizations that represent manufacturers of in vitro diagnostics (IVD) and other device and healthcare companies have published Codes of Ethics. For example, the

Advanced Medical Technology Association (AdvaMed) has revised and published its Code of Ethics that became effective July 1, 2009.[1] Topics discussed in this revised Code include (1) gifts and entertainment, (2) consulting arrangements and royalties, (3) reimbursement for testing, and (4) education. Similarly, the European Diagnostic Manufacturers Association (EDMA) has published its Code of Ethics.[6] In Part A of this document, topics discussed include (1) member-sponsored product training and education, (2) supporting third party educational conferences, (3) sales and promotional meetings, (4) arrangements and consultants, (5) gifts, (6) provision of reimbursements and other economic information, and (7) donations for charitable and philanthropic purposes. Both documents address demands from regulators while nurturing the unique role that laboratorians and other healthcare professionals play in *developing and refining new technology.*[13]

THE FUTURE

Practitioners of clinical chemistry, molecular diagnostics, and laboratory medicine have before them a future full of promise and challenge. New insight into disease and its treatment is exploding, and these insights are based in sciences that are at the heart of the clinical laboratory. The clinical laboratory is the place of translation of these insights into effective healthcare. We honor the important role of ethical laboratory professionals in these efforts and have endeavored to provide in this book chapters prepared by expert authors that help to define the evidence base and knowledge base of the profession.

CHAPTER 2

Selection and Analytical Evaluation of Methods—With Statistical Techniques

Kristian Linnet, M.D., Ph.D., and James C. Boyd, M.D.

The introduction of new or revised methods is a common occurrence in the clinical laboratory. Method selection and evaluation are key steps in the process of implementing new methods (Figure 2-1). A new or revised method must be selected carefully and its performance evaluated thoroughly in the laboratory before it is adopted for routine use. Establishment of a new method may also involve evaluation of the features of the automated analyzer on which the method will be implemented.

When a new method is to be introduced to the routine clinical laboratory, a series of evaluations are commonly conducted. Assay imprecision is estimated and comparison of the new assay versus an existing method or versus an external comparative method is undertaken. The allowable measurement range is assessed with estimation of the lower and upper limits of quantification. Interferences and carryover are evaluated when relevant. Depending on the situation, a limited verification of manufacturer claims may be all that is necessary, or, in the case of a newly developed method in a research context, a full validation must be carried out. Subsequent subsections provide details for these procedures. With regard to evaluation of reference intervals or medical decision limits, please see Chapter 5.

Method evaluation in the clinical laboratory is influenced strongly by guidelines.[26,105,106] The Clinical and Laboratory Standards Institute [CLSI, formerly National Committee for Clinical Laboratory Standards (NCCLS)] has published a series of consensus protocols[11-19] for clinical chemistry laboratories and manufacturers to follow when evaluating methods (see the CLSI website at http://www.clsi.org). The International Organization for Standardization (ISO) has also developed several documents related to method evaluation.[43-50] In addition, meeting laboratory accreditation requirements has become an important aspect in the method selection and/or evaluation process with accrediting agencies placing increased focus on the importance of total quality management and assessment of trueness and precision of laboratory measurements. An accompanying trend has been the emergence of an international nomenclature to standardize the terminology used for characterizing method performance. This chapter presents an overview of considerations in the method selection process, followed by sections on method evaluation and method comparison. The latter two sections focus on graphical and statistical tools that are used to aid in the method evaluation process; examples of the application of these tools are provided, and current terminology within the area is summarized.

METHOD SELECTION

Optimal method selection involves consideration of medical need, analytical performance, and practical criteria.

Medical Need and Quality Goals

The selection of appropriate methods for clinical laboratory assays is a vital part of rendering optimal patient care, and advances in patient care are frequently based on the use of new or improved laboratory tests. Ascertainment of what is necessary clinically from a laboratory test is the first step in selecting a candidate method. Key parameters, such as desired turnaround time and necessary clinical utility for an assay, are often derived by discussions between laboratorians and clinicians. When new diagnostic assays are introduced, reliable estimates of clinical sensitivity and specificity must be obtained from the literature or by conducting a clinical outcome study (see Chapter 4). With established analytes, a common scenario is the replacement of an older, labor-intensive method with a new, automated assay that is more economical in daily use. In these situations, consideration must be given to whether the candidate method has sufficient precision, accuracy, analytical measurement range, and freedom from interference to provide clinically useful results (see Figure 2-1).

Analytical Performance Criteria

In evaluation of the performance characteristics of a candidate method, (1) precision, (2) accuracy (trueness),

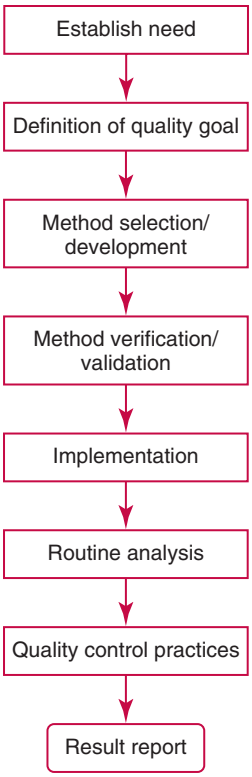

Figure 2-1 A flow diagram that illustrates the process of introducing a new method into routine use.

(3) analytical range, (4) detection limit, and (5) analytical specificity are of prime importance. The sections in this chapter on method evaluation and comparison contain detailed outlines of these concepts and their assessment. Estimated performance parameters for a method are then related to quality goals that ensure acceptable medical use of the test results (see section on "Analytical Goals"). From a practical point of view, the "ruggedness" of the method in routine use is of importance and reliable performance when used by different operators and with different batches of reagents over long time periods is essential.

When a new clinical analyzer is included in the overall evaluation process, various instrumental parameters require evaluation, including (1) pipetting, (2) specimen-to-specimen carryover, (3) reagent lot-to-lot variation, (4) detector imprecision, (5) time to first reportable result, (6) onboard reagent stability, (7) overall throughput, (8) mean time between instrument failures, and (9) mean time to repair. Information on most of these parameters should be available from the instrument manufacturer; the manufacturer should also be able to furnish information on what user studies should be conducted in estimating these parameters for an individual analyzer. Assessment of reagent lot-to-lot variation is especially difficult for a user, and the manufacturer should provide this information.

Other Criteria

Various categories of candidate methods may be considered. New methods described in the scientific literature may require "in-house" development. [Note: Such a test is also referred to as a Laboratory-Developed Test(LDT).] Commercial kit methods, on the other hand, are ready for implementation in the laboratory, often in a "closed" analytical system on a dedicated instrument. When prospective methods are reviewed, attention should be given to the following:

1. Principle of the assay, with original references.
2. Detailed protocol for performing the test.
3. Composition of reagents and reference materials, the quantities provided, and their storage requirements (e.g., space, temperature, light, humidity restrictions) applicable both before and after the original containers are opened.
4. Stability of reagents and reference materials (e.g., their shelf life).
5. Technologist time and required skills.
6. Possible hazards and appropriate safety precautions according to relevant guidelines and legislation.
7. Type, quantity, and disposal of waste generated.
8. Specimen requirements (e.g., conditions for collection and transportation, specimen volume requirements, the necessity for anticoagulants and preservatives, necessary storage conditions).
9. Reference interval of the method, including information on how it was derived, typical values obtained in health and disease, and the necessity of determining a reference interval for one's own institution (see Chapter 5 for details on how to generate a reference interval).
10. Instrumental requirements and limitations.
11. Cost-effectiveness.
12. Computer platforms and interfacing with the laboratory information system.
13. Availability of technical support, supplies, and service.

Other questions concerning placement of the method in the laboratory should be taken into account. They include:

1. Does the laboratory possess the necessary measuring equipment? If not, is there sufficient space for a new instrument?
2. Does the projected workload match with the capacity of a new instrument?
3. Is the test repertoire of a new instrument sufficient?
4. What is the method and frequency of calibration?
5. Is staffing of the laboratory sufficient for the new technology?
6. If training the entire staff in a new technique is required, is such training worth the possible benefits?
7. How frequently will quality control samples be run?
8. What materials will be used to ensure quality control?
9. What approach will be used with the method for proficiency testing?
10. What is the estimated cost of performing an assay using the proposed method, including the costs of calibrators, quality control specimens, and technologists' time?

Questions applicable to implementation of new instrumentation in a particular laboratory may also be relevant. Does the instrument on which the method is implemented

satisfy local electrical safety guidelines? What are the power, water, drainage, and air conditioning requirements of the instrument? If the instrument is large, does the floor have sufficient load-bearing capacity?

A qualitative assessment of these factors is often completed, but it is possible to use a value scale to assign points to the various features of a method weighted according to their relative importance; the latter approach allows a more quantitative selection process. Decisions are then made regarding the analytical methods that best fit the laboratory's requirements, and that have the potential for achieving the necessary analytical quality.

BASIC STATISTICS

In this section, fundamental statistical concepts and techniques are introduced in the context of typical analytical investigations. The basic concepts of (1) populations, (2) samples, (3) parameters, (4) statistics, and (5) probability distributions are defined and illustrated. Two important probability distributions—Gaussian and Student *t*—are introduced and discussed.

Frequency Distribution

A graphical device for displaying a large set of data is the *frequency distribution,* also called a *histogram*. Figure 2-2 shows a frequency distribution displaying the results of serum gamma-glutamyltransferase (GGT) measurements of 100 apparently healthy 20- to 29-year-old men. The frequency distribution is constructed by dividing the measurement scale into cells of equal width, counting the number, n_i, of values that fall within each cell, and drawing a rectangle above each cell whose area (and height, because the cell widths are all equal) is proportional to n_i. In this example, the selected cells were 5 to 9, 10 to 14, 15 to 19, 20 to 24, 25 to 29, and so on, with 60 to 64 being the last cell. The ordinate axis of the frequency distribution gives the number of values falling within each cell. When this number is divided by the total number of values in the data set, the relative frequency in each cell is obtained.

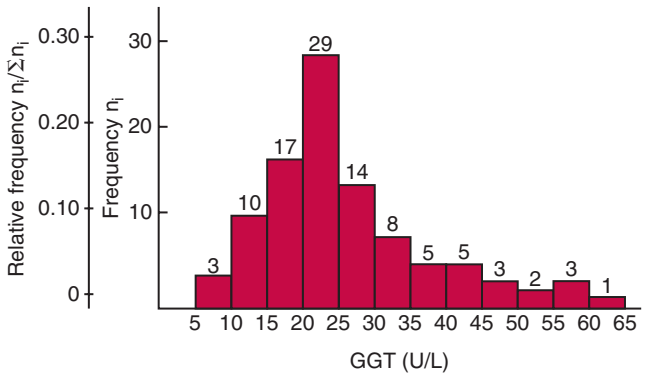

Figure 2-2 Frequency distribution of 100 gamma-glutamyltransferase (GGT) values.

Often, the position of the value for an individual within a distribution of values is useful medically. The *nonparametric* approach can be used to determine directly the *percentile* of a given subject. Having ranked N subjects according to their values, the n-percentile, Perc_n, may be estimated as the value of the $[N(n/100) + 0.5]$ ordered observation.[23] In the case of a noninteger value, interpolation is carried out between neighbor values. The 50-percentile is the median of the distribution.

Population and Sample

The purpose of analytical work is to obtain information and draw conclusions about characteristics of one or more populations of values. In the GGT example, interest is focused on the location and spread of the population of GGT values for 20- to 29-year-old healthy men. Thus, a working definition of a *population* is the complete set of all observations that might occur as a result of performing a particular procedure according to specified conditions.

Most populations of interest in clinical chemistry are infinite in size and so are impossible to study in their entirety. Usually a subgroup of observations is taken from the population as a basis for forming conclusions about population characteristics. The group of observations that has actually been selected from the population is called a *sample*. For example, the 100 GGT values make up a sample from a respective population. However, a sample is used to study the characteristics of a population only if it has been properly selected. For instance, if the analyst is interested in the population of GGT values over various lots of materials and some time period, the sample must be selected to be representative of these factors, as well as of age, sex, and health factors. Consequently, exact specification of the population(s) of interest is necessary before a plan for obtaining the sample(s) can be designed. In the present chapter, a sample is also used as a specimen, depending on the context.

Probability and Probability Distributions

Consider again the frequency distribution in Figure 2-2. In addition to the general location and spread of the GGT determinations, other useful information can be easily extracted from this frequency distribution. For instance, 96% (96 of 100) of the determinations are less than 55 U/L, and 91% (91 of 100) are greater than or equal to 10 but less than 50 U/L. Because the cell interval is 5 U/L in this example, statements such as these can be made only to the nearest 5 U/L. A larger sample would allow a smaller cell interval and more refined statements. For a sufficiently large sample, the cell interval can be made so small that the frequency distribution can be approximated by a continuous, smooth curve, similar to that shown in Figure 2-3. In fact, if the sample is large enough, we can consider this a close representation of the true *population frequency distribution*. In general, the functional form of the population frequency distribution curve of a variable x is denoted by $f(x)$.

The population frequency distribution allows us to make probability statements about the GGT of a randomly selected

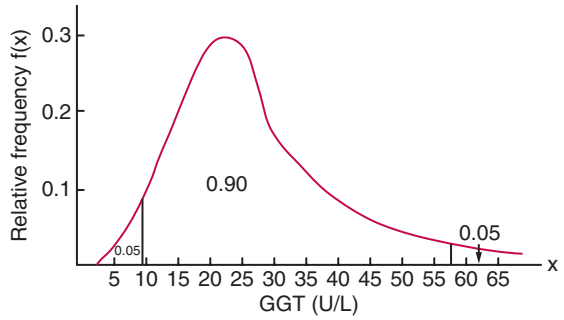

Figure 2-3 Population frequency distribution of gamma-glutamyltransferase (GGT) values.

member of the population of healthy 20- to 29-year-old men. For example, the probability $Pr(x > x_a)$ that the GGT value x of a randomly selected 20- to 29-year-old healthy man is greater than some particular value x_a is equal to the area under the population frequency distribution to the right of x_a. If $x_a = 58$, then from Figure 2-3, $Pr(x > 58) = 0.05$. Similarly, the probability $Pr(x_a < x < x_b)$ that x is greater than x_a but less than x_b is equal to the area under the population frequency distribution between x_a and x_b. For example, if $x_a = 9$ and $x_b = 58$, then from Figure 2-3, $Pr(9 < x < 58) = 0.90$. Because the population frequency distribution provides all information related to probabilities of a randomly selected member of the population, it is called the probability distribution of the population. Although the true probability distribution is never exactly known in practice, it can be approximated with a large sample of observations.

Parameters: Descriptive Measures of a Population

Any population of values can be described by measures of its characteristics. A *parameter* is a constant that describes some particular characteristic of a population. Although most populations of interest in analytical work are infinite in size, for the following definitions we shall consider the population to be of finite size N, where N is very large.

One important characteristic of a population is its *central location*. The parameter most commonly used to describe the central location of a population of N values is the *population mean* (μ):

$$\mu = \frac{\sum x_i}{N}$$

An alternative parameter that indicates the central tendency of a population is the *median,* which is defined as the 50-percentile, $Perc_{50}$.

Another important characteristic of a population is the *dispersion* of values about the population mean. A parameter very useful in describing this dispersion of a population of N values is the *population variance* σ^2 (sigma squared):

$$\sigma^2 = \frac{\sum (x_i - \mu)^2}{N}$$

The *population standard deviation* σ, the positive square root of the population variance, is a parameter frequently used to describe the population dispersion in the same units (e.g., mg/dL) as the population values.

Statistics: Descriptive Measures of the Sample

As noted earlier, the clinical chemist usually has at hand only a sample of observations from the population of interest. A *statistic* is a value calculated from the observations in a sample to describe a particular characteristic of that sample. As introduced above, the sample mean x_m is the arithmetical average of a sample, which is an estimate of μ. Likewise, the sample SD is an estimate of σ, and the coefficient of variation (CV) is the ratio of the SD to the mean multiplied by 100%. The equations used to calculate x_m, SD, and CV, respectively, are as follows:

$$x_m = \frac{\sum x_i}{N}$$

$$SD = \sqrt{\frac{\sum (x_i - x_m)^2}{N-1}} = \sqrt{\frac{\sum x_i^2 - \frac{\left(\sum x_i\right)^2}{N}}{N-1}}$$

$$CV = \frac{SD}{x_m} \times 100\%$$

where x_i is an individual measurement and N is the number of sample measurements.

Random Sampling

A random selection from a population is one in which each member of the population has an equal chance of being selected. A *random sample* is one in which each member of the sample can be considered to be a random selection from the population of interest. Although much of statistical analysis and interpretation depends on the assumption of a random sample from some fixed population, actual data collection often does not satisfy this assumption. In particular, for sequentially generated data, it is often true that observations adjacent to each other tend to be more alike than observations separated in time. A sample of such observations cannot be considered a sample of random selections from a fixed population. Fortunately, precautions can usually be taken in the design of an investigation to validate approximately the random sampling assumption.

The Gaussian Probability Distribution

The *Gaussian* probability distribution, illustrated in Figure 2-4, is of fundamental importance in statistics for several reasons. As mentioned earlier, a particular analytical value x will not usually be equal to the true value μ of the specimen being measured. Rather, associated with this particular value x will be a particular measurement error $\varepsilon = x - \mu$, which is the result of many contributing sources of error. Pure measurement errors tend to follow a probability distribution similar to that shown in Figure 2-4, where the errors are

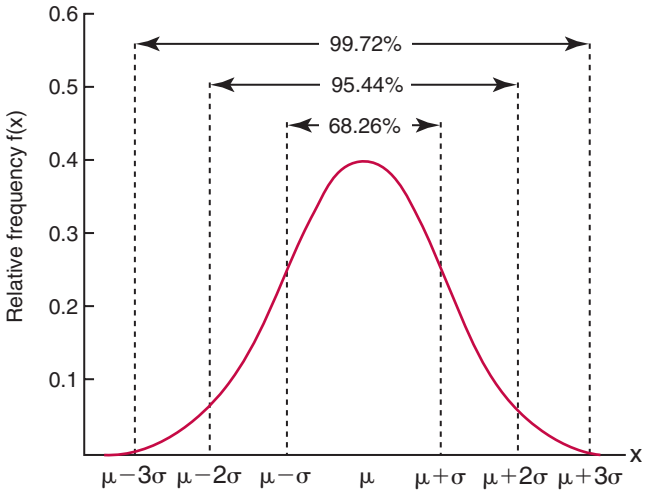

Figure 2-4 **The Gaussian probability distribution.**

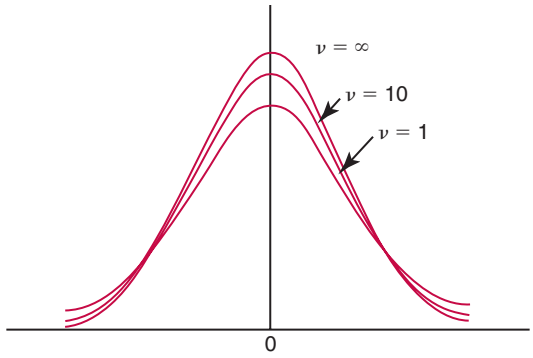

Figure 2-5 **The *t* distribution for ν = 1, 10, and ∞.**

symmetrically distributed, with smaller errors occurring more frequently than larger ones, and with an expected value of 0. This important fact is known as the central limit effect for distribution of errors: if a measurement error ε is the sum of many independent sources of error, such as $\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_k$, several of which are major contributors, the probability distribution of the measurement error ε will tend to be Gaussian as the number of sources of error becomes large.

Another reason for the importance of the Gaussian probability distribution is that many statistical procedures are based on the assumption of a Gaussian distribution of values; this approach is commonly referred to as *parametric*. Furthermore, these procedures usually are not seriously invalidated by departures from this assumption. Finally, the magnitude of the uncertainty associated with sample statistics can be ascertained based on the fact that many sample statistics computed from large samples have a Gaussian probability distribution.

The Gaussian probability distribution is completely characterized by its mean μ and its variance σ^2. The notation $N(\mu, \sigma^2)$ is often used for the distribution of a variable that is Gaussian with mean μ and variance σ^2. Probability statements about a variable x that follows an $N(\mu, \sigma^2)$ distribution are usually made by considering the variable z,

$$z = \frac{x - \mu}{\sigma}$$

which is called the *standard Gaussian variable*. The variable z has a Gaussian probability distribution with $\mu = 0$ and $\sigma^2 = 1$, that is, z is $N(0, 1)$. The probably that x is within 2 σ of μ [i.e., $\Pr(|x - \mu| < 2\sigma) =$] is 0.9544. Most computer spreadsheet programs can calculate probabilities for all values of z.

Student *t* Probability Distribution

To determine probabilities associated with a Gaussian distribution, it is necessary to know the population standard deviation σ. In actual practice, σ is often unknown, so we cannot calculate z. However, if a random sample can be taken from the Gaussian population, we can calculate the sample standard deviation (SD), substitute SD for σ, and compute the value t:

$$t = \frac{x - \mu}{SD}$$

Under these conditions, the variable t has a probability distribution called the *Student* t *distribution*. The t distribution is really a family of distributions depending on the degrees of freedom ν (= $N - 1$) for the sample SD. Several t distributions from this family are shown in Figure 2-5. When the size of the sample and the degrees of freedom for SD are infinite, there is no uncertainty in SD, and so the t distribution is identical to the standard Gaussian distribution. However, when the sample size is small, the uncertainty in SD causes the t distribution to have greater dispersion and heavier tails than the standard Gaussian distribution, as illustrated in Figure 2-5. Most computer spreadsheet programs can calculate probabilities for all values of t, given the degrees of freedom for SD.

Suppose that the distribution of fasting serum glucose values in healthy men is known to be Gaussian and have a mean of 90 mg/dL. Suppose also that σ is unknown, and that a random sample of size 20 from the healthy men yielded a sample SD = 10.0 mg/dL. Then, to find the probability $\Pr(x > 105)$, we proceed as follows:

1. $t_a = (x_a - x_m)/\text{SD} = (105 - 90)/10 = 1.5$.
2. $\Pr(t > t_a) = \Pr(t > 1.5) = 0.08$, approximately, from a t distribution with 19 degrees of freedom.
3. $\Pr(x > 105) = 0.08$.

The Student t distribution is commonly used in significance tests, such as comparison of sample means, or in testing conducted if a regression slope differs significantly from 1. Descriptions of these tests can be found in statistics textbooks[98] and in *Tietz Textbook of Clinical Chemistry,* 3rd edition, 2006, pages 274-287.

Nonparametric Statistics

Distribution-free statistics, often called nonparametric statistics, provides an alternative to parametric statistical procedures that assume data to have Gaussian distributions. Nonparametric descriptive statistics is based on the median

(50-percentile mentioned earlier) and percentiles. For the GGT example mentioned previously, we would order the 100 values according to size. The median or 50-percentile is then the value of the [100(50/100) + 0.5] ordered observation (interpolated if needed). The 2.5- and 97.5-percentiles are values of the [100(2.5/100) + 0.5] and [100(97.5/100) + 0.5] ordered observations, respectively. When a 95%-reference interval is estimated, a nonparametric approach is often preferable, because many distributions of reference values are asymmetric. Generally, distributions based on biological sources of variation are often non-Gaussian as compared with distributions of pure measurement errors that usually are Gaussian.

When the significance of a difference between two estimated mean values is tested, the parametric approach is to use the *t*-test as described in standard textbooks and included in most computer statistical programs. Although the *t*-test assumes Gaussian distributions of values in the two groups to be compared, it is generally robust toward deviations from the Gaussian distribution. The *t*-test occurs in two versions: a paired comparison, where two values are measured for each case; and a nonpaired version, where values of two separate groups are compared. The nonparametric counterpart to the paired *t*-test is the Wilcoxon test, for which paired differences are ordered and tested; for the two-group case, the Mann-Whitney test can be substituted for the *t*-test. The Mann-Whitney test provides a significance test for the difference between median values of the two groups to be compared.[98]

BASIC CONCEPTS IN RELATION TO ANALYTICAL METHODS

This section defines the basic concepts used in this chapter: (1) calibration, (2) accuracy, (3) precision, (4) linearity, (5) limit of detection, (6) limit of quantification, (7) specificity, and (8) others.

Calibration

The calibration function is the relation between instrument signal *(y)* and concentration of analyte *(x),* that is,

$$y = f(x)$$

The inverse of this function, also called the measuring function, yields the concentration from response:

$$x = f^{-1}(y)$$

This relationship is established by measurement of samples with known quantities of analyte (calibrators).[22] One may distinguish between solutions of pure chemical standards and samples with known quantities of analyte present in the typical matrix that is to be measured (e.g., human serum). The first situation applies typically to a reference measurement procedure that is not influenced by matrix effects; the second case corresponds typically to a routine method that often is influenced by matrix components, and so preferably is calibrated using the relevant matrix.[90] Calibration functions may be linear or curved and, in the case of immunoassays, may often take a special form (e.g., modeled by the four-parameter logistic curve).[92] This model (logistic in log *x*) has been used for immunoassay techniques and is written in several forms (Table 2-1). An alternative, model-free approach is to estimate a smoothed spline curve, which often is performed for immunoassays; however, a disadvantage of the spline curve approach is that it is insensitive to aberrant calibration values, fitting these just as well as the correct values. If the assumed calibration function does not correctly reflect the true relationship between instrument response and analyte concentration, a systematic error or bias is likely to be associated with the analytical method. A common problem with some immunoassays is the "hook effect" which is a deviation from the expected calibration algorithm in the high concentration range. (The hook effect is discussed in more detail in Chapter 16).

TABLE 2-1 The Four-Parameter Logistic Model Expressed in Three Different Forms

Algebraic Form	Variables*	Parameters†
$y = (a - d)/[1 + (x/c)^b] + d$	(x, y)	a, b, c, d
$R = R_0 + K_c/[1 + \exp(-\{a + b \log[C]\})]$	(C, R)	R_0, K_c, a, b
$y = y_0 + (y_¥ - y_0)(x^d)/(b + x^d)$	(x, y)	y_0, $y_¥$, b, d

*Concentration and instrument response variables shown in parentheses.
†Equivalent letters do not necessarily denote equivalent parameters.

The precision of the analytical method depends on the stability of the instrument response for a given quantity of analyte. In principle, a random dispersion of instrument signal (vertical direction) at a given true concentration transforms into dispersion on the measurement scale (horizontal direction), as is shown schematically (Figure 2-6). The detailed statistical aspects of calibration are complex,[96,98] but in the following sections, some approximate relations are outlined. If the calibration function is linear and the imprecision of the signal response is the same over the analytical measurement range, the analytical standard deviation (SD_A) of the method tends to be constant over the analytical measurement range (see Figure 2-6). If the imprecision increases proportionally to the signal response, the analytical SD of the method tends to increase proportionally to the concentration *(x),* which means that the *relative* imprecision [coefficient of variation (CV) = SD/*x*] may be constant over the analytical measurement range if it is assumed that the intercept of the calibration line is zero.

With modern, automated clinical chemistry instruments, the relation between analyte concentration and signal is often very stable, so that calibration is necessary only infrequently (e.g., at intervals of several months).[89] Built-in process control mechanisms may help ensure that the relationship remains

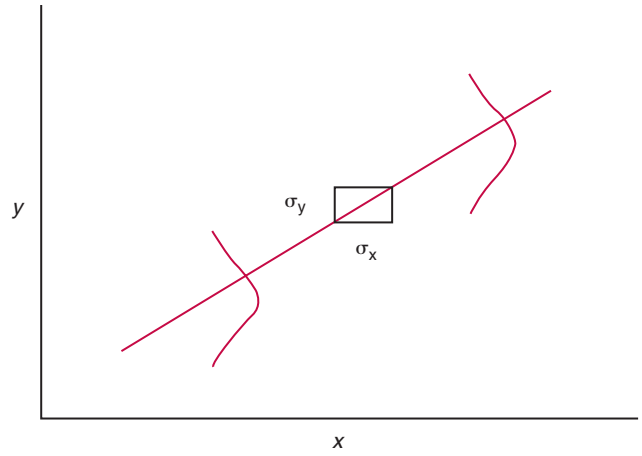

Figure 2-6 Relation between concentration *(x)* and signal response *(y)* for a linear calibration function. The dispersion in signal response (σ_y) is projected onto the *x*-axis and is called assay imprecision [σ_x (=σ_A)].

TABLE 2-2 An Overview of Qualitative Terms and Quantitative Measures Related to Method Performance

Qualitative Concept	Quantitative Measure
Trueness	*Bias*
Closeness of agreement of mean value with "true value"	A measure of the systematic error
Precision	*Imprecision (SD)*
Repeatability (within run)	A measure of the dispersion of random errors
Intermediate precision (long term)	
Reproducibility (interlaboratory)	
Accuracy	*Error of measurement*
Closeness of agreement of a single measurement with "true value"	Comprises both random and systematic influences

stable and may indicate when recalibration is necessary. In traditional chromatographic analysis [e.g., high-performance liquid chromatography (HPLC)], on the other hand, it is customary to calibrate each analytical series (run), which means that calibration is carried out daily. Aronsson and associates[1] established a detailed simulation model of the various factors influencing method performance with focus on the calibration function.

Trueness and Accuracy

Trueness of measurements is defined as closeness of agreement between the average value obtained from a large series of results of measurements and the true value.[43] The difference between the average value (strictly, the mathematical expectation) and the true value is the *bias,* which is expressed numerically and so is inversely related to the trueness. Trueness in itself is a qualitative term that can be expressed, for example, as low, medium, or high. From a theoretical point of view, the exact true value for a clinical sample is not available; instead, an "accepted reference value" is used, which is the "true" value that can be determined in practice.[29] Trueness can be evaluated by comparison of measurements by a given routine method and a reference measurement procedure. Such an evaluation may be carried out through parallel measurements of a set of patient samples. The ISO has introduced the trueness expression as a replacement for the term *accuracy,* which now has gained a slightly different meaning. *Accuracy* is the closeness of agreement between the result of a measurement and a true concentration of the analyte.[50] Accuracy thus is influenced by both bias and imprecision and in this way reflects the total error. Accuracy, which in itself is a qualitative term, is inversely related to the "uncertainty" of measurement, which can be quantified as described later (Table 2-2).

In relation to trueness, the concepts *recovery, drift,* and *carryover* may also be considered. *Recovery* is the fraction or percentage increase in concentration that is measured in relation to the amount added. Recovery experiments are typically carried out in the field of drug analysis. One may distinguish between *extraction recovery,* which often is interpreted as the fraction of compound that is carried through an extraction process, and the recovery measured by the entire analytical procedure, in which the addition of an internal standard compensates for losses in the extraction procedure. A recovery close to 100% is a prerequisite for a high degree of trueness, but it does not ensure unbiased results, because possible nonspecificity against matrix components (e.g., an interfering substance) is not detected in a recovery experiment. *Drift* is caused by instrument instability over time, so that calibration becomes biased. Assay *carryover* also must be close to zero to ensure unbiased results. Drift or carryover or both may be conveniently estimated by multifactorial evaluation protocols[58] (see CLSI guideline EP10-A3, "Preliminary Evaluation of Quantitative Clinical Laboratory Measurement Procedures").[14]

Precision

Precision has been defined as the closeness of agreement between independent results of measurements obtained under stipulated conditions.[29] The degree of precision is usually expressed on the basis of statistical measures of imprecision, such as SD or CV (CV = SD/*x,* where *x* is the measurement concentration), which is inversely related to precision. Imprecision of measurements is solely related to the random error of measurements and has no relation to the trueness of measurements.

Precision is specified as follows[29,44]:

Repeatability: closeness of agreement between results of successive measurements carried out under the same conditions (i.e., corresponding to within-run precision).

Reproducibility: closeness of agreement between results of measurements performed under changed conditions of measurements (e.g., time, operators, calibrators, reagent

lots). Two specifications of reproducibility are often used: total or between-run precision in the laboratory, often termed *intermediate precision,* and interlaboratory precision [e.g., as observed in external quality assessment schemes (EQAS)] (see Table 2-2).

The total SD (σ_T) may be divided into within-run and between-run components using the principle of analysis of variance of components (variance is the squared SD)[98]:

$$\sigma^2_T = \sigma^2_{\text{Within-run}}{}^2 + \sigma_{\text{Between-run}}$$

It is not always clear in clinical chemistry publications what is meant by "between-run" variation. Some authors use the term to refer to the total variation of an assay, whereas others apply the term *between-run variance component* as defined earlier. The distinction between these definitions is important but is not always explicitly stated.

In laboratory studies of analytical variation, it is *estimates* of imprecision that are obtained. The more observations, the more certain are the estimates. Commonly the number 20 is given as a reasonable number of observations (e.g., suggested in the CLSI guideline on the topic).[12] To estimate both the within-run imprecision and the total imprecision, a common approach is to measure duplicate control samples in a series of runs. Suppose, for example, that a control is measured in duplicate for 20 runs, in which case 20 observations are present with respect to both components. The dispersion of the means (x_m) of the duplicates is given as follows:

$$\sigma^2_{xm} = \sigma^2_{\text{Within-run}}/2 + \sigma^2_{\text{Between-run}}$$

From the 20 sets of duplicates, we may derive the within-run SD using the following formula:

$$\text{SD}_{\text{Within-run}} = [\Sigma d_i{}^2/(2\times 20)]^{0.5}$$

where d_i refers to the difference between the *i*th set of duplicates. When SDs are estimated, the concept degrees of freedom (df) is used. In a simple situation, the number of degrees of freedom equals $N-1$. For N duplicates, the number of degrees of freedom is $N(2-1) = N$. Thus, both variance components are derived in this way. The advantage of this approach is that the within-run estimate is based on several runs, so that an average estimate is obtained rather than only an estimate for one particular run if all 20 observations had been obtained in the same run. The described approach is a simple example of a *variance component analysis.* The principle can be extended to more components of variation. For example, in the CLSI EP5-A2 guideline, a procedure is outlined that is based on the assumption of two analytical runs per day, in which case within-run, between-run, and between-day components of variance are estimated by a *nested* component of variance analysis approach.[12]

Nothing definitive can be stated about the selected number of 20. Generally, the estimate of the imprecision improves as more observations become available. Exact confidence limits for the SD can be derived from the χ^2 distribution. Estimates of the variance, SD^2, are distributed according to the χ^2 distribution (tabulated in most statistics textbooks) as follows: $(N-1)\ SD^2/\sigma^2 \approx \chi^2_{(N-1)}$, where $(N-1)$ is the degrees of freedom.[98] Then the two-sided 95%-confidence interval (CI) (95%-CI) is derived from the following relation:

$$\Pr[\chi^2_{97..5\%(N-1)} < (N-1)\ \text{SD}^2/\sigma^2 < \chi^2_{2.5\%(N-1)}] = 0.95$$

which yields this 95%-CI expression:

$$\text{SD}\times[(N-1)/\chi^2_{2.5\%(N-1)}]^{0.5} < \sigma < \text{SD}\times[(N-1)/\chi^2_{97.5\%(N-1)}]^{0.5}$$

Example

Suppose we have estimated the imprecision as an SD of 5.0 on the basis of $N = 20$ observations. From a table of the χ^2 distribution, we obtain the following 2.5- and 97.5-percentiles:

$$\chi^2_{2.5\%(19)} = 32.9 \text{ and } \chi^2_{97.5\%(19)} = 8.91$$

where 19 within the parentheses refers to the number of degrees of freedom. Substituting in the equation, we get

$$5.0\times(19/32.9)^{0.5} < \sigma < 5.0\times(19/8.91)^{0.5}$$

or

$$3.8 < \sigma < 7.3$$

For reasonable values of N, approximate limits can be derived from the Gaussian approximation[52,53] that the distribution of the SD is based on expression of the standard error of σ equal to $[\sigma^2/(2\{N-1\})]^{0.5}$. Using the Gaussian approximation, the interval equals $5 \pm t_{19}\ [5^2/(2\{20-1\})]^{0.5}$, which corresponds to $5 \pm 2.093 \times 0.81 = 3.30 - 6.7$. Thus at the sample size of 20, the approximation is not so good because of the asymmetric distribution of the SD. For a sample size of 50, the approximate interval can be calculated to 4.0 to 6.0, which is a somewhat better approximation of the exact interval of 4.2 to 6.25. Generally, it is observed that the uncertainty of the estimated SD is considerable at moderate sample sizes. In Table 2-3, factors corresponding to the 95%-CI are given

TABLE 2-3 Factors Corresponding to 95%-Confidence Interval (CI) Limits for a Standard Deviation

	95%-CI	
N	**Lower**	**Upper**
20	0.760	1.460
30	0.797	1.346
40	0.819	1.283
50	0.835	1.243
60	0.848	1.217
70	0.857	1.198
80	0.865	1.183
90	0.872	1.171
100	0.878	1.161
150	0.898	1.128
200	0.911	1.109
250	0.919	1.096
300	0.926	1.087

as a function of sample size for simple SD estimation according to the χ^2 distribution. These factors provide guidance on the validity of estimated SDs for precision. For individual variance components, the relations are more complicated.

Precision Profile

Precision often depends on the concentration of analyte being considered. A presentation of precision as a function of analyte concentration is the precision profile, which usually is plotted in terms of the SD or the CV as a function of analyte concentration (Figure 2-7, *A-C*). Some typical examples may be considered. First, the SD may be constant (i.e., independent of the concentration), as it often is for analytes with a limited range of values (e.g., electrolytes). When the SD is constant, the CV varies inversely with the concentration (i.e., it is high in the lower part of the range and low in the high range). For analytes with extended ranges (e.g., hormones), the SD frequently increases as the analyte concentration increases. If a proportional relationship exists, the CV is constant. This may often apply approximately over a large part of the analytical measurement range. Actually, this relationship is anticipated for measurement error that arises because of imprecise volume dispensing. Often a more complex relationship exists. Not infrequently, the SD is relatively constant in the low range, so that the CV increases in the area approaching the lower limit of quantification. At intermediate concentrations, the CV may be relatively constant and perhaps may decline somewhat at increasing concentrations. A square root relationship can be used to model the relationship in some situations as an intermediate form of relation between the constant and the proportional case. A constant SD in the low range can be modeled by truncating the assumed proportional or square root relationship at higher concentrations. The relationship between the SD and the concentration is of importance (1) when method specifications over the analytical measurement range are considered, (2) when limits of quantification are determined, and (3) in the context of selecting appropriate statistical methods for method comparison (e.g., whether a difference or a relative difference plot should be applied, whether a simple or a weighted regression analysis procedure should be used) (see "Relative Distribution of Differences Plot" and "Regression Analysis" sections).

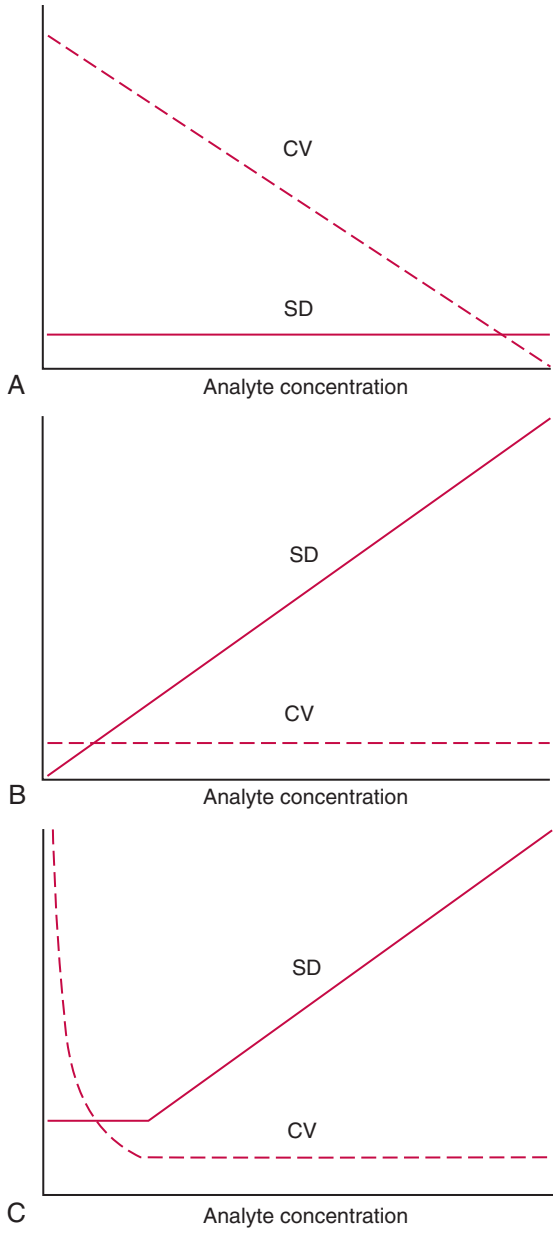

Figure 2-7 Relations between analyte concentration and standard deviation (SD)/coefficient of variation (CV). A, The SD is constant, so that the CV varies inversely with the analyte concentration. B, The CV is constant because of a proportional relationship between concentration and SD. C, A mixed situation with constant SD in the low range and a proportional relationship in the rest of the analytical measurement range.

Linearity

Linearity refers to the relationship between measured and expected values over the analytical measurement range. Linearity may be considered in relation to actual or relative analyte concentrations. In the latter case, a dilution series of a sample may be examined. This dilution series examines whether the measured concentration changes as expected according to the proportional relationship between samples introduced by the dilution factor. Dilution is usually carried out with an appropriate sample matrix [e.g., human serum (individual or pooled serum)].

Evaluation of linearity may be conducted in various ways. A simple, but subjective, approach is to visually assess whether the relationship between measured and expected concentrations is linear. A more formal evaluation may be carried out on the basis of statistical tests. Various principles may be applied here. When repeated measurements are available at each concentration, the random variation between measurements and the variation around an estimated regression line may be evaluated statistically (by an *F*-test).[39] This approach has been criticized because it relates only the magnitudes of random and systematic error without taking the

absolute deviations from linearity into account. For example, if the random variation among measurements is large, a given deviation from linearity may not be declared statistically significant. On the other hand, if the random measurement variation is small, even a very small deviation from linearity that may be clinically unimportant is declared significant. When significant nonlinearity is found, it may be useful to explore nonlinear alternatives to the linear regression line (i.e., polynomials of higher degrees).[32]

Another commonly applied approach for detecting nonlinearity is to assess the residuals of an estimated regression line and test whether positive and negative deviations are randomly distributed. This can be carried out by a runs test[28] (see "Regression Analysis" section). An additional consideration for evaluating proportional concentration relationships is whether an estimated regression line passes through zero or not. The presence of linearity is a prerequisite for a high degree of trueness. A CLSI guideline suggests procedure(s) for assessment of linearity.[11]

Analytical Measurement Range and Limits of Quantification

The analytical measurement range (measuring interval, reportable range) is the analyte concentration range over which measurements are within the declared tolerances for imprecision and bias of the method.[29] Taking drug assays as an example, requirements of a CV% of less than 15% and a bias of less than 15% are common.[95] The measurement range then extends from the lowest concentration [lower limit of quantification (LloQ)] to the highest concentration [upper limit of quantification (UloQ)] for which these performance specifications are fulfilled.

The LloQ is medically important for many analytes. Thyroid-stimulating hormone (TSH) is a good example. As assay methods improved, lowering the LloQ, low TSH results could be distinguished from the lower limit of the reference interval, making the test useful for the diagnosis of hyperthyroidism.

The limit of detection (LoD) is another characteristic of an assay. The LoD may be defined as the lowest value that significantly exceeds the measurements of a blank sample. Thus the limit has been estimated on the basis of repeated measurements of a blank sample and has been *reported* as the mean plus 2 or 3 SDs of the blank measurements. In the interval from LoD up to LloQ, one should report a result as "detected" but not provide a quantitative result. More complicated approaches for estimation of the LoD have been suggested.[18,75,76]

Analytical Sensitivity

The LloQ of a method should not be confused with analytical sensitivity. That is defined as ability of an analytical method to assess small differences in the concentration of analyte.[22] The smaller the random variation of the instrument response and the steeper the slope of the calibration function at a given point, the better is the ability to distinguish small differences in analyte concentrations. In reality, analytical sensitivity depends on the precision of the method. The smallest difference that will be statistically significant equals $2\sqrt{2}\ SD_A$ at a 5% significance level. Historically, the meaning of the term *analytical sensitivity* has been the subject of much discussion.

Analytical Specificity and Interference

Analytical specificity is the ability of an assay procedure to determine the concentration of the target analyte without influence from potentially interfering substances or factors in the sample matrix (e.g., hyperlipemia, hemolysis, bilirubin, antibodies, other metabolic molecules, degradation products of the analyte, exogenous substances, anticoagulants). Interferences from hyperlipemia, hemolysis, and bilirubin are generally concentration dependent and can be quantified as a function of the concentration of the interfering compound.[37] In the context of a drug assay, specificity in relation to drug metabolites is relevant, and in some cases it is desirable to measure the parent drug, as well as metabolites. A detailed protocol for evaluation of interference has been published by the CLSI.[13]

With regard to peptides and proteins, antibodies in different immunoassays may be directed toward different epitopes. Often protein hormones exist in various molecular forms, and differences in specificity of antibodies may give rise to discrepant results. This has been considered for human chorionic gonadotropin (hCG) for which the clinical implications of such molecular variations can be important.[101] Rotmensch and Cole[94] described 12 patients in whom a diagnosis of postgestational choriocarcinoma was made on the basis of false-positive test results for hCG. Most of these patients were subjected to unnecessary surgery or chemotherapy. In each case, the false-positive result was traced to the presence of heterophilic antibodies that interfered with the immunoassay for hCG. Additionally, interference from endogenous antibodies should be recognized. Ismail and colleagues[51] found in a survey comprising more than 5000 TSH results that interference occurred in 0.5% of the samples, leading to incorrect results that in a majority of cases could have changed the treatment. Marks[79] found that almost 10% of immunoassay results from patients with autoimmune disease were erroneous. In many cases, the addition of heterophilic antibody blocking reagent or the study of dilution curves, or both, may help clarify suspected false-positive immunoassay results. Such limitations in the results of immunoassays should be directly communicated to clinicians.

ANALYTICAL GOALS

Setting goals for analytical quality can be based on various principles and a hierarchy has been suggested on the basis of a consensus conference on the subject[85] (Table 2-4). The top level of the hierarchy specifies goals on the basis of clinical outcomes in specific clinical settings, which is a logical principle. For example, one may consider the impact of analytical quality on the error rates of diagnostic or risk classifications.[54,83] A supplementary approach is to study the impact of

TABLE 2-4 Hierarchy of Procedures for Setting Analytical Quality Specifications for Laboratory Methods

EQA, External quality assessment.

imprecision and bias on clinical outcome on the basis of a simulation model, as described by Boyd and Bruns.[6] For a given analyte, a series of specific clinical settings may then be evaluated, and in principle, the most demanding specification then becomes the goal, at least for a general laboratory serving various clinical applications.

Analytical goals related to biological variation have attracted considerable interest.[93] Originally, the focus was on imprecision, and Cotlove and coworkers[21] suggested that the analytical SD (σ_A) should be less than half the within-person biological variation, $\sigma_{Within\text{-}B}$. The rationale for this relation is the principle of adding variances. If a subject is undergoing monitoring of an analyte, the random variation from measurement to measurement consists of both analytical and biological components of variation. The total SD for the random variation during monitoring then is determined by the following relation:

$$\sigma_T^2 = \sigma_{Within\text{-}B}^2 + \sigma_A^2$$

where the biological component includes the preanalytical variation. If σ_A is equal to or less than half the $\sigma_{Within\text{-}B}$ value, σ_T exceeds $\sigma_{Within\text{-}B}$ only by less than 12%. Thus if this relation holds true, analytical imprecision adds limited random noise in a monitoring situation, and the relationship may be called a *desirable* relation. Alternatively, Fraser and associates[35] considered grading of the relationship with additional specifications corresponding to an *optimum* relation (σ_A = 0.25 $\sigma_{Within\text{-}B}$), yielding only 3% additional noise and a *minimum* relation corresponding to 25% additional variation (σ_A = 0.75 $\sigma_{Within\text{-}B}$).[35,36]

In addition to imprecision, goals for bias should be considered. Gowans and colleagues[38] related the allowable bias to the width of the reference interval, which is determined by the combined within- and between-person biological variation, in addition to the analytical variation. On the basis of considerations concerning the included percentage in an interval in the presence of analytical bias, it was suggested that

$$\text{Bias} < 0.25\ (\sigma_{Within\text{-}B}^2 + \sigma_{Between\text{-}B}^2)^{0.5}$$

where $\sigma_{Between\text{-}B}$ is the between-person biological SD component.

Thus the bias should *desirably* be less than one fourth of the combined biological SD. One may further extend the suggested relationships to comprise an optimum relation corresponding to a factor 0.125 and a minimum relation with a factor 0.375. Given a Gaussian distribution of reference values, the desirable relationship corresponds to maximum deviations for proportions outside the interval from the expected 2.5% at each side to 1.4% and 4.4%. This gives an overall deviation of 0.8% from the expected total of 5%, corresponding to a relative deviation of 16%, which may be considered acceptable.[36]

Another principle that has been used is to relate assay goals to the limits set by professional bodies[8] [e.g., the bias goal of 3% for serum cholesterol (originally 5%) set by the National Cholesterol Education Program].[80] Ricos and colleagues[91] have published a comprehensive listing of data on biological variation with a database that is available on the Internet [Ricos et al. Biological variation database. Available at: www.westgard.com/guest17.htm (accessed March 04 2011)].

Qualitative Methods

Qualitative methods, which currently are gaining increased use in the form of point-of-care testing (POCT), are designed to distinguish between results below and above a predefined cutoff value. Note that the cutoff point should not be confused with the detection limit. These tests are assessed primarily on the basis of their ability to correctly classify results in relation to the cutoff value.

Performance Measures

The probability of classifying a result as positive (exceeding the cutoff) when the true value indeed exceeds the cutoff is called *clinical sensitivity.* The probability of classifying a result as negative (below the cutoff) when the true value indeed is below the cutoff is termed *clinical specificity.* Determination of clinical sensitivity and specificity is based on comparison of test results with a gold standard. The gold standard may be an independent test that measures the same analyte, but it may also be a clinical diagnosis determined by definitive clinical methods (e.g., radiographic testing, follow-up, outcomes analysis). Determination of these performance measures is covered in Chapter 3. Clinical sensitivity and specificity may be given as a fraction or as a percentage after multiplication by 100. Standard errors of estimates are derived from the

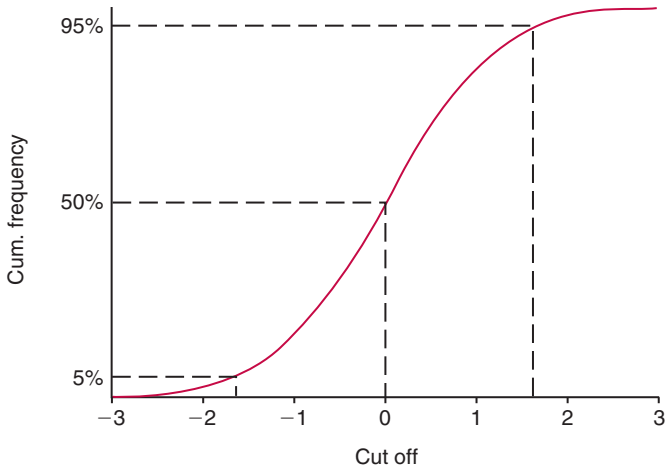

Figure 2-8 Cumulative frequency distribution of positive results. The *x*-axis indicates concentrations standardized to zero at the cutoff point (50% positive results) with unit standard deviation (SD).

binomial distribution.[98] The performance of two qualitative tests applied in the same groups of nondiseased and diseased subjects can be compared using the McNemar test.[64]

One approach for determining the recorded performance of a test in terms of clinical sensitivity and specificity is to determine the true concentration of analyte using an independent reference method. The closer the concentration is to the cutoff point, the larger the error frequencies are expected to be. Actually the cutoff point is defined in such a way that for samples having a true concentration exactly equal to the cutoff point, 50% of results will be positive and 50% will be negative.[33] Concentrations above and below the cutoff point at which repeated results are 95% positive or 95% negative, respectively, have been called the "95% interval" for the cutoff point for that method[33] (note that this is not a CI; Figure 2-8). A CLSI guideline discusses this topic.[15]

Agreement Between Qualitative Tests

As outlined previously, if the outcome of a qualitative test can be related to a true analyte concentration or a definitive clinical diagnosis, it is relatively straightforward to express the performance in terms of clinical specificity and sensitivity. In the absence of a definitive reference or "gold standard," one should be cautious with regard to judgments on performance. In this situation, it is primarily *agreement* with another test that can be assessed. When replacement of an old or expensive routine method with a new or less expensive method is considered, it is of interest to know whether similar test results are likely to be obtained. If both methods are imperfect, however, it is not possible to judge which test has the better performance, unless additional testing by a reference procedure is carried out.

In a comparison study, the same individuals are tested by both methods to prevent bias associated with selection of patients. Basically, the outcome of the comparison study should be presented in the form of a 2 × 2 table, from which various measures of agreement may be derived (Table 2-5). An obvious measure of agreement is the overall fraction or percentage of subjects tested who have the same test result (i.e., both results negative or positive):

TABLE 2-5 2 × 2 Table for Assessing Agreement Between Two Qualitative Tests

		Test 1	
		+	−
Test 2	+	a	b
	−	c	d
Total		a + c	b + d

$$\text{Overall percent agreement} = (a+d)/(a+b+c+d)\times 100\%$$

If agreement differs with respect to diseased and healthy individuals, the overall percent agreement measure becomes dependent on disease prevalence in the studied group of subjects. This is a common situation; accordingly, it may be desirable to separate this overall agreement measure into agreement concerning negative and positive results:

$$\text{Percent agreement given test 1 positive: } a/(a+c)$$
$$\text{Percent agreement given test 1 negative: } b/(b+d)$$

For example, if there is a close agreement with regard to positive results, overall agreement will be high when the fraction of diseased subjects is high; however, in a screening situation with very low disease prevalence, overall agreement will mainly depend on agreement with regard to negative results. Standard errors of the estimates can be derived from the binomial distribution.[66,98]

A problem with the simple agreement measures is that they do not take agreement by chance into account. Given independence, expected proportions observed in fields of the 2 × 2 table are obtained by multiplication of the fraction's negative and positive results for each test. Concerning agreement, it is excess agreement beyond chance that is of interest. More sophisticated measures have been introduced to account for this aspect. The most well-known measure is kappa, which is defined generally as the ratio of observed excess agreement beyond chance to maximum possible excess agreement beyond chance.[34] We have the following:

$$\text{Kappa} = (I_o - I_e)/(1 - I_e)$$

where I_o is the observed index of agreement and I_e is the expected agreement from chance. Given complete agreement, kappa equals +1. If observed agreement is greater than or equal to chance agreement, kappa is larger than or equal to zero. Observed agreement less than chance yields a negative kappa value.

Example

Table 2-6 shows a hypothetical example of observed numbers in a 2 × 2 table. The proportion of positive results for test 1

TABLE 2-6 2 × 2 Table With Example of Agreement of Data for Two Qualitative Tests

		Test 1		
		+	−	Total
Test 2	+	60	20	80
	−	15	40	55
Total		75	60	135

is 75/(75 + 60) = 0.555, and for test 2, it is 80/(80 + 55) = 0.593. Thus by chance, we expect the ++ pattern in 0.555 × 0.593 × 135 = 44.44 cases. Analogously, the — pattern is expected in (1 − 0.555) × (1 − 0.593) × 135 = 24.45 cases. The expected overall agreement percent by chance I_e is (44.44 + 24.45)/135 = 0.51. The observed overall percent agreement is I_o = (60 + 40)/135 = 0.74. Thus we have

$$\text{Kappa} = (0.74 - 0.51)/(1 - 0.51) = 0.47$$

Generally, kappa values greater than 0.75 are taken to indicate excellent agreement beyond chance, values from 0.40 to 0.75 are regarded as showing fair to good agreement beyond chance, and finally, values below 0.40 indicate poor agreement beyond chance. A standard error for the kappa estimate can be computed.[34] Kappa is related to the intraclass correlation coefficient, which is a widely used measure of interrater reliability for quantitative measurements.[34] The considered agreement measures, percent agreement, and kappa can also be applied to assess the reproducibility of a qualitative test when the test is applied twice in a given context.

Various methodological problems are encountered in studies on qualitative tests. An obvious mistake is to let the result of the test being evaluated contribute to the diagnostic classification of subjects being tested (circular argument). Another problem is partial as opposed to complete verification. When a new test is compared with an existing, imperfect test, a partial verification is sometimes undertaken, in which only discrepant results are subjected to further testing by a perfect test procedure. On this basis, sensitivity and specificity are reported for the new test. This procedure (called *discrepant resolution*) leads to biased estimates and should not be accepted.[77] The problem is that for cases with agreement, both the existing (imperfect) test and the new test may be wrong. Thus only a measure of agreement should be reported, not specificity and sensitivity values. In the biostatistical literature, various procedures have been suggested to correct for bias caused by imperfect reference tests, but unrealistic assumptions concerning the independence of test results are usually put forward.

METHOD COMPARISON

Comparison of measurements by two methods is a frequent task in the laboratory. Preferably, parallel measurements of a set of patient samples should be undertaken. To prevent artificial matrix-induced differences, fresh patient samples are the optimal material. A nearly even distribution of values over the analytical measurement range is also preferable. In an ordinary laboratory, comparison of two routine methods will be the most frequently occurring situation. Less commonly, comparison of a routine method with a reference method is undertaken. When two routine methods are compared, the focus is on observed differences. In this situation, it is not possible to establish that one set of measurements is the correct one, and thereby know by how much measurements deviate from the presumed correct concentrations. Rather, the question is whether the new method can replace the existing one without a systematic change in result values. To address this question, the dispersion of observed differences between paired measurements may be evaluated by these methods. To carry out a formal, objective analysis of the data, a statistical procedure with graphics display should be applied. Various approaches may be used: (1) a frequency plot or histogram of the distribution of differences with measures of central tendency and dispersion [distribution of differences (DoD) plot]; (2) a difference (bias) plot, which shows differences as a function of the average concentration of measurements (Bland-Altman plot); or (3) a regression analysis. In the following, a general error model is presented and some typical measurement relationships are considered. Each of the statistical approaches mentioned will be presented in detail, along with a discussion of their advantages and disadvantages.

Basic Error Model

The occurrence of measurement errors is related to the performance characteristics of the assay. It is important to distinguish between pure, random measurement errors, which are present in all measurement procedures, and errors related to incorrect calibration and nonspecificity of the assay. A reference measurement procedure is associated only with pure, random error, whereas a routine method, additionally, is likely to have some bias related to errors in calibration and limitations with regard to specificity. An erroneous calibration function gives rise to a systematic error, whereas nonspecificity gives an error that typically varies from sample to sample. The error related to nonspecificity thus has a random character, but in contrast to the pure measurement error, it cannot be reduced by repeated measurements of a sample. Although errors related to nonspecificity for a group of samples look like random errors, for the individual sample, this type of error is a bias. Because this bias varies from sample to sample, it has been called a *sample-related random bias*.[55,59,60,62] In the following section, the various error components are incorporated into a formal error model.

Measured Value, Target Value, Modified Target Value, and True Value

Upon taking into account that an analytical method measures analyte concentrations with some random measurement error, one has to distinguish between the actual, measured value and the average result we would obtain if the given

sample was measured an infinite number of times. If the method is a reference method without bias and nonspecificity, we have the following, simple relationship:

$$x_i = X_{\text{True}i} + \varepsilon_i$$

where x_i represents the measured value, $X_{\text{True}i}$ is the average value for an infinite number of measurements, and ε_i is the deviation of the measured value from the average value. If we were to undertake repeated measurements, the average of ε_i would be zero and the SD would equal the analytical SD (σ_A) of the reference measurement procedure. Pure, random, measurement error will usually be Gaussian distributed.

In the case of a routine method, the relationship between the measured value for a sample and the true value becomes more complicated:

$$x_i = X_{\text{True}i} + \text{Cal-Bias} + \text{Random-Bias}_i + \varepsilon_i$$

The *Cal-Bias* term (calibration bias) is a systematic error related to the calibration of the method. This systematic error may be a constant for all measurements corresponding to an offset error, or it may be a function of the analyte concentration (e.g., corresponding to a slope deviation in the case of a linear calibration function). The *Random-Bias*$_i$ term is a bias that is specific for a given sample related to nonspecificity of the method. It may arise because of codetermination of substances that vary in concentration from sample to sample. For example, a chromogenic creatinine method codetermines some other components with creatinine in serum.[48] Finally, we have the random measurement error term ε_i.

If we performed an infinite number of measurements of a specific sample by the routine method, the random measurement error term ε_i would be zero. The cal-bias and the random-bias$_i$, however, would be unchanged. Thus, the average value of an infinite number of measurements would equal the sum of the true value and these bias terms. This average value may be regarded as the target value ($X_{\text{Target}i}$) of the given sample for the routine method. We have

$$X_{\text{Target}i} = X_{\text{True}i} + \text{Cal-Bias} + \text{Random-Bias}_i$$

As mentioned, the calibration bias represents a systematic error component in relation to the true values measured by a reference measurement procedure. In the context of regression analysis, this systematic error corresponds to the intercept and the slope deviation from unity when a routine method is compared with a reference measurement procedure (outlined in detail later). It is convenient to introduce a modified target value expression ($X'_{\text{Target}i}$) for the routine method to delineate this systematic calibration bias, so that

$$X'_{\text{Target}i} = X_{\text{True}i} + \text{Cal-Bias}$$

Thus, for a set of samples measured by a routine method, the $X_{\text{Target}i}$ values are distributed around the respective $X'_{\text{Target}i}$ values with an SD, which is called σ_{RB}.

If the method is a reference method without bias and nonspecificity, the target value and the modified target value equal the true value, that is,

$$X_{\text{Target}i} = X'_{\text{Target}i} = X_{\text{True}i}$$

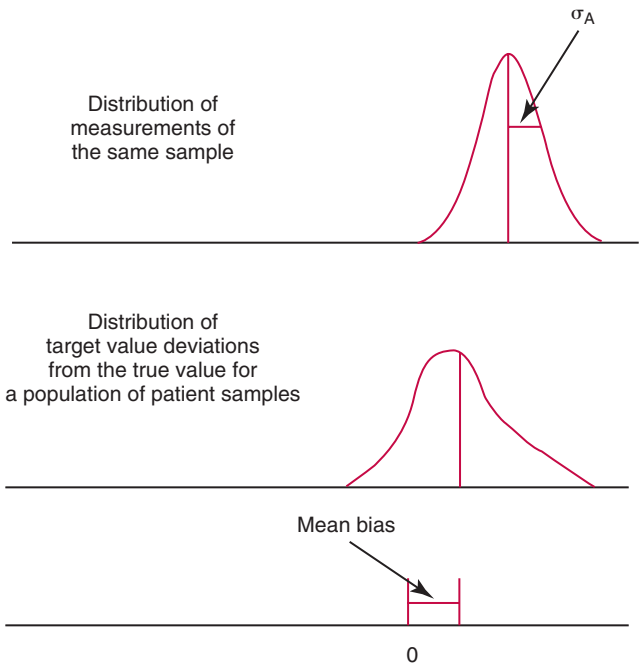

Figure 2-9 Outline of basic error model for measurements by a routine method. *Upper part,* The distribution of repeated measurements of the *same* sample, representing a normal distribution around the target value ($X_{\text{Target}i}$) *(vertical line)* of the sample with a dispersion corresponding to the analytical standard deviation, σ_A. *Middle part,* Schematic outline of the dispersion of target value deviations from the respective true values for a population of patient samples. A distribution of an arbitrary form is displayed. The standard deviation equals σ_{RB}. The vertical line indicates the mean of the distribution. *Lower part,* The distance from zero to the mean of the target value deviations from the true values represents the calibration bias (Mean bias = CAL-Bias) of the method.

The error model is outlined in Figure 2-9.

Calibration Bias and Random Bias

For an individual measurement, the total error is the deviation of x_i from the true value, that is,

$$\text{Total error of } x_i = \text{Cal-Bias} + \text{Random-Bias}_i + \varepsilon_i$$

Estimation of the bias terms requires parallel measurements between the method in question and a reference method as outlined in detail later. With regard to calibration bias, one should be aware of the possibility of lot-to-lot variation in analytical kit sets. The manufacturer should provide documentation on this lot-to-lot variation, because often it will not be possible for the individual laboratory to investigate a sufficient number of lots to assess this variation. Lot-to-lot variation will show up as a calibration bias that changes from lot to lot.

The previous exposition defines the total error in somewhat broader terms than is often seen. A traditional total error expression is[108]

$$\text{Total error} = \text{Bias} + 2\,\text{SD}_\text{A}$$

which often is interpreted as the calibration bias plus 2 SD_A. If a one-sided statistical perspective is taken, the expression is modified to Bias + 1.65 SD_A, indicating that 5% of results are located outside the limit. If a lower percentage is desired, the multiplication factor is increased accordingly, supposing a normal distribution. Interpreting the bias as identical with the calibration bias may lead to an underestimation of the total error.

Random bias related to sample-specific interferences may take several forms. It may be a regularly occurring additional random error component, perhaps of the same order of magnitude as the analytical error. In this context, it is natural to quantify the error in the form of an SD or coefficient of variation. The most straightforward procedure is to carry out a method comparison study based on a set of patient samples in which one of the methods is a reference method, as outlined later. Krouwer[59] formally quantified sample-related random interferences in a comparison experiment of two cholesterol methods and found that the CV of the sample-related random interference component exceeded the analytical CV. Kringle and Bogavich[55] considered random bias of a Jaffe creatinine method by components of variance analysis and found random bias to be a pronounced random error component, constituting 80% of the total random error. This relatively high amount should be interpreted in light of the limited specificity of the Jaffe creatinine measurement principle.

Another form of sample-related random interference is more rarely occurring gross errors, which typically are seen in the context of immunoassays and are related to unexpected antibody interactions (see "Interference" section).[51,79,94] Such an error usually will show up as an outlier in method comparison studies. A well-known source is the occurrence of heterophilic antibodies. Outliers should not just be discarded from the data analysis procedure. Outliers must be investigated to identify their cause, which may be an important limitation in using a given method. Supplementary studies may help clarify such random sample-related interferences and may provide specifications for the assay that limit its application in certain contexts (e.g., with regard to samples from certain patient categories).

Blunders or Clerical Errors

Another reason for outliers in method comparison studies and in daily practice is *blunders* or *clerical errors*. In the past, this type of error usually arose in relation to manual transfer of results. Today, this type of error typically is related to computer error originating at interfaces between computer systems or to instrument failure not detected by the on-analyzer error detection system. Plebani[87] focused on laboratory errors associated with the preanalytical and postanalytical phases. Errors on test order forms and errors related to handling of order forms appear to occur relatively frequently (1 to 5% of recorded cases). In the postanalytical phase, inappropriate interpretation may take place (e.g., in relation to erroneous reference intervals).

Method Comparison Data Model

We here consider the error model described earlier in relation to the method comparison situation. For a given sample measured by two analytical methods, 1 and 2, we have

$$\begin{aligned} x1_i &= X1_{\text{Target}i} + \varepsilon 1_i = X_{\text{True}i} + \text{Cal-Bias1} + \text{Random-Bias1}_i + \varepsilon 1_i \\ x2_i &= X2_{\text{Target}i} + \varepsilon 2_i \\ &= X_{\text{True}i} + \text{Cal-Bias2} + \text{Random-Bias2}_i + \varepsilon 2_i \end{aligned}$$

From this general model, we may study some typical situations. First, comparison of a routine method with a reference measurement procedure will be treated. Second, comparison of two routine methods is considered.

Comparison of a Routine Method With a Reference Measurement Procedure

Assuming that method 1 is a reference method, the bias components disappear by definition, and we have the following situation:

$$\begin{aligned} x1_i &= X1_{\text{Target}i} + \varepsilon 1_i = X_{\text{True}i} + \varepsilon 1_i \\ x2_i &= X2_{\text{Target}i} + \varepsilon 2_i \\ &= X_{\text{True}i} + \text{Cal-Bias2} + \text{Random-Bias2}_i + \varepsilon 2_i \end{aligned}$$

The paired differences become

$$(x2_i - x1_i) = \text{Cal-Bias2} + \text{Random-Bias2}_i + (\varepsilon 2_i - \varepsilon 1_i)$$

We thus have an expression consisting of a systematic error term (calibration bias of method 2) and two random terms. The Random-Bias2 term is distributed around Cal-Bias2 according to an undefined distribution. $(\varepsilon 2_i - \varepsilon 1_i)$ is a difference between two random measurement errors that are independent and, commonly, Gaussian distributed. However, we remind the reader that the SD for analytical methods often depends on the concentration, as mentioned earlier. For analytes with a wide analytical measurement range (e.g., some hormones), both sample-related random interferences and analytical SDs are likely to depend on the measurement concentration, often in a roughly proportional manner. It may then be more useful to evaluate the *relative* differences—$(x2_i - x1_i)/[(x2_i + x1_i)/2]$—and accordingly express mean and random bias and analytical error as proportions. An alternative is to partition the total analytical measurement range into segments (e.g., three parts) and consider calibration bias, random bias, and analytical error separately for each of these segments. The segments may be divided preferably in relation to important decision concentrations (e.g., in relation to reference interval limits and/or treatment decision concentrations).

Comparison of Two Routine Methods

In the comparison of two routine methods, the paired differences become

$$(x2_i - x1_i) = (\text{Cal-Bias2} - \text{Cal-Bias1}) + (\text{Random-Bias2}_i - \text{Random-Bias1}_i) + (\varepsilon 2_i - \varepsilon 1_i)$$

The expression again consists of a constant term, the difference between the two calibration biases, and two random terms. The first random term is a difference between two random-bias components that may or may not be independent. If the two field methods are based on the same measurement principle, the random bias terms are likely to be correlated. For example, two chromogenic methods for creatinine are likely to be subject to interference from the same chromogenic compounds present in a given serum sample. On the other hand, a chromogenic method and an enzymatic creatinine method are subject to different types of interfering compounds, and the random bias terms may be relatively independent. In the $\varepsilon 2_i - \varepsilon 1_i$ term, the same relationships as described previously are likely to apply. One may note that the general form of the expressed differences is the same in the two situations. Thus the same general statistical principles actually apply. In the following sections, we will consider the distribution of differences under various circumstances, as well as the measurement relations between methods 1 and 2 on the basis of regression analysis.

Preliminary Practical Work in Relation to a Method Comparison Study

When a method comparison study is to be conducted, the analytical methods to be examined first should be established in the laboratory according to written protocols and should be stable in routine performance. Reagents are commonly supplied as ready-made analytical kits, perhaps implemented on a dedicated analytical instrument (open or closed system). Technologists performing the study should be trained in the procedures and associated instrumentation. Further, it is important that a quality control system is in place to ensure that the methods being compared are running in an in-control state.

Planning a Method Comparison Study

In the planning phase of a method comparison study, several points require attention, including the (1) number of samples necessary, (2) distribution of analyte concentrations (preferably uniform over the analytical measurement range), and (3) representativeness of the samples. To address the latter point, samples from relevant patient categories should be included, so that possible interference phenomena can be discovered. Practical aspects related to storage and treatment of samples (e.g., container) and possible artifacts induced by storage (e.g., freezing of samples) and addition of anticoagulants should be considered. Comparison of measurements should preferably be undertaken over several days (e.g., at least 5 days), so that the comparison of methods does not become dependent on the performance of the methods in one particular analytical run. Finally, ethical aspects (e.g., informed consent from patients whose samples will be used) should be considered in relation to existing legislation.

When the comparison protocol is considered, various guidelines may be consulted. The CLSI Evaluation Protocol (EP) guidelines give advice on various aspects. For example, the CLSI guideline EP-9A2 "Method Comparison and Bias Estimation Using Patient Samples" suggests measurement of 40 samples in duplicate by each method when a new method is introduced in the laboratory as a substitute for an established one.[10] Additionally, it is proposed that a vendor of an analytical test system should have made a comparison study based on at least 100 samples measured in duplicate by each method. The principle of a more demanding requirement for vendors appears reasonable. This initial validation should be comprehensive to disclose the performance of the assay system in detail. Then the requirement for the ordinary user may be more modest. The EP15 guideline "User Verification of Manufacturer's Claims" suggests a more condensed approach based on a bias or difference plot, which does not involve regression analysis and can be carried out using 20 samples.[17] Although these general guidelines on sample size are useful, additional aspects are important. The probability of detecting rarely occurring interferences showing up as outliers should be taken into account when the necessary sample size is considered. Finally, in relation to evaluation of automated methods, special consideration should be given to the sample sequence to evaluate drift, carryover, and nonlinearity (e.g., by a multifactorial design).[58]

Distribution of Differences Plot (DoD plot)

From the end-user viewpoint, it is the differences per se that matter. Thus with regard to the outcome of replacing an established routine method with a new one that perhaps is less expensive or more practical, it is important to focus on the distribution of differences between paired measurements by the old and the new method. A graphic display with assessment of the central tendency and dispersion of differences in the form of an ordinary histogram or frequency polygon plot is useful. The differences may or may not be Gaussian distributed. Because both analytical error components and sample-related random interferences may contribute to the differences, the distribution may be irregular and outliers may occur. Further, the random dispersion elements may be dependent on analyte concentration. Therefore, a nonparametric approach for interpreting the distribution of differences may generally be preferable as a starting point.

Nonparametric Approach

Both the central tendency (median) and extreme percentiles are of interest when the nonparametric approach to the distribution of differences is used. With a traditional 95% level, 2.5- and 97.5-percentiles are considered. A 99% or higher extreme level may be selected, and the related percentiles (0.5- and 99.5-, or more extreme ones) may then be applied for a description of method differences. Nonparametric estimation of the 2.5- and 97.5-percentiles requires 2.5 times as many observations as the parametric approach to obtain the same uncertainty, which implies that sample sizes cannot be too small.[74] Estimating confidence limits of the percentiles

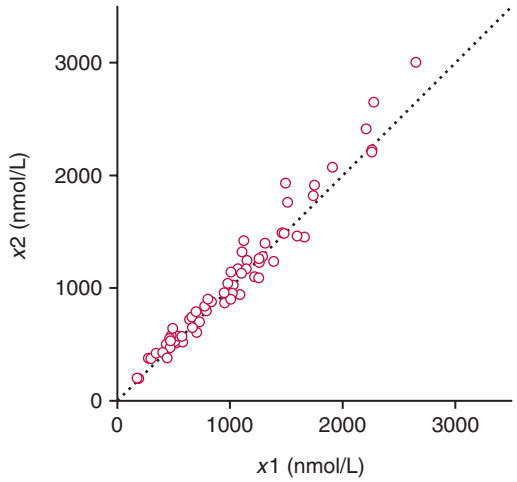

Figure 2-10 A scatter plot of $N = 65$ ($x1$, $x2$) data points for comparison of two drug assays. The *dashed line* is the line of identity.

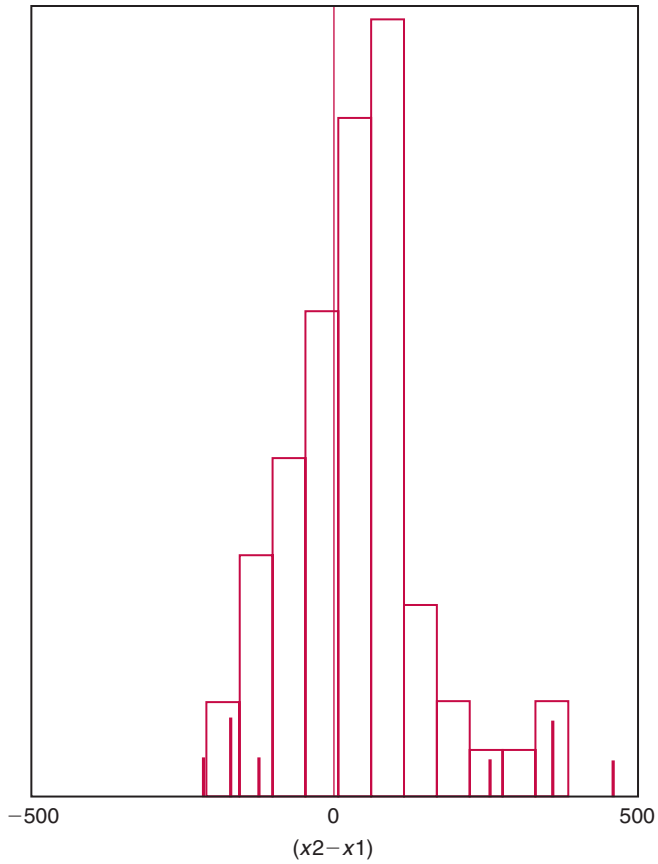

Figure 2-11 Distribution of differences (DoD) plot for comparison of two drug assays: nonparametric analysis. A histogram shows the relative frequency of $N = 65$ differences with demarcated 2.5- and 97.5-percentiles determined nonparametrically. The 90%-confidence intervals (CIs) of the percentiles are shown. These were derived by the bootstrap technique.

can give an indication of their imprecision. The CIs can be estimated from the ordered observations as described in Chapter 5 in the section on nonparametric estimation of the 95%-reference interval. Alternatively, a bootstrap procedure can be applied as described.[74] The advantage of the bootstrap procedure is that standard errors can be derived using smaller sample sizes than are used with the simple nonparametric approach.[19]

A method comparison example from the laboratory of one of the authors (K.L.) is considered. Two drug assays developed in-house for serum concentrations of the antipsychotic drug clozapine are compared. The established assay (method 1) is an HPLC method based on manual liquid-liquid extraction. The new method (method 2) is an HPLC method with an automated on-column extraction step. An initial impression of the relation between $x1$ and $x2$ measurements can be obtained from a scatter plot of the 65 measurement sets ($x1$, $x2$) with the identity line outlined (Figure 2-10). The $x1$ measurements range from 177 to 2650 nmol/L, and the range of $x2$ values is from 200 to 3004 nmol/L (i.e., we have a relatively wide analytical measurement range in the present example). A histogram of the difference ($x2 - x1$) is shown in Figure 2-11. Applying a nonparametric data description, we order the observed differences according to size and derive the median difference as the value of the $(0.5N + 0.5)^{th}$ ordered observation, here 26 nmol/L. In case the order is a noninteger, interpolation between neighbor-ordered values is carried out. A paired nonparametric test, the Wilcoxon test,[98] shows that the median difference was significantly different from zero ($P < 0.02$). The 2.5- and 97.5-percentiles correspond to the values of the $(0.025N + 0.5)^{th}$ and $(0.975N + 0.5)^{th}$ ordered observations, respectively, as displayed in Table 2-7.[23,74] For a sample size smaller than 120, it is not possible to derive CIs for the percentiles by the simple nonparametric procedure. Therefore, we also applied the bootstrap procedure to estimate nonparametric percentiles with 90%-CIs[30,74] (see Table 2-7). The bootstrap procedure, which is based on computerized random resampling of the observations, provides slightly different percentile estimates, as shown in Table 2-7. In this way, we obtain an estimation of the size of negative and positive differences with uncertainties. The present example shows a considerable range of differences, with the 2.5-percentile being −169 nmol/L (90%-CI: −214 to −123) and the 97.5-percentile being 356 nmol/L (90% CI: 255 to 457). These relatively large differences should be related to the considerable analytical measurement range for the analyte, and an evaluation of *relative* differences may be more relevant for the present example (see later in this chapter).

In the presented examples, no evident outliers were present. However, outliers deserve special attention.[23] Unless they are related to obvious method or apparatus malfunction, discarding of outliers should be considered with caution. Outliers may indicate the presence of large sample-related random interferences, which may be of major clinical importance (e.g., interference by antibodies or degradation products that occur only rarely). Thus a special investigation of

CI, Confidence interval; *ns,* not significant; *SD,* standard deviation.

outlying results with reanalysis and exploration of the reasons for the outlying observations should be considered.

Parametric Approach

If application of a goodness-of-fit test does not disprove that the distribution of differences is Gaussian distributed, a parametric statistical approach may be undertaken. In the example presented, a significant deviation from normality was present, as assessed by the Anderson-Darling test[65] ($P < 0.01$); therefore, a parametric analysis in principle should not be carried out. However, to demonstrate the procedure, the parametric approach is also carried out (Figure 2-12 and Table 2-7). The mean and SD (SD_{Dif}) of the paired differences ($x2 - x1$) are estimated according to standard procedures. A paired t-test is used to determine whether the mean difference is significantly different from zero ($P < .01$ in this case). The 2.5- and 97.5-percentiles for the differences are estimated as the mean $\pm t_{0.025(N-1)}$ SD_{Dif}. A standard error for the percentiles (SE_{perc}) may be computed and the 90%-CI limits are then derived as ± 1.65 SE_{perc} around the percentiles (see Figure 2-12 and Table 2-7). The parametrically derived 2.5- and 97.5-percentiles (−202 and 286 nmol/L) differ somewhat from the nonparametrically derived percentiles, which in the present context with proven non-normality may be regarded as the most reliable estimates.

Relative Distribution of Differences Plot (Rel DoD plot)

In some cases in which a wide analytical measurement range (i.e., corresponding to 1 or several decades) is used, the random error components depend on the concentration, as previously mentioned. Analytical SDs may be approximately proportional to the concentration over the major part of the analytical measurement range. In the present example, the

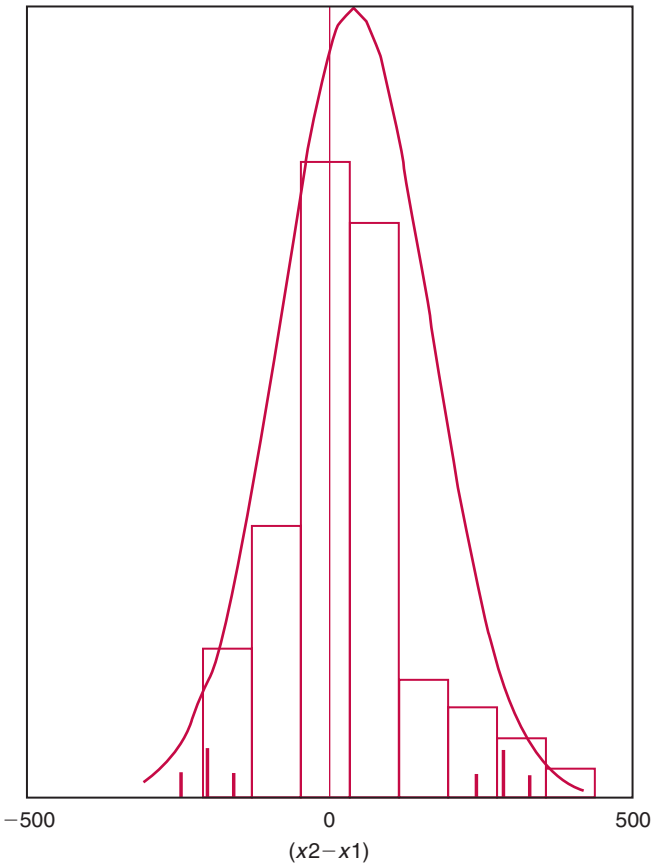

Figure 2-12 Distribution of differences (DoD) plot for comparison of two drug assays: parametric analysis. A histogram shows the relative frequency of N = 65 differences with the estimated Gaussian density distribution. Parametrically estimated 2.5- and 97.5-percentiles are shown with 90%-confidence intervals (CIs).

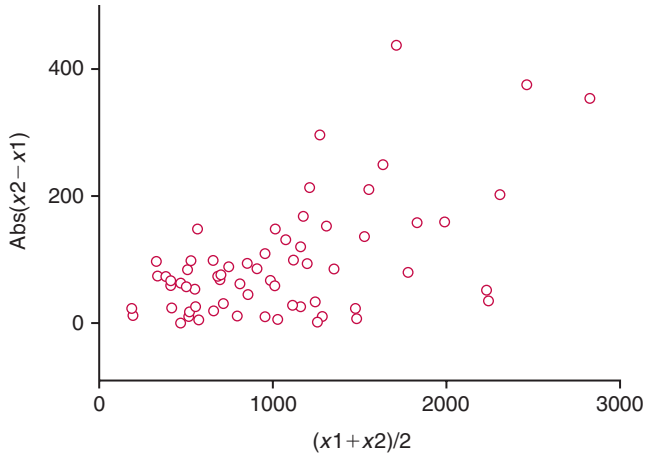

Figure 2-13 Plot of absolute differences (ordinate) against average concentration (abscissa) for the comparison of drug assays example. The scatter increases with the average concentration ($r = +0.57$).

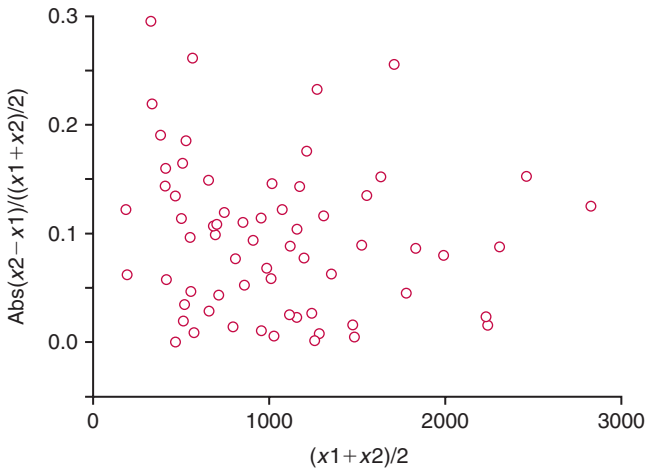

Figure 2-14 Plot of absolute *relative* differences (ordinate) against average concentration (abscissa) for the comparison of drug assays example. The scatter is not significantly correlated with the average concentration ($r = -0.15$, not significant).

initial scatter plot of ($x1$, $x2$) values suggests that the random error of the differences increases with the concentration (see Figure 2-10). A formal test for this possible relation is to compute the correlation coefficient between the average concentration and the *absolute* value of the differences. This correlation coefficient, r, is +0.57, which is significantly different from zero ($P < 0.001$), and it confirms the relationship of scatter increasing with concentration, which also can be visualized in a scatter plot of the absolute differences against the average concentration (Figure 2-13). A natural next step is to assess the *relative* differences in relation to the average concentration. The correlation coefficient between the absolute values of the relative differences $[|x2 - x1|/(\{x1 + x2\}/2)]$ and the average concentration $[(x1 + x2)/2]$ was not significantly different ($P > 0.05$) from zero ($r = -0.15$); a scatter plot also suggests a more homogeneous dispersion (Figure 2-14). In this situation, it is more reasonable to deal with *relative* differences or percentage differences $[(\{x2 - x1\}/\{x1 + x2\}/2) \times 100\%]$. The same nonparametric descriptive measures as used earlier may be applied for the central tendency and the dispersion (Figure 2-15). The median relative difference amounts to 0.042, or 4.2%, which is significantly higher than zero ($P < 0.01$) (Wilcoxon test) (Table 2-8). The 2.5- and 97.5-percentiles are −0.15 and 0.26, respectively. The 90%-CIs derived by the bootstrap procedure were −0.16 to −0.14 and 0.21 to 0.30, respectively. Thus from this analysis, we may conclude that the 95% interval for percentage differences ranges from about −15 to +26%.

Finally, we may consider a parametric analysis of the relative differences (Figure 2-16 and Table 2-8). A goodness-of-fit test (Anderson-Darling test; $P > .05$) showed that the relative differences did not depart significantly from a normal distribution, which in this case supports the parametric approach (Figure 2-17). The parametric 2.5- and 97.5-percentiles were

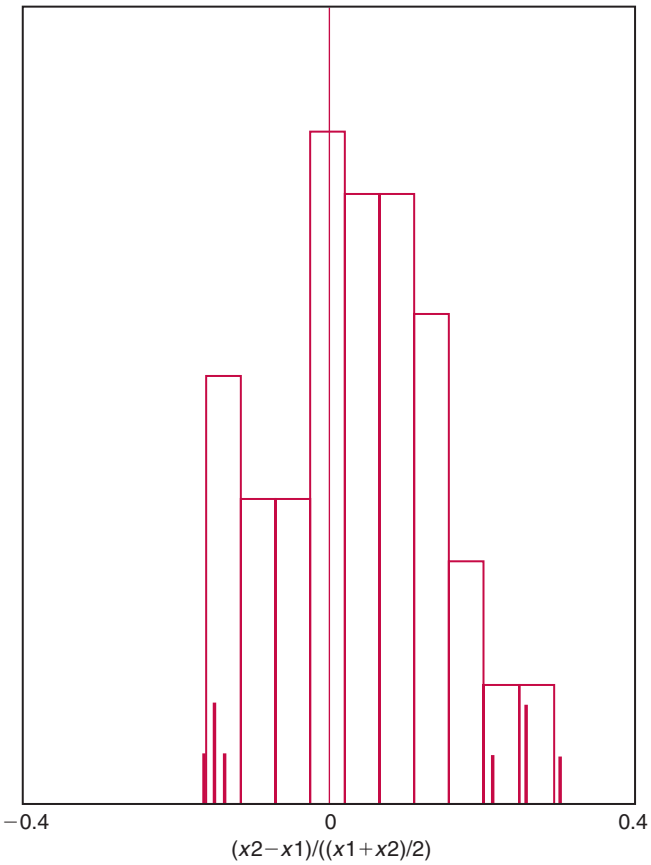

Figure 2-15 Relative distribution of differences (Rel DoD) plot for comparison of two drug assays: nonparametric analysis. A histogram shows the relative frequency of relative differences with demarcated 2.5- and 97.5-percentiles determined nonparametrically. The 90%-confidence intervals (CIs) (bootstrap) of the percentiles are shown.

–0.18 and 0.26, respectively. The mean was 0.042, and the SD of the relative differences was 0.11. Thus we may conclude that there is an average bias of about 4%, which might rely on a calibration difference [an estimate of (Cal-Bias2 − Cal-Bias1)], and a random error corresponding to a CV of 11%. The random error CV of 11% is an estimate of the combined dispersion of $[(\text{Random-Bias2}_i - \text{Random-Bias1}_i) + (\varepsilon 2_i - \varepsilon 1_i)]$. If we ascribe the random variation equally to the two assays, it corresponds to a random error level of $11\%/\sqrt{2} = 7.8\%$ for each assay. In the present example, the average bias of 4% and the estimated random variation of differences between the two assays were considered acceptable in relation to the clinical use of the assay, and it was decided to replace the manual assay with the new, automated assay.

Verification of Distribution of Differences in Relation to Specified Limits

In situations in which a field method is being considered for implementation, it may be desired primarily to *verify* whether the differences in relation to the existing method are located within given specified limits, rather than *estimating* the distribution of differences. For example, one may set limits corresponding to ±15% as clinically acceptable and may desire that a majority (e.g., 95% of differences) are located within this interval.

By counting, it may be determined whether the expected proportion of results is within the limits (i.e., 95%). One may accept percentages that do not deviate significantly from the supposed percentage at the given sample size derived from the binomial distribution (Table 2-9). For example, if 50 paired measurements have been performed in a method comparison study, and if it is observed that 46 of these results (92%) are within specified limits (e.g., ±15%), the study supports that the achieved goal has been reached, because the lower boundry for acceptance is 90%. It is clear that a reasonable number of observations should be obtained for the assessment to have acceptable power. If very few observations are available, the risk is high of falsely concluding that at least 95% of the observations are within specified limits, in case it is not true (i.e., committing a type II error).

TABLE 2-9 Lower Bounds (One-Sided 95%-CI) of Observed Proportions (%) of Results Being Located Within Specified Limits for Paired Differences That Are in Accordance With the Hypothesis of at Least 95% of Differences Being Within the Limits

Difference (Bland-Altman) Plot

The difference plot suggested by Bland and Altman is widely used for evaluating method comparison data.[3,4] The procedure was originally introduced for comparison of measurements in clinical medicine, but it has also been adopted in clinical chemistry.[69,84,88] The Bland-Altman plot is usually understood as a plot of the differences against the average results of the methods. Thus the difference plot in this version provides information on the relation between differences and concentration, which is useful in evaluating whether problems exist at certain ranges (e.g., in the high range) caused by nonlinearity of one of the methods. It may also be of interest to observe whether differences tend to increase proportionally with the concentration, or whether they are independent of concentration. In some situations, particular interest may be directed toward the low-concentration region. Information on the relation between differences and concentration is useful in the context of how to adjust for an irregularity (e.g., by changing the method to correct for nonlinearity, by restricting the analytical measurement range).

The basic version of the difference plot requires plotting of the differences against the average of the measurements. Figure 2-18 shows the plot for the drug assay comparison

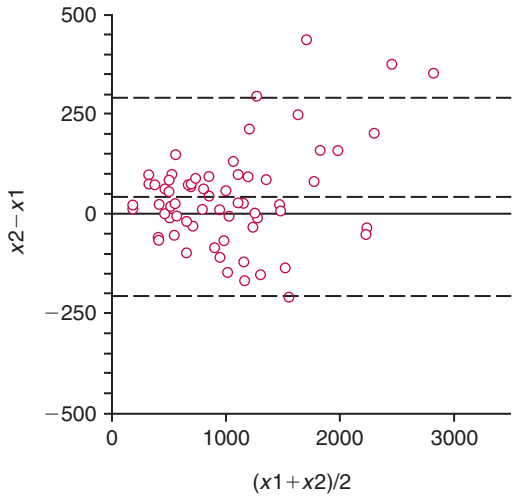

Figure 2-18 Bland-Altman plot of differences for the drug comparison example. The differences are plotted against the average concentration. The mean difference (42 nmol/L) with ±2 standard deviation (SD) of differences is shown *(dashed lines).*

data. The interval ±2 SD of the differences is often delineated around the mean difference (i.e., corresponding to the mean and the 2.5- and 97.5-percentiles considered in the parametric DoD plot).[4]

Nonparametric limits may also be considered. The distribution of the differences as measured on the *y*-axis of the coordinate system corresponds to the relations outlined for the DoD plot, which represents a projection of the differences on the *y*-axis. A constant bias over the analytical measurement range changes the average concentration away from zero. The presence of sample-related random interferences increases the width of the distribution. If the calibration bias depends on the concentration, if the dispersion varies with the concentration, or if both occur, the relations become more complex, and the interval mean ±2 SD of the differences may not fit very well as a 95% interval throughout the analytical measurement range.

The displayed Bland-Altman plot for the drug assay comparison data (see Figure 2-18) shows a tendency toward increasing scatter with increasing concentration, which is a reflection of increasing random error with concentration, as considered in detail in previous paragraphs. Thus a plot of the relative differences against the average concentration is of relevance (Figure 2-19). This plot has a more homogeneous dispersion of values, agreeing with the estimated limits for the dispersion, that is, the relative mean difference $\pm t_{0.025(N-1)}$ SD_{RelDif} equal to $0.042 \pm 1.998 \times 0.11$ corresponding to −0.18 and 0.26, analogous to the situation with the relative DoD plot considered earlier.

Use of *relative* differences in situations with a proportional random error relationship prevents very large differences in the high concentration range from dominating the analysis and making a balanced interpretation difficult. In the low range, the proportional relationship may not necessarily hold true, and sometimes the relative difference plot overcompensates for lack of proportionality in this region. It is then possible to truncate the proportional relationship at some lower limit and assume a constant SD for differences below this limit[70] (i.e., corresponding to the relationship in Figure 2-3, *C*). In the actual drug example (see Figure 2-19) with a slightly negative correlation coefficient between relative differences and average concentration, a tendency toward this pattern is seen. An alternative to the relative difference plot is to plot the logarithm of the differences against the average concentration, but this type of plot is more difficult to interpret, because the scale is changed.

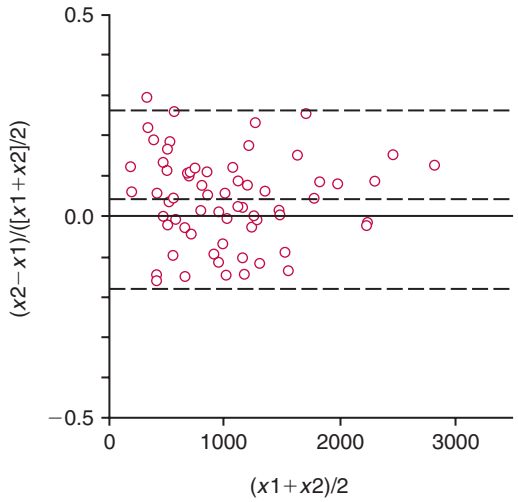

Figure 2-19 Bland-Altman plot of *relative* differences for the drug comparison example. The differences are plotted against the average concentration. The mean relative difference (0.042) with ±2 standard deviation (SD) of relative differences is shown *(dashed lines)*.

Although it is customary to display the *estimated* limits for the differences (often, mean ± 2 SD_{dif}), one may, as an alternative, display specification limits considered reasonable, as mentioned for the DoD plot.[84] It may then be assessed whether the observed differences conform to these limits, as discussed earlier (see Table 2-9). Application of the difference plot in various specific contexts has been considered.[9,99] It has also been suggested to estimate a regression line for the differences as a function of the average measurement concentration.[103]

A Caution Against Incorrect Interpretation of Paired *t*-Tests in Method Comparison Studies

In association with the difference plot, the paired *t*-test is usually applied as described earlier[3] but one should be careful with regard to the interpretation. For example, consider the case shown below, in which method 2 ($x2$) measurements tend to exceed method 1 ($x1$) measurements in the low range and vice versa at high concentrations (Figure 2-20, *A*). This corresponds to a positive calibration bias in the low range, changing to a negative calibration bias in the high range. In this situation, the overall averages of both sets of measurements are nearly equal, and the paired *t*-test yields a nonsignificant result, because the average paired difference (i.e., the overall bias) is close to zero (Table 2-10). This does not mean that the measurements are equivalent. Subjecting the data to Deming regression analysis (see the next section) clearly discloses the relation[72] (Figure 2-20, *B*). Results of the regression analysis confirm the existence of both a systematic constant error (intercept different from zero) and a systematic proportional error (slope different from 1). Therefore, as pointed out previously, the statistical significance revealed by the paired *t*-test cannot be used to indicate whether measurements are equivalent. The paired *t*-test is just a test for the average bias; it does not say anything about the equivalency of measurements throughout the analytical measurement range.

Regression Analysis

Regression analysis is commonly applied in comparing the results of analytical method comparisons. Typically, an experiment is carried out in which a series of paired values is collected when a new method is compared with an established method. This series of paired observations ($x1_i$, $x2_i$) is then used to establish the nature and strength of the relationship between the tests. This discussion outlines various regression

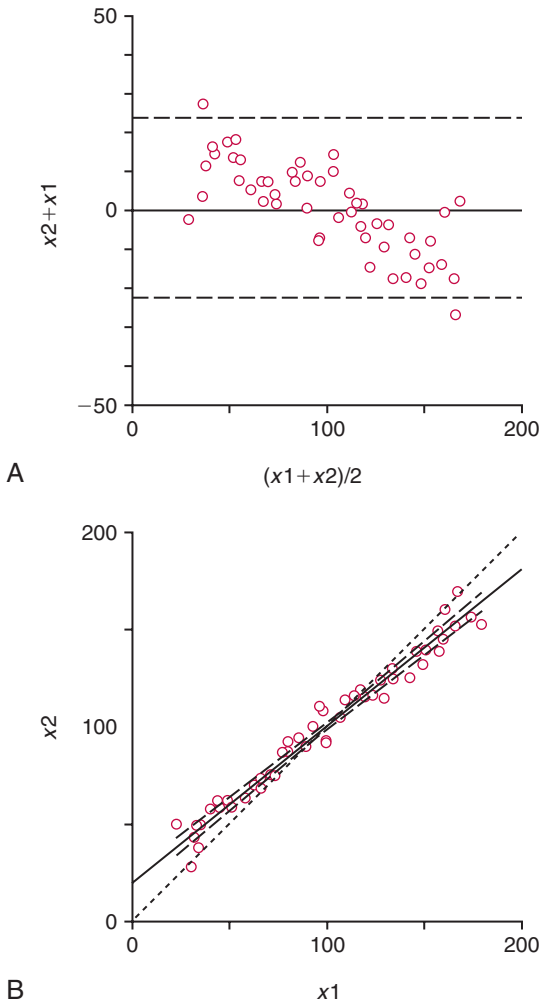

Figure 2-20 Simulated example with positive and negative differences in the low and high ranges, respectively. A, Bland-Altman plot. B, *x*-*y* plot with diagonal *(dotted straight line)* and estimated Deming regression line *(solid line)* with 95%-confidence curves *(dashed lines).*

models that may be used, gives criteria for when each should be used, and provides guidelines for interpreting the results.

Regression analysis has the advantage that it allows the relation between the target values for the two compared methods to be studied over the full analytical measurement range. If the systematic difference between target values (i.e., the calibration bias between the two methods, or the systematic error) is related to the analyte concentration, such a relationship may not be clearly shown when the previously mentioned types of difference plots are used. Although nonlinear regression analysis may be applied, the focus is usually on linear regression analysis. In linear regression analysis, it is assumed that the systematic difference between target values can be modeled as a constant systematic difference (intercept deviation from zero) combined with a proportional systematic difference (slope deviation from unity), usually related to a discrepancy with regard to calibration of the

TABLE 2-10 Comparison of Paired *t*-Test Results and Deming Regression Results for a Simulated Method Comparison Example With Positive Intercept (a_0 = 20) and Slope Below Unity (b = 0.80). N = 50 ($x1$, $x2$) Measurements

methods. In situations where random errors have a constant SD, unweighted regression procedures are used (e.g., Deming regression analysis). For cases with SDs that are proportional to the concentration, the weighted Deming regression procedure is preferred.

Error Models in Regression Analysis

As outlined previously, we distinguish between the measured value (x_i) and the target value ($X_{\mathrm{Target}i}$) of a sample subjected to analysis by a given method. In linear regression analysis, we assume a linear relationship between values devoid of random error of any kind. In statistical terminology, a so-called structural relationship is assumed.[68,78] Thus, to operate with a linear relationship between values without random measurement error and sample-related random bias, we have to introduce modified target values:

$$X1_{\mathrm{Target}i} = X1'_{\mathrm{Target}i} + \text{Random-Bias1}_i$$
$$X2_{\mathrm{Target}i} = X2'_{\mathrm{Target}i} + \text{Random-Bias2}_i$$

where we now assume a linear relationship between these modified target values:

$$X2'_{\mathrm{Target}i} = \alpha_0 + \beta X1'_{\mathrm{Target}i}$$

In this model, α_0 corresponds to a constant difference with regard to calibration, and $(\beta - 1)$ is a proportional deviation. Thus, the systematic error or calibration difference between the measurements corresponds to

$$X2'_{\mathrm{Target}i} - X1'_{\mathrm{Target}i} = \alpha_0 + (\beta - 1)X1'_{\mathrm{Target}i}$$

Because of sample-related random interferences and measurement imprecision (of the type that can be described by a Gaussian distribution, e.g., caused by pipetting variability, signal variability), individually measured pairs of values ($x1_i$, $x2_i$) will be scattered around the line expressing the relationship between $X1'_{\mathrm{Target}i}$ and $X2'_{\mathrm{Target}i}$. Figure 2-21 outlines schematically how the random distribution of $x1$ and $x2$ values occurs around the regression line. We have

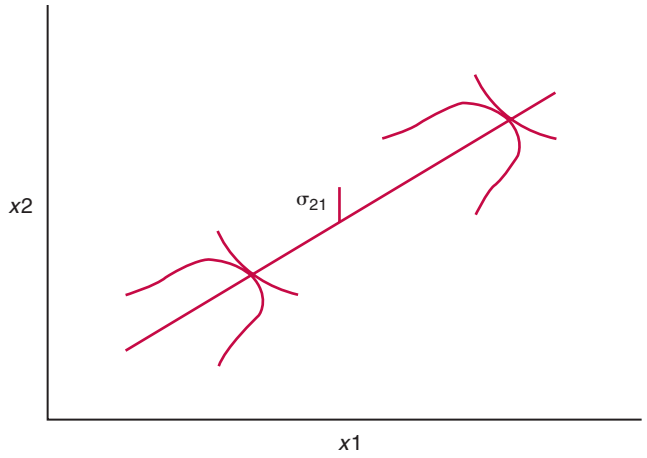

Figure 2-21 Outline of the relation between *x*1 and *x*2 values measured by two methods subject to random errors with constant standard deviations (SDs) over the analytical measurement range. A linear relationship between the modified target values ($X1'_{Target i}$, $X2'_{Target i}$) is presumed. The $x1_i$ and $x2_i$ values are Gaussian distributed around $X1'_{Target i}$ and $X2'_{Target i}$, respectively, as schematically shown. σ_{21} (σ_{yx}) is demarcated.

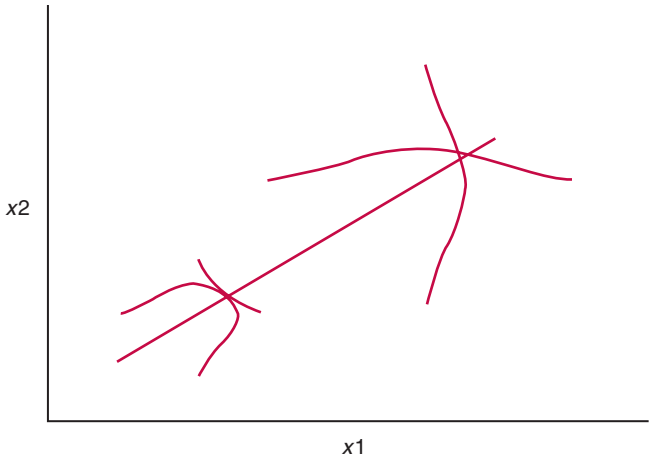

Figure 2-22 Outline of the relation between *x*1 and *x*2 values measured by two methods subject to proportional random errors. A linear relationship between the modified target values is assumed. The $x1_i$ and $x2_i$ values are Gaussian distributed around $X1'_{Target i}$ and $X2'_{Target i}$, respectively, with increasing scatter at higher concentrations, as is shown schematically.

$$x1_i = X1_{Target i} + \varepsilon 1_i = X1'_{Target i} + \text{Random-Bias1}_i + \varepsilon 1_i$$
$$x2_i = X2_{Target i} + \varepsilon 2_i = X2'_{Target i} + \text{Random-Bias2}_i + \varepsilon 2_i$$

The random error components may be expressed as SDs, and generally we can assume that sample-related random bias (SD σ_{RB}) and analytical imprecision (SD σ_A) are independent for each analyte, yielding the relations

$$\sigma^2_{ex1} = \sigma^2_{RB1} + \sigma^2_{A1}$$
$$\sigma^2_{ex2} = \sigma^2_{RB2} + \sigma^2_{A2}$$

σ_{ex1} and σ_{ex2} are the total SDs of the distributions of $x1_i$ and $x2_i$ around their respective modified target values, $X1'_{Target i}$ and $X2'_{Target i}$. The sample-related random bias components for methods 1 and 2 may not necessarily be independent. They also may not be Gaussian distributed, contrary to the analytical components. Thus when a regression procedure is applied, the explicit assumptions to take into account should be considered. In situations without random bias components of any significance, the relationships simplify to

$$\sigma^2_{ex1} = \sigma^2_{A1}$$
$$\sigma^2_{ex2} = \sigma^2_{A2}$$

In this situation, it usually can be assumed that the error distributions are Gaussian, and estimates of the analytical SDs may be available from quality control data.

Another methodologic problem concerns the question of whether the dispersion of sample-related random bias and the analytical imprecision are constant or change with the analyte concentration, as considered previously in the difference plot sections. In cases with a considerable range (i.e., a decade or longer), this phenomenon should also be taken into account when a regression analysis is applied. Figure 2-22 schematically shows how dispersions may increase proportionally with concentration.

Deming Regression Analysis and Ordinary Least-Squares Regression Analysis (OLR) (Constant SDs)

To reliably estimate the relationship between modified target values (i.e., a_0 for α_0 and b for β), a regression procedure taking into account errors in both $x1$ and $x2$ is preferable (i.e., Deming approach) (see Figure 2-21).[22] Although the OLR procedure is commonly used in method comparison studies, it does not take errors in $x1$ into account but is based on the assumption that only the $x2$ measurements are subject to random errors (Figure 2-23). In the Deming procedure, the sum of squared distances from measured sets of values ($x1_i$, $x2_i$) to the regression line is minimized at an angle determined by the ratio between SDs for the random variations of $x1$ and $x2$. It can be proven theoretically that, given Gaussian *error* distributions, this estimation procedure is optimal. It should here be noted that it is the *error* distributions that should be Gaussian, not the dispersion of values over the measurement range. This is often misunderstood. In Figure 2-24, the symmetric case is illustrated with a regression slope of 1 and equal SDs for the random variations of $x1$ and $x2$, in which case the sum of squared distances is minimized orthogonally in relation to the line.

OLR is not recommended except in special situations. In OLR, the sum of squared distances is minimized in the vertical direction to the line (see Figure 2-24). It can be proven theoretically that neglect of the random error in $x1$ induces a downward biased slope estimate

$$\beta' = \beta[\sigma^2_{X1'target}/(\sigma^2_{X1'target} + \sigma^2_{ex1})] = \beta/[1 + (\sigma_{ex1}/\sigma_{X1'target})^2]$$

tahir99-VRG & vip.persianss.ir

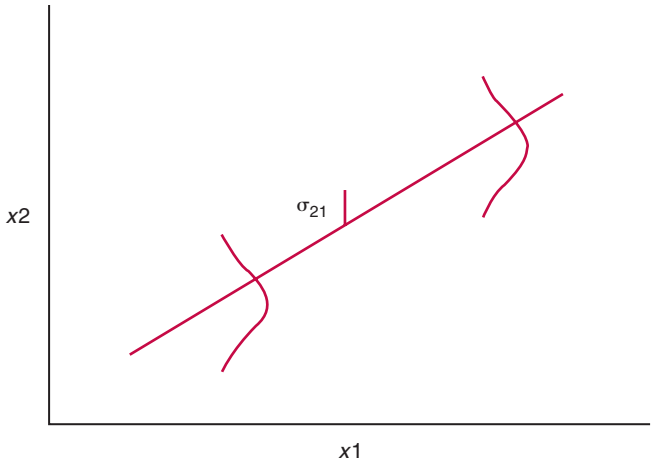

Figure 2-23 The model assumed in ordinary least-squares regression (OLR). The *x*2 values are Gaussian distributed around the line with constant standard deviation (SD) over the analytical measurement range. The *x*1 values are assumed to be without random error. σ_{21} (σ_{yx}) is shown.

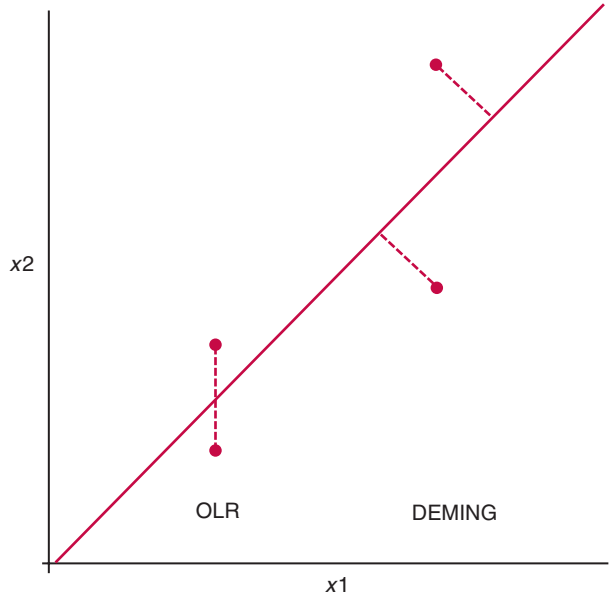

Figure 2-24 In ordinary least-squares regression (OLR), the sum of squared deviations from the line is minimized in the vertical direction. In Deming regression analysis, the sum of squared deviations is minimized at an angle to the line, depending on the random error ratio. Here the symmetric case is displayed with orthogonal deviations. [*Reproduced with permission from* Reference 71 *(Figure 1).*]

where $\sigma_{X1'target}$ is the SD of $X1'$ target values.[98] The magnitude of the bias depends on the ratio between the SD for the random error in *x*1 and the SD of the $X1'$ target values. Figure 2-25 shows the bias as a function of the ratio of the random error SD to the SD of the $X1'$ target value dispersion. For a ratio up to 0.1, the bias is less than 1%. At a ratio of 0.33, the bias amounts to 10%; it increases further for increasing ratios.

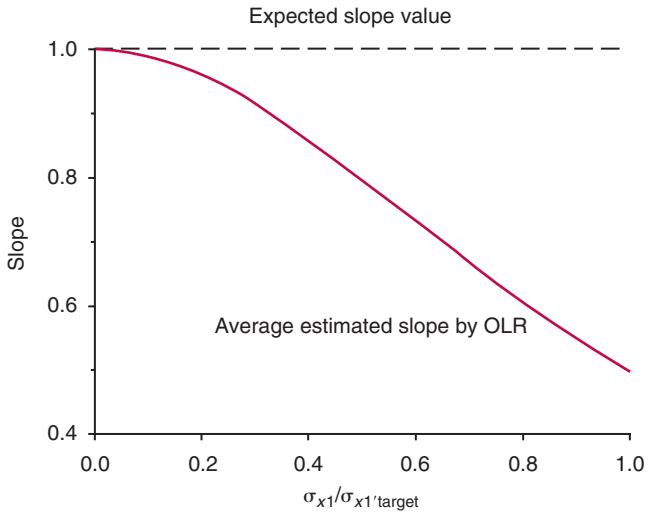

Figure 2-25 Relations between the true (expected) slope value and the average estimated slope by ordinary least-squares regression (OLR). The bias of the OLR slope estimate increases negatively for increasing ratios of the standard deviation (SD) random error in *x*1 to the SD of the *X*1 target value distribution.

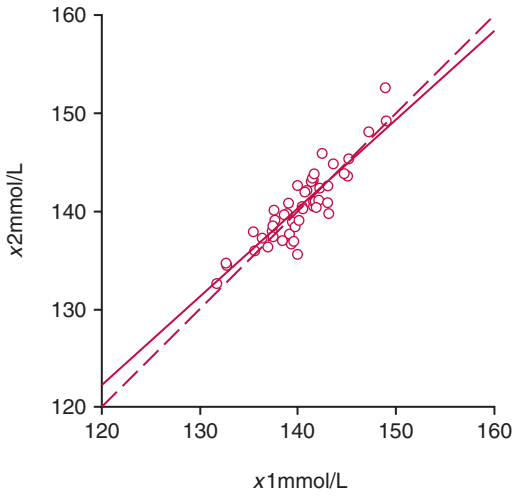

Figure 2-26 Simulated comparison of two sodium methods. The *solid line* indicates the average estimated ordinary least-squares regression (OLR) line, and the *dotted line* is the identity line. Even though no systematic difference is evident between the two methods, the average OLR line deviates from the identity line corresponding to a downward slope bias of about 10%.

In a given case, one can take the analytical SD (e.g., from quality control data) and divide by the SD of the measured *x*1 values, which approximately equals the SD of $X1'$ target values. As an example, a typical comparison study for two serum sodium methods may be associated with a downward directed slope bias of about 10% (Figure 2-26).

In the example presented previously, the ratio of the analytical SD to the SD of the target value distribution is large because of the tight physiologic regulation of electrolyte

tahir99-VRG & vip.persianss.ir

concentrations, which means that the biological variation is limited. Most other types of analytes exhibit wider distributions, and the ratio of error to target value distribution is smaller. For example, for analytes with a distribution of longer than 1 decade and an analytical error corresponding to a CV of 5% at the middle of the analytical measurement range, the OLR slope bias amounts to about −1%.

Computation Procedures for OLR and Deming Regression

Assuming no errors in $x1$ and a Gaussian error distribution of $x2$ with constant SD throughout the analytical measurement range, OLR is the optimal estimation procedure, as proved by Gauss in the eighteenth century. Given errors in both $x1$ and $x2$, the Deming approach is the method of choice.[20] It should be noted for these parametric procedures that only the *error* distributions must be Gaussian or normal. The least-squares principle does not require normality to be applied, but it is optimal under normality conditions, and the nominal type I errors for associated statistical tests for slope and intercept hold true under this assumption. The procedures are generally robust toward deviations from normality, but they are sensitive to outliers because of the squaring principle. Finally, the distribution of the $x1$ and $x2$ values over the measurement range does not have to be normal. A uniform distribution over the analytical measurement range is generally of advantage, but the distribution in principle may take any form. For both procedures, we may evaluate the SD of the dispersion in the *vertical* direction around the line (commonly denoted $SD_{y\text{-}x}$ and here given as SD_{21}). We have

$$SD_{21} = [\Sigma(x2_i - X2'_{\text{Targetest}i})^2/(N-2)]^{0.5}$$

Further discussion regarding the interpretation of SD_{21} will be given later.

To compute the slope in Deming regression analysis, the ratio between the SDs of the random errors of $x1$ and $x2$ is necessary, that is,

$$\lambda = (\sigma^2_{RB1} + \sigma^2_{A1})/(\sigma^2_{RB2} + \sigma^2_{A2})$$

SD_As can be estimated from duplicate sets of measurements as

$$SD^2_{A1} = (1/2N)\Sigma[x1_{2i} - x1_{1i})^2$$
$$SD^2_{A2} = (1/2N)\Sigma[x2_{2i} - x2_{1i})^2$$

or they may be available from quality control data. The latter is a practical approach that avoids the need for duplicate measurements by each measurement procedure.

If a specific value for λ is not available and the two routine methods that are compared are likely to be associated with random errors of the same order of magnitude, λ can be set to 1. The Deming procedure is generally relatively insensitive to a misspecification of the λ value.[71]

Formulas for computing slope (β), intercept (α_0), and their standard errors are available from other sources[20,70,98] and will not be provided here. Commonly available software packages for performing regression analysis by both methods will be mentioned later.

Evaluation of the Random Error Around an Estimated Regression Line

The estimated slope and intercept provide an estimate of the systematic difference or calibration bias between two methods over the analytical measurement range. Additionally, an estimate of the random error is important. It is commonplace to consider the dispersion around the line in the vertical direction, which is quantified as $SD_{y\text{-}x}$ (here denoted SD_{21}). SD_{21} was originally introduced in the context of OLR, but it also can be considered in relation to Deming regression analysis.

Interpreting $SD_{y\text{-}x}$ (SD_{21}) With Random Errors in Both $x1$ and $x2$

With regard to σ_{21}, we have here without sample-related random interferences

$$\sigma^2_{21} = \beta^2\sigma^2_{A1} + \sigma^2_{A2}$$

Thus, σ_{21} reflects the random error both in $x1$ (with a rescaling) and in $x2$. Often β is close to unity, and in this case σ^2_{21} becomes approximately the sum of the individual squared SDs. This relation holds true for both Deming and OLR analyses. Frequently, OLR is applied in situations associated with random measurement error in both $x1$ and $x2$, and in these situations σ_{21} reflects the errors in both.

The presence of sample-related random interferences in both $x1$ and $x2$ gives the following expression:

$$\sigma^2_{21} = (\beta^2\sigma^2_{A1} + \sigma^2_{A2}) + (\beta^2\sigma^2_{RB1} + \sigma^2_{RB2})$$

Thus, the σ_{21} value is influenced by the slope value and the analytical error components σ_{A1} and σ_{A2} (grouped in the first bracket) and σ_{RB1} and σ_{RB2} (grouped in the second bracket). In many cases, the slope is close to unity, in which case we have simple addition of the components. As mentioned earlier, the sample-related random interferences may not be independent. In this case, simple addition of the components is not correct, because a covariance term should be included. However, in a real case, we can estimate the combined effect corresponding to the bracket term. Information on the analytical components is usually available from duplicate sets of measurements or from quality control data. On this basis, the combined random bias term in the second bracket can be derived by subtracting the analytical components from σ_{21}. Overall, it can be judged whether the total random error is acceptable or not. The systematic difference can be adjusted for relatively easily by rescaling one of the sets of measurements. However, if the random error term is very large, such a rescaling does not ensure equivalency of measurements with regard to individual samples. Thus it is important to assess both the systematic difference and the random error when deciding whether a new routine method can replace an existing one.

Assessment of Outliers

The principle of minimizing the sum of squared distances from the line makes the described regression procedures sensitive to outliers, and an assessment of the occurrence of outliers should be carried out routinely. The distance from a

tahir99-VRG & vip.persianss.ir

suspected outlier to the line is recorded in SD units, and the outlier is rejected if the distance exceeds a predetermined limit (e.g., 3 or 4 SD units). In the case of OLR, the SD unit equals SD_{21}, and the vertical distance is considered. For Deming regression analysis, the unit is the SD of the deviation of the points from the line at an angle determined by the error variance ratio λ. A plot of these deviations, a so-called residuals plot, conveniently illustrates the occurrence of outliers.[68] Figure 2-27, *A*, illustrates an example of Deming regression analysis with occurrence of an outlier and the associated residuals plot *(B)*, which clearly shows the outlier pattern. In this example, the residuals plot was standardized to unit SD. Use of an outlier limit of 4 SD units in this example led to rejection of the outlier, and a reanalysis was undertaken. In this example, rejection of the outlier changed the slope from 1.14 to 1.03. With regard to outliers, these measurements should not be rejected automatically; the reason for their presence should be investigated as a method limitation (e.g., possibly a nonspecificity for the analyte).

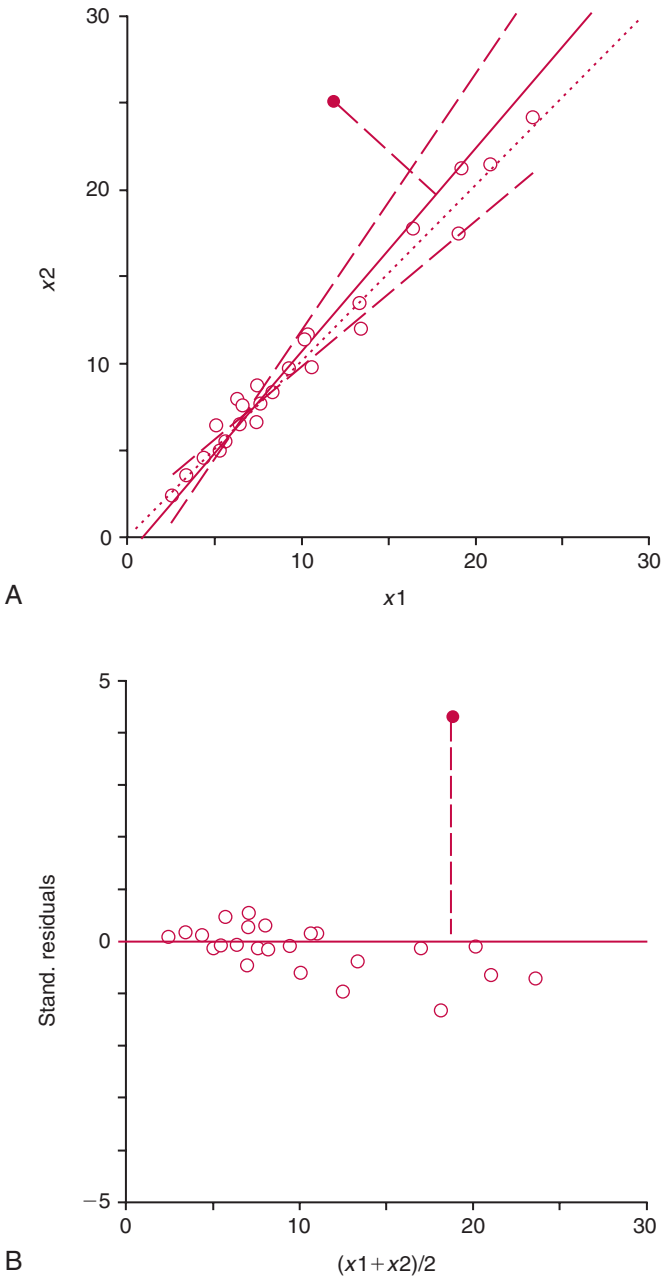

Figure 2-27 **A, A scatter plot with the Deming regression line *(solid line)* with an outlier *(filled point)*. The *dotted straight line* is the diagonal, and the *curved dashed lines* demarcate the 95%-confidence region. B, Standardized residuals plot with indication of the outlier.**

The Correlation Coefficient

Now that the random error components related to regression analysis have been outlined, some comments on the correlation coefficient may be appropriate. The ordinary correlation coefficient, ρ, also called the Pearson product moment correlation coefficient, is estimated as r from sums of squared deviations for $x1$ and $x2$ values as follows:

$$r = p/(uq)^{0.5}$$

where

$$p = \Sigma(x1_i - x1_m)(x2_i - x2_m)$$
$$u = \Sigma(x1_i - x1_m)^2 \, q = \Sigma(x2_i - x2_m)^2$$

and

$$> x1_m = \Sigma x1_i / N \qquad x2_m = \Sigma x2_i / N$$

A look at the theoretical model reveals that ρ is related to the ratio between the SDs of the distributions of target values ($\sigma_{X1'target}$ and $\sigma_{X2'target}$) and the associated independent total random error components (σ_{ex1} and σ_{ex2})[5]:

$$\rho = \sigma_{X1'target}\sigma_{X2'target} / [(\sigma^2_{X1'target} + \sigma^2_{ex1})(\sigma^2_{X2'target} + \sigma^2_{ex2})]^{0.5}$$

The total random error components comprise both imprecision error and sample-related random interferences (i.e., $\sigma^2_{ex1} = \sigma^2_{A1} + \sigma^2_{RB1}$ and $\sigma^2_{ex2} = \sigma^2_{A2} + \sigma^2_{RB2}$). Thus ρ is a *relative* indicator of the amount of dispersion around the regression line. If the numeric interval of values is short, ρ tends to be low and vice versa for a long range of values. For example, consider simulated examples, where the random errors of $x1$ and $x2$ are the same, but the width of the distributions of measured values differs (Figure 2-28, *A* and *B*). In *(A)*, the target values are uniformly distributed over the range 1 to 3, and in *(B)*, the range is 1 to 6. The random error SD is presumed constant, and it is set to 0.15 for both $x1$ and $x2$, corresponding to a CV of 5% at the value 3. Given sets of 50 paired measurements, the correlation coefficient is 0.93 in case *(A)* and 0.99 in case *(B)*. Further, a single point located outside the range of the rest of the observations exerts a strong influence (Figure 2-28, *C*). In *(C)*, 49 of the observations are distributed within the range 1 to 3, with a single point located apart from the others around the value 6, other factors being equal. The correlation coefficient here takes an intermediate value, 0.97. Thus a single point located away from the rest has a strong influence (a so-called influential point). Note that it is not an outlying point, just an aberrant point with regard to the range.

tahir99-VRG & vip.persianss.ir

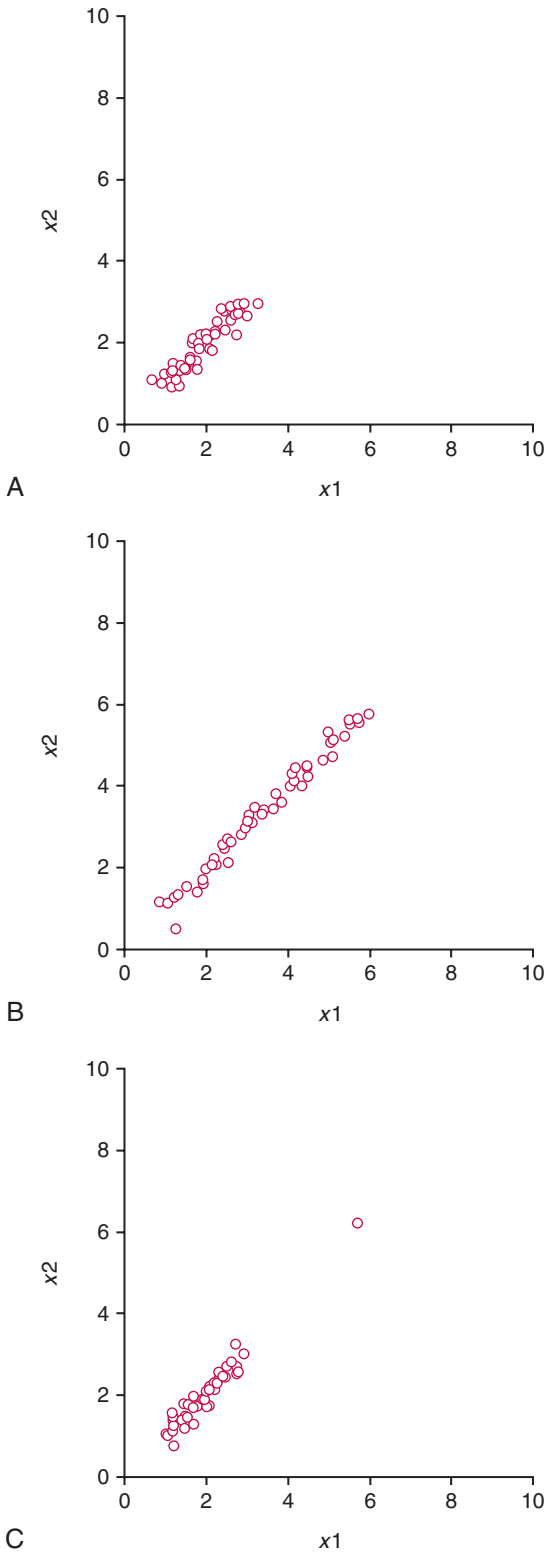

Figure 2-28 **Scatter plots illustrating the effect of the range on the value of the correlation coefficient ρ. A, Target values are uniformly distributed over the range 1 to 3 with random errors of both *x*1 and *x*2 corresponding to a standard deviation (SD) of 5% of the target value at 3 (constant error SDs). B, The range is extended to 1 to 6 with the same random error levels. The correlation coefficient equals 0.93 in A and 0.99 in B. C, The effect of a single aberrant point is shown. Forty-nine of the target values are distributed over the range 1 to 3, with a single point at 6. The correlation coefficient is 0.97.**

tahir99-VRG & vip.persianss.ir

Although σ_{21} is the relevant measure for random error in method comparison studies, ρ is still incorrectly used as a supposed measure of agreement between two methods. It should be noted that a systematic difference due to a difference with regard to calibration is not expressed through ρ but solely in the form of an intercept (α_0) deviation from zero and/or a slope (β) deviation from unity. Thus even though the correlation coefficient is very high, a considerable calibration bias may be noted between the measurements of two methods.

Regression Analysis in Cases of Proportional Random Error

As discussed in relation to the precision profile, for analytes with extended ranges (e.g., 1 or several decades), the SD_A is seldom constant. Rather, a proportional relationship may apply. This may also be true for the random bias components. In this situation, the regression procedures described previously may still be used, but they are not optimal because the standard errors of slope and intercept become larger than is the case when a weighted form of regression analysis is applied. The optimal approaches are weighted forms of regression analysis that take into account the relationship between random error and analyte concentration.[68,70] Given a proportional relationship, a weighted procedure assigns larger weights to observations in the low range; low-range observations are more precise than measurements at higher concentrations that are subject to larger random errors. More specifically, weights are applied in the computations that are inversely proportional to the squared SDs (variances) that express the random error. In the weighted modification of the Deming procedure, distances from ($x1_i$, $x2_i$) to the line are inversely weighted according to the squared SDs at a given concentration (Figure 2-29). The regression procedures are most conveniently performed using dedicated software.

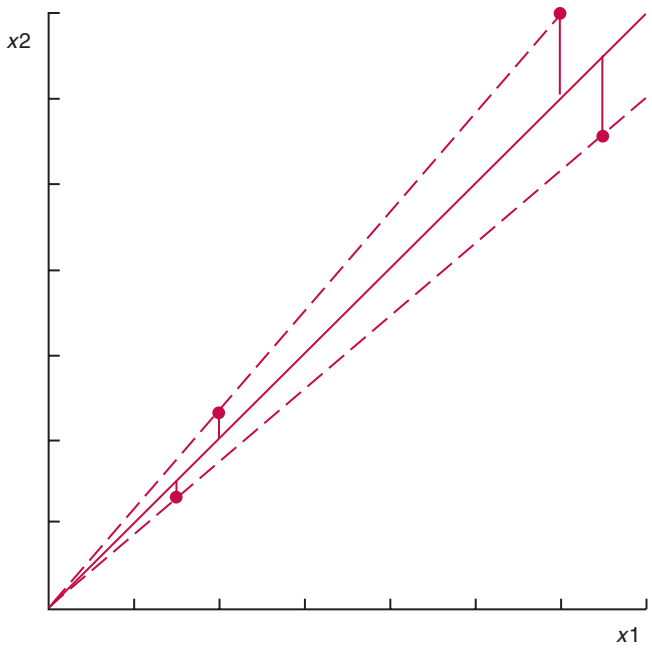

Figure 2-29 Distances from data points to the line in weighted Deming regression assuming proportional random errors in *x*1 and *x*2. The symmetric case is illustrated with equal random errors and a slope of unity yielding orthogonal projections onto the line. *(From Linnet K. Necessary sample size for method comparison studies based on regression analysis. Clin Chem 1999;45:882-94.)*

Testing for Linearity

Splitting of the systematic error into a constant and a proportional component depends on the assumption of linearity, which should be tested. A convenient test is a runs test, which in principle assesses whether negative and positive deviations from the points to the line are randomly distributed over the analytical measurement range. The term *run* here relates to a sequence of deviations with the same sign. Consider for example the situation with a downward trend of *x*2 values at the upper end of the analytical measurement range (Figure 2-30, *A*). The SDs from the line (i.e., the residuals) will tend to be negative in this area instead of being randomly distributed above and below the line[28] (Figure 2-30, *B*). Given a sufficient number of points, such a sequence will turn out to be statistically significant in a runs test.

Nonparametric Regression Analysis (Passing-Bablok)

The slope and the intercept may be estimated by a nonparametric procedure, which is robust to outliers and requires no assumptions of Gaussian error distributions.[81,82] Note, however, that the parametric regression procedures do not presume Gaussian distributions of *x*1 and *x*2 values over the measurement range, but only of the *error* distributions. Thus the main advantage of the nonparametric procedure is its robust performance in the presence of outliers. The method takes measurement errors for both *x*1 and *x*2 into account, but it presumes that the ratio between random errors is related to the slope in a fixed manner:

$$\lambda = (SD_{RB1}^2 + SD_{A1}^2)/(SD_{RB2}^2 + SD_{A2}^2) = 1/\beta^2$$

Otherwise, a biased slope estimate is obtained.[70,82] The procedure may be applied both in situations with random errors with constant SDs and in cases with proportional SDs. The method is not as efficient as the corresponding parametric procedures (i.e., Deming and weighted Deming procedures).[70] Slope and intercept with CIs are provided, together with Spearman's rank correlation coefficient. A software program is required for the procedure.

Interpretation of Systematic Differences Between Methods Obtained on the Basis of Regression Analysis

A systematic difference between two methods is identified if the estimated intercept differs significantly from zero, or if the slope deviates significantly from 1. This is decided on the basis of *t*-tests:

$$t = (a_0 - 0)/SE(a_0)$$
$$t = (b - 1)/SE(b)$$

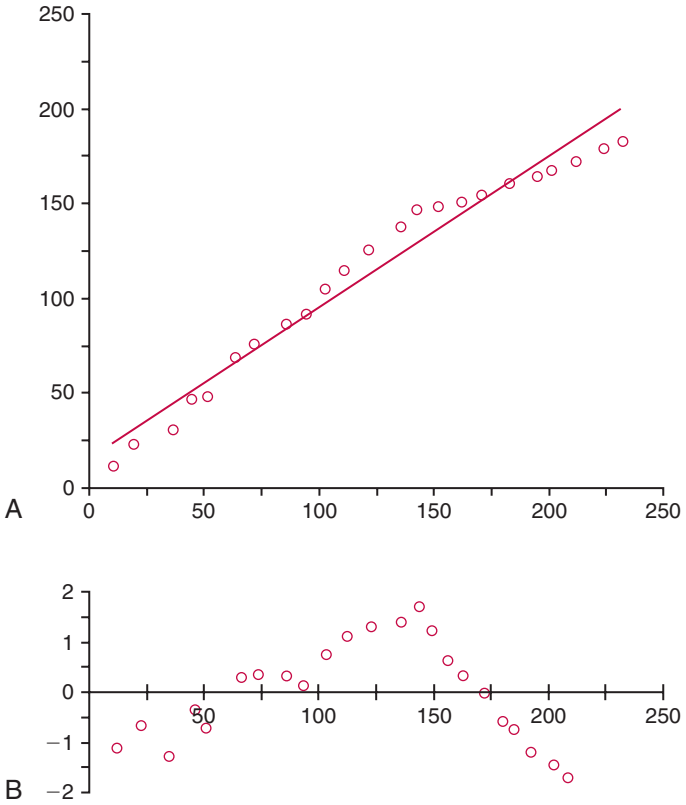

Figure 2-30 ***A,*** **Scatter plot showing an example of nonlinearity in the form of downward deviating *x*2 values at the upper part of the range.** ***B,*** **Plot of residuals showing the effects of nonlinearity. At the upper end of the analytical measurement range, a sequence (run) of negative residuals is present.**

SE(a_0) and SE(b) are the standard errors of the estimated intercept a_0 and the slope b, respectively. Standard errors can be derived by a computerized resampling principle called *the jackknife procedure,* which in practice can be carried out using appropriate software[73] (see section on software). Having estimated a_0 and b, we have the estimate of the systematic difference between the methods, D_c, at a selected concentration, $X1'_{\text{Targetc}}$:

$$D_c = X2'_{\text{Targetestc}} - X1'_{\text{Targetc}} = a_0 + (b-1)X1'_{\text{Targetc}}$$

$X2'_{\text{Targetestc}}$ is the estimated $X2'$ target value at $X1'_c$. Note that D_c refers to the *systematic* difference (i.e., the difference between modified target values corresponding to a calibration difference). The standard error of D_c can be derived by the jackknife procedure using a software program. By evaluating the standard error throughout the analytical measurement range, a confidence region for the estimated line can be displayed. If method comparison is performed to assess the calibration to a reference measurement procedure, correction of a significant systematic difference $Delta_c$ will often be performed by recalibration [$x2_{rec} = (x1 - a_0)/b$]. The associated standard uncertainty is the standard error of $Delta_c$. Even though the intercept and the slope are not significantly different from zero and 1, respectively, the combined expression $Delta_c$ may be significantly different from zero.

Example of Application of Regression Analysis (Weighted Deming Analysis)

Application of weighted Deming regression analysis may be illustrated by the comparison of drug assays example [$N = 65$ ($x1$, $x2$) single measurements]. As outlined in the section on the Bland-Altman plot (see Figure 2-14), in this example the random error of the differences increases with the concentration, suggesting that the weighted form of Deming regression analysis is appropriate. Figure 2-31 shows *(A)* the estimated regression line with 95%-confidence bands and *(B)* a plot of normalized residuals. The nearly homogeneous scatter in the residuals plot supports the assumed proportional random error model and the assumption of linearity. The slope estimate (1.014) is not significantly different from 1 (95%-CI: 0.97 to 1.06), and the intercept is not significantly different from zero (95%-CI: −6.7 to 47.4) (Table 2-11). A runs test for linearity does not contradict the assumption of linearity. The amount of random error is quantified in the form of the SD_{21} proportionality factor equal to 0.11, or 11%. In the present example, with a slope close to unity and two routine methods with assumed random errors of about the same magnitude, we divide the random error by the square root of 2 and get $CV_{x1} = CV_{x2} = 7.8\%$. Quality control data in the laboratory have provided CV_As of 6.1% and 7.2% for methods 1 and 2, respectively. Thus in this example, the random error may be

tahir99-VRG & vip.persianss.ir

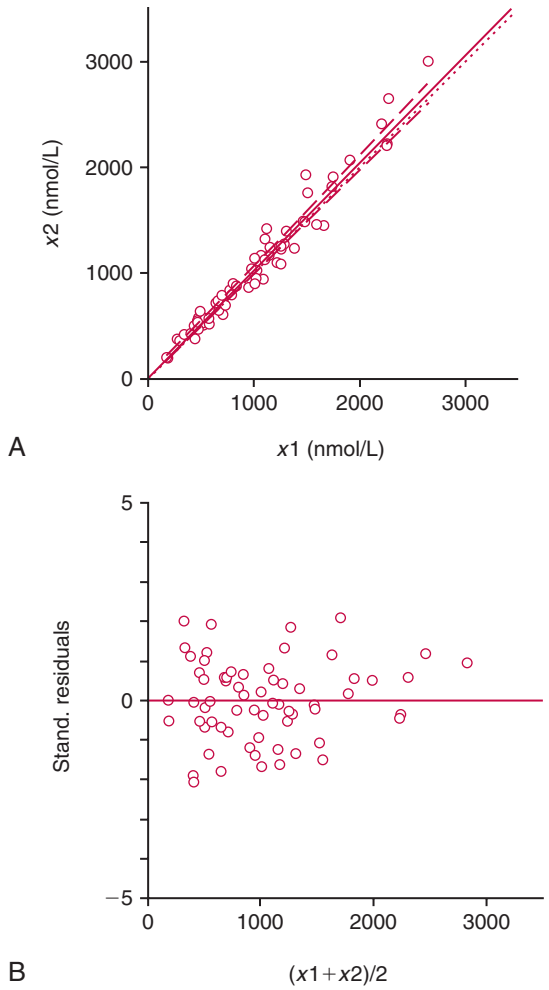

Figure 2-31 An example of weighted Deming regression analysis for the comparison of drug assays. A, The *solid line* is the estimated weighted Deming regression line, the *dashed curves* indicate the 95%-confidence region, and the *dotted line* is the line of identity. B, A plot of residuals standardized to unit standard deviation (SD). The homogeneous scatter supports the assumed proportional error model and the assumption of linearity.

attributed largely to analytical error. The assay principle for both methods is HPLC, which generally is a rather specific measurement principle; considerable random bias effects are not expected in this case.

In the table, estimated systematic differences at the limits of the therapeutic interval (300 and 2000 nmol/L) are displayed (24.6 and 48.9 nmol/L, respectively). This corresponds to percentage values of 8.2% and 2.4%, respectively. Estimated standard errors by the jackknife procedure yield the 95%-CIs as shown in the table. At the low concentration, the difference is significant (95%-CI: 5.7 to 44 nmol/L, does not include zero), which is not the case at the high level (95%-CI: −19 to 117 nmol/L). Even though the intercept and slope estimates separately are not significantly different from the null hypothesis values of zero and 1, respectively, the combined difference $Delta_c$ is significant at low concentrations in this example. If the difference is considered of medical importance and both methods are to be used simultaneously in the laboratory, recalibration of one of the methods might be considered.

TABLE 2-11 Results of Weighted Deming Regression Analysis for the Comparison of Drug Assays Example, N = 65 Single ($x1$, $x2$) Measurements

	Estimate	SE	95%-CI
Slope *(b)*	1.014	0.022	0.97 to 1.06
Intercept (a_0)	20.3	13.5	−6.7 to 47.4
Weighted correlation coefficient	0.98		
SD_{21} proportionality factor	0.11		
Runs test for linearity	ns		
$Delta_c = X_2 - X_1$ at $X_c = 300$	24.6	9.5	5.72 to 43.6
$Delta_c = X_2 - X_1$ at $X_c = 2000$	48.9	34.2	−19.3 to 117

CI, Confidence interval; *ns,* not significant; *SD,* standard deviation; *SE,* standard error.

Discussion of Application of Regression Analysis

Generally, it is recommended that Deming or weighted Deming regression analysis should be used to operate with a type of regression analysis that is based on a correct error model. Most published method evaluations are based on unweighted regression analysis; here the use of unweighted analysis is considered in the setting of proportional random errors.

Basically, the Deming procedure provides unbiased estimates of slope and intercept when the SDs vary, provided that their ratio is constant throughout the analytical measurement range. This aspect is important and means that generally the estimates of slope and intercept are reliable in this frequently encountered situation. However, application of the unweighted Deming analysis in cases of proportional SD_As is less efficient than applying the weighted approach. For uniform distributions of values with range ratios from 2 to 100, 1.2 to 3.7 times as many samples are necessary to obtain the same uncertainty of the slope estimated by the unweighted compared with the weighted approach.[73] Thus the larger the range ratio, the more inefficient is the unweighted method.

MONITORING SERIAL RESULTS

An important aspect of clinical chemistry is monitoring of disease or treatment (e.g., tumor markers in cases of cancer, drug concentrations in cases of therapeutic drug monitoring). To assess changes in a rational way, various imprecision components have to be taken into account. Biological within-subject variation ($SD_{within\text{-}B}$) and preanalytical (SD_{PA}) and

tahir99-VRG & vip.persianss.ir

analytical variation (SD_A) all have to be recognized. We assume in the following discussion that preanalytical variation is already included in the estimated within-subject variation SD, which often is the case. On this basis, using the principle of adding squared SDs (variances), a total SD (SD_T) can be estimated as follows:

$$SD_T^2 = SD_{Within\ B}^2 + SD_A^2$$

The limit for statistically significant changes then is $k\sqrt{2}\ SD_T$, where k depends on the desired probability level. Considering a two-sided 5% level, k is 1.96. The corresponding one-sided factor is 1.65. If a higher probability level is desired, k should be increased.

Limits for statistically significant changes ($Delta_{stat}$) may be related to changes that are considered of medical importance by clinicians [i.e., action limits ($Delta_{med}$)].[97] Here we will consider a one-sided situation in which an increase is of importance and a 5% significance level is selected (i.e., $Delta_{stat} = 1.65\sqrt{2}\ SD_T = 1.65\ SD_{delta}$). Suppose as a starting point that the true change ($Delta_{true}$) for a patient is zero (Figure 2-32, *A*). If $Delta_{stat}$ is less than $Delta_{med}$, the frequency of false-positive alarms will be less than 5%. If, on the other hand, $Delta_{stat}$ exceeds $Delta_{med}$, the frequency of false-positive alarms will exceed 5% (i.e., medical action will be taken too frequently). Figure 2-32, *A,* illustrates the situation with $Delta_{stat}$ equal to $Delta_{med}$. We now consider the situation with a true change equal to the medically important change (i.e., $Delta_{true} = Delta_{med}$) (Figure 2-32, *B*), where exactly 50% of observed changes exceed the medically important limit. If $Delta_{stat}$ is less than or equal to $Delta_{med}$, less than 5% of patients will exhibit an observed delta value in the opposite direction of the true change (an obviously misleading trend). If the condition is not met, more than 5% will have a misleading change. Finally, in the case where the true change equals the sum of $Delta_{med}$ and $Delta_{stat}$ (Figure 2-32, *C*), more than 95% of observed changes exceed the medically important change, and appropriate action will be taken for most patients.

The outline presented previously illustrates that in the monitoring situation, not only the requirement for statistical significance (i.e., the type I error problem concerning false alarms), but also the type II error problem or the risk of overlooking changes, should be addressed; the latter is an aspect that often is overlooked.[67] Provided that $Delta_{stat}$ is small relative to $Delta_{med}$, both type I and type II errors can be kept small. On the other hand, if $Delta_{stat}$ equals or exceeds $Delta_{med}$, the relative importance of type I and type II errors may be weighed against each other. If the consequences of overlooking a medically important change are serious, one should keep the type II error small and accept a relatively large type I error (i.e., accept the occurrence of false alarms). On the contrary, if overlooking changes only gives rise to minor or transient problems, the priority may be to keep the type I error small. In addition to simple evaluation of a shift between two measurements, as considered here, sequential results may be analyzed using more refined time-series models.[40]

TRACEABILITY AND MEASUREMENT UNCERTAINTY

As outlined previously in the error model sections, laboratory results are likely to be influenced by systematic and random errors of various types. Obtaining agreement of measurements between laboratories or agreement over time in a given laboratory often can be problematic.

Traceability

To ensure reasonable agreement between measurements of routine methods, the concept of traceability comes into focus (See Chapter 8). *Traceability* is based on an unbroken chain of comparisons of measurements leading to a known reference value (Figure 2-33). A hierarchical approach for tracing the values of routine clinical chemistry measurements to reference measurement procedures was proposed by Tietz[105] and has been adapted by the ISO. For well-established analytes, a hierarchy of methods exists with *a reference measurement procedure* at the top, *selected measurement procedures* at an intermediate level, and finally *routine measurement procedures* at the bottom.[8,50,105] A reference measurement procedure is a fully understood procedure of highest analytical quality containing with a complete uncertainty budget given in SI units.[29,46] Reference procedures are used to measure the analyte concentration in *secondary reference materials,* which typically have the same matrix as samples that are to be measured by routine procedures (e.g., human serum). Secondary reference materials are usually of high analytical quality, and certified secondary reference materials must be validated for commutability with clinical samples if they are intended for use as trueness controls for routine methods.[110,111] Otherwise, their use is restricted to those selected measurement procedures for which they are intended. The certificate of analysis should state the methods for which the secondary reference materials have been validated to be commutable with clinical samples. When no information is given for commutability, it must be assumed that the reference material is not commutable with clinical samples, and the user has the responsibility to validate commutability for the methods of interest.[16] Uncertainty of the measurement procedure results in increases from the top level to the bottom. ISO guidelines (15193 and 15194) address requirements for reference methods and reference materials.[46,47]

Using cortisol as an example, the primary reference material is crystalline cortisol with a chemical analysis for impurities [NIST SRM 921, cortisol (hydrocortisone)]. A primary calibrator is then a cortisol preparation with a stated mass fraction (purity) (e.g., 0.998 and a 95% CI of ±0.001). The reference measurement procedure is an isotope-dilution gas chromatography–mass spectrometry method that is calibrated with the primary calibrator. A panel of individual frozen serum samples that have values assigned by the primary reference measurement procedure is available from the Institute for Reference Materials and Measurements (IRMM) as secondary reference materials (ERM-DA451/IFCC).[42] A manufacturer's *selected measurement* procedure is

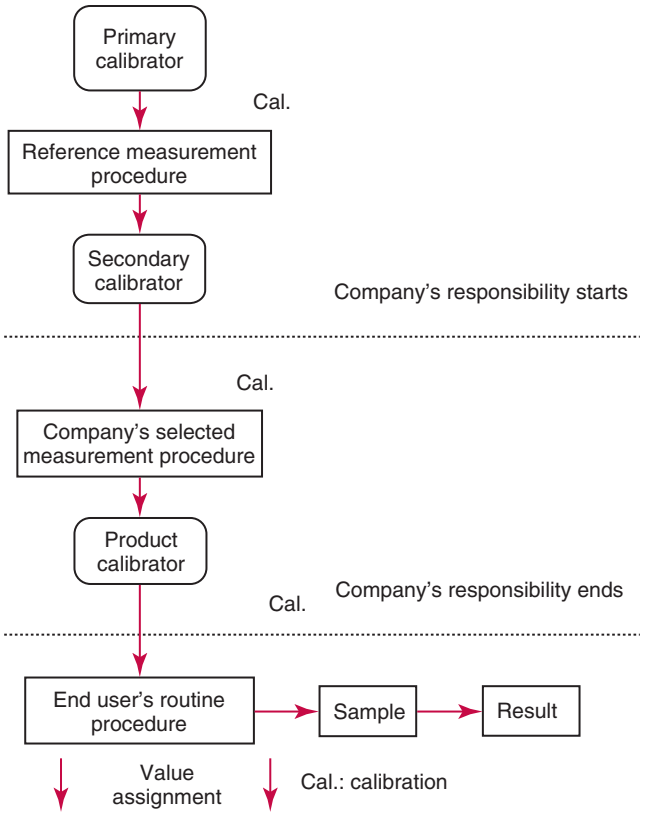

Figure 2-33 The calibration hierarchy from a reference measurement procedure to a routine method. The uncertainty increases from top to bottom.

calibrated with the secondary reference materials and is used for measurement of the quantity in the manufacturer's *product calibrator,* which is the calibrator used for the routine method in clinical laboratories.

Only 25 to 30 of clinical chemistry analytes currently are traceable to SI units, such as electrolytes, some metabolites (glucose, creatinine, and uric acid), steroids, and some thyroid hormones).[104] For plasma proteins, a human reference serum material is available with certified mass concentrations of 12 serum proteins (ERM-DA470k/IFCC) from IRMM. With protein hormones, the existence of heterogeneity or microheterogeneity complicates the problem of traceability.[101,104]

The Uncertainty Concept

To assess in a systematic way, errors associated with laboratory results, the *uncertainty* concept has been introduced into laboratory medicine.[31,45] According to the ISO "Guide to the Expression of Uncertainty in Measurement" (GUM), *uncertainty* is formally defined as "a parameter associated with the result of a measurement that characterizes the dispersion of the values that could reasonably be attributed to the measurand."[45] In practice, this means that the uncertainty is given as an interval around a reported laboratory result that specifies the location of the true value with a given probability (e.g., 95%). In general, the uncertainty of a result, which is traceable to a particular reference, is the uncertainty of that reference together with the overall uncertainty of the traceability chain.[31] Updated information on traceability aspects is available on the website of the Joint Committee on Traceability in Laboratory Medicine (www.bipm.org/en/committees/jc/jctlm/; accessed March 08 2011).

The Standard Uncertainty (u_{st})

The uncertainty concept is directed toward the end user (clinician) of the result, who is concerned about the total error possible, and who is not particularly interested in the question of whether the errors are systematic or random. In the outline of the uncertainty concept, it is assumed that any known systematic error components of a measurement method have been corrected, and the specified uncertainty includes uncertainty associated with correction of the systematic error(s).[45] Although this appears logical, one problem may be that some routine methods have systematic errors dependent on the patient category from which the sample originates. For example, kinetic Jaffe methods for creatinine are subject to positive interference by 2-OXO compounds and to negative interference by bilirubin and its metabolites, which means that the direction of systematic error will be patient dependent and not generally predictable.

In the theory on uncertainty, a distinction between type A and B uncertainties is made. Type A uncertainties are frequency-based estimates of SDs (e.g., an SD of the imprecision). Type B uncertainties are uncertainty components for which frequency-based SDs are not available. Instead, uncertainty is estimated by other approaches or by the opinion of experts. Finally, the total uncertainty is derived from a combination of all sources of uncertainty. In this context, it is practical to operate with *standard uncertainties* (u_{st}), which are equivalent to SDs. By multiplication of a standard uncertainty with a *coverage factor (k),* the uncertainty corresponding to a specified probability level is derived. For example, multiplication with a coverage factor of 2 yields a probability level of ≈95%, given a Gaussian distribution. When the total uncertainty of an analytical result obtained by a routine method is considered, preanalytical variation, method imprecision, sample-related random interferences, and uncertainty related to calibration and bias corrections (traceability) should be taken into account. In expressing the uncertainty components as standard uncertainties, we have the following general relation:

$$u_{st} = [u^2_{PAst} + u^2_{Ast} + u^2_{RBst} + u^2_{Tracst}]$$

where the individual components refer to preanalytical, analytical, sample-related random bias and traceability uncertainty.

Uncertainty can be assessed in various ways; often a combination of procedures is necessary. In principle, uncertainty can be judged *directly* from measurement comparisons or *indirectly* from an analysis of individual error sources according to the law of error propagation ("error budget"). Measurement comparison may consist of a method comparison study with a reference method based on patient samples according to the principles outlined previously or

tahir99-VRG & vip.persianss.ir

by measurement of commutable certified matrix reference materials (CRMs).

Example of Direct Assessment of Uncertainty on the Basis of Measurements of a Commutable Certified Reference Material

Suppose a CRM is available that was validated to be *commutable* with patient samples for a given routine method with a specified value 10.0 mmol/L and a standard uncertainty of 0.2 mmol/L. Ten repeated measurements in independent runs give a mean value of 10.3 mmol/L with SD 0.5 mmol/L. The standard error of the mean is then $0.5/\sqrt{10} = 0.16$ mmol/L. The mean is not significantly different from the assigned value [$t = (10.3 - 10.0)/(0.2^2 + 0.16^2)^{0.5} = 1.17$]. The total standard uncertainty with regard to traceability is then $u_{\text{Trac st}} = (0.16^2 + 0.2^2)^{0.5} = 0.26$ mmol/L. If the bias had been significant, one might have considered making a correction to the method, and the standard uncertainty would then be the same at the given concentration. Thus measurements of the CRM provide an estimate of the uncertainty related to traceability, *given the assumption of commutability with patient samples*. The other components have to be estimated separately. Concerning method imprecision, long-term imprecision (e.g., observed from quality control measurements) should be used rather than the short-term SD observed for CRM material. Here we suppose that the long-term SD_A is 0.8 mmol/L. Data on preanalytical variation can be obtained by sampling in duplicates from a series of patients or can be a matter of judgment (type B uncertainty) based on literature data or data on similar analytes. We here suppose that SD_{PA} equals half the analytical SD (i.e., 0.4 mmol/L). Finally, we lack data on a possible sample-related random bias component, which we may choose to ignore in the present example. The standard uncertainty of the results then becomes

$$\begin{aligned} u_{st} &= [u_{PAst}^2 + u_{Ast}^2 + u_{RBst}^2 + u_{Tracst}^2]^{0.5} \\ &= (0.4^2 + 0.8^2 + 0.26^2)^{0.5} \\ &= 0.93\,(\text{mmol/L}) \end{aligned}$$

In this case, the major uncertainty component is the long-term imprecision in the laboratory.

Example of Direct Assessment of Uncertainty on the Basis of a Method Comparison Study With a Reference Measurement Procedure Using Patient Samples

Suppose a set of patient samples have been measured by a routine method ($X2$) in parallel with a reference measurement procedure ($X1$), and that a linear relationship exists between measurements. We want to assess a possible calibration bias and evaluate the standard uncertainty of results of the routine method on the basis of regression analysis results and information on standard uncertainty related to the traceability of reference method results. The imprecision of the reference method is 2.5% or, as a fraction (used in the following), 0.025 (= CV_{A1}), and the component related to the uncertainty of the traceability chain for the reference method is 0.020 (= $u_{\text{trac st}}$). Proportional measurement errors are assumed for both methods, and a weighted form of Deming regression analysis is applied. The error variance ratio λ is not known exactly, but the reference method is devoid of sample-related random bias, so it is assumed that the random error is about half that of the routine method (i.e., λ is set to $1/2^2 = 1/4$). At a decision point ($X1'_{\text{Targetc}}$) (e.g., corresponding to the upper limit of the 95% reference interval), the systematic difference between methods [$D_c = a_0 + (b-1)\,X1'_{\text{Targetc}}$] is estimated with standard error (see section on regression):

$$D_c = X2'_{\text{Targetc}} - X1'_{\text{Targetc}} = 20\ \text{mg/L with SE}(D_c) = 1.0\ \text{mg/L}$$

corresponding to a relative SE(D_c) of 0.050 [= (1.0 mg/L)/(20 mg/L)]. For the Deming procedures, the standard error can be conveniently computed by the jackknife procedure. We observe that the difference is highly significant and decide to recalibrate the routine method in relation to the reference method using the estimated slope and intercept [i.e., the recalibrated $x2$ values equals $(x2 - a_0)/b$]. Having done this, the routine method is assumed to have no systematic error in relation to the reference method, but when the uncertainty of the results is considered, we have to add the standard uncertainty of the bias correction. The uncertainty related to traceability for the routine method is now obtained as the uncertainty inherent to the reference method and the comparison step, that is,

$$u_{\text{Tracst}} = (0.020^2 + 0.050^2)^{0.5} = 0.054$$

We are now further interested in deriving estimates of random error components for the routine method from regression analysis results. Both analytical error [e.g., estimated from quality control (QC) data] and sample-related random bias should be assessed, and it should be recognized that the observed total random error is the result of contributions from both measurement methods. Suppose that CV_{21} of the regression analysis has been calculated to be 0.10 (CV_{21} is analogous to SD_{21} or SD_{yx}), given constant measurement errors over the analytical measurement range (i.e., an expression for the random error in the vertical direction in the *x-y* plot). From the regression section, we have

$$CV_{21}^2 = [CV_{A1}^2 + CV_{A2}^2] + [CV_{RB1}^2 + CV_{RB2}^2]$$

By substituting $CV_{A1} = 0.025$, $CV_{RB1} = 0$, and $CV_{21} = 0.10$, we derive

$$CV_{A1}^2 + CV_{A2}^2 = 0.009375$$

and get

$$CV_{A2}^2 + CV_{RB2}^2 = 0.009372\,[CV_{A2}^2 + CV_{RB2}^2]^{0.5} = 0.0968$$

Thus the total random error of the routine method corresponds to a CV of 0.097. If we had measured samples in duplicate in the method comparison experiment or had available QC data, we could split the total random error into its components. CV_{A2} was here determined to be 0.035 from QC data, which gives 0.090 corresponding to CV_{RB2}. We may here note that the assumed error ratio λ of $(½)^2$ is not quite correct. According to our results, λ should be (0.025/0.0968).[2]

Although the Deming regression principle is rather robust toward misspecified λ values, we could choose to carry out a reanalysis with the more correct λ value—a process that could be iterated. Finally, assuming a value of 0.03 for the preanalytical coefficient of variation, we derive a total standard uncertainty estimate of

$$u_{st} = [u_{PAst}^2 + u_{Ast}^2 + u_{RBst}^2 + u_{Tracst}^2]^{0.5}$$
$$(0.03^2 + 0.0968^2 + 0.054^2)^{0.5} = 0.115$$

At the given decision level of 20 mg/L and with a coverage factor of 2, we obtain the 95% uncertainty interval of a single routine measurement as

$$20\ \text{mg/L} \pm (2 \times 0.115 \times 20)\ \text{mg/L} = 15.4 - 24.6\ \text{mg/L}$$

Having estimated the uncertainty as outlined, additional uncertainty sources should be considered. If the comparison was undertaken within a short time period, one might consider adding an additional long-term imprecision component as a variance component to the standard uncertainty expression.

When the two approaches briefly outlined are compared, the latter is the more informative. Using a series of patient samples instead of a pooled sample, individual random bias components are included in the uncertainty estimation, assuming that the patient samples are representative. Also, natural patient samples are preferable to a stabilized pool that perhaps is distributed in freeze-dried form, which may introduce artifactual errors into some analytical systems. Using a commutable CRM, on the other hand, is more practical and in many situations is the only realistic alternative.

With regard to uncertainty estimation from a comparison study of patient samples as outlined previously, one should be careful concerning the uncertainty estimation. First, it is important to estimate correctly the standard error of the difference at selected decision points or at points covering the analytical measurement range (i.e., at the lower limit, in the middle part, and at the upper limit). From the expression of the estimated difference $[D_c = a_0 + (b-1)\,X1'_{\text{Targetc}}]$, one might at a first glance estimate the standard error (standard uncertainty) by adding (squared) the standard errors of the intercept and the slope. However, simple squared addition of standard errors is correct only when the independence of estimates is given (see later). Estimates of intercept and slope in regression analysis are negatively correlated, which implies that simple squared addition of standard errors leads to an overestimation of the total standard uncertainty.[24] Rather, a direct estimation procedure for the standard error should be applied, as mentioned earlier.

A method comparison study based on genuine patient samples represents as mentioned a real assessment of traceability. In Figure 2-33, the focus is on the calibration aspect intended to *mediate* traceability. One should recognize that the matrix of product calibrators for practical reasons often is artificial (e.g., the matrix of a calibrator may be bovine albumin instead of human serum). Many routine methods are matrix sensitive, which implies that calibrators and patient samples are not commutable. To ensure traceability in this situation, the assigned concentration of a calibrator has to be different from the real concentration.

Indirect Evaluation of Uncertainty by Quantification of Individual Error Source Components

On the basis of a detailed quantitative model of the analytical procedure, the standard approach is to assess the standard uncertainties associated with individual input parameters and combine them according to the law of propagation of uncertainties.[31] The relationship between the combined standard uncertainty $u_c(y)$ of a value y and the uncertainty of the *independent* parameters x_1, x_2, … x_n, on which it depends, is

$$u_c[y(x_1, x_2, \ldots)] = [\Sigma c_I^2 u(x_1)^2]^{0.5}$$

where c_i is a sensitivity coefficient (the partial differential of y with respect to x_i). These sensitivity coefficients indicate how the value of y varies with changes in the input parameter x_i. If the variables are not independent, the relationship becomes

$$u_c[y(x_1, x_2, \ldots)] = [\Sigma c_I^2 u(x_1)^2 + \Sigma c_i c_k u(x_i, x_k)^2]^{0.5}$$

where $u(x_i, x_k)$ is the covariance between x_i and x_k, and c_i and c_k are the sensitivity coefficients. The covariance is related to the correlation coefficient ρ_{ik} by

$$u(x_i, x_k) = u(x_i)u(x_k)\rho_{ik}$$

This is a complex relationship that usually will be difficult to evaluate in practice. In many situations, however, the contributing factors are independent, thus simplifying the picture. Below, some simple examples of combined expressions are shown. The rules are presented in the form of combining SDs or CVs given *independent* input components.

$q = x + y$	$\text{SD}(q) = [SD(x)^2 + SD(y)^2]^{0.5}$
$q = x - y$	$\text{SD}(q) = [\text{SD}(x)^2 + \text{SD}(y)^2]^{0.5}$
$q = ax$	$\text{SD}(q) = a\text{SD}(x)$ and $\text{CV}(q) = \text{CV}(x)$
$q = x^p$	$\text{CV}(q) = p^{0.5}\text{CV}(x)$
$q = xy$	$\text{CV}(q) = [\text{CV}(x)^2 + \text{CV}(y)^2]^{0.5}$
$q = x/y$	$\text{CV}(q) = [\text{CV}(x)^2 + \text{CV}(y)^2]^{0.5}$

The formulas shown may be used (e.g., to calculate the combined uncertainty of a calibrator solution from the uncertainties of the reference compound, the weighting, and dilution steps) (see later).

Some relations between the SD and non-Gaussian distributions may also be of relevance for uncertainty calculations (type B uncertainties) (Table 2-12). For example, if the uncertainty of a CRM value is given with some percentage, it may be understood as referring to a rectangular probability distribution. In relation to calibration of flasks, the triangular distribution is often assumed.

Example

Briefly, computation of the standard uncertainty of a calibrator solution will be outlined. The concentration C equals the mass M divided by the volume V($C = M/V$). We will here express the standard uncertainties as relative values and will

TABLE 2-12 Relations Between Standard Deviation and Range for Various Types of Distributions

Normal Distribution	Rectangular Distribution	Triangular Distribution
SD = Half width of 95%-interval/$t_{0.975}(\nu)$ ≈ Half width of 95%-interval/2	SD = Half width/√3	SD = Half width/√6

derive the approximate total standard uncertainty by squared addition of the individual contributions. Starting with the mass, the purity is stated on the certificate as 99.4 ± 0.4%. Assuming a rectangular distribution, the relative SD becomes 0.004/√3 = 0.0023. The uncertainty of the weighing process is known in the laboratory to have a CV of 0.1%, or 0.0010. Thus the relative standard uncertainty of the mass becomes

$$u_{\mathrm{M\,st}} = (0.0023^2 + 0.0010^2)^{0.5} = 0.0025$$

The certificate of the flask (50 mL at 20 °C) indicates ±0.1 mL as uncertainty. Assuming here a triangular distribution, we derive the standard uncertainty as 0.10 mL/√6 = 0.0408 mL, which is converted to a relative value of 0.000816. The temperature expansion coefficient is given as 0.020 mL per degree change of temperature. Assuming a variability of 20 ± 4 °C, this contribution amounts to ±0.080 mL. Assuming here a rectangular distribution, we get an SD of 0.080/√3 mL, or 0.00092 as a relative SD. The repeatability of the volume dispensing process in the laboratory has been assessed to 0.020 mL expressed as an SD, which corresponds to a relative value of 0.00040. The total standard uncertainty of the volume dispensing process becomes

$$u_{\mathrm{V\,st}} = (0.000816^2 + 0.00092^2 + 0.00040^2)^{0.5} = 0.0013$$

The total standard uncertainty of the calibrator solution is

$$\begin{aligned} u_{Cal\,st} &= (u_{M\,st}^2 + u_{v\,st}^2)^{0.5} \\ &= (0.0025^2 + 0.0013^2)^{0.5} \\ &= 0.0028, \text{ or } 0.28\% \end{aligned}$$

Generally, when squared CVs are added, minor contributions in practice can be ignored (e.g., CVs less than a third or a quarter of the other components).[31]

The indirect procedure is mainly of relevance for relatively simple procedures. In some situations, a simulation model of a complex analytical method may be established to estimate the combined uncertainty of the method on the basis of input uncertainties.[1] For closed, automated clinical chemistry procedures, it often will not be possible to discern the individual error elements. Further, the correlation aspect is difficult to take into account in practice. In these cases, the direct procedure of measurement comparison is preferable. However, the indirect procedure has been applied in clinical chemistry.[41,63]

Uncertainty in Relation to Traditional Systematic and Random Error Classifications

As mentioned previously, systematic errors are not included in the uncertainty expression, because it is assumed that they have been corrected. Therefore, it is the uncertainty of the correction procedure that should be taken into account. Otherwise, systematic errors have been added linearly or squared in error propagation models.[86,102] One may further consider that the distinction between systematic effects and random effects may be a matter of the reference frame. For example, a systematic error over time may turn into a random error, because a bias may change over time. Lot-to-lot reagent effects may be interpreted as systematic or random errors. When a laboratory changes from an old to a new lot, a shift in measurement values may occur. Initially this will be considered a systematic change. However, over a long time period involving several lots of reagents, the recorded shifts typically will be up and down and will be regarded as a long-term random error component. Additionally, a bias in a particular laboratory may be viewed as a random error component when dealing with a whole group of laboratories, because individual laboratory biases appear randomly distributed and are quantified as the interlaboratory SD. Thus there are arguments for using the uncertainty concept as outlined earlier to end up with one overall uncertainty expression directed toward the end user of the laboratory result. Still, as mentioned previously, systematic errors linked to samples from specific patient subcategories may constitute a problem because a general correction is not possible. A way to quantify this error contribution is to include samples from all patient subgroups in a balanced way in a method comparison study, so that this error type is incorporated into the uncertainty component related to traceability. Another problem with systematic errors is that they often depend on the analyte concentration. Thus if a commutable CRM is measured at a particular concentration, one should consider whether a bias correction is valid only at the given concentration or generally over the analytical measurement range. Further, the occurrence of outliers caused by rarely occurring interference (e.g., heterophilic antibodies in relation to immunoassays) constitutes a problem.[61] If the uncertainty estimation is based on parametric statistics (standard uncertainty expanded by a coverage factor), inclusion of gross outliers may increase the standard uncertainty considerably and make the uncertainty specification useless. A solution might here be to omit the outliers in the first hand, compute the 95% uncertainty interval, and then finally add a special note with regard to the probability of occurrence of outliers in the uncertainty specification.

Although it may appear complicated to specify the uncertainty in a detailed manner, a rough estimate may be obtained by adding the squares of CVs corresponding to essential uncertainty elements (e.g., grouped as factors outside the laboratory) (derived from the traceability chain), the analytical factors inside the laboratory (intermediate precision), and the preanalytical elements.[56] In estimating uncertainty, it is important to include relevant elements, but one must be careful to avoid counting the same elements twice.

Application of the uncertainty concept in the field of clinical chemistry is subject to some discussion.[57,61]

SOFTWARE PACKAGES

In practice, statistical analyses usually are conducted in spreadsheets or by statistical programs. Concerning the latter, large, general program packages or smaller programs more or less specialized toward the field of clinical chemistry are available. In addition, large, general packages are on the market [e.g., Statistical Package for the Social Sciences (SPSS), SAS, Stata, Systat, StatGraphics]. Among programs of intermediate size, GraphPad (www.graphpad.com) and SigmaStat are worthy of note. Excel (Microsoft) contains various statistical routines. The general programs may lack procedures of interest to clinical chemists (e.g., Deming and Passing-Bablok

BOX 2-1 Abbreviations and Vocabulary

Abbreviations

CI	Confidence interval
CV	Coefficient of variation (= SD/x, where x is the concentration)
CV%	= CV × 100%
CV_A	Analytical coefficient of variation
CV_{RB}	Sample-related random bias coefficient of variation
DoD	Distribution of differences (plot)
ISO	International Organization for Standardization
IUPAC	International Union of Pure and Applied Chemistry
OLR	Ordinary least-squares regression analysis
SD	Standard deviation
SEM	Standard error of the mean (= SD/√N)
SD_A	Analytical standard deviation
SD_{RB}	Sample-related random bias standard deviation
x_m	Mean
x_{mv}	Weighted mean
WLR	Weighted least-squares regression analysis

Vocabulary*

Analyte Compound that is measured.

Bias Difference between the average (strictly the expectation) of the test results and an accepted reference value (ISO 3534-1). Bias is a measure of trueness.[44]

Certified reference material (CRM) is a reference material, one or more of whose property values are certified by a technically valid procedure, accompanied by or traceable to a certificate or other documentation that is issued by a certifying body.

Commutability Ability of a material to yield the same results of measurement by a given set of measurement procedures.

Limit of detection The lowest amount of analyte in a sample that can be detected but not quantified as an exact value. Also called lower limit of detection, minimum detectable concentration (or dose or value).[18]

Lower limit of quantification (LloQ) The lowest concentration at which the measurement procedure fulfills specifications for imprecision and bias (corresponds to the *lower limit of determination* mentioned under *Measuring interval*).

Matrix All components of a material system, except the analyte.

Measurand The "quantity" that is actually measured (e.g., the concentration of the analyte). For example, if the analyte is glucose, the measurand is the concentration of glucose. For an enzyme, the measurand may be the enzyme *activity* or the *mass concentration* of enzyme.

Measuring interval Closed interval of possible values allowed by a measurement procedure and delimited by the *lower limit of determination* and the *higher limit of determination.* For this interval, the total error of the measurements is within specified limits for the method. Also called the *analytical measurement range.*

Primary measurement standard Standard that is designated or widely acknowledged as having the highest metrologic qualities and whose value is accepted without reference to other standards of the same quantity.[47]

Quantity The amount of substance (e.g., the concentration of substance).

Reference material (RM) A material or substance, one or more properties of which are sufficiently well established to be used for the calibration of a method, or for assigning values to materials.

Random error Arises from unpredictable variations in influence quantities. These random effects give rise to variations in repeated observations of the measurand.

Reference measurement procedure Thoroughly investigated measurement procedure shown to yield values having an uncertainty of measurement commensurate with its intended use, especially in assessing the trueness of other measurement procedures for the same quantity and in characterizing reference materials.

Selectivity and/or Specificity Degree to which a method responds uniquely to the required analyte.

Systematic error A component of error that, in the course of a number of analyses of the same measurand, remains constant or varies in a predictable way.

Traceability "The property of the result of a measurement or the value of a standard whereby it can be related to stated references, usually national or international standards, through an unbroken chain of comparisons all having stated uncertainties."[43] This is achieved by establishing a chain of calibrations leading to primary national or international standards, ideally (for long-term consistency) the Système Internationale (SI) units of measurement.

Uncertainty A parameter associated with the result of a measurement that characterizes the dispersion of values that could reasonably be attributed to the measurand, or, more briefly, *uncertainty* is a parameter characterizing the range of values within which the value of the quantity being measured is expected to lie.

Upper limit of quantification (UloQ) The highest concentration at which the measurement procedure fulfills specifications for imprecision and bias (corresponds to the *upper limit of determination* mentioned under *Measuring interval*).

*A listing of terms of relevance in relation to analytical methods is displayed. Many of the definitions originate from Dybkær[29] with statement of original source where relevant (e.g., ISO document number). Others are derived from the Eurachem/Citac guideline on uncertainty.[31] In some cases, slight modifications have been performed for the sake of simplicity.

procedures). Other programs that are specialized for clinical chemistry include Analyze-it (www.analyze-it.com), MedCalc (www.medcalc.be), EP-Evaluator (D. Rhoads Associates, www.dgrhoads.com), and a program distributed by one of the authors (K.L.) called CBstat (www.cbstat.com).

CHAPTER 3

Clinical Utility of Laboratory Tests

*Edward R. Ashwood, M.D., and David E. Bruns, M.D.**

A vast majority of medical decisions rely on laboratory testing. Clinicians often ask which test or sequence of tests (1) provides the best information in a specific setting, (2) is the most cost-effective, and (3) offers the most efficient route to diagnosis or considered medical action. In addition, it is often asked, "How does one combine a testing result or testing information with previously obtained information?" In addressing these questions, this chapter focuses on how to use the diagnostic information obtained from a test or a group of tests, and how to compare test results with those of other tests. Designing studies to assess diagnostic accuracy is addressed in Chapter 4, Evidence-Based Laboratory Medicine.

The analytical performance of the methods used for many clinical tests has improved dramatically. However, a test that has high analytical accuracy and precision may provide less useful clinical information than a test that performs worse analytically. For example, a test for free ionized calcium is often more accurate and precise than one for parathyroid hormone (PTH), yet knowledge of ionized calcium is of less value in the assessment of hyperparathyroidism. Pertinent questions include: (1) How does one evaluate the information content of a test? And (2) What procedure should one use to decide among different tests based on their disease discrimination ability? This chapter discusses these and other nonanalytical aspects of test performance that affect a test's overall medical usefulness. Although the techniques described in this chapter have been recommended to clinicians for nearly two decades, few physicians avail themselves of their use. Laboratorians need to take a more active role in promoting these techniques.[5]

DIAGNOSTIC ACCURACY OF TESTS

Whenever a clinician uses a laboratory test, he or she needs to have a clear understanding of the clinical performance characteristics of that test. The extent of agreement of test results with accurate patient diagnosis is represented in several ways, including (1) sensitivity and specificity, (2) predictive values, (3) receiver operating characteristic (ROC) curves, and (4) likelihood ratios.

Sensitivity and Specificity

The *sensitivity* of a test reflects the fraction of those with a specified disease that the test correctly predicts. The *specificity* is the fraction of those without the disease that the test correctly predicts. Table 3-1 shows the classification of unaffected and diseased individuals by test result. *True positives (TP)* are those diseased individuals who are correctly classified by the test. *False positives (FP)* are nondiseased individuals misclassified by the test. *False negatives (FN)* are those diseased patients misclassified by the test. *True negatives* (*TN)* are nondiseased patients correctly classified by the test.

$$\text{Sensitivity} = \frac{\text{TP}}{\text{TP} + \text{FN}}$$

$$\text{Specificity} = \frac{\text{TN}}{\text{TN} + \text{FP}}$$

Both high sensitivity (few FN) and high specificity (few FP) are desirable characteristics for a test, but one is typically preferred over the other, depending on the clinical situation.

By design, some tests have only positive or negative results and provide qualitative results. These tests, which are termed *dichotomous,* have a single sensitivity and specificity pair for a designated assay cutoff. If a cutoff value is selected to produce high sensitivity, the specificity often will be compromised. Likewise, cutoffs that maximize specificity lower sensitivity.

An example of a dichotomous test is the human immunodeficiency virus (HIV) screening test. This test detects HIV antibodies, producing results that may be nonreactive (negative) or reactive (positive). False positives occur owing to technical errors such as mislabeling or contamination and the

TABLE 3-1 Classifications of a Test Result Applied to Unaffected and Diseased Populations

	No. of Patients With Positive Test Result	No. of Patients With Negative Test Result
No. of patients with disease	TP	FN
No. of patients without disease	FP	TN

FN, False negatives (number of diseased patients misclassified by the test); *FP,* false positives (number of nondiseased patients misclassified by the test); *TN,* true negatives (number of nondiseased patients correctly classified by the test); *TP,* true positives (number of diseased patients correctly classified by the test).

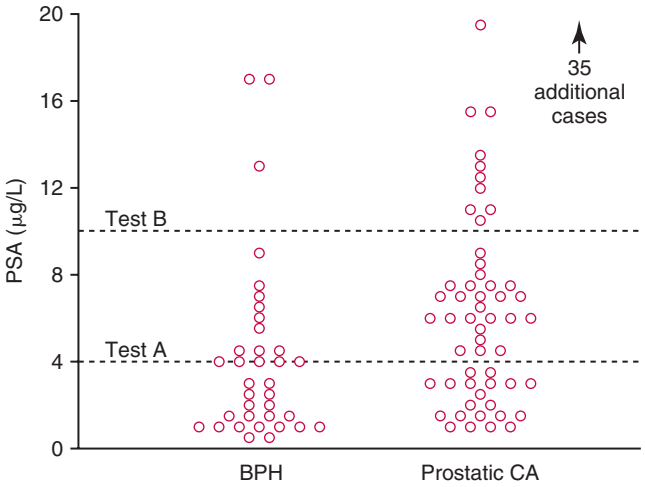

Figure 3-1 Prostate-specific antigen (PSA) concentrations for patients with benign prostatic hyperplasia (BPH) and known prostatic carcinoma (CA) are shown with two decision-level cutoffs.

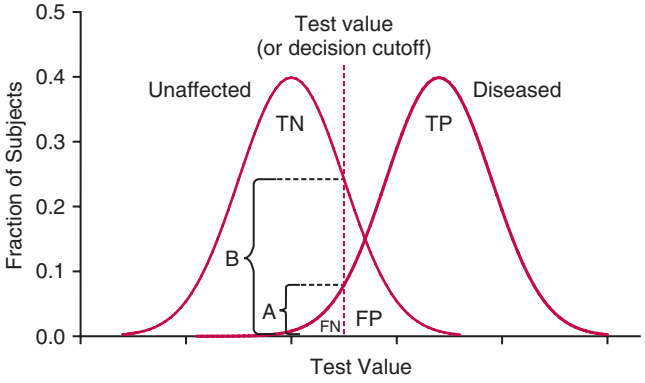

Figure 3-2 Simulated distributions of unaffected and diseased populations. Note that the ratio of diseased patients to healthy patients, A to B, is less than 1 and is very different at the point of decision (the likelihood ratio) from the ratio of TP to FP, which is much greater than 1. *FN,* False negatives; *FP,* false positives; *TN,* true negatives; *TP,* true positives.

presence of cross-reacting antibodies found in individuals such as multiparous women and multiply transfused patients.[28] False negatives occur because of technical errors such as mispipetting and sampling determinants such as testing in early infection (3 to 4 weeks) prior to antibody production. Reported sensitivities and specificities for the HIV screening test vary widely,[16] but reasonable estimates are 96% and 99.8%, respectively. Thus, 4 of 100 HIV-infected subjects will test negative. Only 2 of 1000 noninfected subjects will test positive. The clinical usefulness of an HIV test result from an unknown subject will be explained later in the "Probabilistic Reasoning" section.

As opposed to dichotomous tests, *continuous* tests are those that produce quantitative results. Continuous tests have an infinite number of sensitivity and specificity pairs, as the cutoff varies from lowest to highest decision value.

Figure 3-1 is a dot plot of the performance of a continuous assay for prostatic-specific antigen (PSA) in patients with benign prostatic hyperplasia (BPH) and in those with established carcinoma of the prostate (stages A through D).[8] Often continuous tests are used in a dichotomous fashion by choosing one or more decision cutoffs. Note the two dashed lines crossing the graphs that represent two diagnostic cutoffs. Both tests A and B are PSA tests, but they have different decision cutoffs, namely, 4 μg/L and 10 μg/L. When test A is compared with test B, the decision cutoff of 4 μg/L for test A produces increased sensitivity but at the cost of a decrease in specificity. Thus increased true-positive detection has been traded for an increase in the number of false-positive results. This tradeoff occurs in every test performed in medicine. Not only does it affect the interpretation of quantitative laboratory results, it also affects the opinions of surgical pathologists and radiologists and of the care provider who performs a physical examination.

Figure 3-2 illustrates a hypothetical test that shows higher results in patients who have a disease compared with those who are unaffected. As the decision cutoff is increased, FP decrease and FN increase. At extremely low and extremely high cutoffs, sensitivity and specificity are 100%.

Receiver Operating Characteristic Curves[48]

The dot plot (see Figure 3-1) displays quantitative performance in a limited fashion. For example, one cannot easily estimate sensitivity and specificity for various decision cutoffs using the dot plot. A graphical technique for displaying the same information, called a *receiver operating characteristic (ROC)* curve, began to be used during World War II to examine the sensitivity and specificity associated with radar detection of enemy aircraft. An ROC curve is generated by plotting sensitivity (y-axis) versus 1 − specificity (x-axis).[10a]

Figure 3-3 shows the ROC curve for the data in Figure 3-1. The x-axis plots the fraction of nondiseased patients who

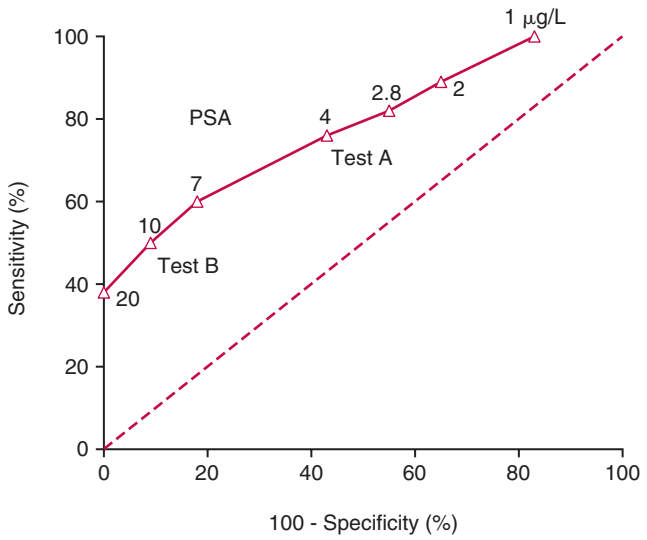

Figure 3-3 Receiver operating characteristic curve of prostate-specific antigen (PSA). Each point on the curve represents a different decision level. The sensitivity and 1 – specificity can be read for tests *A* and *B*, having 4 and 10 µg/L as decision thresholds, respectively.

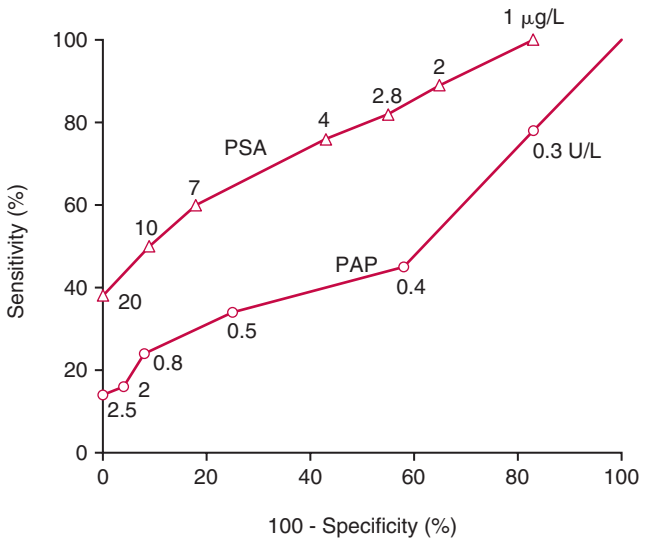

Figure 3-4 Receiver operating characteristic curves of prostatic acid phosphatase (PAP) and prostate-specific antigen (PSA) assays for patients with benign prostatic hyperplasia and prostatic carcinoma. Because the PSA assay curve is above the PAP assay curve at all points, the PSA assay is the better assay for the patients tested.

were erroneously categorized as positive for a specific decision threshold. This "false-positive rate" is mathematically the same as 1 – specificity. The *y*-axis plots the "true-positive rate" (the sensitivity). A "hidden" third axis is contained within the curve itself: the curve is drawn through points that represent different decision cutoff values. Those decision cutoffs are listed as labels on the curve.[18] The entire curve is a graphical display of the performance of the test.

Tests A and B from Figure 3-3 are displayed as two decision points on the ROC curve. The dotted line extending from the lower left to the upper right represents a test with no discrimination and is designated the random guess line. A curve that is "above" the diagonal line describes performance that is better than random guessing. A curve that extends from the lower left to the upper left and then to the upper right is a perfect test. The area under the curve describes the test's overall performance, although usually one is interested only in its performance in a specific region of the curve.[1] One strength of the ROC graph lies in its provision of a meaningful comparison of the diagnostic performance of different tests. In the medical literature, the use of 2×2 tables to present the sensitivity and specificity of a test has led to the common logical misconception that a quantitative test has a single sensitivity and specificity. When the initial publication of an assay recommends a cutoff for analysis purposes, the assay is often categorized as sensitive or specific based on this cutoff. Yet, as seen in the ROC curve, every assay can be as sensitive as desired at some cutoff, and as specific as desired at another.

When two procedures are compared, confusion is avoided by using ROC curves instead of accepting statements such as, "Test A is more sensitive, but test B is more specific." For example, the usefulness of the prostatic acid phosphatase assay had been compared for years with that of the PSA assay for diagnostic and follow-up purposes. Various claims were made regarding the relative sensitivity and specificity of the two assays.[12,35]

Figure 3-4 compares the performance of an acid phosphatase assay with that of the PSA assay for discrimination between BPH and prostatic carcinoma in the same cohort of patients. Although each test has been claimed to be "more sensitive but less specific" than the other by various authors, it is clear from the ROC curves that the authors were choosing different points on the two curves. No matter what level of sensitivity is chosen, the PSA assay offers greater specificity than the acid phosphatase assay at the same level of sensitivity. This does not mean that one should conclude that the PSA assay is always superior. It does indicate that for the cohort of patients used to compare the assays, the PSA assay offers superior performance compared with the prostatic acid phosphatase assay. However, the acid phosphatase assay may provide superior diagnostic information to that provided by the PSA assay in subpopulations of the cohort.

The area under the ROC curve is a relative measure of a test's performance. A Wilcoxon statistic (or equivalently, the Mann-Whitney *U*-test) statistically determines which ROC curve has more area under it. These methods are particularly helpful when the curves do not intersect. When the ROC curves of two laboratory tests assessing for the same disease intersect, the tests may exhibit different diagnostic performances, even though the areas under the curve are identical. Test performance depends on the region of the curve (i.e., high sensitivity vs. high specificity) chosen. Details on how individual points on two curves can be compared statistically have been provided elsewhere.[1]

PROBABILISTIC REASONING

Although the ROC curve improves our capability to judge a test's performance, a result should not be interpreted in isolation. The clinician must take into account the clinical setting before rendering an interpretation. For example, a positive HIV screening test has a different meaning for an adult as compared with a newborn. In the newborn, antibodies detected by an HIV test are maternal antibodies; thus the result is an indication of the HIV status of the newborn's mother.

Interpretation of almost all laboratory test results is affected by the probability of the disorder prior to testing. For example, an elevated PSA concentration in a 35-year-old is not interpreted in the same way as in a 70-year-old because the rate of occurrence of prostatic cancer in 35-year-olds is much lower than that in older men.[29] Interpretation must be tempered by knowledge of the prevalence of the disease.

Prevalence

Prevalence is defined as the frequency of disease in the population examined.[44] For example, with step sectioning of prostate tissue from a random sample of men older than 50 years of age, at least a 25% probability of histologic carcinoma is expected (most of the carcinomas identified will never become clinically important, but they are carcinomas nevertheless).[17,34] Several useful techniques have been applied to combine the prevalence with information previously obtained in the results of testing.

Predictive Values

The results of dichotomous tests (and continuous tests used in a dichotomous manner) can be interpreted using predictive values. The *predictive value of a positive test* (PV^+) is the fraction of subjects with a positive test who have the disease. The *predictive value of a negative test* (PV^-) is the fraction of subjects with a negative test who do not have the disease. The predictive value equations are as follows:

$$PV^+ = \frac{TP}{TP + FP}$$

$$PV^- = \frac{TN}{TN + FN}$$

Predictive values are a function of sensitivity, specificity, and prevalence. It is regrettable that clinicians often confuse sensitivity with PV^+. For example, suppose that 1,000,000 U.S. residents were randomly chosen and tested for HIV infection using the HIV screening test. The Centers for Disease Control and Prevention estimates that the prevalence of HIV infection in the United States is 330.4 per 100,000 population.[7] On the basis of this prevalence, about 3304 infected individuals would be expected in a population of 1 million. Because the sensitivity of the HIV test is 96%, about 3172 infected individuals would have a positive test result (i.e., TP = 3172). Similarly, because the specificity of the HIV test is 99.8%, about 2 false positives per 1000 subjects would be expected. Thus about 1993 individuals would have false-positive results (i.e., FP = 1993). Therefore, the PV^+ is 3172/(3172 + 1993), or 61%. Thus an individual with a positive test result has a moderate chance of having a false-positive result. Additional testing is necessary to separate TP individuals from FP individuals. Most laboratories automatically test all specimens having a positive HIV screening result with a confirmatory test such as the HIV Western blot (see Chapter 12).

In this example, the PV^- is much higher than the PV^+. Calculations reveal 132 false-negative results (3304 − 3172) and about 994,703 true negatives [99.8% × (1,000,000 − 3304)]. Thus, the PV^- is 99.987%. Note that many of the false negatives could reflect these infected individuals with early HIV infection prior to antibody development. The limitation of false negatives can be overcome by frequent testing of high-risk individuals.

Odds Ratio

The *odds ratio* (OR) is defined as the probability of the presence of a specific disease divided by the probability of its absence. The odds ratio reflects the prevalence of the disease in a population. For example, the probability of occurrence of a 1.3-cm^3 carcinoma in a 75-year-old man is about 8%. The odds ratio of finding histologic carcinoma measuring greater than 1.3 cm^3 after the prostate is sectioned from the autopsy specimen of a man older than 70 years is thus 0.08/(1 − 0.08), or 1 to 11.5. Findings from a digital rectal examination, from transrectal ultrasonography, or from both consist of other data that affect the previous probability of the presence of prostatic disease.

$$\text{Odds Ratio} = \frac{\text{probability of event}}{1 - \text{probability of event}}$$

Likelihood Ratio

The *likelihood ratio* (LR) is the probability of occurrence of a specific test value given that the disease is present divided by the probability of the same test value if the disease was absent. Many sources (e.g., Henry[20]) indicate that the slope of the ROC curve is equal to the LR for a given test value. Assertions such as these oversimplify the concept of LR. Choi[10] describes three different slopes of the ROC curve, which represent LR in different settings (as illustrated in Figure 3-5):

1. The tangent slope, which is equal to the LR of a *continuous* test at a given test value.
2. The slope from the origin to a test value equal to a decision cutoff, the LR^+ for a positive result of a *dichotomous* test; this slope has a companion slope (which is the slope from the cutoff value to the upper right hand corner of the ROC plot), which represents the LR^- for a negative result of a *dichotomous* test.
3. A slope between any two test values (not illustrated in Figure 3-5), which is termed the *interval LR* and represents the LR of a result that lies between the values; the interval LR is useful for continuous tests that have results grouped into intervals.

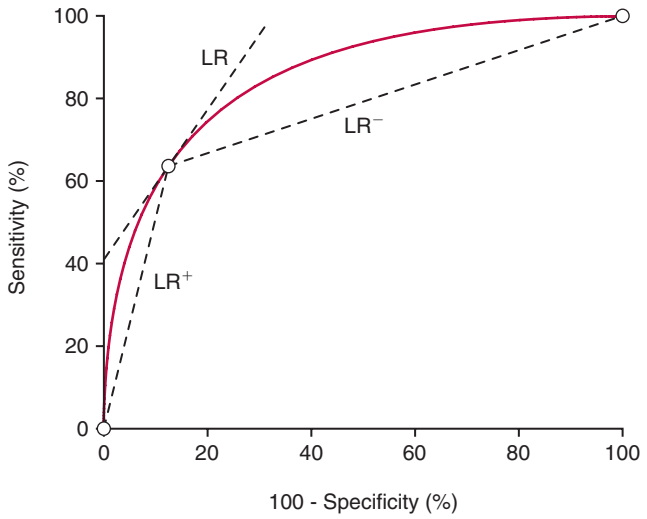

Figure 3-5 Receiver operating characteristic curve illustrating the slopes that define the likelihood ratio (LR) for a continuous test at a specific test result (the gray point), and the positive likelihood ratio (LR^+) and the negative likelihood ratio (LR^-) of a dichotomous test.[10]

For qualitative tests, the *positive likelihood ratio* (LR^+) is equal to the sensitivity/(1 − specificity). Conversely, the *negative likelihood ratio* (LR^-) is the probability of occurrence of a specific test value given that the disease is absent divided by the probability of the same test value if the disease were present. Thus for qualitative tests, the LR^- is specificity/(1 − sensitivity).

For quantitative tests, the LR is the tangent slope of the ROC curve, which equals the ratio of the heights A and B of the two curves at the test value in Figure 3-2. Note that the areas under each curve in Figure 3-2 are the same. The likelihood ratio does not take disease prevalence or any other prior information into account. To arrive at a final probability, one must adjust for the best estimate of the probability of disease before obtaining the test result.

Bayes' Theorem

Bayes' theorem provides a method to calculate the probability of a disease after new information is added to previously obtained information. The basic theorem is usually written as follows:

$$P(D\,|\,R)=\frac{P(R\,|\,D)\times P(D)}{P(R)}$$

where D is disease and R is a positive result. Thus the above equation is "the probability of disease given a particular result is equal to the probability of that result given the disease (i.e., sensitivity) times the probability of disease (i.e., prevalence) divided by the overall probability of having that result." For a dichotomous test, the probability of a positive result is equal to the numerator of the equation plus $P(R|\text{not } D) \times P(\text{not } D)$, or (1 − specificity) × (1 − prevalence). Thus, Bayes' theorem can be rewritten to express the probability of disease given a positive test result as follows:

$$P(D\,|\,R)=\frac{\text{Sensitivity}\times\text{Prevalence}}{\text{Sensitivity}\times\text{Prevalence}+(1-\text{Specificity})\times(1-\text{Prevalence})}$$

Most formulas for Bayes' theorem require computer assistance for rapid solutions. One method, which is performed without a computer, involves using the likelihood version of Bayes' theorem. The odds ratio of the occurrence of a disease is calculated before the test result is known; this information is then combined with the LR. The final result is again in the form of an odds ratio, which can be converted into a probability, if desired. The advantages of this method are that it is relatively easily memorized, and it requires little mathematical calculation. Thus:

$$\text{Odds ratio after testing} = \text{Odds ratio before testing} \times \text{Likelihood ratio of a given test result}$$

Consider interpretation of a slightly elevated PSA (4.0 to 10.0 µg/L) in a patient with BPH. A urologist follows with a transrectal ultrasound examination, which he interprets as giving a positive result for cancer. The urologist has performed biopsies on numerous patients similar to this patient and has had many results that he interprets as negative for cancer. The urologist finds the high number of negative biopsies perplexing, because both screening tests produced positive results. He or she then requests an estimate of the probability of cancer in this patient.

1. *Calculate the odds ratio that carcinoma is present before performing the ultrasound.* Given a PSA of 4.0 to 10.0 µg/L, there is an estimated probability of 12% with biopsy-verifiable carcinoma in a BPH population; thus the probability of no disease is (1 − 0.12) = 0.88. Therefore, the odds ratio for the presence of carcinoma before transrectal ultrasound is performed is 0.12/0.88 = 0.14, or about 1 to 7.3.
2. *Calculate the likelihood ratio of the new information (findings of the transrectal ultrasound).* Screening studies on urology patients report sensitivities for cancer of approximately 92% and specificities that average about 50% for transrectal ultrasound.[6,11,30] The LR^+ is the sensitivity divided by (1 − specificity), or 0.92/0.50 = 1.8.
3. *Calculate the odds ratio after incorporation of the new information.* The revised odds ratio estimate (the product of Steps 1 and 2) is 0.14 × 1.8 = 0.25, or about 1 to 4.
4. *Convert the odds ratio back into probabilities.* The probability equals the odds ratio divided by (1 + odds ratio), or 0.25/1.25 = 0.2.

Although both the PSA and transrectal ultrasound were positive, the probability of a biopsy result positive for carcinoma is only 20%. The urologist had been anticipating a much higher probability because of confusion between sensitivity and predictive value of the PSA and transrectal ultrasound tests.

If the ultrasound findings had been negative, we would use the inverse of the odds ratio coupled with the negative likelihood ratio. The odds ratio of no disease after the PSA assay, (0.88/0.12) = 7.3, multiplied by the negative likelihood ratio

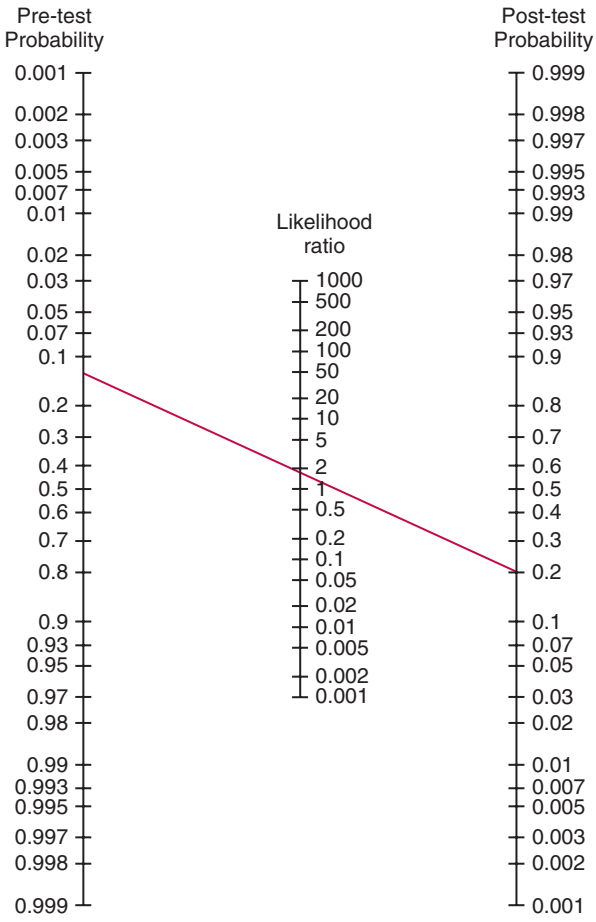

Figure 3-6 Nomogram estimating the post-test probability of a condition given the pretest probability and the likelihood ratio. *(Modified from Boyd JC. Statistical analysis and presentation of data. In: Price CP, Christenson RH, eds. Evidence-based laboratory medicine principles, practice and outcomes, 2nd edition. Washington, DC: AACC Press, 2007:113-40.)*

[specificity/(1 − sensitivity) = 0.5/0.08 = 6.25], is 43. Converting to probabilities yields 43/(43 + 1) = 98% probability of no disease.

The calculation of the post-test probability has also been solved using a convenient nomogram[4] (Figure 3-6). Knowing the pretest probability and the LR, one constructs a line between those two points and extrapolates the line onto the post-test scale.

Limitations of Bayes' Theorem

Although Bayes' theorem is widely recommended as an aid to refine the probabilistic estimates of disease, it rests on the assumption of *test independence,* which often is not present. As an extreme example of the possible errors that can occur when nonindependent tests are used, consider testing the PSA concentration of a BPH patient on three consecutive days. Each day, the PSA value is approximately 10 µg/L. The LR for this result can be estimated from the tangent of the slope at 10 µg/L in Figure 3-2. This slope is approximately 1.2. Using the likelihood form of Bayes' theorem, next multiply the prior odds ratio (assume 10 to 90) by the LR to obtain the odds ratio after 0.13, or a probability of 12% after the first test. The odds ratio is 1.2 × 0.13 = 0.16 after the second test, and finally 0.19 after the third test. This gives a 16% probability of disease. Very little new information has been provided by the second and third tests, yet the probability of disease has apparently increased from 10 to 16%. A less obvious and less extreme example would result from the combination of the prostatic acid phosphatase results with the PSA results. Although this combination does provide some new information, an acid phosphatase result is related to the amount of prostatic tissue, much as a PSA result is. In contrast, the ultrasound examination is a different approach to the diagnosis, and the information it yields should be more independent of the PSA assay than information yielded by the acid phosphatase results. The lack of test independence is also a problem when computerized diagnostic programs that employ a Bayesian approach are used. The amount of independence among different tests for various diseases often must be estimated and tried using a set of test cases.

Judging independence is difficult without collecting a large set of clinical data and examining them mathematically. A useful approach is to think about the incorrect results given by each test. If both tests tend to yield incorrect results for the same patients, then the tests are not independent, and thus Bayes' theorem cannot be applied to the combination of their results to correctly estimate the probability of disease. For example, the presence of prostatitis or BPH will result in a large number of false-positive results for both PSA and prostatic acid phosphatase assays. Although these tests are not measuring the same analyte and do provide some independent information, combining their results using Bayes' theorem is not appropriate. Alternatively, if the tests seem intuitively to be independent, then the errors made by assuming independence are likely to be small.

Combination Testing

Panels of tests are commonly used to increase sensitivity and specificity or are used sequentially to decrease costs. For the practicing laboratorian, the value of panels is limited by sparse literature on the performance of combinations of tests. The same issue of test independence addressed in the previous section makes it difficult to calculate the performance of panels of tests. In addition, the use of multiple tests can increase the probability of the occurrence of false-positive or false-negative results, depending on how the tests are combined. The often used maternal serum screening panel described in Chapter 57 uses four tests, but combines the results using a log normal covariate distribution model, which adjusts for lack of independence among the tests.[41]

Because most reference intervals exclude a fraction of those patients without disease, there is an expected false-positive rate. As multiple tests are added to panels, the probability of false-positive results increases. Efforts to establish multivariate reference intervals that correct for multiple tests and their interrelationships have been made, but the concept has not found widespread acceptance. Although this concept

TABLE 3-2 Performance of Different Test Combinations in Prediction of Prostatic Carcinoma

Test Combination	Sensitivity, %	Specificity, %
PSA > 4 µg/L	78	58
PAP > 0.6 U/L	77	25
PSA > 4 µg/L or PAP > 0.6 U/L	92	19
PSA > 1.5 µg/L	91	36

PAP, Prostatic acid phosphatase; *PSA,* prostate-specific antigen.

TABLE 3-3 Combination Test Performance Maximizing Specificity*

	Sensitivity, %	Specificity, %	Cost
Test A	80	99	$100
Test B	99	80	$100
A followed by B	79.2	99.8	
Prevalence = 0.2			$117
Prevalence = 0.8			$164
B followed by A	79.2	99.8	
Prevalence = 0.2			$136
Prevalence = 0.8			$183

*Results of test A *and* test B must be positive to make a positive diagnosis.

is mathematically reasonable, those who have investigated the utility of multivariate reference intervals believe that more work is needed before they will prove useful.

The gain in test performance to be achieved by combining test results may be illusory. As demonstrated by the dot plot in Figure 3-1, and by the ROC curve in Figure 3-3, it is possible to increase sensitivity at the expense of decreased specificity. This does not guarantee that the individual test, if the decision threshold were modified to improve sensitivity, would not have comparable performance. For example, consider the data of Chan and associates[8,9,14,15] for PSA and prostatic acid phosphatase values in patients with BPH and in those with prostatic disease, shown in Table 3-2 (and also in Figure 3-4). Although combining the two individual tests does improve sensitivity, specificity is decreased. Note that using a lower decision threshold for the PSA assay gives comparable sensitivity with improved specificity over the combination.

Two observations are important. First, tables can be as misleading for combinations of tests as they can be for single tests. For example, if only the first three rows of Table 3-2 were published, one might conclude that the combination of the two tests offered superior sensitivity. Second, although in this case the two tests do not offer performance that is comparable with that of the single test, in many cases they do. Although it might be assumed that using a single test is to be preferred given equal performance, it is not always the most cost-effective approach. In this example, the prostatic acid phosphatase assay costs less than the PSA assay. If the combination in row three of Table 3-2 offered performance comparable with that of the PSA assay alone, then using the acid phosphatase assay to exclude some patients and subsequently performing PSA assays on patients with higher PSA values may well be the more economical approach.

A widely held belief[43] is that one should test first with a sensitive test and then follow up the occurrence of positive results with a specific test for best performance. The logic is that if the first test determines which patients are to undergo a second test, then the first test should be the more sensitive of the two, to ensure that the disease has not been missed. It is surprising that even when the first test determines which patients will undergo a second test, the order in which the tests are performed does not affect the combination of sensitivity and specificity. However, it does affect the overall cost. In the following examples, two hypothetical tests that are independent are used sequentially. It is assumed that fixed decision limits are used for the two tests, and that the two tests cost the same. Although these tests are hypothetical, the principles are generally applicable to other sequential testing situations.

Example 1. Often care is optimized if it can be confirmed that a disease is not present. In this case, if screening test A yields a positive result, it will be followed by test B; otherwise, testing stops. If test B yields a positive result, then the overall interpretation is a positive result. Because tests A *and* B are necessary for the diagnosis, specificity is improved; however, sensitivity decreases compared with the use of test A alone. As shown in Table 3-3, the average cost of the combination varies with disease prevalence; however, note that performance of the more *specific* test first results in lower expected costs. This lower cost would be accentuated if the second test were to cost more than the first.

The net effect of the use of the test combination compared with the use of test A alone has been to decrease our false-positive rate fivefold while decreasing the true-positive rate by 0.8%. Whether this tradeoff is desirable depends on the implications of missing a diagnosis versus generating false-positive results.

Example 2. Diagnosing a curable disease that has a low-cost therapy often increases the relative worth of sensitivity over specificity. If the first test result is negative, the second test might still be performed to maximize sensitivity. When either of two tests yields a positive result, this would be interpreted as a positive finding overall. This is more typically seen when tests are done simultaneously, but it

TABLE 3-4 Combination Test Performance Maximizing Sensitivity*

	Sensitivity, %	Specificity, %	Cost
Test A	80	99	$100
Test B	99	80	$100
A followed by B	99.8	79.2	
Prevalence = 0.2			$183
Prevalence = 0.8			$136
B followed by A	99.8	79.2	
Prevalence = 0.2			$164
Prevalence = 0.8			$117

*Results of test A *or* test B must be positive to make a positive diagnosis.

also occurs in sequential testing. In Table 3-4, a negative result on the first test is followed by performance of the second test; otherwise, testing stops. If the result of the second test is negative, then the overall interpretation is negative. The cost of performing tests sequentially with this rule varies with prevalence, as seen in Table 3-4.

Using this rule, the combination sensitivity increases as the specificity decreases. Note that the strategy of first using the test with *lower* specificity results in lower average cost.

Following the strategy outlined in Table 3-3, the first test's specificity determines the cost of sequential testing. When the strategy is to confirm all negative results of the first test (see Table 3-4), the first test should be the more sensitive, so as to minimize costs. As demonstrated in the two examples presented earlier, the decision rule used preferentially trades off sensitivity at the expense of specificity, or vice versa. Although independent tests have been used in these examples, the conclusions are the same for dependent tests. It should be remembered that it is the interpretive rule and the two tests that determine the overall panel performance and costs; the order of testing does not affect performance but can dramatically affect costs.

METHODS FOR ASSESSING DIAGNOSTIC ACCURACY

Most studies of diagnostic accuracy are cross-sectional as opposed to longitudinal, attempting to determine the utility of a test at a single point in time. The results of a new test (often referred to as the *index test,* the test of interest) are compared with those from a "gold standard test" using the same subjects, which is more formally called a *reference standard* (the best current practice for establishing the presence of a disorder). The reference standard can include many methods for establishing a subject's health status, such as (1) additional laboratory tests, (2) imaging tests, (3) medical history, (4) physical examination, and (5) clinical changes over time.

Around 1980, some investigators realized that most diagnostic accuracy studies contained serious flaws, introducing biases into reported performance characteristics. The work of advocates for improved study design and reporting led to the development of many important assessment tools.[14] Of note are QUADAS (Quality Assessment of Diagnostic Accuracy Studies)[45] and STARD (Standards for Reporting of Diagnostic Accuracy).[2,3] Both QUADAS and STARD are described in detail in Chapter 4.

Well-designed studies minimize several sources of bias and variation, including those that affect the selection of study subjects (both patients and controls), verification using the reference standard, observer/technician bias, missing or incomplete patient data, and analysis techniques that affect estimates of diagnostic accuracy. A 2006 meta-analysis concluded that most reported studies have shortcomings that variably affect estimates of diagnostic accuracy.[31] Often, an incomplete study description prevents full assessment of potential sources of bias and variation.

Study Subject Ascertainment

Selection of study subjects is a major source of variation in diagnostic accuracy studies. Study subjects can be selected prospectively or retrospectively, consecutively or nonconsecutively, from a variety of medical settings. *Spectrum* describes the breadth of the medical characteristics of subjects involved in the test evaluation. Important aspects include (1) the duration and severity of the disease state, (2) its specific pathologic categorization, and (3) the existence of conditions that may affect test performance. The severity of disease among studied patients with the target condition (varying from mild to life-threatening) and the range of other conditions in the other patients (controls) can affect the apparent diagnostic accuracy of a test. Patient groups can also have variable simultaneously existing medical (comorbid) conditions or alternative diagnoses. Three factors can introduce spectrum variation during the selection of study subjects: (1) study design, (2) method of selection, and (3) consecutive/nonconsecutive series.

Study Design

The best study is one of cohort design, where the index test is performed before it is known whether subjects have the target condition.[31] The alternative design is case-control, in which patients known to have the target condition are selected.[32] Then similar patients are enrolled to form a control group. The discovery that maternal serum inhibin was higher in Down syndrome pregnancies than in unaffected pregnancies used a case-control design.[40] Case-control studies are often used to assess test potential before a prospective cohort study is undertaken. This approach is cost-effective, especially for target conditions with low prevalence. For example, the

first report of combining four analyte results into a "quadruple" test for predicting fetal Down syndrome risk used a case-control design,[41] and the follow-up study used a series of patients in a cohort design.[42]

A poorly designed case-control study could include subjects with severe disease and healthy controls (e.g., medical students).[24] Distorted subject selection such as this will uniformly overestimate sensitivity[46] and sometimes will overestimate specificity.[46] Alternatively, selection could be designed to exclude the extreme ends of the spectrum, thereby leading to underestimates of sensitivity and specificity.[32]

Method of Selection

The best method of study subject selection is based on symptoms or signs of the target condition only.[22] For a screening test designed to be used on the general population, study subjects should have no symptoms or signs of the target condition. If a test that is designed to detect early cancer is evaluated in patients with clinically apparent cancer, the test is likely to perform better than when used for persons who do not yet show signs of the condition. This design flaw is called *spectrum variation* (although some authors call this flaw *spectrum bias*).[46] Similarly, if a test were developed to distinguish patients with the target condition from patients with a similar condition, it would be misleading to use healthy subjects as controls when evaluating the diagnostic accuracy of the test. Likewise, demographic features (e.g., sex) should be similar between study subjects and the group to be clinically tested. Cardiovascular studies that enroll only men generally may not be applicable to women.

Consecutive/Nonconsecutive Series

A best design is one that considers a consecutive series of patients, all suspected of having the target condition. Each consenting patient is enrolled, and all study subjects undergo both the index test and then the clinical reference standard. The design must avoid any form of selection bias. All subjects meeting the a priori definition for inclusion are asked to enroll. When other methods are used for subject selection, variation is likely to occur. For example, choosing nonconsecutive patients with very advanced disease is likely to produce an overestimation of sensitivity because the disease severity will be greater (and therefore the index test more abnormal) than observed when the test is used clinically, and many patients have only mild disease.

Test Protocol

Diagnostic accuracy studies should describe the index text well enough to reveal sources of variation between similar tests.

Test technology can evolve over time, improving the diagnostic accuracy of a test. For example, the glycated hemoglobin A_{1c} (HbA_{1c}) methods used in 1993 produced strikingly different results and the National Glycohemoglobin Standardization Program was established to better harmonize methods, and dramatic improvements followed under its leadership.[25] For example, by 2008, harmonization between methods was so successful that HbA_{1c} was recommended for diagnosis.[33]

Verification Procedure

How should the presence or absence of the target condition be established? This question introduces the concept of *verification bias.* The ideal verification of study subjects would rely on a single, instant, 100% accurate reference standard that is independent of the index text.[46] Unfortunately, finding an ideal medical reference standard is rare.

Improper Reference Standard

Often, alternative candidates for gold standards exist, and this confounds simple interpretation. For example, Cooner and associates[11] assumed that patients who had negative ultrasound and digital examination results had no prostatic disease. Based on this assumption, they derived estimates of the performance of the PSA assay in detecting disease. Their standard for the establishment of disease absence was the assessment of biopsy and other test results. This type of reference standard underestimates disease burden cases. When step sections of prostates obtained at autopsy or from patients undergoing radical cystectomy were examined, prostatic carcinoma was found at a rate more than 10 times higher than Cooner and associates had estimated.[13,17,21,26,34] The silent fraction of nonsymptomatic control subjects who were called "normal" in Cooner's study clearly were not free of carcinoma. This resulted in a higher estimate of the disease detection capability (sensitivity) of PSA at a specific decision threshold.

A more subtle issue here is the designation of a true-positive result. Medical professionals have been both frustrated and protected in the past owing to their inability to detect early-stage limited disease; they have been frustrated because earlier detection often would have offered the opportunity to treat disease at a time when a cure is possible, and protected because the temptation to overtreat incidental, clinically insignificant disease did not come into play because of detection limits. This protection is diminishing as the sensitivity and specificity of diagnostic tools increase. The desire to detect early disease now must often be tempered by reflection on what is clinically relevant disease.

It would appear that examination of step sections of patient prostates, although more difficult, might at first seem to be as near an absolute gold standard as possible. However, a great majority of prostatic carcinomas (>99%) are clinically indolent and do not decrease life span or increase morbidity.[15,37] A more reasonable true-positive result should reflect identification of those carcinomas that will progress to cause increased morbidity or mortality if neglected.

In the case of prostatic carcinoma, it has been argued that the size of the carcinoma is the best predictor of morbidity and mortality.[15,37] Minimum tumor sizes from 0.2 to 3 cm^3 have been suggested as worth detecting.[15,37] The Hybritech PSA assay uses 4 µg/L as its cutoff. This can be shown to correspond to an average prostatic carcinoma volume, if present, of approximately 1.3 cm^3.[8,39] A tumor of this size would serve

as a reasonable cutoff for a gold standard,[47] but it is difficult to size a tumor before complete prostate removal. Using the biopsy as a gold standard is also problematic. Biopsy will detect clinically insignificant disease by chance, but will miss large tumors owing to sampling error. Yet, by its nature, the sampling error of the biopsy is weighted in favor of ignoring small tumors and detecting large ones.

A subtle example that involves both spectrum variation and improper verification can be seen in the well-known study by Light and coworkers[23] of the utility of the ratio of activity of serum lactate dehydrogenase to that of pleural fluid lactate dehydrogenase. Results appear to document excellent differentiation between effusions and transudates. Unfortunately, when a clinical diagnosis could not be made using the remainder of the clinical information available, the case was excluded from the analysis. For remaining cases, the test offered excellent discrimination. One would expect that small malignancies, which would be less obvious clinically, would have a more indeterminate ratio. The lack of a gold standard resulted in an overly optimistic appraisal of the test's ability to discriminate between effusions and transudates. Similarly, assumptions have been made about the existence of prostatic disease in nonsymptomatic patients, because it has been impractical to take biopsy specimens from these individuals.

Independence

The index test should not be incorporated as part of the reference standard. Some studies have used elevated PSA as a criterion for determining which patients should undergo biopsy. When the test in question is used to determine which patients will have the gold standard test and which ones will be included in the diagnostic set, *test referral bias* occurs. Test referral bias can be shown to erroneously increase the true-positive rate in a study population compared with the clinically relevant population.[36]

Partial Verification

Partial verification occurs when a subset of subjects are evaluated with the reference standard. In a systematic review, Mol and colleagues[27] reported on the effects of partial verification in studies evaluating the usefulness of nuchal translucency for detecting Down syndrome. Ten of the 25 studies suffered from partial verification and reported higher sensitivities than were reported by nonbiased studies.

COST-EFFECTIVENESS AND OUTCOMES RESEARCH

Optimal use of the laboratory requires examination of both the cost of obtaining the result and the value or quality of the information obtained. Determining the quality of various procedures in medicine has been a subject of increasing interest. Key aspects of value received include the amount of improvement noted in healthcare, the extent to which testing is consistent with the wishes and expectations of patients, and the degree to which testing addresses social concerns as embodied in laws and regulations.

The Clinical Laboratory Improvement Act of 1967 (CLIA '67) and the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88) mandate quality control and external quality assurance programs in large part as an effort to address social concerns regarding the quality of testing results. The U.S. Congress appropriated $1.1 billion for Comparative Effectiveness Research (CER) as part of the 2009 American Recovery and Reinvestment Act.[19]

Only indirect measures of the quality of testing in terms of individual or population health benefit are available. The most valuable instruments for measuring the quality of a healthcare intervention, including laboratory testing, assess healthcare outcomes. Outcomes are defined and discussed in Chapter 4. By connecting specific analytical procedures and performance to patient outcomes, it may be possible to directly trade off the increase in cost associated with achieving enhanced performance for actual patient benefit. New tests are often heralded into medical practice enthusiasm. Some are used for years before mounting evidence of their lack of utility becomes available.

An example of the issues involved is seen in the outcomes analysis of screening for prostate cancer. Prostate screening programs are increasing each year, partially accounting for a 600% increase in radical prostatectomies between 1984 and 1990.[29] For each man who dies each year from prostate cancer, prostate cancer progresses slowly in a much larger number, never causing any morbidity. Screening is expensive, and the iatrogenic side effects of surgical treatment for prostate cancer are significant. As a result of these observations, studies have called into question the overall cost-effectiveness of prostate screening. In 2004, Stamey and colleagues concluded that PSA was no longer useful for prostate cancer screening.[38] Their 20-year study showed that in recent years, PSA was related to prostate size, not to the presence of prostate cancer. They concluded that new tests should be sought.

CHAPTER 4

Evidence-Based Laboratory Medicine

Christopher P. Price, Ph.D., F.R.S.C., F.R.C.Path.,
Patrick M. M. Bossuyt, Ph.D.,
and David E. Bruns, M.D.

This chapter expands upon the "Principles of Laboratory Medicine." We begin with consideration of the meaning of the term *laboratory medicine* and then go on to describe the role that laboratory medicine plays in an individual's well-being and in patient care. We describe the concepts of evidence-based medicine (EBM) and evidence-based practice (EBP), and illustrate how these are equally applicable to the practice of laboratory medicine. The remainder of the chapter focuses on key concepts of evidence-based laboratory medicine (EBLM). It is hoped that the reader will see these principles as defining one of the key tools operating at the interface between the basic science of medicine and the analytical science applied to diagnostic testing, leading to an emphasis on improving health outcomes. Key chapter topics include diagnostic accuracy of tests, prognostic accuracy of tests, health outcome studies, economic evaluation of diagnostic tests, systematic reviews of diagnostic tests, clinical practice guidelines, and clinical audit. The principles provide a foundation for the rational and appropriate use of diagnostic tests.

CONCEPTS, DEFINITIONS, AND RELATIONSHIPS

In this section, laboratory medicine and its major disciplines are defined, and consideration is given to the roles that they play in the provision of healthcare and well-being.

What Is Laboratory Medicine?

As described in Chapter 1, the term *laboratory medicine* refers to the discipline involved in the selection, provision, and interpretation of diagnostic testing, together with the associated decision making, which uses primarily samples of biological fluids provided by patients. The field of laboratory medicine comprises a number of disciplines, including clinical chemistry (also known as clinical biochemistry), hematology, blood banking (transfusion medicine), clinical immunology, microbiology, and virology. Within this structure there may be a range of subdisciplines, such as toxicology and drug monitoring, endocrinology, hemostasis, genetics, parasitology, and mycology. In some parts of the world, laboratory medicine also encompasses cytology and anatomic pathology (histopathology). However, from the perspective of the patient and the clinical user, these are artificial delineations, as they see the laboratory as a single key diagnostic resource that plays a critical role in clinical decision making. Molecular techniques have come into routine use in recent years, often being developed from an initial academic interest in one particular part of laboratory medicine (e.g., biochemical genetics, identity testing, bacterial subtyping). However, these techniques are being used more widely across the spectrum of laboratory medicine; thus although the analytical element of the service may be consolidated, the emphasis now is on the integration of information to address the clinician's or the patient's needs. Indeed, with the advent of more complex automation, integrating a wider range of analytical methods onto a single platform, aligned with high throughput capability, the boundaries between disciplines are becoming blurred (e.g., with the advent of "blood sciences" laboratories). This notwithstanding, the analytical components of these specialties are delivered from central laboratories or through a more distributed type of service involving smaller satellite laboratories and point-of-care testing (POCT), or both.

Although the core of the practice of laboratory medicine is based on the preanalytical, analytical, and postanalytical elements of routine service, it is underpinned by research and education (with respect to users of the service, as well as those delivering the service), with the whole delivered efficiently through strong clinical leadership and business management. In many cases, the laboratory medicine service also encompasses clinical service, involving direct patient care. The preanalytical service is concerned with ensuring that the *right* patient gets the *right* test at the *right* time, while the analytical service is concerned with getting the *right* result. The postanalytical service works to ensure the *right* interpretation of the result, that the *right* decision is made, and that the *right* action is taken—with the overall objective of obtaining the *best outcome* for the patient. Quality management of the whole process is an important feature of both leadership and

management of the service, including service accreditation and clinical governance embracing data management, quality control and proficiency testing, clinical audit, and benchmarking. Some of the concepts of good laboratory practice are discussed in greater detail in other chapters, including automation (see Chapter 19), quality control and quality management (see Chapter 8), and the theory and practice of reference values (see Chapter 5), as well as the broader concept of the use of diagnostic tests (which are illustrated in several of the ensuing chapters). However, it is worth pointing out at this early stage that the term *diagnostic test* is a bit of a misnomer, as the test result is not always used to make a diagnosis; this will be discussed in greater detail when we discuss the underlying concepts of EBM and EBLM.

The use of the laboratory medicine service will vary according to the perspective of the customer, or user. Thus the patient may be interested in one specific question, as might the clinician at the time that he/she sees the patient. They and others may take a longer term view, looking at the way the service can help in longer term management of the patient. The purchaser or commissioner of the service, as well as a policymaker, may take a more holistic view, embracing the full care pathway, or patient journey—a journey in which the laboratory may play different important roles at different stages. Furthermore, different stakeholders may have different expectations.[98] It can be helpful in understanding this to consider the care pathway and the points at which testing may be relevant in a hypothetical pathway, as illustrated in Figure 4-1. Thus testing in laboratory medicine may be directed at (1) *screening* an asymptomatic individual for early evidence of the presence of disease, (2) *confirming* a clinical suspicion (which could include *making* a diagnosis), (3) *excluding* a diagnosis, (4) assisting in the *selection* and *optimization* of treatment, (5) *monitoring* compliance with a treatment protocol, and (6) providing a *prognosis*. Within this framework, test results can be used to establish and monitor the severity of a pathologic disturbance.

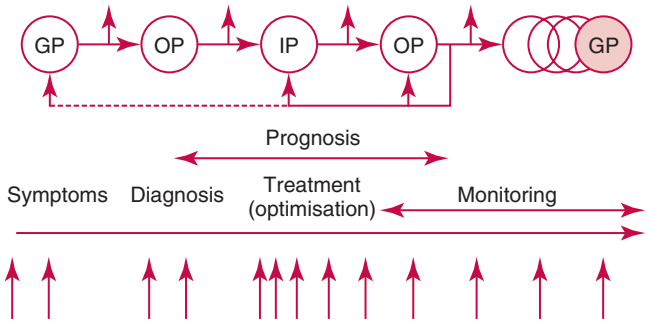

Figure 4-1 A hypothetical patient pathway, different types of clinical questions, and the point at which a diagnostic test might be used. At the point where a diagnosis might be made, it might be a rule-in or a rule-out decision and might include a question about prognosis. *GP,* General practitioner or primary care physician; *IP,* inpatient episode; *OP,* outpatient visit; ↑, point at which a diagnostic test might be required.

WHAT IS EVIDENCE-BASED MEDICINE?

In this brief section, EBM is defined, and its concepts and objectives are outlined; this is followed by a discussion of how these concepts are applied in laboratory medicine.

Definitions, Concepts, and Objectives of Evidence-Based Medicine

EBM has been defined as "the conscientious, judicious, and explicit use of the best evidence in making decisions about the care of individual patients."[121] It has been described in terms of "the integration of best research evidence with clinical expertise and patient values."[51] A key objective of EBM is "to incorporate the best evidence from clinical research into clinical decisions."[51] The words and phrases of these succinct definitions and descriptions of EBM warrant further examination and thought, as they reflect many of the reasons for the development of these concepts, as well as some of the challenges we face in laboratory medicine.

EBM has also been described as "trying to improve the quality of the information on which decisions are based" and in terms of "thinking not about mechanisms but about outcomes."[44] This comment indicates that the importance of EBM lies not in focusing on the science of the condition, or the pathology of the disease, but on how the intervention (test or treatment) can improve the health outcome. The first comment by Glasziou speaks[44] of "the quality of the information" akin to the "best evidence," referred to in the definition by Sackett and associates,[121] both groups emphasizing the use of such information in making decisions. This is why the concepts of EBM are applicable to laboratory medicine, as laboratory medicine is one of the fundamental tools used in making decisions about the care of patients in the practice of medicine.

The concepts of EBM and EBP were derived from initial discussions among a group of epidemiologists at McMaster University preparing a series of articles advising clinicians on how to read clinical journals. Out of these discussions came the term *critical appraisal;* later, the idea of bringing "critical appraisal to the bedside" was born. Implicit in this thinking was the need for good quality evidence and the ability to appraise that evidence and to determine whether it was applicable to the problem at hand and the decision(s) to be made. The initial group grew and evolved into the Evidence-Based Medicine Working Group under the leadership of Gordon Guyatt. The term *evidence-based medicine* first appeared in an editorial by Gordon Guyatt in 1991,[48] and the Working Group subsequently went on to produce a portfolio of papers under the title, *Users' Guides to the Medical Literature.*[51] Many books have now been written on the concepts, teaching, and practice of EBM which illustrate its origins in clinical epidemiology, as well as the challenges faced in adopting this approach to the practice of medicine and to healthcare management and policymaking.[44,93,119,138] Today many thousands of papers and many textbooks address the application of EBM and EBP in all branches of medicine.

The justifications for an evidence-based approach to medicine are founded on the constant requirement for

information,[103] the constant addition of new information,[92] the poor quality of access to good information,[1] the decline in up-to-date knowledge or expertise or both with advancing years of an individual clinician's practice,[24] the limited time available to spend with the patient, let alone read the literature,[122] and the variability in individual patients' values and preferences. To this one might add, particularly in relation to laboratory medicine, (1) the lack of awareness of the clinical questions being asked by clinicians, with a consequent lack of focus on patient benefit, (2) the limited number and poor quality of studies linking test results to patient benefit,[85] (3) the poor perception of the value of diagnostic tests, (4) the ever-increasing demand for tests, and (5) the disconnected approach to resource allocation (reimbursement) in laboratory medicine—*silo budgeting*—which addresses only laboratory costs without consideration of benefit outside the laboratory, thus forcing decisions to save expense in the laboratory with insufficient attention to the needs of patients, their caregivers, and payers.

The Practice of EBM

Guyatt and colleagues[49] summarized the practice of EBM as follows: "An evidence-based practitioner must understand the patient's circumstances or predicament; identify knowledge gaps and frame questions to fill those gaps; conduct an efficient literature search; critically appraise the research evidence; and apply that evidence to patient care."

Efficient, and effective, practice of EBM requires the following:

- Knowledge of the *clinical process* and the ability to convert the clinical problem into an answerable question
- Facility to generate focused clinical questions
- Facility to generate evidence [i.e., information (through primary research or searching of the literature)]
- The ability to critically appraise information to generate knowledge
- A critically appraised knowledge resource
- The ability to use the knowledge resource
- A means of accessing and delivering the knowledge resource
- The ability to apply the knowledge appropriately to the clinical problem
- The ability to integrate the knowledge with previous experience in the context of the problem at hand
- A framework of clinical and economic accountability
- A framework of quality management, namely, proper clinical and financial governance

The identification of a clinical problem is both the starting point and the foundation of the service provided by the healthcare professional. Doctors and other healthcare professionals are constantly asking questions, and these can be divided into background questions and foreground questions. *Background questions,* to date more commonly observed being asked by newly qualified professionals by virtue of the way they have been taught, typically deal with knowledge (or underlying science) of the condition (e.g., Why is the circulating level of troponin I increased in a patient suffering with an acute coronary syndrome?). *Foreground questions* are related specifically to the application of knowledge, of experience in treating the condition and using tests (e.g., Will a troponin I measurement help me determine whether this patient is suffering from an acute coronary syndrome?). Clinicians tend to ask more foreground (and fewer background) questions as their experience develops. This may change in coming years as a more evidence and outcomes–based approach to teaching medical students, and training doctors, evolves. Richardson and coworkers[115] argued that all clinical problems could be expressed in the form of a question, and went on to describe a framework for formulating an answerable question: the PICO framework. This will be described in detail later, when the practice of EBLM is discussed. In the area of laboratory medicine, as described later in this chapter, the goal can be expressed in terms of answering a clinical question; appropriate laboratory investigations help to answer the question.[108,109,112] Knowledge of the characteristics of these investigations is needed to decide which test to use, when to use it, and how to interpret the results.

Finding and appraising knowledge that is relevant to the question requires awareness of available information resources, ready access to them, an ability to search the resources effectively, and an ability to critically appraise the relevance of available data. If no evidence is available, then consideration should be given to undertaking a piece of research; in this case, a correctly formulated question becomes the core of the research question. This is called *primary research;* searching for and critically appraising existing peer-reviewed research literature is called *secondary research.*

A knowledge resource in the form of a systematic review (see later in this chapter) should provide critically reviewed evidence of the efficacy, benefits, limitations, and risks of using a test, intervention, or device. Access classically has been gained through scientific journals and textbooks; electronic communications of various sorts (including textbooks and journals) are making access faster and more up-to-date. Professional bodies are now beginning to move away from narrative review to the generation of practice guidelines, their synthesis being based on the discipline of critical appraisal and the process of systematic review. Indeed many health purchasing and commissioning organizations are looking to agencies [e.g., the Agency for Health Research and Quality (AHRQ), www.ahrq.gov, accessed on February 12, 2009] and the National Institute for Health and Clinical Excellence (NICE) (www.nice.org.uk accessed on February 12, 2009) to develop practice guidelines through identification of the best evidence available, generated through both primary and secondary research.

Knowledge on the use of a test or intervention ultimately has to be placed in the context of a framework for clinical and economic accountability, ensuring the highest quality and lowest risk to patients within the resources available. One of the biggest challenges lies in the implementation of new practices and of required changes in existing practices. Many anecdotes tell of a new test being introduced to replace an old

test, with the old test remaining on the repertoire of the laboratory! A major part of the implementation process is the education of those involved in using the new test or treatment. Clinical audit, a key element of meeting this objective, underpins the process of clinical governance.

EVIDENCE-BASED MEDICINE AND LABORATORY MEDICINE

When a doctor first sees a patient, that doctor will go through a routine of questioning and observing to identify the signs and symptoms that may be associated with the current health problem; from this process, he/she seeks to establish hypotheses about their etiology. Competing hypotheses may need to be resolved; this may be done in a number of ways, leading to a working diagnosis. Signs and symptoms alone may lead to a diagnosis, or the doctor may want to perform a number of diagnostic tests, including those offered by laboratory medicine. In some cases, the definitive diagnosis may become clear only over time as the nature of the condition evolves, or when a treatment is given (e.g., in the case of prescribing antibiotics in certain situations). In rare instances, a diagnosis is made only following death, with the aid of an autopsy. After a diagnosis, or working diagnosis, has been made, decisions can be made about the process of providing further care (e.g., to treat or not to treat). At this time, in some instances, the nature and severity of the condition will also be assessed to provide a prognosis. Each of these steps, as will be described later, represents a clinical problem (or clinical question) requiring a decision to be made—and action taken. The services of laboratory medicine are included among the tools at the disposal of the clinician to answer questions posed along this pathway, from initial hypothesis generation through to decision making.[119]

The tools of laboratory medicine are called *diagnostic* tests, but—as was mentioned earlier—these tests are used far more broadly than in making a diagnosis. As mentioned earlier and discussed later, they are also used in making a prognosis, excluding a diagnosis, monitoring a treatment or disease process, screening for disease, selecting therapy, evaluating the effects of therapy, and looking for side effects. The process of using a diagnostic test can be described as two processes: one at a macro level, and the other at a micro level. These are illustrated in Figures 4-1 and 4-2.

What Is Evidence-Based Laboratory Medicine?

EBLM is simply the application of principles and techniques of EBM to laboratory medicine. A clinician requesting an investigation has a question and needs to make a decision. The clinician hopes that the test result will help to answer the question and will assist in making the decision. Thus a definition of evidence-based laboratory medicine could be "the conscientious, judicious, and explicit use of best evidence in the use of laboratory medicine investigations for assisting in decision making about the care of individual patients." It might also be expressed more directly in terms of health outcomes as "ensuring that the best evidence on testing is made available, and the clinician is assisted in using the best evidence to ensure that the best decisions are made about the care of the individual patient, and that the probability of improved health outcomes increases." As discussed later, clearly the primary focus is on improving clinical outcomes, but in the delivery of the routine laboratory service, it is also important to consider the operational and economic impact of laboratory investigations.[107,109,112]

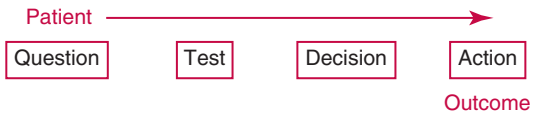

Figure 4-2 A summary of the process from a question leading to a test request, through to action leading to outcome.

The Practice of Evidence-Based Laboratory Medicine

The practice of EBLM employs the skills that have been identified in the practice of EBM, and it is important to acknowledge that the context in which EBLM is practiced is exactly the same as for EBM, focusing on the patient and overall improvement of health outcomes. Three key questions need to be answered:

- Is it a good test?
- If the test is used properly, will it improve patient outcomes?
- Is it worth investing in the test?

A good test is one that reliably answers the question being asked. To do this, the test has to meet three criteria, as will be described in other chapters of this book: (1) analytically the test has to meet accuracy and precision criteria (see Chapter 2), (2) the biological variability and other preanalytical criteria must be understood, and (3) given that the first two criteria are met, the test result must provide an answer to the question being asked; this is called *diagnostic accuracy* (see Chapter 3).

However, having a good test is not sufficient. It has to be used properly, as part of an integrated pathway of care. This is often summarized as "ensuring the *right* patient, gets the *right* test, at the *right* time, that the *right* result is generated, the *right* decision is made, and the *right* action taken, in order that the *right* outcome can be delivered."[112] This is about ensuring that the use of a test leads to a better outcome.

It is also important to be aware of the cost of care, and so it is important to be aware of the value of a test—looking at the value of the test in the immediate context of the care pathway, and more broadly the patient journey, and society as a whole—rather than limiting understanding to the cost of providing the test.

The basic tools required to practice EBLM can be summarized in the A5 cycle for EBLM (Figure 4-3). This EBLM cycle embraces five areas of activity related to the clinical problem[112]:

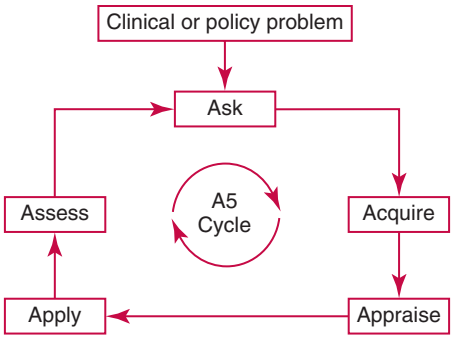

Figure 4-3 The A5 evidence-based laboratory medicine (EBLM) cycle. *(Adapted from Price CP, Lozar Glenn J, Christenson RH. Applying evidence-based laboratory medicine: a step-by-step guide. Washington, DC: AACC Press, 2009.)*

- Asking or formulating the question that describes the problem
- Acquiring the evidence that addresses the question
- Appraising the evidence for relevance and quality
- Applying the knowledge gained from the evidence in resolving the problem
- Assessing or auditing the application to test the process of application, as well as the robustness of the knowledge

However, this may not be enough, and it is helpful to know where and when these skills may be required (i.e., the context).[112] Some examples of the scenarios in which EBLM skills have been applied are given in Table 4-1, and it is evident that a question is being asked in each of these scenarios—from patient through to policymaker.

Types of Questions Addressed in Laboratory Medicine

Referring back to the hypothetical patient, or care, pathway illustrated in Figure 4-1, a number of questions are being asked during the course of this journey. Obviously a patient does not necessarily progress down the whole pathway, as the problem may be resolved by a simple intervention at an early stage. The key clinical questions can be summarized as follows:

- Does this patient have any evidence of the condition? A screening question
- Does this patient have condition X? A "rule-in" diagnostic question
- Can I rule out the patient having condition X? A "rule-out" question
- What is this patient's prognosis? A prognosis question
- Will this treatment work for this patient? A treatment selection question
- Have I got the dose right? A treatment optimization question
- Is this treatment working for this patient? A treatment effectiveness question
- Is the patient following the treatment protocol correctly? A treatment adherence question

Clearly not every question applies in all situations. However, this is not the only perspective that should be considered in the commitment to delivering the highest quality of healthcare. Donabedian[28] advocated an approach to assessing the quality of care based on *structure, process,* and *outcome.* So although the above may represent the main clinical questions, which for these purposes might be grouped under the heading of "Structure," we have also to consider the questions surrounding process and outcomes, and how laboratory medicine services have an impact on these elements of healthcare delivery. We will return to these considerations later.

In the first case, the question relates to the use of a test to screen for early signs of a condition, and in individuals with no evidence of the condition (asymptomatic individuals). Thus an example would be the use of the urine albumin : creatinine ratio to screen for early indications of renal dysfunction in a patient with diabetes. A second example would be the use of fecal occult blood measurement for the early detection of colon cancer in people over the age of 50 years. In both instances, the tests identified are *first-line tests,* and further testing would be undertaken to make or refute the putative diagnosis. Well-accepted criteria for the use of a screening test are often used when population screening is established, as in the second example. These criteria include the diagnostic performance of the test, as well as the existence of an effective treatment and demonstration of improved outcomes for those detected and treated in such a program. So, we are already seeing the close link between the diagnostic test and the intervention when looking at the outcome.

In the second and third cases, the doctor has a clinical suspicion, presumably based on signs and symptoms, and has developed a diagnostic hypothesis, that is, a diagnosis is being sought (rule-in) or rejected (rule-out). A positive diagnostic conclusion would lead to a decision on some form of action, which often involves an intervention. The intention would always be that the cascade from diagnostic question through result, decision, and action should lead to an improved outcome. An example of this scenario in which a test has been used to rule-in a diagnosis would be when a test for acetaminophen indicates that an excessive amount of drug has been ingested, and administration of *N*-acetylcysteine reduces the risk of a fatal outcome. Measurement of acetaminophen in this scenario is referred to as a *rule-in test.* In the scenario for a *rule-out test,* the actions resulting from excluding a diagnosis will invariably involve the evaluation or creation of another hypothesis, and possibly consideration of additional tests. Thus, as an example, when a patient is admitted with atypical chest pain and acute myocardial infarction is suspected, the measurement of troponin may be used to rule-out (or rule-in) acute myocardial necrosis.

At the time that a diagnosis is made, an investigation of prognosis is often undertaken, which may be considered as the assessment of risk. For example, measurement of human immunodeficiency virus (HIV) RNA plasma concentration following initial diagnosis of HIV infection can be used to predict the time interval before immune collapse if the condition is not treated.

Once a diagnosis has been made, consideration moves on to patient management, and it is in this sphere of care that

TABLE 4-1 Examples of Clinical Questions for Which a Laboratory Assessment May Be of Value, and the Associated Action and Potential Outcome (Benefit)

Test	Question	Result	Action	Outcome
Rule-in				
B-type natriuretic peptide (BNP)	Is this breathless patient suffering from heart failure?	450 ng/L	Confirm with cardiac ultrasound, decide to admit and treat	Reduced symptoms, improved morbidity and mortality
Troponin I (TnI)	Has this patient had a myocardial infarction?	7.2 µg/L	Decide to admit, intensity of care required, and treat	Improved morbidity and mortality
Thyroid-stimulating hormone (TSH)	Does this child have hypothyroidism?	12.2 mIU/L	Treat with thyroxine	Improved morbidity and mortality
Urine leukocyte esterase (LE) and nitrite	Does this patient have a urinary tract infection?	Positive LE, positive nitrite, or both	Send urine to laboratory for microscopy, culture and sensitivity, and treat if positive	Appropriate use of antibiotics, improved morbidity
Rule-out				
BNP	Is this breathless patient suffering from heart failure?	56 ng/L	Seek alternative diagnosis	Avoid incorrect diagnosis and treatment
TnI	Has this patient had a myocardial infarction?	<0.1 µg/L	Consider other possible diagnoses and early discharge	Less worry for patient, reduce unnecessary admissions to cardiac care unit
TSH	Does this patient have hypothyroidism?	2.1 mIU/L	No further action	Any parent disquiet allayed
Urine LE and nitrite	Does this patient have a urinary tract infection?	Normal dipstick result	Do not send urine to laboratory, look for alternative causes of symptoms	Inappropriate antibiotic treatment avoided, unnecessary laboratory work avoided
Monitoring				
BNP	Is this patient taking the correct dosage of β-blocker?	No change	Review dosage and patient compliance	No change in symptoms, risk of cardiac event, more clinic visits
BNP	Is this patient taking the correct dosage of β-blocker?	Fallen from 500 to 160 ng/L	No change to dosage, encourage patient	Reduced symptoms and risk of cardiac event
HbA_{1c}	Is this patient complying with treatment protocol?	10.6% (no change in a year)	Consider changing treatment, closer monitoring of compliance, clinic visits, and consultations with diabetes nurse	Increased risk of complications
HbA_{1c}	Is this patient complying with treatment protocol?	5.8%	Congratulate patient, maintain treatment regime	Reduced risk of complications

TABLE 4-1 Examples of Clinical Questions for Which a Laboratory Assessment May Be of Value, and the Associated Action and Potential Outcome (Benefit)—cont'd

Test	Question	Result	Action	Outcome
Prognosis				
BNP	Is this patient's heart failure deteriorating?	Increase from 450 to 2400 ng/L in last year	Advise on palliative care	Poor prognosis
TnI	What is this patient's risk of a further cardiac event?	0.9 μg/L	Consider intervention (e.g., stent)	Increased risk without intervention
Her-2/*neu*	What is this patient's prognosis?	3+ by immunohistochemical staining at primary diagnosis	Consider Herceptin treatment	Poor prognosis

laboratory investigations provide the greatest level of support, certainly as measured by the volume of investigations performed. It is also the most complex area, with tests being used to answer a range of questions, including (1) whether a particular drug is likely to be effective, (2) whether the patient is at risk of suffering an adverse reaction, (3) how to guide the dosing of a drug, (4) how to check for the occurrence of adverse reactions, and (5) in a patient with a chronic disease, how to check for compliance with, and effectiveness of, therapy. In women with metastatic breast cancer, the HER-2/*neu* status is used to assess the potential usefulness of Herceptin therapy. In patients with inflammatory bowel disease prescribed azathioprine, the thiopurine methyltransferase activity status is assessed to warn of the risk of myelosuppression in those with a deficiency of the enzyme. In patients treated with methotrexate, hepatic and kidney function tests are performed at regular intervals to check for evidence of hepatic and renal toxicity. In patients with heart failure, brain natriuretic peptide measurement has been used to guide, or optimize, therapy. Finally, in a person with diabetes, HbA_{1c} measurements are used to assess glycemic control and thus the effectiveness of therapy.

These scenarios illustrate the importance of identifying the triad of *question, decision,* and *action*. Identifying these three components proves to be critical in designing studies of utility or outcomes of testing, as well in the critical appraisal of evidence. They are also important in audit (see later) of the use of investigations from the perspective of both clinical governance (clinical accountability) and financial governance (controlling the test demand in the context of economic governance). Recognition of this triad has led to the definition of an *appropriate test request* as one in which there is a clear clinical question for which the result will provide an answer, enabling the clinician to make a decision and initiate some form of action leading to a health benefit for the patient.[108] In light of the earlier comment, this benefit could be extended to the health provider and to society as a whole to encompass more directly the potential for economic benefit.

BOX 4-1 Examples of Questions That Can Be Asked in Different Settings

Clinicians inquire about what test to use
Clinicians inquire how to use a test
Clinicians and patients inquire about the meaning of a specific test result
Clinicians inquire about what decision to make upon receipt of a test result
Clinicians and patients request the introduction of a new test
Managers request a business case for the introduction of a new test
National health policymakers want to introduce a screening program
Laboratory director requires evidence of method performance and the impact on outcome
Managers want to change the mode of delivery of care (e.g., to a community setting)
Managers request an audit of utilization of a test
Laboratory director wishes to stop the use of a test

Examples of questions that specify the detail required to accurately qualify the use of a test result are given in Box 4-1. In practice, the clinical episode involves a series of diagnostic questions with binary responses.[20]

Formulating an Answerable Question in Laboratory Medicine

Reference was made earlier to the PICO framework for the formulation of an answerable question; in its general form, PICO comprises four elements, as illustrated in Box 4-2.

A number of variants of this framework have been described. Given the patient pathway described in Figure 4-1 and the different stages at which a test might be used, the addition of "S" for *setting* has been suggested, giving PICOS or PSICO. The alternative is to qualify the "P" for population or patient according to setting, so that only data appropriate

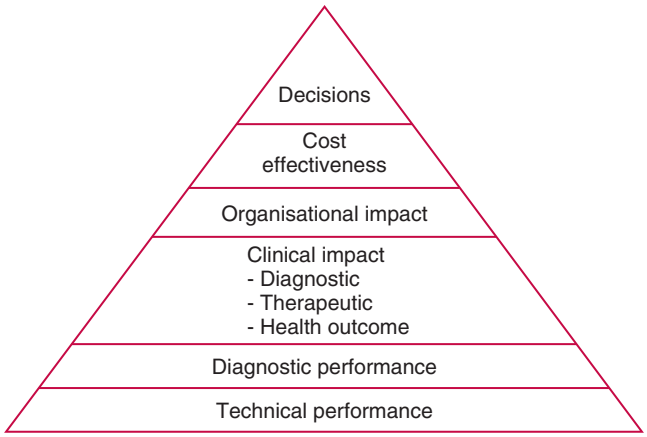

Figure 4-4 A hierarchy of evidence for decision making from technical performance through to impact on health outcomes. *(Adapted from Price CP. Evidence-based laboratory medicine: supporting decision-making. Clin Chem 2000;46:1041-50.)*

BOX 4-2 The PICO Framework: The Core of Structured Question Formulation for Diagnostic Tests

Population, patient, or problem of interest
Intervention, which in laboratory medicine could be the test of interest—the index test
Comparator or control, against which the intervention will be compared
Outcome, which may vary according to the question or the type of study

to that setting are considered. Clinicians who use probabilistic reasoning and likelihood ratios may wish to know the probability associated with the use of earlier tests or observations, and in this case "P" for *prior test* has been suggested, giving PPICO. Finally, time is an important consideration when tests are used (e.g., when looking at the prognostic accuracy of a test and the time over which a patient is observed after the laboratory test has been performed). The time at which samples are taken may also be important (e.g., when the effectiveness of digoxin therapy is monitored). This has led to the use of PICOT.[112]

From Evidence to Outcomes

Fryback and Thornbury[40] developed a hierarchy of evidence in support of their thesis that patient outcome data are the sine qua non of efficacy from the individual patient's perspective. This has been applied to laboratory medicine and is illustrated in Figure 4-4.[107] Surveys of the literature, as well as many systematic reviews, have shown that many of the papers concerned with laboratory medicine, to date, have been concerned with technical (namely, analytical accuracy and precision) and diagnostic (namely, diagnostic accuracy) performance.

Sackett and Haynes[120] described an "architecture for diagnostic research," which was based on four questions:

- Do test results in affected patients differ from those in normal individuals?
- Are patients with certain test results more likely to have the target disorder?
- Do test results distinguish patients with and without the target disorder among those in whom it is clinically sensible to suspect the disorder?
- Do patients undergoing the diagnostic test fare better than similar untested patients?

The first of these questions deals with the basic diagnostic accuracy question, basic because it does not take into consideration the setting in which the question is being asked—which is covered in the third question. The fourth question is the outcome-related question.

CHARACTERIZATION OF THE DIAGNOSTIC ACCURACY OF TESTS

When a new test is developed or an old test is applied to a new clinical question, users need information about the extent of agreement of the test's results with the correct diagnoses of patients. For this purpose, researchers design studies in which results from the new test are compared with results obtained with the clinical reference standard on the same patients. Results of the comparison can be expressed in a number of ways, including clinical sensitivity and specificity, predictive values, likelihood ratios, diagnostic odds ratios, and areas under receiver operating characteristic (ROC) curves (see Chapter 3). We refer to such studies as diagnostic accuracy studies.

Study Design

The following discussion is applicable to the design of a primary research study, in critical appraisal in secondary research, and in the application of information gained from research.

In studies of diagnostic accuracy, the results of one test (often referred to as the index test, the test of interest—I in the PICO framework) are compared with those from the clinical reference standard (sometimes referred to as the reference test). A test can be any method of obtaining additional information on a patient's health status, including not only laboratory tests, imaging tests, and function tests, but also data from the history and physical examination, and genetic data.

The *clinical reference standard* is the best available method for establishing the presence or absence of the target disease or, more generally, the target condition, that is, the suspected condition or disease for which the test is to be applied. The reference standard can be a single test, or a combination of methods and techniques, including clinical follow-up of tested patients. When there is no clear reference procedure, it has been suggested that the best way to assess a new test is by analyzing the consequences when there is disagreement between the new tests and the test in current use.[45] Finally, in some instances, the reference standard may consist of information obtained from an autopsy.

Several potential threats to the internal and external validity of a study of diagnostic accuracy are known, of which only the major ones will be addressed in this section. Poor *internal validity* will produce bias, or systematic error, because the estimates do not correspond to what one would have obtained using optimal methods, whereas poor *external validity* limits the generalizability of the findings, in that the results of the study, even if unbiased, do not correspond to settings encountered by the decision maker. For example, the results of a study of patients in a tertiary care medical center may not be generalizable to patients seen in a general practice, and studies done exclusively in older men may not be applicable to women or children. This shows the importance of the P element in the PICO framework, as well as the S variant.

The ideal study examines a consecutive series of patients, enrolling all consenting patients suspected of the target condition within a specific period. All of these patients then undergo the index test, and then the reference standard. The term *consecutive* refers to total absence of any form of selection, beyond the a priori definition of criteria for inclusion and exclusion, and requires explicit efforts to identify and enroll patients qualifying for inclusion.

Alternative designs are possible; Mol and associates have reviewed the characteristics of good studies of diagnostic tests.[91] Some studies first select patients known to have the target condition, and then contrast the results from these patients with those from a control group. This approach has been used to characterize the performance of tests in settings in which the condition of interest is uncommon, as in maternal serum screening testing for detecting Down syndrome in the fetus. It is also used in preliminary studies to assess the potential of a test before prospective studies of a series of patients are undertaken. With this design, selection of the control group is critical. If the control group consists of healthy individuals only, the diagnostic accuracy of the test will tend to be overestimated, as has been shown in an analysis that compared the results of such studies with results of studies of consecutive series of patients.[83] (See Chapter 3 for further discussion.)

In the ideal study, the results of all patients tested with the test under evaluation are contrasted with the results of a single reference standard. If fewer than all patients are verified with the reference standard, then *partial verification* exists, and verification bias may occur if the selection of subjects for reference testing is not purely random. For example, if selection is associated with the outcome of the index test, or the strength of prior suspicion, or both, then verification bias is certain. In a typical case, some patients with negative test results (test negatives) are not verified by the reference standard if this involves a costly or invasive procedure, and these patients are not included in the analysis. This may result in an underestimation of the number of false-negative results.

A different form of verification bias can happen if more than one reference standard is used and the two reference standards correspond to different manifestations of disease. The use of multiple standards can produce *differential verification bias*. Suppose test-positive patients are verified with further testing, and test-negative patients are verified by clinical follow-up. An example is the verification of suspected appendicitis, with histopathology of the appendix versus natural history as the two forms of the reference standard. A patient is classified as having a false-positive test result if the additional test does not confirm the presence of disease after a positive index test result. Alternatively, a patient is classified as false-negative if an event compatible with appendicitis is observed during follow-up after a negative test result. Yet these are different definitions of disease because not all patients who have positive pathology results would have experienced an event during follow-up if they had been left untreated. The use of two reference standards, one pathologic and the other based on clinical prognosis, can affect the assessment of diagnostic accuracy. It is likely to artificially inflate the estimates of accuracy, compared with the use of a single reference standard in all patients. For additional discussion, see Chapter 3.

A long-standing debate continues on whether or not clinical data should be provided to those performing or reading the index test, especially when that test has a subjective component. Withholding this information is known as *blinding* or *masking*. Often, some clinical information is routinely known by the reader of the test, such as when radiologists see the patients on whom they are performing a test, or a pathologist is told the site from which a biopsy is obtained. Attempts to withhold such information in the context of a study of diagnostic accuracy may create an artificial scenario that has no counterpart in patient care. Thoughtful attention to this question is important in the early phases of designing a study. For most study questions, masking is preferable, because knowledge of the results will tend to increase agreement of the results of the studied (index) test with those of the reference standard (test).

Severity of disease among studied patients with the target condition and the range of other conditions in those without the target condition can affect the apparent diagnostic accuracy of a test. For example, if a test that is designed to detect early cancer is evaluated in patients with clinically apparent cancer, the test is likely to perform better than when used for persons who do not yet show signs of the condition. This problem has been called *spectrum bias* and *spectrum variation* (see Chapter 3). Similarly, if a test is developed to distinguish diseased patients from those with similar complaints but without the target disease, then it may be misleading to use healthy subjects as controls when the diagnostic accuracy of the test is evaluated.

Reporting of Studies of Diagnostic Accuracy: The Role of the STARD Initiative

Complete and accurate reporting of studies of diagnostic accuracy should allow the reader to detect the potential for bias in the study and to assess its ability to generalize the results and their applicability to an individual patient or group. Reid, Lachs, and Feinstein[114] documented that most studies of diagnostic accuracy published in leading general medical journals had poor adherence to standards of clinical

epidemiologic research or failed to provide information about adherence to those standards.[7] Similar observations have continued to be made with a number of categories of tests.[86] These reports led to efforts at the journal *Clinical Chemistry* in 1997 to produce a checklist for reporting of studies of diagnostic accuracy.[15] The quality of reporting in that journal increased after introduction of this checklist,[84] although not to an ideal level.[11]

The work of Lijmer and colleagues[83] showed that poor study design and poor reporting are associated with overestimation of the diagnostic accuracy of evaluated tests, indicating the necessity to improve the reporting of studies of diagnostic accuracy for all types of tests, not only those in clinical chemistry. An initiative on Standards for Reporting of Diagnostic Accuracy (STARD) was begun at the 1999 meeting of the Cochrane Diagnostic and Screening Test Methods Working Group. This initiative aimed to improve the quality of reporting of diagnostic accuracy studies by following the model of the successful Consolidated Standards of Reporting Trials (CONSORT) initiative for reporting of trials of therapies (see discussion of outcomes studies later in this chapter).[9]

Key components of the STARD document include a checklist of items to be included in reports of studies of diagnostic accuracy and a flow diagram to document the flow of participants in the study.[9] The checklist was developed from an extensive literature search that identified 75 potential items. The list was pared to 25 items (Figure 4-5) in a consensus meeting of researchers, editors, methodologists, and representatives of professional organizations. The flow diagram (Figure 4-6) has the potential to clearly communicate vital information about the *design* of a study—including the method of recruitment and the order of test execution—and about the *flow* of participants.

The final, single-page checklist (see Figure 4-5) has been endorsed by numerous journals [such as *Journal of the American Medical Association (JAMA)* and *Annals of Internal Medicine*] and published in many of them, including all the major journals of clinical chemistry and other leading journals such as *Radiology*, *British Medical Journal (BMJ)*, and *Lancet*. A separate document explaining the meaning and rationale of each item and briefly summarizing the available evidence was published in *Annals of Internal Medicine* and *Clinical Chemistry*.[10] The STARD group will prepare updates of the STARD document when new evidence on sources of bias or variability becomes available. In the experience of one of the authors of this chapter (D.B.), use of the checklist has enhanced the information content of all manuscripts to which it has been applied at *Clinical Chemistry,* and use of the flow diagram has led to correction of errors in many manuscripts.

Use of the STARD initiative is recommended for all reports on studies of diagnostic accuracy. Most, if not all, of the content of STARD also applies to studies of tests used for prognosis, monitoring, or screening. It is interesting to note that Simel and coworkers recently reported on use of the STARD approach for reporting of diagnostic accuracy of the history and physical examination[133]; this is important in that laboratorians need to be aware of the role that these play in the diagnostic armamentarium of the practicing physician.[141] Smidt and associates[136] found a small improvement in reporting, specifically, in reproducibility of the index test, in assessment of the severity of the condition and other diagnoses, and in estimates of variability of diagnostic accuracy between subgroups. On the other hand, Wilczynski found no improvement to date.[151]

Using the Test Result

In the area of laboratory medicine, the objective can be described in terms of answering a clinical question; appropriate laboratory investigations help to answer the question.[108] Knowledge of the characteristics of these investigations is needed to decide which test to use, when to use it, and how to interpret the results.

The value of test results depends on consideration of a range of preanalytical, analytical, and postanalytical characteristics. Thus, evidence from a study may be unreliable when differences exist in age, sex, ethnic origin, lifestyle, prevalence of the disease in the population, or prevalence of comorbidities. Transferability of study results may be affected by analytical variables, such as patient preparation (effects of fasting, posture, exercise, and biological variation) and method performance (accuracy and precision).

Analytical performance of the test may also have an impact on the outcome of the use of that test, although this is not a factor that is commonly studied. Some information has come from modeling studies, as for example in the case where the impact of the accuracy and precision of blood glucose tests on insulin dosage has been calculated.[13] The impact of the accuracy and precision of total prostate-specific antigen (PSA) methods on the number of cancers detected and of biopsies required has also been modeled.[118] Differences in analytical performance can have an impact on outcomes through differences in the decisions that are made.

At the postanalytical stage, if a result is not received or accessed, then clearly it cannot contribute to an improved outcome. In a systematic study, Kilpatrick and Holding[72] found that when they introduced electronic transmission of data to the emergency department and admissions unit, a notable number of results were never accessed. In another study of POCT for HbA_{1c}, Khunti and colleagues after consultation merely replaced the phlebotomy service with the POCT, with no apparent immediate discussion of the result,[71] thus omitting the key objective for introducing the POCT.[18]

OUTCOME STUDIES

Medical and public health interventions are intended to improve the well-being of patients, the population at large, or population segments, as stated by Fryback and Thornbury[40] and Sackett and Haynes.[120] For therapeutic interventions, patients are interested, for example, not only in whether a drug decreases serum cholesterol or blood pressure (risk factors), but more importantly, whether it decreases the risks of heart attack, stroke, and cardiovascular death. Similarly, on

Participants	3	The study population: The inclusion and exclusion criteria, setting, and locations where the data were collected.	
	4	Participant recruitment: Was recruitment based on presenting symptoms, results from previous tests, or the fact that the participants had received the index tests or the reference standard?	
	5	Participant sampling: Was the study population a consecutive series of participants defined by the selection criteria in items 3 and 4? If not, specify how participants were further selected.	
	6	Data collection: Was data collection planned before the index test and reference standard were performed (prospective study) or after (retrospective study)?	
Test methods	7	The reference standard and its rationale.	
	8	Technical specifications of material and methods involved, including how and when measurements were taken, and/or cite references for index tests and reference standard.	
	9	Definition of and rationale for the units, cutoffs, and/or categories of the results of the index tests and the reference standard.	
	10	The number, training, and expertise of the persons executing and reading the index tests and the reference standard.	
	11	Whether or not the readers of the index tests and reference standard were blind (masked) to the results of the other test and describe any other clinical information available to the readers.	
Statistical methods	12	Methods for calculating or comparing measures of diagnostic accuracy, and the statistical methods used to quantify uncertainty (e.g., 95% confidence intervals).	
	13	Methods for calculating test reproducibility, if done.	
RESULTS		Report	
Participants	14	When study was done, including beginning and ending dates of recruitment.	
	15	Clinical and demographic characteristics of the study population (e.g., age, sex, spectrum of presenting symptoms, comorbidity, current treatments, recruitment centers).	
	16	The number of participants satisfying the criteria for inclusion that did or did not undergo the index tests and/or the reference standard; describe why participants failed to receive either test (a flow diagram is strongly recommended).	
Test results	17	Time interval from the index tests to the reference standard, and any treatment administered between.	
	18	Distribution of severity of disease (define criteria) in those with the target condition; other diagnoses in participants without the target condition.	
	19	A cross tabulation of the results of the index tests (including indeterminate and missing results) by the results of the reference standard; for continuous results, the distribution of the test results by the results of the reference standard.	
	20	Any adverse events from performing the index tests or the reference standard.	
Estimates	21	Estimates of diagnostic accuracy and measures of statistical uncertainty (e.g., 95% confidence intervals).	
	22	How indeterminate results, missing responses, and outliers of the index tests were handled.	
	23	Estimates of variability of diagnostic accuracy between subgroups of participants, readers, or centers, if done.	
	24	Estimates of test reproducibility, if done.	
DISCUSSION	25	Discuss the clinical applicability of the study findings.	

Figure 4-5 The Standards for Reporting of Diagnostic Accuracy (STARD) checklist.

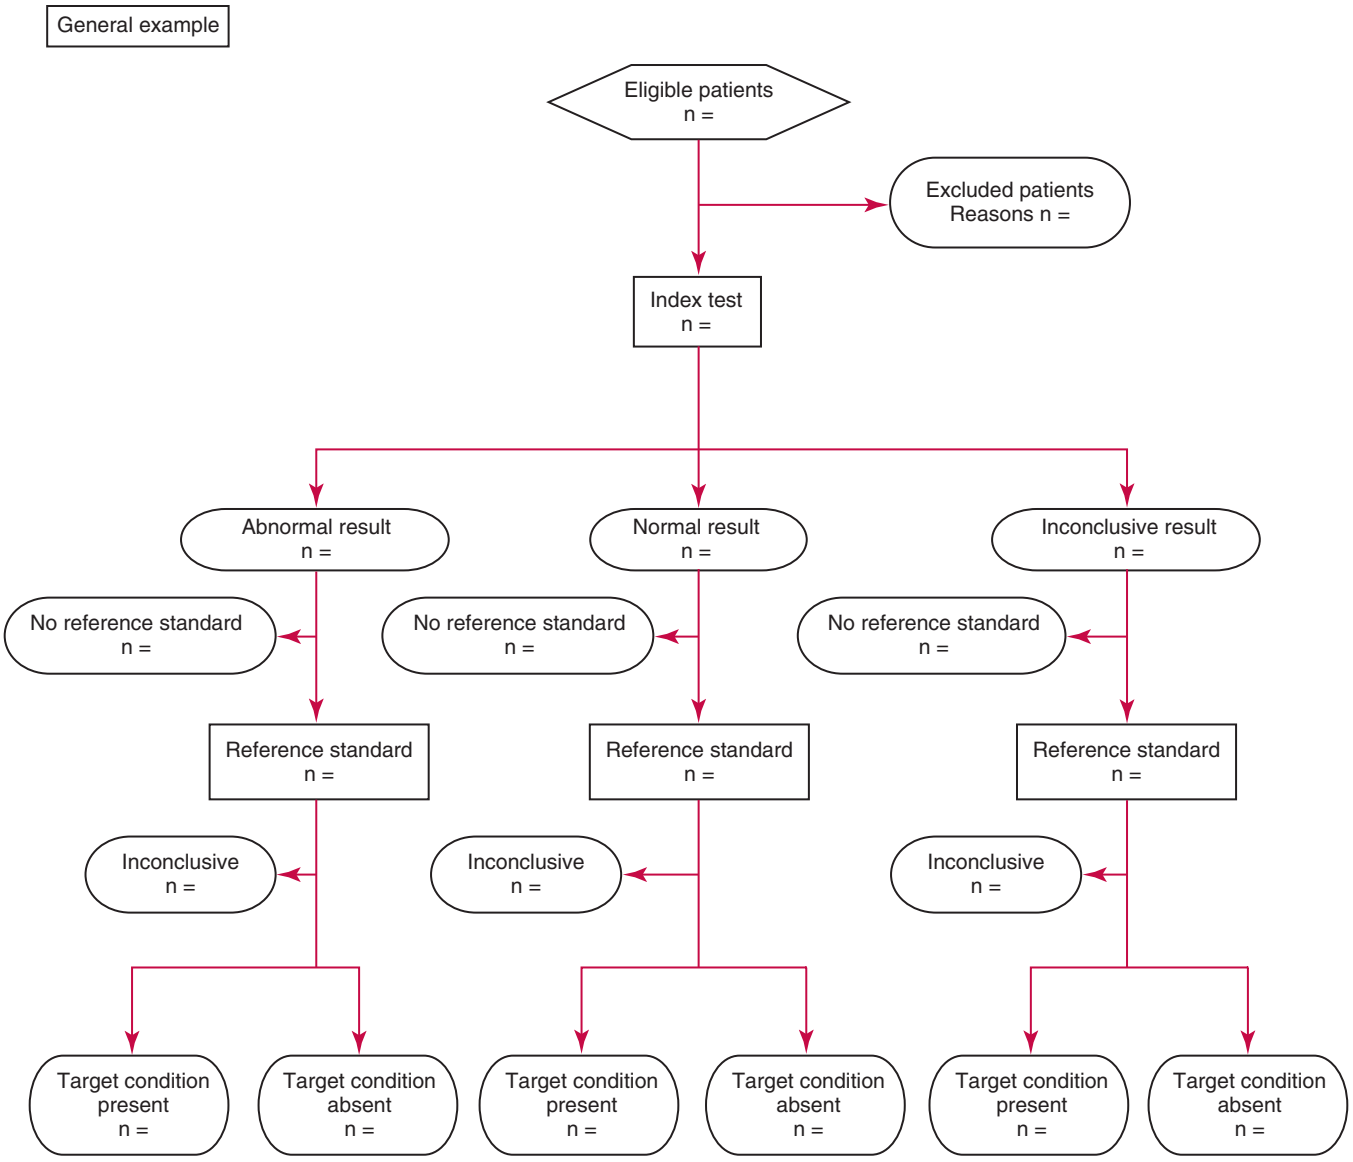

Figure 4-6 The Standards for Reporting of Diagnostic Accuracy (STARD) flow diagram.

the diagnostic side of medicine, patients have little interest in knowing the numeric value of their serum cholesterol concentration or blood pressure unless that knowledge will lead to actions that in some way will improve their quality or quantity of life. For example, a test result may identify the need for a life-saving therapeutic intervention for an existing disease, or it may lead to a change in lifestyle that will decrease the risk of developing a disease. At other times, the test result itself can provide valuable reassurance, as when a genetic test indicates that a family member does not carry a mutation that is present in the family. In still other cases, a laboratory test may provide prognostic information that allows the patient to better plan for the future despite a bad prognosis, or it may provide reassurance that symptoms are not signs of serious disease, thus allowing him or her to better manage the symptoms without fear. Test-related outcomes in these examples range from preventing imminent death to being better able to plan for death.

Who Is Interested in Health Outcomes?

Outcomes studies have taken on considerable importance in medicine. On the therapeutic side of medicine, few drugs can be approved by modern government agencies (or paid for by healthcare organizations or health insurers) without undergoing randomized, controlled trials of their safety and effectiveness. Increasingly, diagnostic testing is entering a similar environment in which physicians, governments, purchasers, commissioners of healthcare (e.g., commercial health insurers), and patients demand evidence of effectiveness of diagnostic procedures. To appreciate this, one need only recall the enormous interest in controversies about the value of mammography and the effectiveness of measuring PSA in serum.

These issues (and many others) hinge on demonstration of improved outcomes.

In the United States, the important Joint Commission defines *quality* as increased probability of desired outcomes and decreased probability of undesired outcomes. The Institute of Medicine defines quality as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge."[127]

Up until this point, the focus has been on the patient and his or her interaction with the doctor as the primary caregiver; these individuals may be considered as the two primary stakeholders. Yet we know that healthcare is the product of many healthcare professionals, sometimes referred to as the *clinical team*. The complexity of interactions in this group has to be extended, when the broader issues of healthcare delivery are considered, to include the roles of service provider managers, service purchasers or commissioners, and policymakers. This has been brought more sharply into focus with increased pressure to improve the quality of care and to make more efficient and effective use of resources.[61,62,98] So in the case of laboratory medicine, the identity of stakeholders should be extended to include all of those who have an interest in how the laboratory service can be, and is, used.

Test Results Alone Do Not Generate Improved Health Outcomes

In many clinical scenarios, the first criterion for a useful test is that the result must lead to a change in the probability of the presence of the target condition. Boyd and Deeks,[14] for example, showed that the (pretest) probability of pulmonary embolism fell from about 0.28 to a post-test probability of 0.041 when the D-dimer test result was less than 500 μg/L. The change in probability does not, in itself, make the decision. The clinician must use this information along with other findings and clinical judgment to make decisions or recommendations about care. So, even the knowledge that a test has good diagnostic accuracy is of no value unless it is used correctly, and results are integrated with other observations and the expertise of the clinician.[140]

In most cases, testing is followed by an appropriate intervention to produce a desired outcome, particularly when the outcome is defined as improved morbidity or mortality. A test result alone may provide reassurance or an understanding of the origin of one's complaint, but usually improved outcomes require an intervention in the form of an explanation of the result in the context of the patient's symptoms. Most laboratory medicine research encompasses only test characteristics, including diagnostic accuracy. If these characteristics are not linked to clear consequences for downstream decisions and interventions, such research leads to poor understanding and appreciation of the contribution that the test result makes to improved outcomes. In relation to certain scenarios, it is possible to find valid study data, most particularly when the test result is being used to exclude a diagnosis. Thus in a randomized study of a rapid chest pain evaluation protocol, cardiac markers had a high negative predictive value in the evaluation of patients with chest pain. Testing led to fewer admissions to the coronary care unit, without adverse effects on morbidity and mortality.[99] Reducing the turnaround time for certain tests may improve triage time in the emergency room[82] unless other evaluations (such as other laboratory tests or radiologic investigations) are rate limiting.[69] Reduced length of stay appeared to occur primarily because normal results with the POCT approach enabled some patients to be discharged more quickly (i.e., a rule-out decision).[95] These examples are process outcomes.

What Are Outcomes Studies?

Outcomes may be defined as results of medical interventions in terms of health; evaluation of economic outcomes is discussed later. *Patient outcomes* are results that are perceptible to the patient[5] and are also of importance to caregivers, service provider organizations, and purchasers and commissioners. Outcomes that have been studied commonly include mortality, physiologic measures, clinical events, symptoms, function measures, and patients' experiences with care complication rates (such as the nosocomial infection rate). In studying and comparing diagnostic tests, an improved ability to make a correct diagnosis of a treatable condition may lead to an improvement in one or more of these outcomes. Test results themselves are not widely considered to be outcomes, but an argument can be made that they should be considered as proxy measures of outcome when it is certain that real outcomes will change for the better with a superior test. Some tests are increasingly being used as surrogate outcome measures in intervention studies when a strong relationship has been documented between test results and morbidity or mortality; examples include the use of HbA_{1c} and the urine albumin : creatinine ratio in studies on the management of diabetes mellitus.

Outcomes studies must be distinguished from studies of prognosis. Studies of the prognostic value of a test ask the question, "Can the test be used to predict the future course of disease, in terms of patient outcome?" By contrast, outcomes studies ask questions such as, "Does use of the test improve outcomes?" For example, a study of the former type asks the question, "Does the concentration of a cardiac troponin in serum correlate with the mortality rate after myocardial infarction?" An outcomes study might ask, "Is the mortality rate of patients with suspected myocardial infarction decreased when physicians use troponin testing to guide therapy?" Recent outcomes studies have asked questions such as the following: "Is availability of POCT in the emergency room, compared with testing performed in the hospital laboratory, associated with a decreased length of stay for patients in the emergency department?"[69,82,95,104] and "Does routine testing of elderly patients before cataract surgery decrease postoperative complication rates?"[125]

Design of Clinical Outcomes Studies

The randomized controlled trial (RCT) is the de facto standard for studies of the health effects of medical interventions. In these studies, patients are randomized to receive either a

therapy to be tested or an alternative (a placebo or a conventional treatment), and outcomes are measured. RCTs have been used to evaluate therapeutic interventions, including drugs, radiation therapy, and surgical interventions, among others. Measured outcomes vary from hard evidence, such as mortality and morbidity, to softer evidence, such as patient-reported satisfaction and surrogate end points typified by markers of disease activity (e.g., HbA_{1c}, urine albumin : creatinine ratio as mentioned earlier).

The high impact of RCTs of therapeutic interventions has led to scrutiny of their conduct and reporting. An interdisciplinary group (largely clinical epidemiologists and editors of medical journals) developed a guideline known as CONSORT[90] for the conduct of these studies. Although initially designed for trials of therapies, CONSORT provides useful reminders when outcomes studies of tests in laboratory medicine are designed or appraised. Key features of the guideline include a checklist (Figure 4-7) of items to include in the report and a flow diagram (Figure 4-8) of patients in the study, which are similar to those used for STARD.

The optimal design of an RCT of a diagnostic test is not always obvious. A classical design is to randomize patients to receive or not receive a test, and then to modify therapy from conventional therapy to a different therapy based on test results among tested patients. This approach leads to interpretive problems.[8] For example, if the new therapy is always effective, the tested group will always fare better even if the test is a coin toss, because only the tested group had access to the new therapy. The conclusion that the testing was valuable would thus be wrong. A similar problem occurs if the tested group had merely an increased access to the therapy. (A

Checklist of items to include when reporting a randomized trial

PAPER SECTION and topic	Item	Description	Reported on page #
TITLE & ABSTRACT	1	How participants were allocated to interventions (*e.g.*, "random allocation," "randomized," or "randomly assigned").	
INTRODUCTION Background	2	Scientific background and explanation of rationale.	
METHODS Participants	3	Eligibility criteria for participants and the settings and locations where the data were collected.	
Interventions	4	Precise details of the interventions intended for each group and how and when they were actually administered.	
Objectives	5	Specific objectives and hypotheses.	
Outcomes	6	Clearly defined primary and secondary outcome measures and, when applicable, any methods used to enhance the quality of measurements (*e.g.*, multiple observations, training of assessors).	
Sample size	7	How sample size was determined and, when applicable, explanation of any interim analyses and stopping rules.	
Randomization—Sequence generation	8	Method used to generate the random allocation sequence, including details of any restriction (*e.g.*, blocking, stratification).	
Randomization—Allocation concealment	9	Method used to implement the random allocation sequence (*e.g.*, numbered containers or central telephone), clarifying whether the sequence was concealed until interventions were assigned.	
Randomization—Implementation	10	Who generated the allocation sequence, who enrolled participants, and who assigned participants to their groups.	
Blinding (masking)	11	Whether or not participants, those administering the interventions, and those assessing the outcomes were blinded to group assignment. When relevant, how the success of blinding was evaluated.	

Figure 4-7 The Consolidated Standards of Reporting Trials (CONSORT) checklist.

Statistical methods	12	Statistical methods used to compare groups for primary outcome(s); methods for additional analyses, such as subgroup analyses and adjusted analyses.	
RESULTS Participant flow	13	Flow of participants through each stage (a diagram is strongly recommended). Specifically, for each group report the numbers of participants randomly assigned, receiving intended treatment, completing the study protocol, and analyzed for the primary outcome. Describe protocol deviations from study as planned, together with reasons.	
Recruitment	14	Dates defining the periods of recruitment and follow-up.	
Baseline data	15	Baseline demographics and clinical characteristics of each group.	
Numbers analyzed	16	Number of participants (denominator) in each group included in each analysis and whether the analysis was by "intention-to-treat." State the results in absolute numbers when feasible (*e.g.*, 10/20, not 50%).	
Outcomes and estimation	17	For each primary and secondary outcome, a summary of results for each group, and the estimated effect size and its precision (*e.g.*, 95% confidence interval).	
Ancillary analyses	18	Address multiplicity by reporting any other analyses performed, including subgroup analyses and adjusted analyses, indicating those pre-specified and those exploratory.	
Adverse events	19	All important adverse events or side effects in each intervention group.	
DISCUSSION Interpretation	20	Interpretation of the results, taking into account study hypotheses, sources of potential bias or imprecision, and the dangers associated with multiplicity of analyses and outcomes.	
Generalizability	21	Generalizability (external validity) of the trial findings.	
Overall evidence	22	General interpretation of the results in the context of current evidence.	

Figure 4-7, cont'd

possible example is the apparent benefit of fecal occult blood testing in decreasing the incidence of colon cancer when the tested group is more likely to undergo colonoscopy and removal of premalignant lesions in the colon. Even a random selection of patients for colonoscopy might achieve results similar to those obtained for the group tested for fecal occult blood.) This problem will lead to the erroneous conclusion that the test itself is useful. By contrast, if the new therapy is always worse than the conventional treatment, patients in the tested group will do worse and the test will be judged worse than useless, no matter how accurate it is. Similarly, if the two treatments are equally effective, the outcomes will be the same with or without testing; this scenario will lead to the conclusion that the test is not good, no matter how diagnostically accurate it is. When a truly better therapy becomes available, the test may prove to be valuable, so it is important to not discount the test's potential based on a study with a new therapy that offers no advantage over the old therapy.

Bossuyt and colleagues[8] described a study design to determine whether ultrasound testing of the fetus can be used to identify those women with growth-restricted fetuses who can be safely managed at home rather than in the hospital. In a common study design, women with fetuses showing intrauterine growth restriction (IUGR) are randomized to receive Doppler ultrasound. Women with positive test results would be kept in the hospital, and those with negative test results would go home. Women in the control arm would stay in the hospital—the usual approach. One can see here that if some women benefit from home care, whereas all other women do equally well with either of the two treatments, home care patients will do better regardless of the intrinsic value of the ultrasound test. Thus patients in the tested arm will fare

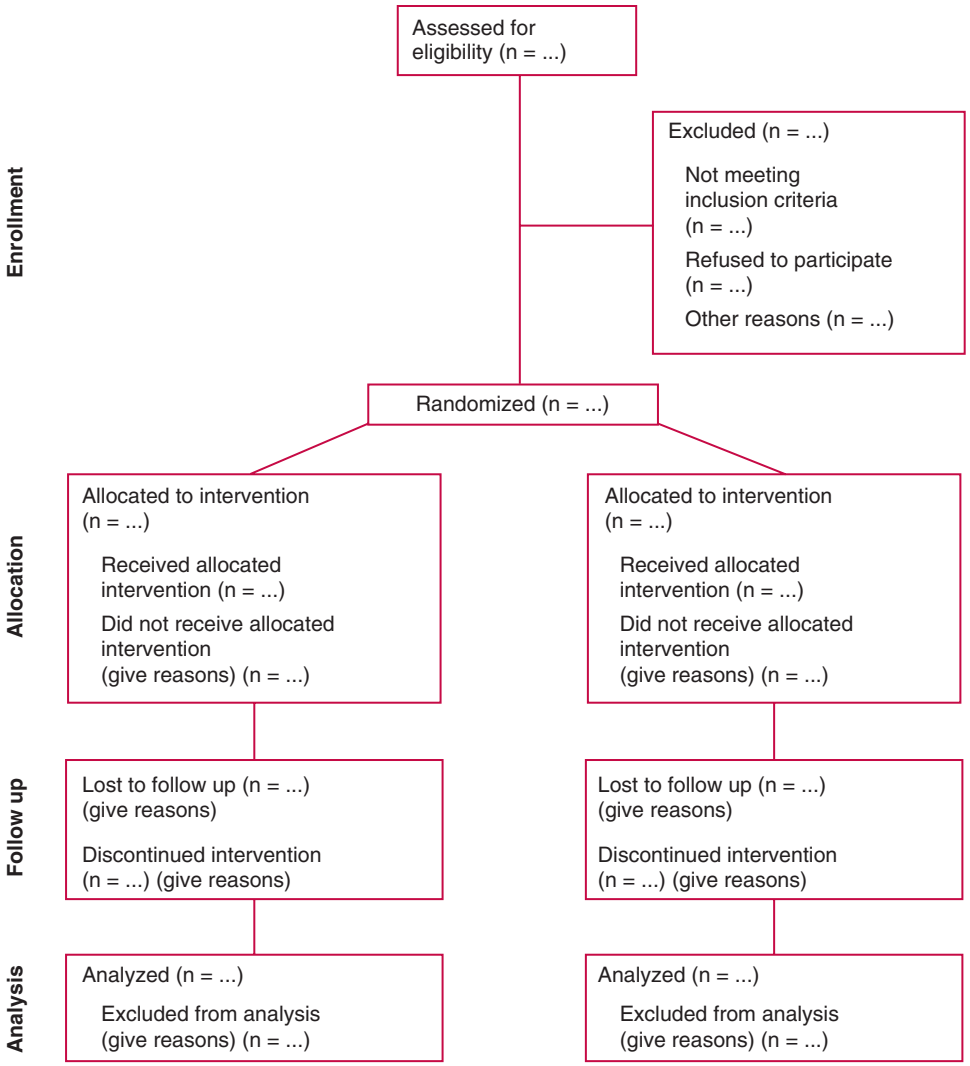

Figure 4-8 The Consolidated Standards of Reporting Trials (CONSORT) flow diagram for patients in a randomized controlled trial (RCT).

better, and the testing itself will erroneously be declared a success. By contrast, a proper interpretation would be that the strategy worked well, and a testable hypothesis might be generated from the study that all patients can be sent home without testing.

Alternative designs have been described to address the question of use of ultrasound in women with IUGR.[8] In one design, all patients undergo the new test, but the results are hidden during the trial. Patients are randomized to receive or not receive the new therapy. In this design, the new test should be adopted only if there is an improvement in patient outcome caused by switching to the new therapy, and if that improvement in outcome is associated with the test outcome. For example, the improvement may be larger in the subgroup that had positive test results on ultrasound compared with the subgroup that had negative test results.

An RCT is not always feasible. Alternatives to the RCT include studies that use historical or contemporaneous control patients in whom the intervention was not undertaken. Other studies include patients with and patients without the outcome of interest. These studies are called case-control studies. Uncertainty about the comparability of the controls and the patients in such designs is a threat to the validity of these studies. One approach that has been proposed for the study of diagnostic tests is the *before-and-after study,* in which patients are cared for using one test or testing strategy for a given period of time (the "before" period), and then the testing strategy is changed (e.g., to the new test) for another (equal) period (the "after" period) and the outcome measures collected and compared between the two periods. A number of concerns have been raised about the validity of this approach, including the size of the patient cohorts required to ensure homogeneity and other effects that may occur during the two periods (e.g., differences between summer and winter). It has been suggested that this approach is valid when an *add-on test* is considered.[77]

Researchers have turned to other methods of exploring the outcomes of testing strategies. To address the multitude of options when several tests are available, decision analysis has been proposed. These studies rely on a model that links data on diagnostic accuracy with data on health outcomes. Patients with true-positive test results receive the benefits of treatment for the target condition, in contrast with patients who have true-negative test results. On the other hand, those with false-positive test results undergo the risk of the side effects associated with treatment, without the benefits. For an example, see Perrier and associates.[106]

Comparative Effectiveness

In 2008, the U.S. Senate introduced legislation under the Comparative Effectiveness Research Act "to improve the quality of healthcare that Americans receive, by creating national priorities for, and conducting and distributing research findings of, the effectiveness of different health care treatments." Although this legislation stalled in committee, it was reintroduced as part of the 2009 American Recovery and Reinvestment Act, which appropriated $1.1 billion to establish the Health Care Comparative Effectiveness Research Institute. This institute will "review evidence and produce new information on how diseases, disorders, and other health conditions can be treated to achieve the best clinical outcome for patients. The Congressional Budget Office has signalled that national healthcare spending could be reduced if physicians and patients had more unbiased data on the effectiveness of the treatments available to them."

On comparative effectiveness, the Institute of Medicine has said that "within the overall umbrella of clinical effectiveness research, the most practical need is for studies of comparative effectiveness, the comparison of one diagnostic or treatment option to one or more others. In this respect, primary comparative effectiveness research involves the direct generation of clinical information on the relative merits or outcomes of one intervention in comparison to one or more others. Secondary comparative effectiveness research involves the synthesis of primary studies (usually multiple) to allow conclusions to be drawn. Secondary comparisons of the relative merits of different diagnostic or treatment interventions can be done through collective analysis of the results of multiple head-to-head studies, or indirectly, in which the treatment options have not been directly compared to each other in a clinical evaluation but reside in larger databases. Conclusions utilize inferential adjustments based on the relative effect of each intervention to a specific comparison, often a placebo."[63]

In a briefing to the Center for Medical Technology Policy, Tunis observed that comparative effectiveness comprised "a set of analytic tools that allow for the comparison of one treatment—drug, device, or procedure—to another treatment on the basis of risks, benefits, and potentially, cost." Tools include systematic reviews of evidence; modeling; retrospective analyses of databases [either electronic health records (EHRs) or administrative data used to process claims]; and prospective, but nonrandomized controlled trials research (e.g., adaptive trials, practical trials). The research setting is real-world healthcare interactions, rather than randomized and controlled trials. Thus it includes key methods associated with the practice of EBLM, as well as other initiatives in the field of EBP, including health technology assessment and outcomes research.[55,146,149]

CRITICAL APPRAISAL AND SYSTEMATIC REVIEWS OF DIAGNOSTIC TESTS

Critical appraisal of data is an important part of determining whether they provide robust information in both primary (experimental) and secondary (literature) research. Information from a number of studies can then be brought together and summarized in systematic reviews, and this can increase the certainty or strength of the information. Systematic reviews are recent additions to the medical literature. In contrast to traditional narrative reviews, these reviews aim to answer a precisely defined clinical question (hence the value of the PICO framework), and to do so in a way that is transparent and is designed to minimize bias. The defining features of systematic reviews include (1) a clear definition of the clinical question to be addressed, (2) an extensive and explicit strategy to find all studies (published or unpublished) that may be eligible for inclusion in the review, (3) criteria by which studies are included and excluded, (4) a mechanism to assess the quality of each study, and, in some cases, (5) synthesis of results with the use of statistical techniques of meta-analysis. By contrast, traditional reviews are subjective, are rarely well focused on a clinical question, lack explicit criteria for selection of studies to be reviewed, do not indicate criteria by which to assess the quality of included studies, and rarely use meta-analysis.

The explicit method of systematic reviews suggests that persons skilled in the art of systematic reviewing should be able to reproduce the data of a systematic review, just as researchers in chemistry or biochemistry expect to be able to reproduce published primary studies in their fields. This concept strengthens the credibility of systematic reviews, and workers in the field of EBM generally consider well-conducted systematic reviews of high-quality primary studies to constitute the highest level of evidence on a medical question.

Why Systematic Reviews?

The explosion of research and the vastness of the medical literature are such that no one can read, much less digest, all relevant work. The massive amount of new technology, the poor quality of narrative reviews,[94] and the necessity to provide an accurate digest for practicing clinicians[42] constitute the background to the call for a more systematic review of literature. Reference has already been made, earlier in this chapter, to the poor quality of reporting of studies, as well as the poor design of studies, and so although critical appraisal skills are essential to reading individual reports of studies, they are also essential to the process of undertaking a systematic review. Systematic reviewing is essentially secondary research and combines the second and third elements of the

A5 EBLM cycle (see Figure 4-3); both will be described in the next section.

Systematic reviews can achieve multiple objectives. They can identify the number, scope, and quality of primary studies by using an extensive search strategy; provide a summary of the diagnostic accuracy of a test; compare the diagnostic accuracies of tests; determine the dependence of reported diagnostic accuracies on quality of study design; identify the dependence of diagnostic accuracy on characteristics of the patients or method for the test; and identify areas that require further research and recognize questions that are well answered and for which further study may not be necessary.

Conducting a Systematic Review

Systematic reviewing is time consuming and requires multiple skills. Usually a team is required, and the team should include persons with searching skills, statistical skills, and experience in performing such a review. A crucial starting point is that the team must agree on the clinical problem (the question) to be tackled and on the scope of the review. This can be achieved with the help of the PICO framework.

It is also helpful at the outset to identify whether a similar review has been undertaken recently. Such a search will help to focus the review and will indicate whether, indeed, the planned review is required, or if the answer to the question has already been found. The Cochrane Collaboration serves as an excellent source of reviews, but unfortunately few are reviews of diagnostic tests (accessed at www.cochrane.org on March 21, 2011).[57] The Cochrane Collaboration has established a working group on Diagnostic Test Accuracy whose mission is to ensure the preparation and publication of quality systematic reviews (accessed at http://srdta.cochrane.org March 22, 2011). The Database of Abstracts of Reviews of Effectiveness (DARE) (accessed at www.york.ac.uk/inst/crd/ on March 21, 2011), which is run by the Centre for Reviews and Dissemination at the University of York in the United Kingdom, contains reviews of some diagnostic tests. Other resources include electronic databases, such as PubMed and Embase, and recent clinical practice guidelines, which are likely to cite systematic reviews that were available at the time of the guideline's development (see section on guidelines later in this chapter). Horvath and colleagues[58] and Price and coworkers[112] list additional resources.

The review team must develop a protocol for the project. A protocol should include the following,[4,58,70,105] in addition to a title, background information, composition of the review group, and a timetable:

- The clinical question(s) to be addressed in the review
- Search strategy
- Inclusion and exclusion criteria for selection of studies
- Method of and checklists for critical appraisal of studies
- Method of data extraction and data extraction forms
- Method of study synthesis and summary measures to be used

Description of all of the details is beyond the scope of this chapter, and only some highlights will be discussed. Review of the references cited here is recommended before embarking on a systematic review. Leeflang and associates have reviewed the method for conducting a systematic review of diagnostic test accuracy; this article illustrated the limitations of some of the approaches that have been taken.[80] A step-by-step guide published in 2009 can be consulted to take the reader through each of the steps of question formulation, searching strategy, and critical appraisal, together with worked examples.[112]

The Clinical Question and Criteria for Selection of Studies

Among the steps in conducting a systematic review of a diagnostic test (Box 4-3), the most important is identification of the clinical question for which the test result is required to give an answer, and thus formulation of the question that forms the basis of the review. The PICO framework is used to formulate the question. A wide range of questions can be addressed in a systematic review in diagnostic medicine, including (1) the diagnostic accuracy of the test, (2) the prognostic accuracy of the test, (3) the clinical value of using the test, and (4) the operational or economic value of using the test. Questions that arise are similar in structure but require different approaches.

Examples of structured questions, with PICO annotation, are given below:

Diagnostic accuracy of a test: In patients coming to the emergency department with shortness of breath (P), can the measurement of B-type natriuretic peptide (BNP) or N-terminal pro-BNP (I) predict (identify the presence of) heart failure (O) as assessed by the cardiac ejection fraction measured by echocardiography (C)? Note in this case that echocardiography is the control or current procedure rather than the reference standard, which is now regarded as the independent opinion of two experienced cardiologists.

Prognostic accuracy of a test: In patients with chronic kidney disease (P), can the measurement of BNP or N-terminal pro-BNP (I) predict the likelihood of death (O)? Note that in this type of study, there is no comparator (or control) term.

BOX 4-3 Key Steps in Conducting a Systematic Review of a Diagnostic Test

Identify the clinical question.
Define the inclusion and exclusion criteria.
Search the literature.
Identify the relevant studies.
Select studies against explicit quality criteria.
Extract data and assess quality.
Analyze and interpret data.
Present and summarize findings.

Clinical value of a test in improving patient outcomes (called a phase 4 evaluation of a test by Sackett and Haynes[120]): In patients attending the hospital for treatment of heart failure (P), can the measurement of BNP or N-terminal pro-BNP (I) help as a guide to therapy or improve the ability to treat heart failure as assessed by the rate of subsequent readmission for heart failure (O), compared with the current practice, which does not involve the use of a biochemical test (C)? Note that in this example, the rate of readmission for heart failure is a surrogate measure of the quality of management of the heart failure.

Operational value of a test improving the economic outcome in managing a patient: In patients with shortness of breath (P), can the measurement of BNP or N-terminal pro-BNP using POCT in a primary care setting (I) rule out the presence of heart failure (O) as assessed by the cardiac ejection fraction measured by echocardiography (C)? In this case, the economic benefit would be a reduction in the need to refer for echocardiography every breathless patient with suspicion of heart failure.

Note that each question employs the PICO framework. More complex questions often arise. Thus a question may involve comparing the diagnostic accuracies of two or more tests, or it may address improvement in diagnostic accuracy derived by adding results of a new test to results of an existing test or tests. A complex outcome question may involve the utility of therapeutic drug testing at the time of a clinic visit to reduce clinic visits by helping to establish optimum drug dosages; this is an operational question, but it could also be considered as a clinical question, such as "Has the new protocol reduced the number of adverse events (e.g., rejection episodes) or has it improved patient satisfaction?" Similarly when looking at POCT for a monitoring test (e.g., HbA_{1c}), it is possible to consider the clinical benefits (reduction in HbA_{1c} level, or delay in the onset of complications), as well as the economic benefits (reduction in the number of clinic visits or in the need for hospitalization associated with onset of complications).

The clinical question leads to inclusion and exclusion criteria for studies to be included in the review. These criteria include the patient cohort and the setting in which the test is to be used, as well as the outcome measures to be considered. These are all important, as both the patient setting and the nature of the question affect the diagnostic performance of a test.[108]

When the questions to be addressed are defined, the review group must agree on the scope of the review. Irwig and colleagues[64] summarized two main approaches to defining the scope of a systematic review of studies of diagnostic accuracy:

- Restrict the review to studies of high quality directly applicable to the problem of immediate interest to the reviewer.
- Explore the effects of variability in study quality and other characteristics (e.g., setting, type of population, disease spectrum) on estimates of accuracy, using subgroup analysis or modeling.

The second approach is more complex but allows estimates of such things as the applicability of estimates of diagnostic accuracy to different settings and the effects of study design and inherent patient characteristics (e.g., age, sex, symptoms) on estimates of a test's diagnostic accuracy.

Search Strategy

Searching of the primary literature is usually carried out in three ways: (1) an electronic search of literature databases, (2) hand searching of key journals, and (3) review of the references of key review articles. It is usual to search both Medline and Embase, as the overlap between the two can be as low as 35%.[137] Searching of databases is a detailed exercise, and the help of a librarian or information scientist is recommended. An incorrectly structured search can generate a large number of irrelevant references and can miss crucial references.[76] Guidance that is tailored to searching for studies of diagnostic accuracy in the published literature is available in Irwig and associates.[64] A step-by-step guide through a search is given by Price and coworkers.[112]

Additional studies may be found in the "gray" literature that is not indexed by the major databases. These sources include theses, conference proceedings, technical reports, and monographs. Consultation with individuals active in the field may uncover studies in these sources and studies that are being prepared for publication.

Data Extraction and Critical Appraisal of Studies

Depending on the number of papers identified in the search, an initial review of the abstract may be undertaken to check for relevance, in an attempt to reduce the number of papers that need to be read. Identified papers should be read independently by two persons and data extracted according to a template. A checklist of items to extract from primary studies in preparing a systematic review on test diagnostic accuracy [**Qu**ality **A**ssessment of **D**iagnostic **A**ccuracy in **S**ystematic Reviews (QUADAS)] is available online (http://www.ncbi.nlm.nih.gov/pmc/articles/PMC305345/, accessed on March 23, 2011).[152] The STARD checklist can be used as an additional guide in designing the template.[9] Similarly, a checklist of items to extract from primary studies in preparing a systematic review on test prognostic accuracy is available online from the Critical Appraisal Skills Programme for a cohort study appropriate for evaluating a prognostic study (http://www.sph.nhs.uk/what-we-do/public-health-workforce/resources, accessed on March 23, 2011), adapted from Reference 50, as well as in a step-by-step guide to critical appraisal.[50,112] A checklist for an outcome study has also been adapted for use with a diagnostic test.[112]

The quality of studies must be assessed as part of the systematic review. Rating schemes for the quality of primary studies have been concerned mostly with studies of therapeutic interventions. These schemes have focused on the type of study design, with large RCTs routinely considered to have the highest level of quality and other designs given

lower ratings. Glasziou and associates[43] have pointed out, however, that different types of clinical questions (such as questions related to diagnostic approaches) often require different types of study design. Thus, a randomized trial, although ideal for studies of the effects of interventions, is not the most appropriate design for studying whether (their examples) computerized or human reading of cervical smears is better (or to study the natural history of a disease or the cause of a disease). Moreover, a study may use a good design but suffer from serious drawbacks in other dimensions, such as (1) study of a small cohort, (2) the number of patients lost to follow-up, and (3) the characteristics of patients recruited. Thus adequate grading of the quality of studies must go beyond the categorization of study design.[43,80]

Summarizing the Data

Characteristics and data from critically appraised studies should be presented in tables. Data should include sensitivities, specificities, and likelihood ratios wherever possible. These can then be summarized in plots that provide an indication of the variation among studies; Whiting and associates have discussed the graphical presentation of diagnostic information.[153] The summary should also include an assessment of the quality of each study, using an explicit scoring system. A review should present critical analysis of the data highlighted in the review.

Meta-Analysis

It may be possible to undertake a meta-analysis if data are available from a number of similar studies (i.e., asking the same question in the same type of patient and in the same or similar clinical settings). Meta-analyses can explore sources of variability in the results of clinical studies, increase confidence in the data and conclusions, and signal when no additional studies are necessary. However, the conclusions will depend on the papers chosen for analysis; in the case of self-monitoring of blood glucose in patients with type 2 diabetes, a number of systematic reviews have been published in recent years, with the papers chosen for meta-analysis varying between reviews—notwithstanding the fact that later reviews will have included more recent studies.[22,88,89,124,139,145,150] For guidelines on conduct of meta-analyses of RCTs, see the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement at www.prisma-statement.org (accessed March 23, 2011).

Although meta-analyses are hampered in diagnostic research by the paucity of high-quality primary studies,[64] the quality of these studies is improving.[84] For descriptions of meta-analytic techniques in diagnostic research, including the summary ROC curve, see papers by Irwig and colleagues[65,66] and Deeks[25] and book chapters by Boyd[12] and Perera and Heneghen.[105] Deeks has argued that likelihood ratios provide the most transparent expression of the utility of a test, because they enable the clinician to calculate the post-test probability if the pretest probability is known (see examples in Chapter 3).[25]

ECONOMIC EVALUATION OF DIAGNOSTIC TESTS

Healthcare costs worldwide have surged in recent decades. For example, in 2009, the United States spent $2.5 trillion dollars, or 17.2% of its gross domestic product, on healthcare (see www.cms.hhs.gov/NationalHealthExpendData, accessed March 23, 2011); this is expected to rise to $4.5 trillion dollars and 19.6% of gross domestic product by 2019. Although direct laboratory costs are small in comparison, evidence from individual studies shows that test results have a profound influence on medical decision making and therefore on the total cost of healthcare.

Who Uses Economic Evaluations of Diagnostic Test?

The perspective from which an economic evaluation is performed affects the design, conduct, and results of the evaluation. For example, the perspective may be that of a patient, a service provider, a payer (government health agency or health insurance company), or society. The perspective may be long term or short term. The perspective is a practical consideration when one is attempting to assess the benefit of a particular test or device as part of a more complex clinical protocol. Perspective is also important in relation to many of the routine decisions made about a diagnostic test. The questions below illustrate the importance of perspective:

- What is the cost of the test result produced on analyzer A compared with analyzer B?
- What is the cost of the test result produced by laboratory A compared with laboratory B?
- What is the cost of the test result produced by POCT compared with the laboratory?
- Will provision of rapid testing for the emergency department reduce the length of patient stay in the department and thus decrease cost for the hospital?
- Will HbA_{1c} testing in a clinic save time for *patients* by providing results at the time of the clinic visit? Will it save money for the patients' *employers* by reducing employees' time away from work for physician appointments? Will it save time for the physician and thus money for the *clinic?* Will it improve care of diabetes (perhaps by facilitating counseling at the time of the clinic visit) for the *patient* as indicated by independent measures of glycemic control? Will it save money for the *health system* by improving glycemic control and thus decreasing hospitalizations? Will it provide benefit for *society* by decreasing society's healthcare costs (for hospitalizations) and enhancing patients' quality of life and contributions to society?

The first scenario is the type of evaluation made in making a deal for new equipment; this is part of a simple procurement exercise. The outcome is the same: the provision of a given test result, to a given standard of accuracy and precision, within a given time; this is part of the procurement specification. The second question might appear to be the same, but it is not, and undoubtedly, it will have to take into account

tahir99-VRG & vip.persianss.ir

other issues, namely, the logistical issues associated with sample transport or the level of communication support provided by the laboratories; again it is part of a procurement exercise. To make a relevant evaluation concerning the value of POCT, it is important to take into account implications outside of the laboratory that may result from a delay in sending the sample to another laboratory, as well as cost implications outside of the laboratory.

Most economic evaluations of diagnostic tests will have a perspective beyond the bounds of the laboratory if the value of the test is to be appreciated and understood. Unfortunately, many of the early economic data on POCT looked solely at the costs of producing the test result.[81] These studies overlooked the potential value of the key objective of producing the result more quickly, namely, that a decision can be made immediately and a treatment instituted or changed. When a test is proposed to reduce the use of other resources within the hospital (e.g., use of drugs or blood products or other expensive diagnostic technology), the expectation is that the clinical outcome will be unchanged or improved (e.g., the patient is not put at risk by using less blood or less expensive technology). When provision of a test result may have a longer-term impact, as in management of chronic disease, use of intermediate measures of outcome may be especially important.

Quality of Evidence in Economic Evaluations

A hierarchy of evidence regarding clinical tests[40,107] (see Figure 4-4) begins with assessment of the test's technical performance and proceeds through study of the test's diagnostic performance to identification of potential benefits and thus to economic evaluation. The hierarchy has also been expressed as moving up from the efficacy of a test through efficiency to effectiveness of a test.[87] This hierarchy of evidence can also be seen in the context of the data required to make decisions about the implementation of a test.[107] It therefore lies at the heart of the process of policymaking and service management.[93] Economic evaluation provides a means of evaluating the comparative costs of alternative care strategies, as well as health outcomes at the highest level in terms of life-years gained and social benefit.[34,134]

Design of Economic Evaluation Studies

Health economics is concerned with the *costs* and *consequences* of decisions made about the care of patients. It therefore involves identification, measurement, and valuation of both the costs and the consequences. This process is complex and is an inexact science.[96] Approaches to economic evaluation include (1) cost minimization, (2) cost benefit, (3) cost-effectiveness, and (4) cost utility analysis (Table 4-2).

Cost minimization can be considered as the simplest approach and provides the least information; it is an evaluation of the costs of alternative approaches that produce the same outcome. In the area of diagnostic testing, it is applicable only to the costs of alternative suppliers of the same test, device, or instrument. Therefore, it is a technique that is limited to the procurement process, where the specifications of the service are already established and the outcomes clearly defined. It might be considered as providing the "cost per test," an often quoted parameter that is not, however, a true economic evaluation because it does not identify an outcome except the provision of a test result.

Cost-benefit analysis determines whether the cost of the benefit exceeds the cost of the intervention, and therefore whether the intervention is worthwhile. The value of the consequence or benefit is assessed in monetary terms; this can be challenging, because it may require the analyst to equate a year of life to a monetary amount. A number of methods may be used, including the *human capital approach,* which assesses the individual's productivity (in terms of earnings), and the *willingness to pay approach,* which is more of a modeling approach based on determination by questionnaire of what individuals are prepared to pay. Cost-benefit evaluation is not widely used, but it might have some value in comparisons of different testing modalities. An example is the economic evaluation of the use of BNP measurement in the diagnosis of heart failure and the appropriate use of echocardiography, which used decision tree modeling and showed that a test could be justified for ruling-out a diagnosis of heart failure on both clinical and economic grounds.[128]

Cost-effectiveness analysis looks at the most efficient way of spending a fixed budget; the effects are measured in terms of a natural unit. The ultimate natural unit is the life-year, but

TABLE 4-2 Approaches to Economic Evaluation

Type of Evaluation	Test Evaluated	Effect or Outcome	Decision Criteria
Cost-minimization	Alternative tests or delivery options	Identical outcomes	Least expensive alternative
Cost-benefit	Alternative tests or delivery options	Improved effect or outcome	Effect evaluated purely in monetary terms
Cost-effectiveness	Alternative tests or delivery options	Common unit of effect but differential effect	Cost per unit of effect (e.g., dollars per life-years gained)
Cost-utility	Alternative tests or delivery options	Improved effect or outcome	Outcome expressed in terms of survival and quality of life

tahir99-VRG & vip.persianss.ir

more practical measures include reduction in the frequency of hypoglycemic episodes and the number of strokes prevented. Surrogate measures with clear relationships to morbidity and mortality have also been used (e.g., change in blood pressure). When an intervention is assessed, the number of cases of disease prevented may be used as a measure of benefit, as in the case of alternative approaches to the management of patients with suspected peptic ulcer.[36] In this study, investigative and treatment strategies were compared for outcome measures of cost per ulcer cured and cost per patient treated. The serologic testing strategy was found to be more effective than endoscopy by both measures.

Cost-utility analysis includes the quality and the quantity of the health outcome, most often looking at the quality of the life-years gained. The cost of the intervention is assessed in monetary terms, but the outcomes are expressed in quality-adjusted life years (QALYs). Approaches that assess quality of life include Quality of Wellbeing,[67] Health Utilities Index,[144] and EuroQol.[73] Cost-utility analysis has seen little use in the study of diagnostic tests, probably because of the complexity of the clinical process involving both diagnostic test and treatment necessary to produce a measurable clinical outcome. However, it has been used to assess the utility of some screening programs.

The inclusion of a quality of life component can affect choices among alternatives. In the Centers for Disease Control and Prevention Diabetes Cost-Effectiveness Study, the lifetime costs and benefits of opportunistic screening for diabetes were compared with those of current practice,[19] with primary outcome measures of life-years saved and QALYs. The incremental cost effectiveness was found to be $35,768 per life year gained and $13,376 per QALY, showing that adjustment for quality of life has a major impact on cost-effectiveness. This suggests that in addition to extension of life through screening, a gain in quality of life increases the attractiveness of the benefits accruing from screening.

The addition of new technology often increases both cost and benefit. A cost-effectiveness study of screening for colorectal cancer (vs. no screening) showed that the least expensive strategy was a single sigmoidoscopy at 55 years of age, with an incremental cost-effectiveness ratio of $1200 per life-year saved.[39] Alternative strategies gave incremental cost-effectiveness ratios of $21,200, $51,200, and $92,900 with the addition of increasingly complex and frequent screening for fecal occult blood.

When tests increase both cost and benefit, decisions about their use will depend on factors such as willingness to pay and other political and individual pressures. An amount of $50,000 per QALY has been used in the United States as a reference point, the amount deriving from a decision by the U.S. Congress to approve dialysis treatment for end-stage renal failure.[78] Although they provide useful comparative data, concerns have arisen about the use of tables of cost per QALY.[29]

The underlying goal of economic evaluation is to compare the costs that will be incurred with an estimate of the gain; for this, there are four possible findings and three possible decisions:

- Testing more costly but providing greater benefit—possibly introduce depending on overall gain
- Testing more costly but providing less benefit—do not introduce test
- Testing less costly but providing greater benefit—introduce test
- Testing less costly but providing less benefit—possibly introduce test depending on the size of the loss in benefit and the magnitude of savings (which may be able to produce a demonstrably greater benefit if spent on a different intervention or test).

These options have been expressed graphically in a two-dimensional plot called the *cost-effectiveness plane,*[6,101] with cost on the horizontal axis and benefit on the perpendicular axis.

In exactly the same way as for studies on diagnostic performance and for outcomes studies, a minimal set of criteria is used to evaluate an economic study of a diagnostic test. A suggested list of criteria includes the following[31]:

- Clear definition of economic question, including perspective of the evaluation [e.g., patient, society, employer, health insurance company, hospital (provider) administrator] and whether it is a long-term versus a short-term perspective
- Description of competing alternatives
- Evidence of effectiveness of the intervention
- Clear identification and quantification of costs and consequences, including incremental analysis
- Appropriate consideration of effects of differential timing of costs and benefits
- Performance of sensitivity analysis, that is, how sensitive are results to changes in assumptions or in input (e.g., cost of drugs, expected benefit in life-years)?
- Inclusion of summary measure of efficiency, ensuring that all issues are addressed

Two reviews of economic evaluations of diagnostic tests have shown poor adherence to the criteria outlined previously, with only about half of evaluated papers meeting the criteria.[30,129]

Choice of Outcome Measures

Tests are not always evaluated in terms of life-years gained. Even for cost-effectiveness and cost-utility studies, surrogate clinical measures and surrogate economic measures may have a place.[26] Use of surrogate measures of clinical outcomes requires the existence of a clear, demonstrated relationship between the measure and morbidity and mortality. Even if such a relationship is demonstrated, however, changes in the surrogate do not reliably lead to changes in the associated patient-important outcome.[17] This limits the strength of inferences from such studies.

Many of the questions listed above address issues within the clinical episode (i.e., the part of the episode of care that directly involves use of the test), but evaluation of the longer-term value or benefit of a diagnostic test is more complex. Long-term costs and benefits, as in management of a chronic condition such as diabetes, may be influenced by other

tahir99-VRG & vip.persianss.ir

(confounding) factors. Complexity depends on the relationship between test and treatment, and also on the compliance of both patient and clinician in use of the test and the treatment. Thus in the case of diabetes, measurement of blood glucose and HbA_{1c} is an integral part of management. Although short-term studies have been done,[47] rigorous economic evaluations of the long-term use of these tests are rare. Economic modeling of both the Diabetes Control and Complications Trial (DCCT) and the United Kingdom Prospective Diabetes Study (UKPDS) demonstrated the economic benefits of intensive glycemic control[27,46] but did not indicate the value of the testing component. An observational study of the implementation of an intensive glycemic control program demonstrated long-term savings from improved clinical outcomes that reduced clinic visits and hospital admissions and their attendant costs.[148]

Modeling has been used in a number of cases to assess the potential impact of using a test, albeit it has not involved complex pathways. The introduction of screening for *Chlamydia* using a molecular technique was modeled on early experience of the technology in a smaller clinical study.[59,60] Modeling has also been used to determine the potential value of screening for type 2 diabetes using blood glucose testing.[113]

Clinical Outcomes and Economic Evaluation in Decision Making and Changing Practice

The stream of new tests in laboratory medicine requires frequent decisions about whether or not to implement them. Examples of outcomes discussed illustrate that they can be characterized into *clinical* and *economic* outcomes. An alternative approach is to look at these in terms of *clinical* and *process* outcomes,[26] although it can also be helpful to consider economic outcomes in terms of *operational* and *economic/cost* outcomes.[112] Recognition of operational outcomes can be helpful when issues of change in practice and the design of an implementation plan for a new intervention are considered. This can be particularly helpful in the use of POCT.[111] Economic evaluations can help in making these decisions. The finite resources for healthcare require use of an objective means of determining how resources are allocated, and how the efficiency and effectiveness of service delivery can be improved.

Use of economic evaluations faces several challenges. First, the laboratory medicine budget is usually controlled independently of the other costs of healthcare. This is often referred to as *silo budgeting.* In practical terms, the budget for testing is established independently of the budgets for all other services, including budgets for which the contemplated diagnostic test might be able to provide savings. Second, achievement of a favorable outcome (e.g., from a reduction in length of stay or a decrease in admissions to the coronary care unit) is of use from a management standpoint only if the potential savings can be turned into real money (leveraged). Third, the introduction of a new test or testing modality (e.g., POCT) will undoubtedly lead to a change in practice, and so benefits can be achieved only if the change in practice can be implemented. Finally, even if the desired cost savings is achieved, silo budgeting means that the savings are seen in a budget different from that of the laboratory, while the laboratory budget shows only an increased burden of cost. Fortunately, the drawbacks of silo budgeting are being recognized, and a broader view of health economics seems to be developing in some healthcare settings. With the advent of *pay-for-performance,* thought has to be given as to how the incentives can be extended to laboratory medicine.[110]

Regardless of any problems involved in introducing them, economic evaluations can provide an objective measure of what can be achieved and the standard against which the change in practice can be audited after implementation.

CLINICAL PRACTICE GUIDELINES AND CARE PATHWAYS

Patient-centered goals of EBLM cannot be reached by primary studies and systematic reviews alone. The results of these investigations must be turned into action; it has been recognized for many years that translation of research findings into clinical practice takes many years, and furthermore that there is considerable variation in practice once a technology has been disseminated. Increasingly, health systems and professional groups in medicine have turned to the use of clinical practice guidelines as one tool to facilitate implementation of lessons from primary studies and systematic reviews. So, some of the important motivations for development of guidelines have been to decrease variability in practice, to improve the use of best practice, and to make this available to all.

Although most guidelines have been developed primarily for use by clinicians, publication of guidelines on the Internet and descriptions of them in articles in the popular press have led to their use by patients and their families.[16] The development of such guidelines is a challenging new area about which some things are becoming clearer, including the absence of tested guidelines for the development of laboratory-related guidelines. The principles underlying the development of guidelines in laboratory medicine have been described[102]; however, the paucity of outcomes data for laboratory medicine investigations means that the inclusion of laboratory medicine investigations in care pathway guidelines is still limited. This has led to the use of consensus guidelines as an interim measure, while offering the benefit of professional consensus as a means of reducing variability in practice.[135]

What Is a Clinical Guideline?

Clinical practice guidelines have been described as "systematically developed statements to assist practitioner and patient decisions about appropriate healthcare for specific clinical circumstances."[37] This definition appears broad enough to accommodate the laboratory-related guidelines that are appearing in the literature and on the Internet. Guidelines of various sorts have long addressed issues of concern to laboratorians, such as requirements or goals for accuracy, precision, and turnaround time of tests and considerations about the frequency of repeat tests in the monitoring of patients. In

tahir99-VRG & vip.persianss.ir

contrast to many earlier pronouncements on such issues, the focus of modern clinical practice guidelines, such as recent ones on laboratory testing in diabetes[123] and liver disease,[32,33] is the patient in the "specific clinical circumstances" referred to in the definition of clinical practice guidelines. The new ingredient in development of these guidelines is the tool kit of EBM and clinical epidemiology, which allow the guidelines to grow in a more transparent way from well-conducted studies and systematic reviews.

What Is a Care Pathway?

Care pathways have been described as "defining the expected course of events in the care of a patient, with a particular condition, within a set timescale."[74,93] They follow from the clinical guideline in that they define not only the expected flow or sequence of care, but also the times at which care might be expected to be available, and then the expected outcomes. As is implied in the definition of care pathways, this is intended to lead to a more standardized approach to the care of patients with the same condition, which itself has led to the development of the concept of *managed care.*[68]

The Process of Developing Clinical Guidelines

When guidelines are developed by a professional group (such as specialist physicians or laboratory-based practitioners), the recommendations (e.g., to perform a diagnostic procedure in a given setting) may be suspected of promoting the welfare of the professional group. In contrast, when guidelines are prepared under the auspices of payers for healthcare (e.g., governments, insurance companies), the recommendations may be seen as cost-control measures. In this setting, a key danger is that the absence of evidence of benefit from a medical intervention may be interpreted as evidence of absence of benefit. It is therefore helpful to have a transparent process for the development of guidelines.

Steps in the Development of Guidelines

The development of guidelines is best undertaken with a step-by-step plan. One such scheme is shown in Figure 4-9, only selected issues of which will be discussed here. For a more detailed discussion, see Bruns and Oosterhuis[16] or Oosterhuis and coworkers.[102]

Selection and Refinement of a Topic

The critical importance of this first step is analogous to the importance of the corresponding step in development of a systematic review. The scope must not exceed the capabilities (in time, funding, and expertise) of the group, the topic must not be without evidence (or the guideline will lack credibility), and the area must be one requiring attention (or the guideline will have little value and will attract no attention).

Guidelines can address clinical conditions (such as diabetes and liver disease), symptoms (chest pain), signs (abnormal bleeding), or interventions, whether therapeutic (coronary angioplasty and aspirin) or diagnostic (cardiac markers). The priority for a guideline should be as follows: Is there variation in practice that suggests uncertainty? Is the issue of public health importance, such as the increasing problem of diabetes and obesity? Is there a perceived necessity for cost reduction?

The critical issues to be addressed must be identified and distinguished from those that may be considered peripheral or simply beyond the scope that can reasonably be included. Ideally, this process involves a multidisciplinary group, consisting of clinicians, laboratory experts, patients, and likely users of the guidelines. The scope will be affected by the staff (if any) and by financial support available to the guideline group. The cost is usually underestimated.

Determination of Target Group and Establishment of a Multidisciplinary Guideline Development Team

The intended audience must be identified: Is it nurses, general practice physicians, clinical specialty physicians, laboratory specialists, or patients? The Guideline Development team should include representatives of all key groups involved in management of the target condition. In development of guidelines in laboratory medicine, teams ideally include relevant medical specialists, laboratory experts, methodologists (for expertise in statistics, literature search, critical appraisal, and guideline development), and those who deliver services [such as nurse practitioners and patients (for guidelines on home monitoring of glucose), laboratory technicians, and laboratory managers (for a guideline that addresses turnaround times for cardiac markers)].

Because the composition of the guideline development group affects recommendations, with those who perform procedures more likely to recommend their use,[79] potential conflicts of interest of all members must be noted. The role, if any, of sponsors (commercial or nonprofit) in the guideline development process must be agreed upon and reported. Ideally, staff support is available for arranging meetings and conference calls and assisting with publication and other forms of dissemination (e.g., audioconferences).

A minimum group size of six has been recommended.[131] Making the team larger than 12 to 15 persons can inhibit the airing of each person's views. A recommended tool is the use of subgroups to focus on specific questions, with a steering committee responsible for coordination and production of the final guideline. Other ways of using subgroups can be envisioned.

Identifying and Assessing the Evidence

When available, well-performed systematic reviews form the most important part of the evidence base for guidelines. Systematic reviews are necessary when variation between studies is expected, which sometimes is attributable to effects too small to be measured. When no systematic reviews exist, the group effectively must undertake to produce one. The level of evidence supporting each conclusion in the review will affect the recommendations made in the guidelines.

Translating Evidence Into a Guideline and Grading the Strength of Recommendations

The process of reaching recommendations within an expert group is poorly understood. For clinical practice guidelines,

tahir99-VRG & vip.persianss.ir

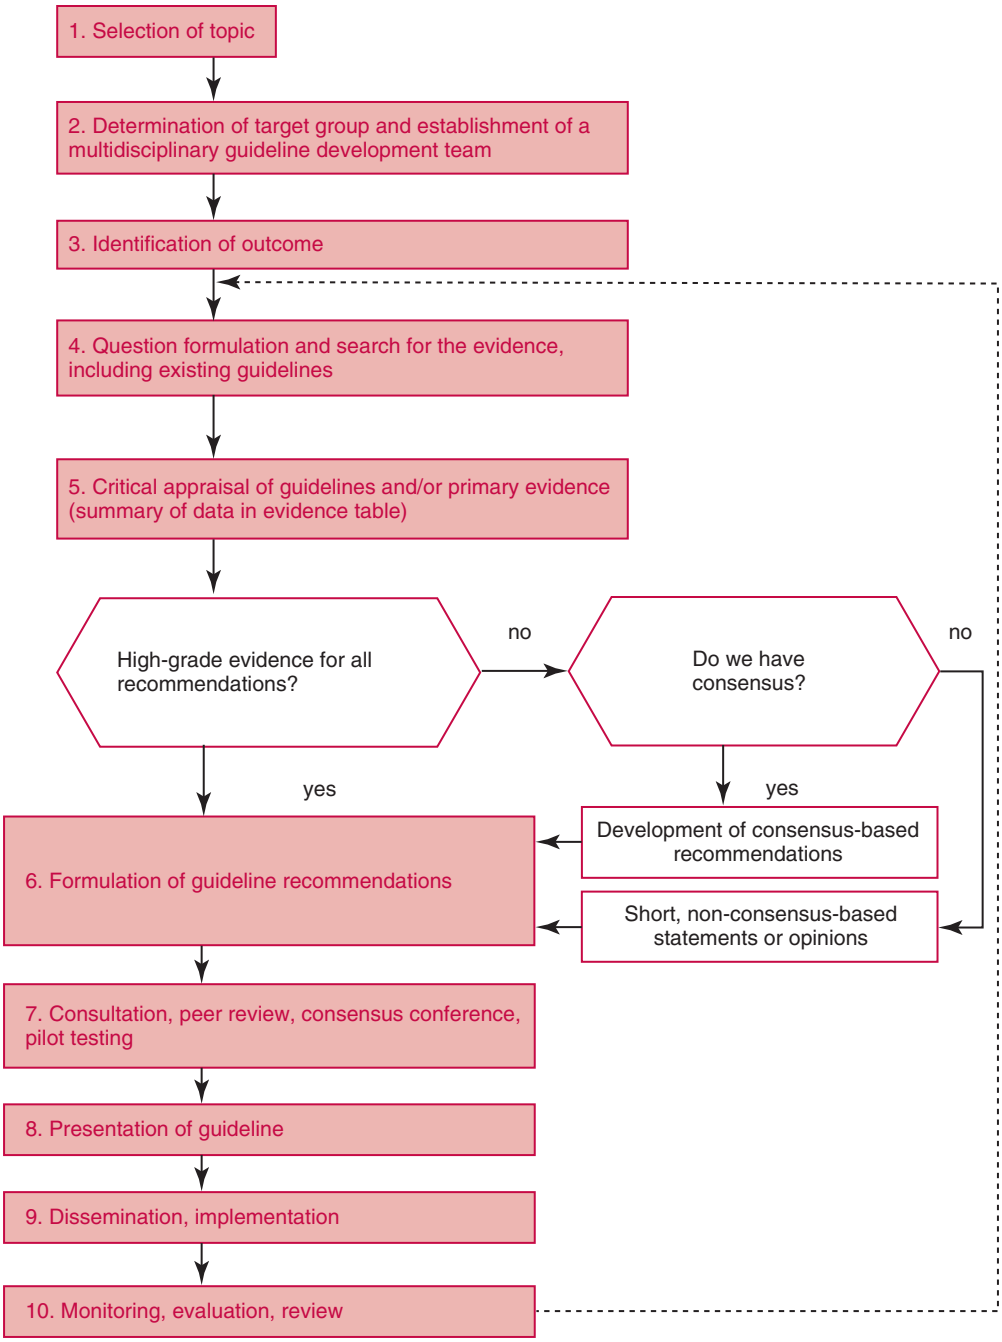

Figure 4-9 Steps in the development of a clinical practice guideline. *(Modified from Oosterhuis WP, Bruns DE, Watine J, Sandberg S, Horvath AR. Evidence-based guidelines in laboratory medicine: principles and methods. Clin Chem 2004;50:806-18.)*

the process may involve balancing of costs and benefits after values are assigned and the strength of evidence is assessed. Conclusive evidence for recommendations is only rarely available. Authors of guidelines thus have an ethical responsibility to make very clear the level of evidence that supports each recommendation.

Various schemes are available for grading the level of evidence, and one of them should be adopted and used explicitly.[16,102] Reservations have been expressed about many of the grading systems, as well as the way in which they are used.[43] In 2000, a group of researchers—the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) Working Group—began to look at the issues surrounding grading the levels of evidence (accessed www.gradeworkinggroup.org/index.htm on February 16, 2009). This group proposed a scheme for grading of evidence that has overcome some of the limitations of other schemes; at its core, it has four levels of evidence, as shown in Table 4-3.[53] The approach developed judges the evidence in relation to the study design, study quality, consistency, and directness for

tahir99-VRG & vip.persianss.ir

TABLE 4-3 A System to Rate the Strength of Evidence

Rating	Qualification
High	Further research is very unlikely to change our confidence in the estimate of effect.
Moderate	Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate.
Low	Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate.
Very low	Any estimate of effect is very uncertain.

Abstracted from Guyatt GH, Oxman AD, Vist GE, Kunz R, Falck-Ytter Y, Alonso-Coello P, et al; GRADE Working Group. GRADE: an emerging consensus on rating quality of evidence and strength of recommendations. BMJ 2008;336:924-6.

each outcome identified[2,52,126] and has been demonstrated in a pilot study.[3] A new grading scheme focused on guidelines for diagnostic testing has been developed in conjunction with the 2011 NACB guidelines on diabetes testing that were in press at the time of writing of this chapter.

The level of evidence does not always predict the strength of a recommendation, as recommendations may follow directly from clinical studies or may be extrapolated from study results. The GRADE Working Group identified four factors that could influence the strength of recommendations: (1) the balance between desirable and undesirable effects (e.g., adverse events, adverse impact on mortality and morbidity), (2) the quality of evidence, (3) the values and preferences of stakeholders, and (4) cost. Specifically, in the context of the use of a diagnostic test, the situation may arise wherein the diagnostic accuracy is excellent, but no effective treatment is available. The GRADE Working Group proposed a binary system for grading the strength of recommendations: strong and weak.[54]

The highest level of evidence (A in some systems) is rare in guidelines on the use of diagnostic tests. Recommendations made in the National Academy of Clinical Biochemistry (NACB) guidelines on laboratory testing in diabetes[123] were graded by the scheme of the American Diabetes Association. A vast majority of the recommendations were graded only as level E (expert opinion) by the authors of the guidelines, and only three were graded as level A. The high proportion of recommendations in the NACB document supported only by expert opinion is far from unique or peculiar to that document or to guidelines for diagnostic tests. A similar experience was found with the NACB practice guidelines for POCT.[100]

For analytical goal setting or quality specifications for analytical methods in guidelines, randomized controlled clinical trials (outcomes studies) are rarely available. As discussed by Bruns and Oosterhuis,[16] a different hierarchy of evidence

TABLE 4-4 Hierarchy of Criteria for Quality Specifications

Level	Basis
1A	Medical decision making: use of test in specific clinical situations
1B	Medical decision making: use of test in medicine generally
2	Guidelines—"experts"
3	Regulators or organizers of external quality assurance schemes
4	Published data on state of the art

From Fraser CG, Petersen PH. Analytical performance characteristics should be judged against objective quality specifications. Clin Chem 1999;45:321-3.

(Table 4-4) may be useful for grading of such laboratory-related recommendations.[38] The highest level of evidence is evidence related to patient outcomes. It is conceivable that even statistical modeling of specific clinical decisions could be considered as a subtype of evidence related to medical needs. For example, Klee and coworkers[75] have shown rates of misclassification of cardiac risk as a function of analytical bias of cholesterol assays, and Roddam and associates[118] have shown the impact of imprecision and inaccuracy of total PSA methods on the numbers of cancers detected and biopsies performed. Similarly, error rates in insulin dosing can be calculated[13] as a function of imprecision (or bias or both) of home glucose measurements, with increasing imprecision (or bias) of the glucose assay leading to increasingly frequent errors in the administered dose of insulin. Although such studies do not directly demonstrate an effect on patient outcomes, they may represent a distinct advance over anecdotes, and an expert group can make reasoned recommendations for imprecision based on such data and mathematical modeling when the clinical action follows a well-defined rule.

Level 1B in Table 4-4 refers primarily to the concepts of within-person and among-person biological variation. Levels of optimum, desirable, and minimum performance for both imprecision and bias have been defined on the basis of these concepts.[38] When a test is to be used for monitoring, use of this type of quality specification for imprecision appears appropriate in guidelines. Failure to use this approach is difficult to justify, because data on within-person and among-person biological variation are available for virtually all commonly used tests.[117] The quality specifications relate directly to the ability to use assays for monitoring and the ability to use common reference intervals within a population. These may be considered patient-centered objectives in a broad sense, if not in a narrow one.

Obtaining External Review and Updating the Guidelines

Three types of external examiners can evaluate the guideline[131]:

tahir99-VRG & vip.persianss.ir

- Experts in the clinical content area—to assess completeness of the literature review and the reasonableness of recommendations
- Experts on systematic reviewing and guideline development—to review the process of guideline development
- Potential users of the guidelines

In addition, journals, sponsoring organizations, and other potential endorsers of the guidelines may undertake formal reviews. Each of these reviews can add value. An approach has been proposed for the evaluation of guidelines, referred to as the AGREE instrument [developed by AGREE (Appraisal of Guidelines, Research, and Evaluation for Europe)] at www.agreecollaboration.org (accessed on March 23, 2011). This instrument has been used for review of guidelines in the management of diabetes, with particular reference to laboratory medicine testing.[97] Participants found that guidelines produced by agencies with clear procedures for guideline development were of a higher quality, and that agencies producing guidelines for laboratory practice tended to have more preanalytical and analytical guidance then those that encompassed both analytical and therapeutic interventions. Horvath[56] has pointed out that there is considerable variation in the approaches used to grade the quality of evidence and the strength of recommendations. A key feature of this variation is the quality of evidence considered acceptable, which, in the case of clinicians, the ultimate users of clinical guidelines, is provided by the RCT. Clinicians make decisions based on a range of indicators, including test results, and the utility of tests is often evaluated in isolation; it is not always possible to perform an RCT in which the diagnostic test is the only variable between experimental and control arms of the study. As Horvath points out, the GRADE group has suggested that if robust data from an RCT are not available, then guidance should be based on studies of diagnostic accuracy, with inferences made about the likely impact on patient outcomes.[126] However, Horvath's conclusion is surely right, that is, that there should be international agreement on the whole process of formulating and reporting guidelines, with transparency of process as the key.

As part of the guideline development process, a plan for updating should be developed. The importance of this step is underscored by the finding that one of the most common reasons for nonadherence to guidelines is that the guidelines are outdated.[147] Consistent with this finding, a study of clinical practice guidelines of the Agency for Healthcare Research and Quality showed that about half the guidelines were outdated in 5.8 years [95%-confidence interval (CI): 5.0 to 6.6 years].[132] No more than 90% of conclusions were still valid after 3.6 years (95%-CI: 2.6 to 4.6 years). These findings suggest that the time interval between completion and review of a guideline should be short.

APPLYING EVIDENCE AND CLINICAL AUDIT

Applying the evidence and auditing the process are the final steps in the EBLM A5 cycle; in themselves, these steps are part of a cycle (Figure 4-10). The term *audit* is associated with a particular connotation in healthcare, namely, clinical audit, and refers to the review of case histories of patients against the benchmark of current best practice.[130] The clinical audit was proposed as a tool to improve clinical practice, and a 2002 study indicates that it can do so, although the effects are modest.[143] A more general role for audit, however, is that it can be used as part of the wider management exercise of benchmarking performance with the use of relevant performance indicators against the performance of peers, as well as for the introduction of new tests and the deletion of redundant tests.[112]

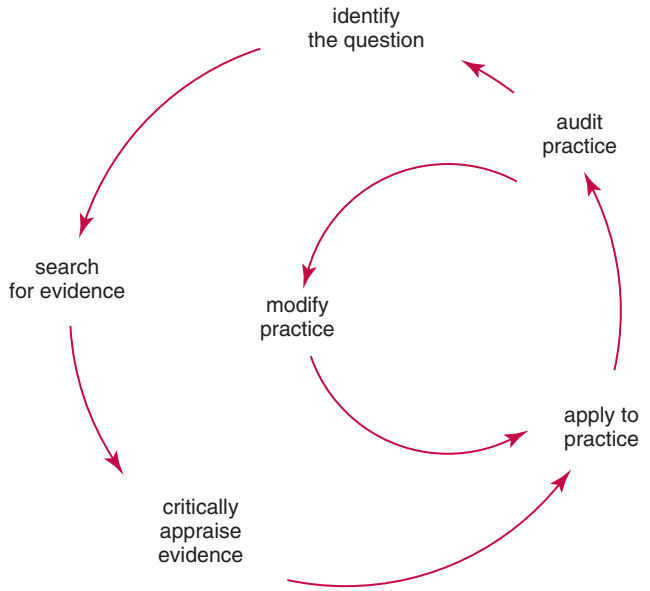

Figure 4-10 The audit cycle. *(From Price CP. Evidence-based laboratory medicine: supporting decision-making. Clin Chem 2000; 46:1041-50.)*

Five distinct activities can be considered under the broad umbrella of an audit: (1) solving problems associated with the process or outcome, (2) monitoring workload in the context of controlling demand, (3) monitoring the introduction of a new test and/or changes in practice, (4) deleting a redundant test, and (5) monitoring compliance with best practices (e.g., with guidelines).

The components of the audit cycle are depicted in Figure 4-10. All audit activities embrace the principles of EBLM, namely, that there is a clinical question for which the test result should provide an answer, and that the answer will lead to a decision made and an action taken, followed by an improved health outcome. Evidence should be available to support the use of the test in the setting for which it is being developed.

Audit to Help Solve Problems

All audits involve the collection of observational data and comparison against a standard or specification. In many cases, a standard does not exist, and maybe not even a specification. In those cases, it is important to establish a

tahir99-VRG & vip.persianss.ir

specification as the first stage of auditing a process. This specification should be built on the PICO framework (i.e., a properly structured question). Such a specification may then generate observations, which can lead to the creation of a standard. At the outset, it provides the comparative measure against which the performance data collected can be judged.

Solving a problem related to a process may first involve collecting data on aspects of the process that are considered to have an influence on outcome, with the goal of identifying rate-limiting steps. For example, a study of test result turnaround times might collect data on phlebotomy waiting time, quality of patient identification, transport time, sample registration time, quality of sample identification, sample preparation time, analysis time, test result validation time, and result delivery time.

The study of process may extend to the way in which the results are accessed and used. For example, the use of POCT in an emergency department (not in an audit) did not decrease the length of stay, despite the fact that delivery time for the results was much shorter than when results were provided by the laboratory.[69] The authors concluded that the test result generation was not the rate-limiting step.[69] Murray, in a similar study,[95] did find a reduction in the length of stay and identified a subset of patients in whom the POCT results could be used to rule-out diagnoses, allowing a faster discharge. Investigators noted that in other cases, the triage decision was delayed by the need for results from the laboratory. Lee-Lewandrowski and colleagues,[82] when looking at how to reduce turnaround times and length of stay in the emergency department, began their study by identifying which tests might be contributing to triage delays (i.e., they identified the clinical need and formulated the appropriate question before commencing their study).

Monitoring Workload and Demand

The true demand for a test will depend on the number of patients and the spectrum of disease in each case for which the test is appropriate. The appropriateness of the test request is a valuable arbiter in situations in which workload or demand for tests is questioned. A portfolio of evidence helps to define the basis for the appropriate use of tests. When an audit of workload for a test is conducted, it is possible to ask a number of questions, usually by questionnaire, that are directly related to the original generation of evidence upon which use of the test should be based (guidelines). These include the following:

- What clinical question is being asked?
- What decision will be aided by the results of the test?
- What action will be taken following the decision?
- What risks are associated with not receiving the result?
- What are the expected outcomes?
- Is there evidence to support the use of the test in this setting?
- And, for tests ordered urgently, why was this test result required urgently?

This approach is likely to identify unnecessary use of tests, misunderstandings about the use of tests, and instances of use of the wrong test. With the advent of electronic requesting and the electronic patient record, it is possible to build this approach into a routine practice.

After receipt of results from the questionnaire, a number of actions may be taken, depending on the findings of the survey. They are likely to include (1) feedback of results to users; (2) reeducation of users; (3) identification of unmet needs and research to satisfy, for example, a need for advice on alternative tests; (4) creation of an algorithm or guideline on use of the test; and (5) reaudit in 6 months' time to review for changes in practice. Any algorithm may be embedded in the electronic requesting package to provide an automatic bar to inappropriate requesting (e.g., to prevent liver function tests from being requested every day).

Monitoring the Introduction of a New Test

In this situation, the main objectives of the audit are to ensure (1) that the change in practice that is often consequent upon the introduction of a new test has been made, and (2) that the outcomes originally predicted are being delivered. The development of any new test should lead to evidence that identifies the following ways in which the test is going to be used:

- Identification of the clinical question(s), patient cohort, clinical setting, etc.
- Identification of preanalytical and analytical requirements for the test
- Identification of any decision support algorithm into which the test might have to be inserted (e.g., use in conjunction with other tests, signs, or symptoms)
- Identification of the decision(s) that is (are) likely to be made on receipt of the result
- Identification of the action(s) likely to be taken on receipt of the result
- Identification of the likely outcome(s)
- Identification of any risks associated with introduction of a new test
- Evidence (and strength of that evidence) that supports the use of the test and the outcomes to be expected
- Identification of any changes in practice (e.g., deletion of another test from the repertoire, move to POCT, reduction in laboratory workload)

This summary of use with portfolio of evidence forms the basis of the *standard operating procedure* for clinical use of the test, the core of the educational material for users of the service, and the basis for conducting the audit.

Before auditing the introduction of a new test, it is obviously important to have ensured that a full program of education of users has been completed, and that any changes in practice have been accommodated in the clinic and/or ward routines. Thus if a test is moving to the point-of-care, then the necessary training and certification of operators must have been completed.

Deleting a Redundant Test

This may be one of the most challenging aspects of demand management, as it involves a change in practice. However,

tahir99-VRG & vip.persianss.ir

when an evidence base exists to underpin the use of a new test, the replacement an older test can be of immense value, particularly because it can help to frame the education program that is made available to all users of the laboratory as part of the introduction of the test. This is also where evidence from comparative effectiveness research can be of value. Audit can play an important part at several stages in deleting a redundant test, from demonstrating that the old test does not deliver the required outcomes, through to introduction through a pilot study and auditing of full implementation.

Monitoring Adherence to Best Practice

This is the scenario that probably best reflects the way in which the clinical audit was first envisaged and practiced. Typically, it is based on a review of randomly selected cases from a clinical team with the review undertaken by an independent clinician. This approach is the most likely to identify when a test has not been performed and to identify unnecessary testing. The audit is best performed against some form of benchmark, which may be a local, regional, or national guideline; a guideline appropriately written (see earlier) will have taken into account the best evidence available, and in so doing will take away any bias that may exist between clinical teams.

In recent years, registers have been established to track the performance of health institutions and organizations. Typically, such registers are disease specific and will measure outputs at a high level (e.g., morbidity, mortality).[23,35,41] In some cases (e.g., the U.K. Renal Registry), the data collected are extensive and include laboratory information.[142] This depth of data is extremely helpful to the laboratory specialist because it begins to provide a basis for looking at issues, such as the impact of the analytical performance of certain tests on clinical outcomes.

APPLYING THE PRINCIPLES OF EVIDENCE-BASED LABORATORY MEDICINE IN ROUTINE PRACTICE

It is worth reflecting back on a few of the statements highlighted at the outset of this chapter as they apply to the practice of laboratory medicine:

- EB(L)M is about the explicit use of best evidence in the care of individual patients.
- EB(L)M is about integrating evidence with clinical expertise and patient preferences and values.
- EB(L)M is not about mechanisms, but about outcomes.
- EB(L)M is about improving knowledge on which decisions are made.

The concepts of EBLM provide the logic on which all of the elements of practice are founded. The tools of EBLM provide the means of delivering the highest quality of service in meeting the needs of all stakeholders involved in healthcare—from patient through to policymaker. However, it should be realized that the application of EBP appears more challenging in the specific case of laboratory medicine, especially in the case of the generation of evidence of benefit, compared with, for example, the generation of evidence for pharmaceutical interventions. Yet this may be a myth born solely out of an excessive focus on the basic science of disease and the pursuit of analytical excellence—at the expense of an emphasis on outcomes. In addition, a preponderance of studies on diagnostic tests have employed retrospective sampling; in themselves these investigations are unable to test whether the availability of a diagnostic test result can have any impact on decision making—which has to be one of the key requirements for improving outcomes.

The ways in which the test is used, once its efficacy has been demonstrated, will be embodied in the laboratory handbook, which, increasingly, will be electronic, fully searchable in real time, and built into clinical protocols and care pathways. Such a handbook can then be supported by an information resource, again searchable, which will inform the clinician (and the patient) of the strength of evidence to support use of the test in a specific situation. Use of these resources is practical, as shown by Richardson and Burdette, who observed that information resources could be accessed during patient consultations, with each access completed in 4 to 5 seconds.[116]

Demonstration of improved outcomes provides validation of the test and provides the data on which some form of economic analysis can be undertaken. As indicated earlier, this will show where the benefits are generated and what the costs and savings will be—costs to the laboratory medicine budget and savings elsewhere in the health economy. This information will enable a business case to be produced, supporting a reimbursement strategy, the style of which will depend on the type of healthcare system. The real challenge, however, comes in identifying the changes in practice that undoubtedly will have to be implemented should the test be introduced (e.g., to leverage benefits derived from reduction in length of stay, faster optimization of therapy, earlier discharge, and rule-out decisions in primary care).[112]

The evidence base then underpins the activities that ensure maintenance of a high quality of service: (1) provision of a knowledge resource that summarizes the evidence and its application, (2) use of this resource in education and training of health professionals, and (3) audit to ensure correct implementation and maintenance of good practice.

EBM expects clinicians to use primary studies of diagnostic performance and outcomes to guide decision making. However, as has been observed during the course of this chapter, few such studies are available for diagnostic tests and devices. Furthermore, in the case of many tests, it will be difficult to undertake such studies, in that use of established markers has become embedded in routine practice and consensus guidelines. In these cases, it will be necessary to depend on a more audit style of evaluation to attempt to validate the use of a test.[21] Although this may appear as a limitation, it still embodies many of the principles of EBP in laboratory medicine—crucially, recognition of the question for which the test result is seeking to provide an answer.

tahir99-VRG & vip.persianss.ir

Furthermore, the focus on outcomes will certainly help to demonstrate the value of the laboratory medicine service.

CHAPTER 5

Establishment and Use of Reference Values

*Gary L. Horowitz, M.D.**

Medicine is an art and a science in the service of fellow human beings. To improve the health of their patients, physicians (1) collect empirical data, (2) interpret these data using scientific knowledge and professional experience, (3) make decisions concerning diagnoses, (4) recommend preventive measures, and (5) execute therapeutic actions.

THE CONCEPT OF REFERENCE VALUES

Health is necessarily a relative concept.[27] However, to say that health is *relative* implies that the condition of individuals must be related to something.

Interpretation by Comparison

Data collected during the medical interview, clinical examination, and supplementary investigations must be interpreted by *comparison* with reference data. The physician does this when making a diagnosis. If the condition of the patient resembles what is considered typical of a particular disease, the physician may base the diagnosis on this observation (positive diagnosis). This diagnosis is made more likely if observed symptoms and signs do not fit the patterns characterizing a set of alternative diseases (diagnosis by exclusion). Such disease patterns are examples of reference data necessary for the medical interpretation. Also, the different degrees of health have their sets of characteristics that serve as reference sources for judging the health of an individual.

The process of medical interpretation by comparison may be more or less formalized. Some diagnoses are recognized by an intuitive assessment based on clinical experience. Others are based on reasoning using advanced knowledge of normal and pathologic anatomy, physiology, and biochemistry and of other relevant areas of medical science. Sometimes, the evaluation is of a qualitative nature; in other cases, it may be quantitative. The decision making may even be computer assisted, using rules based on the laws of probability and statistical techniques or on formalized medical knowledge (expert systems, artificial intelligence).

The interpretation of medical laboratory data is an example of decision making by comparison. Therefore, *reference values* are needed for all tests performed in the clinical laboratory, not only from healthy individuals but from patients with relevant diseases.

Ideally, an observed value *in an individual* should be related to *relevant* collections of reference values, such as values from healthy persons, from the undifferentiated hospital population, from persons with typical diseases, and from ambulatory individuals, along with previous values from the same subject.[78] A patient's laboratory result simply is not medically useful if appropriate data for comparison are lacking.

Normal Values—an Obsolete Term

Historically, the term *normal values* was frequently used to refer to medical data used for purposes of comparison. However, use of the term often leads to confusion because the word "normal" has several different connotations.[59] For example, three medically important but very different meanings of "normal" are given in the following:

1. *Statistical sense:* Values are often qualified as "normal" if their observed distribution seems to follow closely the theoretical *normal distribution* of statistics—the Gaussian probability distribution. This use of "normal" has sometimes misled people to believe that the distribution of biological data is symmetric and bell shaped, like the Gaussian distribution. But on closer examination, this usually is not correct. To exorcize the "ghost of Gauss," Elveback and colleagues recommend not using the term *normal limits.*[20] For a similar reason, the term *normal distribution* should be avoided and replaced by the term *Gaussian distribution.*
2. *Epidemiologic sense:* Another meaning of "normal" is illustrated by the following statement: It is "normal" to find that the activity of gamma-glutamyltransferase

*The author gratefully acknowledges the original contribution by Helge Eric Solberg, on which major portions of this chapter are based.

(GGT) in serum is between 7 and 47 IU/L, whereas it is considered "abnormal" to have a serum GGT value outside these limits. Here a more exact statement would read as follows: Approximately 95% of the values obtained, when the activity of GGT in sera collected from individuals considered to be healthy is measured, are included in the interval 7 to 47 IU/L. The obsolete concept of *normal values* in part carried this meaning. Alternative terms for "normal" in this sense are *common, frequent, habitual, usual,* and *typical.*

3. *Clinical sense:* The term "normal" also is often used to indicate that values show the absence of certain diseases or the absence of risks for the development of diseases. In this sense, a *normal value* is considered as a sign of health. Better descriptive terms for such values are *healthy,* nonpathologic, and *harmless.*

Because of confusion resulting from the different meanings of normal, the term *normal values* is obsolete and should not be used.

To prevent the ambiguities inherent in the term *normal values,* the concept of *reference values* was introduced and implemented in the 1980s.[28,78] This was an important event in establishing a scientific basis for clinical interpretation of laboratory data.[84]

Terminology

The International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) recommends the term *reference values* and related terms, such as *reference individual, reference limit, reference interval,* and *observed values.*[42] The definitions given below and the presentation in the following sections of this chapter are in accordance with IFCC recommendations.*

The definition of *reference values* is based on that of the reference individual[42]:

> Reference individual: *An individual selected for comparison using defined criteria.*

As mentioned previously, for the interpretation of values obtained from an individual under clinical investigation, appropriate comparison values are needed. To provide such values, suitable individuals must be selected. The characteristics of the individuals in each group chosen for comparison should be clearly defined. Their age and gender must be specified, along with the conditions for the specimen collection, and whether they should be healthy or have a certain disease. The definition of a reference individual also covers cases in which the individual under clinical investigation is his or her own reference, as discussed in a later section on subject-based reference values.

*A note on the literature: The Expert Panel on Theory of Reference Values of the IFCC has Produced a series of the six recommendations on the establishment and use of reference values.[42] A 1989 review by Solberg and Gräsbeck[78] gives in-depth information on this topic.

A reference value may then be defined as follows[42]:

> Reference value: *A value obtained by observation or measurement of a particular type of quantity on a reference individual.*

If, for example, the activity of GGT is measured in sera collected from a group of reference individuals selected for comparison according to a sufficiently exact set of criteria, the GGT results are considered reference values.

The observed value is defined as follows[42]:

> Observed value: *A value of a particular type of quantity obtained by observation or measurement and produced to make a medical decision. Observed values can be compared with reference values, reference distributions, reference limits, or reference intervals.*

Or, rephrased: an observed value is the laboratory result obtained by analysis of a specimen collected from an individual under clinical investigation. Some call such values "test values," but the word "test" in this term is ambiguous (a laboratory test? a statistical test?), and it should be avoided.

The IFCC also defines other terms related to the concept of reference values: reference population, reference sample group, reference distribution, reference limit, and reference interval.[42] Some of these terms are introduced in later sections of this chapter.

The term *reference range* is sometimes used for the IFCC-recommended term *reference interval.* This use is incorrect, as the statistical term *range* denotes the difference (a single value!) between maximum and minimum values in a distribution.[45]

Clinical Decision Limits

The terms *reference limits* and *clinical decision limits* should not be confused.[63,84] *Reference limits* is descriptive of the reference distribution; they tell us something about the observed variation of values in the selected subset of reference individuals. Comparison of new values with these limits conveys information about similarity to the given reference values. In contrast, *clinical decision limits* provide optimum separation among clinical categories. The latter limits may be based on analysis of reference values from several groups of individuals (healthy persons and patients with relevant diseases) and are used for the purpose of differential diagnosis.[28,63,81] Alternatively, such values are established scientifically on the basis of outcome studies and are used as clinical guidelines for treatment. Examples of current decision limits include the National Cholesterol Education Program guidelines for cholesterol,[21] the American Diabetes Association recommendations for glycated hemoglobin,[60] and the American Academy of Pediatrics guidelines on neonatal bilirubin[5]; each assumes that measurements of the involved analytes are accurate.

In this context, it is critical to point out another difference between reference limits and clinical decision limits. For most analytes, a laboratory should establish (or verify) its own reference limits. This is especially true for new analytes. But for other analytes, in particular those with clinical decision limits, physicians tend to use the national (or international)

guidelines. In the 2010 Clinical and Laboratory Standards Institute (CLSI) guidelines,[15] this point is given much-deserved emphasis. Laboratory efforts that once would have been dedicated to establishing or verifying reference intervals should, for these analytes, be redirected toward establishing accuracy. It does little good to establish one's own reference limits if physicians will (and should) use national guidelines. Methods to establish the accuracy of one's method are discussed in Chapters 2 and 8.

Types of Reference Values

In practice it is often necessary or convenient to give a short description associated with the term *reference values,* such as *health-associated reference values* (close to what was understood by the obsolete term *normal values*). Other examples of such qualifying words are *diabetic, hospitalized diabetic,* and *ambulatory diabetic.* These short descriptions prevent the common misunderstanding that reference values are associated only with health.

Subject-Based and Population-Based Reference Values

Subject-based reference values are previous values from the same individual, obtained when he or she was in a known state of health. *Population-based* reference values are those obtained from a group of well-defined reference individuals and are usually the types of values referred to when the term *reference values* is used with no qualifying words. This chapter deals primarily with population-based values. It should be noted, however, that for some tests, intraindividual variation may be small relative to interindividual differences. In such cases (e.g., creatinine,[25] immunoglobulins[80]), population-based reference intervals may actually mask clinically significant intraindividual changes, as noted later in this chapter.

It is also important to note that this chapter focuses on population-based *univariate reference values* and quantities derived from them. For example, if separate reference values for cholesterol and triglycerides in serum are used, two sets of univariate reference values are produced. The term *multivariate reference values* denotes that results of two or more analytes obtained from the same set of reference individuals are treated in combination. Serum cholesterol and triglyceride values may be used, for example, to define a bivariate reference region. This subject is addressed briefly in a later section.

Requirements

Certain conditions apply for a valid comparison between a patient's laboratory results and reference values[19]:

1. All groups of reference individuals should be clearly defined.
2. The patient examined should sufficiently resemble the reference individuals (in all groups selected for comparison) in all respects other than those under investigation.
3. The conditions under which the specimens were obtained and processed for analysis should be known.
4. All quantities compared should be of the same type.
5. All laboratory results should be produced using adequately standardized methods under sufficient analytical quality control (see Chapters 3 and 8).

To these general requirements one may add others that become necessary when more advanced techniques for decision making are applied.[84]

6. Stages in the pathogenesis of diseases that are the objectives for diagnosis should be demarcated. For example, although some overlap occurs, the clinical grades of congestive heart failure (CHF) are distinguished by progressive increases in levels of N-terminal (NT)-proBNP.[65]
7. Clinical diagnostic sensitivity and specificity, prevalence, and clinical costs of misclassification should be known for all laboratory tests used. For example, in some instances, one might want to know whether a given BNP (or NT-proBNP) value is "healthy," in which case one would want to use reference values for age- and gender-matched individuals with no evidence of CHF. In contrast, faced with a patient complaining of shortness of breath in the emergency room, one might want instead to know, not so much whether any degree of CHF is present, but whether the patient's CHF is sufficiently advanced to be the cause of the shortness of breath.[49,54]

SELECTION OF REFERENCE INDIVIDUALS

A set of *selection criteria* determines which individuals should be included in the group of reference individuals.[42,78] Such selection criteria include statements describing the source population and specifications of criteria for health or for the disease of interest.

Often, separate reference values for each sex and for different age groups,[8A] as well as other criteria, are necessary. Our group of reference individuals therefore may have to be divided into more homogeneous subgroups. For this purpose, specific rules for the division, called *stratification* or *partitioning criteria,* are needed.

It is important to distinguish between selection and partitioning criteria. First, selection criteria are applied to obtain a group of reference individuals. Thereafter, this group is divided into subgroups using partitioning criteria. Whether a specific criterion (e.g., gender) is a selection or a partitioning criterion depends on the purpose of the actual project. For example, gender is a selection criterion if reference values only from female subjects are necessary.

Concept of Health in Relation to Reference Values

There is an obvious requirement for health-associated reference values for quantities measured in the clinical laboratory. But the concept of health[27] is problematic; much confusion may arise if the selection criteria for health are not clearly stated for a specific project.

The World Health Organization has defined health as "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity." This is an

attempt to define *absolute health,* but as such, absolute health is never attained.

Thus in the context of reference values, a more modest concept of health is needed. Past experience has taught that health is a *relative concept*. It is possible to be ill in one respect and healthy in another. For example, what is considered healthy in a developing country may be judged to be rather unhealthy in Western Europe and North America.

Furthermore, the diagnosis of health should not be based solely on excluding pathology. This fact, which has been named the *privative concept of health,* may cause difficulties. If no signs of disease are demonstrated, uncertainty remains, because such signs might be detected on closer examination. The "feeling" of health is not a reliable criterion because of its subjectivity. In addition, an individual may try to conceal an illness for various reasons (e.g., to qualify for life insurance).

When reference values are produced, the following questions are asked: (1) Why are these values needed? (2) How are they going to be used? (3) To what extent does the intended purpose of the project determine how health is identified? In short, a *goal-oriented concept of health* is needed.

Gräsbeck suggested the following general definition of health, which summarizes the relative, privative, and goal-oriented aspects discussed previously[27]: *Health is characterized by a minimum of subjective feelings and objective signs of disease, assessed in relation to the social situation of the subject and the purpose of the medical activity, and it is in the absolute sense an unattainable ideal state.*

Strategies for Selection of Reference Individuals

Several methods have been suggested for the selection of reference individuals. Table 5-1 shows a variety of concepts that may be used to describe a sampling scheme. The concepts of each pair are mutually exclusive. For example, the sampling may be direct or indirect. One may, however, combine one concept from several pairs to obtain a more exact description. For example, the selection may be direct, a priori or a posteriori, and nonrandom.

The merits and disadvantages of these strategies are described in the following sections. It is not possible to recommend one sampling scheme that is superior in all respects and applicable to all situations. One must choose the optimal approach for a given project and state clearly what has been done.

Direct or Indirect Sampling?

Direct selection of reference individuals (see Table 5-1) concurs with the concept of reference values as recommended by the IFCC,[42] and it is the basis for the presentation in this chapter. Its only disadvantages are the problems and costs of obtaining a representative group of reference individuals.

These practical problems have led to the search for simpler and less expensive approaches such as the *indirect* method.[6,28] This method is based on the observation that most analysis results produced in the clinical laboratory seem to be "normal." An example of an indirect method is shown in Figure 5-1. As seen, the values of serum sodium

TABLE 5-1 Strategies for Selection of Reference Individuals

Direct	Individuals are selected from a parent population using defined criteria.
Indirect	Individuals are not considered, but certain statistical methods are applied to analytical values in a laboratory database to obtain estimates with specified characteristic.
A priori*	Direct method (see above) in which individuals are selected for specimen collection and analysis if they fulfill defined inclusion criteria.
A posteriori	Direct method using an already existing database containing both analysis results and information on a large number of individuals. Values of individuals fulfilling defined inclusion criteria are selected.
Random	Process of selection giving each item (individual or test result) an equal chance of being chosen.
Nonrandom	Process of selection giving each item an unequal chance of being chosen.

*Note: The terms a priori and a posteriori signify in this context "before" and "after" and refer to when inclusion criteria are applied.

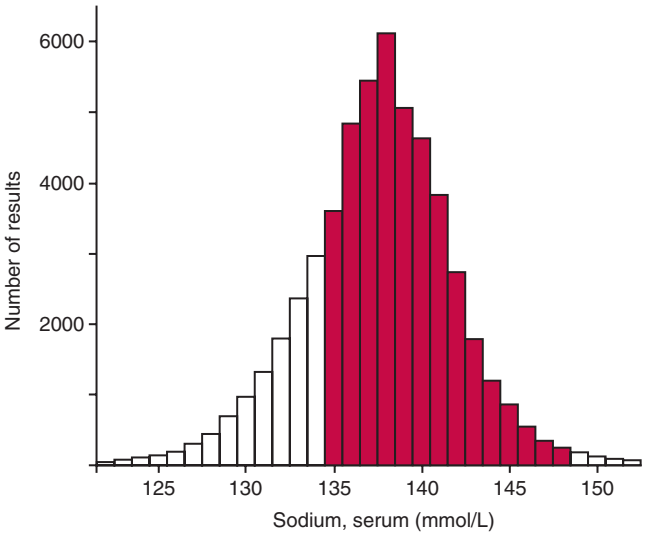

Figure 5-1 Distribution of sodium concentrations in serum obtained in a routine laboratory. The histogram shows the distribution of 53,128 serum sodium concentrations measured in consecutive clinical specimens during a 6-month period in 1982 at Rikshospitalet, Oslo, Norway. The shaded area is within health-associated reference limits (135 to 148 mmol/L), as determined by a direct method (193 healthy adults of both sexes).

concentrations from hospitalized patients have a distribution with a preponderant central peak and a shape similar to a Gaussian distribution. The underlying assumption of the indirect method is that this peak is composed mainly of *normal values.* Advocates of the method therefore claim that it is possible to estimate the *normal interval* if the distribution of *normal values* from this distribution is extracted. However, as shown in Figure 5-1, *normal limits* determined by the indirect method on the basis of this distribution would be seriously biased compared with the health-associated reference limits. Note, for example, the substantial proportion of values below 135 mmol/L—the true, health-associated, lower reference limit. (The term "normal" is used here intentionally to distinguish between the concepts of *normal values* and *reference values.*)

Several mathematical methods have been used to extract the distribution of *normal values* from routine laboratory data.[6,28]

The indirect method, however, has at least two major deficiencies:

1. Estimates of the lower and upper *normal limits* depend heavily on the particular mathematical method used and on its underlying assumptions.
2. The indirect method destroys the scientific basis for obtaining and comparing reference values. The results for each hospital would depend on the characteristics of the hospital's patient group at that particular time. These results would vary not only across hospitals but for the same hospital at different times. The outcome would be a compilation of unstable values for each analyte.

Hospital databases may, however, be used for the establishment of reference values that are fully concordant with IFCC recommendations.[46,76] The requirement is that laboratory data should be *combined with information stored in clinical databases* (i.e., to apply a direct sampling strategy instead of the distribution-based indirect method). Laboratory results are to be used as reference values only if stated clinical criteria are fulfilled. One may define criteria for selecting individuals who have a specified state of health or the disease for which reference data are necessary. Usually certain constraints are imposed on the use of their laboratory results, such as allowing only one result of each analyte under study from each selected individual. Such reference values have a potential advantage over those based on direct sampling from other types of populations: hospital-based reference values are ideal for interpretation of results from hospitalized patients because they are produced under similar conditions.

A Priori or A Posteriori Sampling?

When carefully performed, both a priori and a posteriori sampling (see Table 5-1) may result in reliable reference values. The choice is often a question of practicality. Both require the same set of successive steps, but the order of some of these operations differs depending on the mode of selection: a priori or a posteriori.[28]

The first step in the process of producing reference values for a laboratory test should always be the collection of quantitative information about sources of biological variation for the analyte studied. A search through relevant literature may yield the required information (see Chapter 6).[71,85] If relevant information cannot be found in the literature, pilot studies may be necessary before the selection of reference individuals is planned in detail.

Serum sodium is an example of a biological analyte that is affected by only a few sources of biological variation. However, the list of factors may be rather long for other analytes, such as serum enzymes, proteins, and hormones.

It is important to distinguish between controllable and noncontrollable sources of biological variation. Some factors may be controlled by standardization of the procedure for preparation of reference individuals and specimen collection (see a later section of this chapter). Other factors, such as age and gender, may be relevant partitioning criteria. Remaining sources of variation should be considered when criteria for the selection of reference individuals are defined.

The a priori strategy is best suited for smaller studies. Possible reference individuals from the parent population are interviewed and examined clinically and by selected laboratory methods to decide whether they fulfill the defined inclusion criteria. If the decision is positive, specimens for analysis are collected by a standardized procedure (including the necessary preparation of individuals before the collection).

The a posteriori method is based on the availability of a large collection of data on medically examined individuals and measured quantities. Studies thoroughly planned by centers for health screening or preventive medicine may provide such data. It is important that data be collected by a strictly standardized and comprehensive protocol concerning (1) sampling from the parent population, (2) registration of demographic and clinical data on participating individuals, (3) preparation for and execution of specimen collection, and (4) handling and analysis of the specimens. If these requirements are met, values may be selected after application of the defined inclusion criteria to individuals found in the database. The selection of individuals from large hospital databases (see earlier discussion) is another example of the application of an a posteriori method. In this case, however, the quality of data may be lower than in well-planned population studies.

A study performed in Kristianstad, Sweden,[8] highlights a practical problem often met when reference individuals are selected: the number of subjects fulfilling the inclusion criteria may be too small. In this study, only 17% of participants were accepted into the study, according to the criteria used, leaving an insufficient reference sample group. The frequency of exclusion was higher among women and in older age groups.

This problem has two possible solutions:

1. The exclusion criteria may be relaxed. As already discussed, the set of relevant sources of biological variation differs among different analytes. One may define a minimum set of exclusion criteria for a given laboratory test. In the Kristianstad study, the complete group of individuals could probably be used for establishment of

reference values for serum sodium, and most of the individuals would be acceptable for the determination of reference values for several other analytes.[8]

2. Another design of the sampling procedure could reduce the practical problems and costs of obtaining a sufficiently large group of reference individuals. The Kristianstad study showed that 75% of excluded subjects could have been identified using only a simple questionnaire.[8] In the upper age group, this percentage was even higher. Therefore, preliminary screening of a large number of individuals from the parent population, using a carefully designed autoanamnestic questionnaire (i.e., of or related to the current or previous medical history of a patient), would result in a much smaller sample of individuals for examination clinically and by laboratory methods. If 3000 individuals had been prescreened in Kristianstad, and if only the individuals remaining in the reduced sample were subjected to a closer examination, a group of 240 reference individuals would have been obtained.

The two modifications of the protocol may also be combined.

Random or Nonrandom Sampling?

Ideally, the group of reference individuals should be a random sample of all individuals fulfilling the inclusion criteria defined in the parent population. Statistical estimation of distribution parameters (and their confidence intervals) and statistical hypothesis testing require this assumption.

For several reasons, most collections of reference values are, in fact, obtained by a nonrandom process.[33] This means that all possible reference individuals in the entire population under study do not have an equal chance of being chosen for inclusion in the usually much smaller sample of individuals studied. A strictly random sampling scheme in most cases is impossible for practical reasons. It would imply the examination of and application of inclusion criteria to the entire population (thousands or millions of persons), and then the random selection of a subset of individuals from among those accepted.

It is important to realize that a random sample is not obtained, in the strict sense, if individuals are randomly selected from the entire population, and then inclusion criteria are applied to sort out the subset of individuals fulfilling these criteria, even though this may be the best approximation to be obtained. Usually the situation is less satisfactory. A sample of reference individuals obtained by selecting among (1) blood donors, (2) persons working in a factory, or (3) hospital staff, or by (4) selection from hospital databases definitely is not the result of random sampling of possible reference individuals in the general population.

The conclusions are obvious: (1) the best reference sample obtainable must be used with all practical considerations taken into account, and (2) the data should be used and interpreted with due caution, with awareness of the possible bias introduced by the nonrandomness of the sample selection process.

Selection Criteria and Evaluation of Subjects

The selection of reference individuals consists essentially of applying defined criteria to a group of examined candidate persons.[42] The required characteristics of the reference values determine which criteria should be used in the selection process. Box 5-1 lists some important criteria to consider when production of health-associated reference values is the aim.

In practice, consideration of which *diseases* and *risk factors* to exclude is difficult (see the discussion on the concept of health earlier in this chapter). The answer lies in part in the intended purpose of establishing reference values; the project must be goal oriented.

For example, even the definition of *obesity* is problematic. It might be based on a known or assumed contribution to the risk for development of a specified disease. However, scientific data of this type are seldom available for the studied population. Another possibility for establishing obesity is to use upper limits based on weight measurements in different age, gender, and height groups of the general population, using, for example, the national age-, gender-, and height-specific mean weight + 20% as the upper limit. However, national differences are great. Tables of optimum or ideal weights have been published by life insurance companies; they may be more appropriate for delineation of obesity than this formula.

Similar problems affect the definition of *hypertension* in relation to the establishment of health-associated reference values and exclusion criteria based on *laboratory examinations*. It has been argued that a circular process might happen when laboratory tests are used to assess the health of subjects

BOX 5-1 Examples of Exclusion Criteria for Health-Associated Reference Values*

Diseases

Risk Factors
Obesity
Hypertension
Risks from occupation or environment
Genetically determined risks

Intake of Pharmacologically Active Agents[46,86]
Drug treatment for disease or suffering
Oral contraceptives
Drug abuse
Alcohol
Tobacco

Specific Physiologic States
Pregnancy
Stress
Excessive exercise

*The box lists only some major classes of criteria. It should be supplemented with other relevant criteria based on known sources of biological variation (see Chapter 6).[71,85]

who are subsequently used as healthy control subjects for laboratory tests. But actually there is no difference, in this context, between measuring height, weight, and blood pressure and performing selected laboratory tests, provided that these laboratory tests are neither those for which reference values are produced nor tests that are significantly correlated with them.[27]

It is particularly difficult to define selection criteria when establishing reference values for a geriatric population.[22] In higher age groups, it is "normal" to have minor or major diseases and to take drugs. One solution is to collect values at one time and to use the values of survivors after a defined number of years.[27,61]

Usually the clinical evaluation of candidate individuals is based on (1) an anamnestic interview or questionnaire (i.e., the complete history recalled and recounted by a patient), (2) a physical examination, and (3) supplementary investigations. Anamnestic and examination forms tailored to the requirements of the actual project facilitate the evaluation and document the decisions made.

Partitioning of the Reference Group

It may also be necessary to define *partitioning criteria* for the subclassification of the set of selected reference individuals into more homogeneous groups (Box 5-2).[42] (The question of determining when stratification of the reference sample group is necessary and justified is discussed in later sections.) In practice, the number of partitioning criteria should usually be kept as small as possible to ensure sufficient sample sizes to derive valid estimates.

Age and *gender* are the most frequently used criteria for subgrouping, because several analytes vary notably among different age and gender groups (see Chapter 6).[22,71,85] Age may be categorized by equal intervals (e.g., by decades) or by intervals that are narrower in the periods of life where greater variation is observed. In some cases, it is more convenient to use qualitative age groups, such as (1) postnatal, (2) infancy, (3) childhood, (4) prepubertal, (5) pubertal, (6) adult, (7) premenopausal, (8) menopausal, and (9) geriatric. Height and weight also have been used as criteria for categorizing children.

Additional factors are discussed in Chapter 6.[71,85]

BOX 5-2 Examples of Partitioning Criteria for Possible Subgrouping of the Reference Group

- Age (not necessarily categorized by equal intervals)
- Gender
- Genetic factors
  - Ethnic origin
  - Blood groups (ABO)
  - Histocompatibility antigens (HLA)
  - Genes
- Physiologic factors
  - Stage in menstrual cycle
  - Stage in pregnancy
  - Physical condition
- Other factors
  - Socioeconomic
  - Environmental
  - Chronobiological

HLA, Human leukocyte antigen.

SPECIMEN COLLECTION

Several preanalytical factors influence the values of biological quantities, such as the concentrations of components in blood and in other specimens and the amount excreted in feces, urine, or sweat. This topic is covered elsewhere (see Chapter 6).* In this discussion, only aspects of special relevance to the generation of reliable reference values are highlighted.[4,42]

Preanalytical standardization of the (1) preparation of individuals before specimen collection, (2) procedure of specimen collection itself, and (3) handling of the specimen before analysis may eliminate or minimize bias or variation from these factors. This reduces biological "noise" that might otherwise conceal important biological "signals" of disease, risk, or treatment effect.

Preanalytical Standardization

Preanalytical procedures used before routine analysis of patient specimens and when reference values are established should be as similar as possible. In general, it is much easier to standardize routines for studies of reference values than those used in the daily clinical setting, especially when specimens are collected in emergency or other unplanned situations. Thus two approaches have been suggested:

1. Only such factors that may be relatively easily controlled in the clinical setting should be part of the standardization when reference values are produced.
2. The rules for preanalytical standardization when reference values are produced (Table 5-2) should also be used for the clinical situation. For example, it has been shown that it is possible to apply these rules rather closely in the clinical setting for both hospitalized and ambulatory patients.[78] The same philosophy forms the basis for recommendations concerning routine blood specimen collection.†

However, either philosophy is concordant with the concept of reference values, provided that the conditions under which reference values are produced are clearly stated.

Analyte-Specific Considerations

The magnitudes of preanalytical sources of variation clearly are not equal for different analytes (see Chapter 6).‡ In fact, some believe that only those factors that cause unwanted variation in the biological quantities for which reference values are being generated should be considered. For example,

TABLE 5-2 Standardization of Preanalytical Factors in the Establishment of Reference Values for Adult Individuals

The Day Before Specimen Collection	
Food	Ordinary intake; last meal before 2200 hours
Alcohol	Maximum of one small bottle of beer (or equivalent of other beverage) taken with a meal
Abstinence	No solid food or tobacco and maximum of one glass of water after 2200 hours
Subjects Lying in Bed; Collection in the Morning	
Rest	Bed rest from 2200 hours until collection; a short visit to the toilet allowed, but minimum of 1 hour before collection
Collection	Between 0700 and 0900 hours (record time); supine position with the arm approximately in the horizontal plane
Ambulatory Subjects; Collection in the Morning	
Rise	1 to 3 hours before collection (record time)
Transport	Public or car transport for maximum of 45 minutes; walking a maximum of 500 meters (<550 yd) at moderate speed
Rest	Sitting for at least 15 minutes; arm muscle work not allowed
Collection	Between 0800 and 1000 hours (record time); sitting position with the arm approximately 45° below the horizontal position
Ambulatory Subjects; Collection in the Afternoon	
Breakfast	A light meal in the morning (approximately 310 kcal, 1300 kJ) composed of milk, coffee, or tea (maximum two cups); two open sandwiches with butter, slices of lunch meat/cheese, or marmalade
Activity	No exercise or heavy work
Rest	Sitting at least 15 minutes; arm muscle work not allowed
Collection	Between 1300 and 1500 hours (record time); minimum of 4 hours after breakfast; otherwise as above
Collection and Handling of Specimen*	
Venipuncture	In the cubital fold; no tourniquet; finger pressure proximal to the site allowed
Difficulties	A new attempt on opposite arm after 15 minutes' rest

*Consult Chapter 7 for a discussion of other requirements for the collection and handling of specimens.
Based on Scandinavian recommendations.[4,28]

body posture during specimen collection is highly relevant for the establishment of reference values for nondiffusible analytes, such as albumin in serum, but irrelevant for establishment of serum sodium values.[23]

Alternatively, several constituents are analyzed routinely in the same clinical specimen. Therefore, it would be impractical to devise special systems for every single type of quantity.[78] Consequently, three standardized procedures for blood specimen collection by venipuncture have been recommended[4,28]: (1) collection in the morning from hospitalized patients, (2) collection in the morning from ambulatory patients, and (3) collection in the afternoon from ambulatory patients. Table 5-2 summarizes these procedures. However, such schemes have to be modified depending on local conditions and necessities and on the intended use of the reference values produced. Published checklists[42,78] may be helpful in the design of a scheme.

A special problem is caused by drugs taken by individuals before specimen collection,[44,86,93] and it may be necessary to distinguish between indispensable and dispensable medications. If possible, dispensable medication should always be avoided for at least 48 hours. The use of indispensable drugs, such as contraceptive pills or essential medication, may be a criterion for exclusion or partitioning.

In emergency or other unplanned clinical situations, even a partial application of the standardized procedure for collection has been shown to be of great value.[28]

The Necessity for Additional Information

The clinical situation often is different from a controlled research situation; specimens have to be taken (1) during operations, (2) in emergency situations, and (3) when patients are unwilling or unable to follow instructions. Therefore the clinician needs additional information for interpretation of a patient's values in relation to reference values obtained under fairly standardized conditions.

An *empirical approach*[78] is to produce other sets of reference values, such as postprandial values, postexercise values, or postpartum values.[28] Such a method, however, is very expensive and does not cover all situations that could possibly arise.

Another, more general solution to the problem is called the *predictive approach*.[78] Starting from a set of ordinary reference values and using quantitative information on the effects

of various factors, such as (1) intake of food, alcohol, and drugs; (2) exercise; (3) stress; or (4) posture, expected reference values that fit the actual clinical setting (see Chapter 6) could be estimated.[71,85]

More studies of such effects are needed, especially for the combined effect of two or more sources of variation. For example, is the combined effect of alcohol and contraceptive drugs on GGT activity in serum less than, equal to, or greater than the sum of their individual effects?

ANALYTICAL PROCEDURES AND QUALITY CONTROL

Essential components of the required definition of a set of reference values are specifications concerning (1) the analysis method (including information on equipment, reagents, calibrators, type of raw data, and calculation method), (2) quality control (see Chapter 8), and (3) reliability criteria (see Chapter 2).[28,42]

Specifications should be so carefully described that another investigator will be able to reproduce the study, and the user of reference values will then be able to evaluate their comparability with values obtained by methods used for producing the patient's values in a routine laboratory. To ensure comparability between reference values and observed values, the same analytical method should be used.

It is often claimed that analytical quality should be better when reference values rather than routine values are produced. This may be true for accuracy; all measures should be taken to eliminate bias. The question of imprecision is more difficult because it depends in part on the intended use of the reference values. Increases in analytical random variation result in widening of the reference interval.[28] For some special uses of reference values, the narrower reference interval obtained by a more precise analytical method may be appropriate. However, this usually is not true for routine clinical use of reference values. Interpretation is simplest if a patient's values and reference values are comparable with regard to analytical imprecision. For the same reason, it is advisable to analyze specimens from reference individuals in several runs to include between-run components of variation. A safe way to obtain comparability is to include these specimens in routine runs together with real patient specimens.

STATISTICAL TREATMENT OF REFERENCE VALUES

This section deals with two main topics: the partitioning of reference values into more homogeneous classes, and the determination of reference limits and intervals.[42A] The subject matter is presented in the order in which data often are treated. Figure 5-2 gives an outline and refers to corresponding sections in the text. Before the presentation of methods, some statistical concepts used are briefly discussed (see also Chapter 2). A textbook by Harris and Boyd gives an excellent survey of the statistical bases of reference values in laboratory medicine.[34]

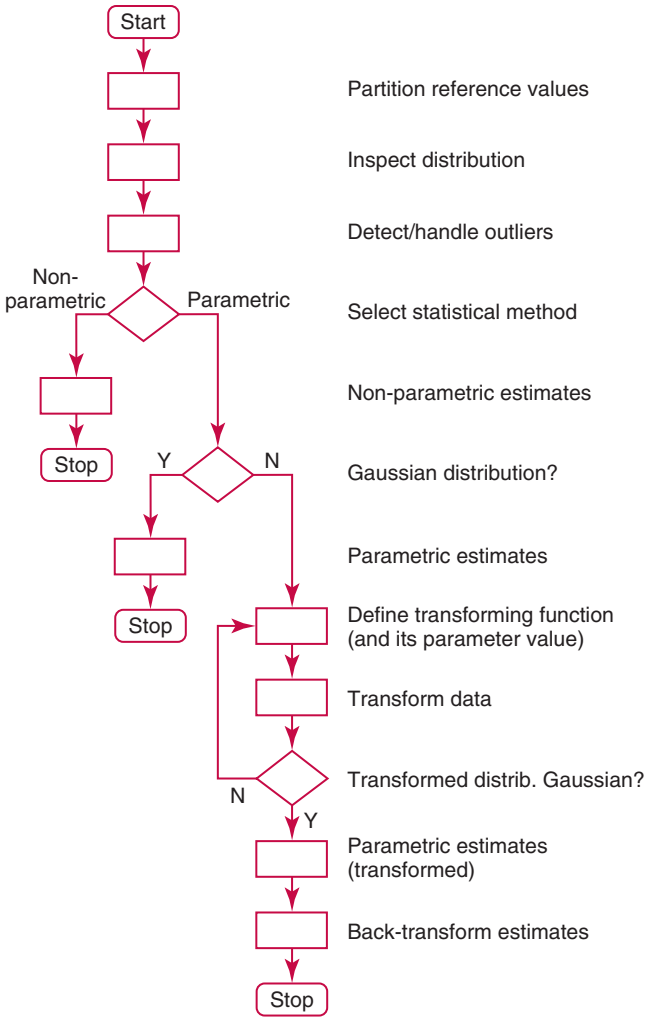

Figure 5-2 The statistical treatment of reference values. The boxes in the flow chart refer to sections in the text. Note: The order of the three first actions (partitioning, inspection, and detection and/or handling of outliers) may vary, depending on the distribution and the statistical methods applied. *N*, No; *Y*, yes.

Basic Statistical Concepts

Sample

The first step in the establishment of reference values is the selection of a group of reference individuals. In practice, it usually is not feasible to gather observations on all possible reference individuals of a certain category of the general population. Therefore, a smaller group (sometimes called the reference *sample* group) is examined. This *subset* is so chosen that it is expected to give the desired information about the characteristics of the complete *set* of individuals (the reference *population*).[42]

The reference *population* is often considered to be *hypothetical* because its characteristics are not observed directly; neither the number (the set size) nor the properties of all of its individuals are known. An obvious requirement is that individuals in the subset are typical of those in the complete

set. Statistical theory usually assumes that items in the subset are selected at *random* from among those in the set; otherwise, the subset may be biased. If items are not randomly selected, statistical techniques are still used, but only with due caution and with awareness of the possible bias introduced.

Two main types of inferences may be made from values obtained from the subset (sample group) to the set (total reference population): estimating properties and testing hypotheses.

Estimating Properties

In practice, properties of the set are estimated. A *reference limit* (a percentile) of a biological quantity, such as the activity of serum GGT, based on subset reference values, is an example of a *point estimate* (a single value). It is considered representative of the property that might have been found if all possible values in the set had been observed. If many randomly selected subsets from the same set are examined, several estimates with some variation around the "true" value of the set are obtained. Also, it is possible to produce an *interval estimate* bounded by limits within which the "true" value is located with a specified confidence: the *confidence interval*. The parameter is expressed as a number in the interval 0 to 1, indicating the degree on the scale between "never" and "always." A reference limit for serum GGT can thus be associated by a confidence interval showing its region of uncertainty.

Testing Hypotheses

Also, the hypotheses about the distribution can be tested. For example, the hypothesis that the distribution of values for serum GGT activities is of the Gaussian type (the *null* hypothesis) can be stated. If true, this will enable determination of the reference limits with relatively few points. If deviations of subset values from the Gaussian distribution are small, they can be ascribed to variation caused by chance alone. In that case, it is possible to use statistical methods based on the Gaussian distribution. However, the hypothesis must be rejected if it is unlikely that observed deviations from the Gaussian distribution are caused by chance alone. *Statistical tests* provide quantitative approaches to these types of decisions: the null hypothesis is rejected if the statistical test shows that the probability of the hypothesis being true is less than a stated *significance level.* The *probability* (*P*) is a number in the interval of 0 to 1, indicating the degree on the scale between "unlikely" and "certain." If a significance level of 0.05 is stated, the Gaussian hypothesis is tested for the distribution of serum GGT activities; it should be rejected if the probability obtained by the test is, for example, $P = 0.01$. Then the alternative hypothesis that the distribution is non-Gaussian is accepted. The *power* of a statistical test is the probability of rejection when the null hypothesis is false.

Describing the Distribution

In the following sections, the term *reference distribution*[42] is used for the distribution of reference values (x). The two statistics *arithmetic mean* $\bar{x}$ and *standard deviation* (s_x) are

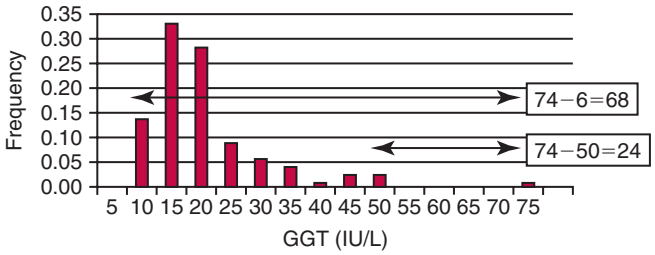

Figure 5-3 Observed distribution of 124 gamma-glutamyltransferase (GGT) values in serum (IU/L). The *upper arrow* indicates the range of observed values (highest − lowest, or 74 − 6 = 68); the *lower arrow* indicates the difference between the highest value and the next highest value (74 − 50 = 24). Because the quotient (24/68 = 0.35) exceeds 0.33, Dixon's range test indicates that the highest value is an outlier and therefore is omitted from all further analyses.

measures of its location and the dispersion of values in it, respectively. They are defined as follows:

$$\bar{x} = \frac{\sum x}{n}$$

$$s_x = \sqrt{\frac{\sum (x - \bar{x})^2}{n-1}} = \sqrt{\frac{\sum x^2 - \frac{\left(\sum x\right)^2}{n}}{n-1}}$$

where x represents each of the n reference values in the subset (or a subclass of it).

An observed distribution may be presented as a table or graph (histogram) showing the number of observations in small intervals (Figure 5-3). The number of observations in an interval divided by the total number of observations in the distribution (its size) is an estimator of the probability of finding a value in the corresponding interval of the hypothetical *probability distribution* of the population (assuming random sampling). By consecutive summing of all these ratios, starting with the leftmost interval of the observed distribution, an estimate is obtained of the hypothetical *cumulative probability distribution,* shown plotted on Gaussian probability paper in Figure 5-4, *B*.

Reference Limits: Interpercentile Interval

As mentioned previously, reference values provide a basis for interpretation of laboratory data. In clinical practice, one usually compares a patient's result with the corresponding *reference interval,* which is bounded by a pair of *reference limits.*[42] This interval, which may be defined in different ways, is a useful condensation of the information carried by the total set of reference values.

Types of reference intervals that have been used include (1) tolerance, (2) prediction, and (3) interpercentile intervals.[42,78] Selection from among these types of intervals may be important for certain well-defined statistical problems, but their numeric differences are negligible when based on at least 100 reference values.

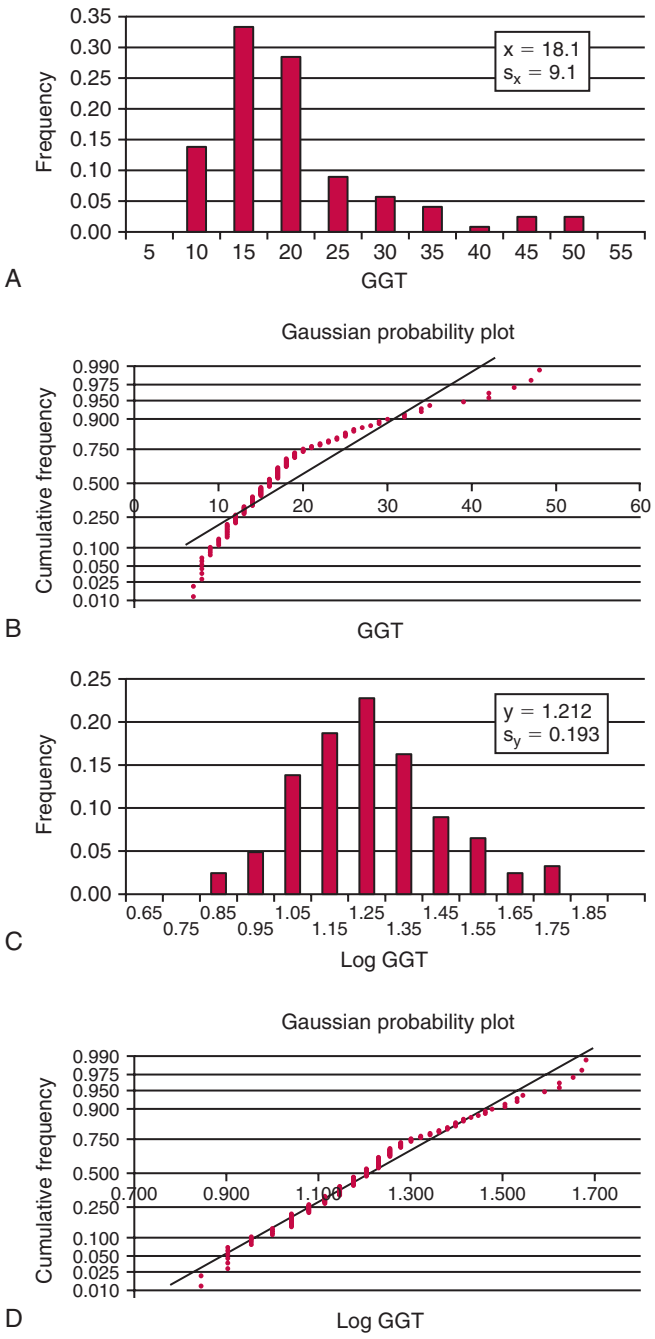

Figure 5-4 Distribution of 123 remaining gamma-glutamyltransferase (GGT) values from reference subjects. A, A histogram of the original, untransformed data. B, Shows the cumulative frequency of the data from A, plotted on Gaussian probability paper. C, A histogram of the logarithmic transformed data. D, The cumulative frequency of the data from C plotted on Gaussian probability paper.

This discussion will be confined to the *interpercentile interval,* which is (1) simple to estimate, (2) more commonly used, and (3) recommended by the IFCC.[42] It is defined as an interval bounded by two percentiles of the reference distribution. A *percentile* denotes a value that divides the reference distribution such that specified percentages of its values have magnitudes less than or equal to the limiting value. For example, if 47 IU/L is the 97.5-percentile of serum GGT values, then 97.5% of the values are equal to or below this value.

It is an arbitrary but common convention to define the reference interval as the *central 95%-interval* bounded by the 2.5- and 97.5-percentiles.[42] Another size or an asymmetric location of the reference interval may be more appropriate in particular cases. To prevent ambiguity, the definition of the interval should always be stated. The estimation of percentiles presented in the following sections is based on the conventional central 95% interval, but the techniques are easily adapted to other locations of the limits.

The percentiles are point estimates of population parameters. Accordingly, they are unbiased estimates only if the subset of values was selected randomly from the population. But, as was discussed earlier, random sampling is often difficult to achieve. The interpercentile interval may always be used, however, as a summary or description of the subset reference distribution.

The precision of a percentile as an estimate of a population value depends on the size of the subset; it is less precise when few observations are reported. If the assumption of random sampling is fulfilled, the *confidence interval* of the percentile (i.e., the limits within which the true percentile is located with a specified degree of confidence) can be determined. The 0.90 confidence interval of the 2.5-percentile (lower reference limit) for serum GGT values may, for example, be 6 to 8 IU/L. Finding the true percentile in this interval with a confidence of 0.90 could be expected if all serum GGT values in the total reference population were measured.

Methods Used To Determine Interpercentile Intervals

The interpercentile interval is typically determined using a parametric or a nonparametric method.[34,42]

The *parametric method* for determination of percentiles and their confidence intervals assumes a certain type of distribution, and it is based on estimates of population parameters, such as the mean and the standard deviation. For example, a parametric method is used if it is thought that the true distribution is Gaussian and the reference limits (percentiles) are determined as the values located 2 standard deviations below and above the mean. In fact, most of the parametric methods are based on the Gaussian distribution. If the reference distribution does not appear to be Gaussian, mathematical functions may be used that transform data to a distribution that approximates a Gaussian shape. Some positively skewed distributions (Figure 5-5, *A*) may, for example, be made symmetric by using logarithms of the data values.

In contrast, the *nonparametric method* makes no assumptions concerning the type of distribution and does not use estimates of distribution parameters. Percentiles are determined simply by cutting off the required percentage of values in each tail of the subset reference distribution (typically 2.5%).

The simple nonparametric method for determination of percentiles is recommended by IFCC[42] and CLSI.[15] The more

tahir99-VRG & vip.persianss.ir

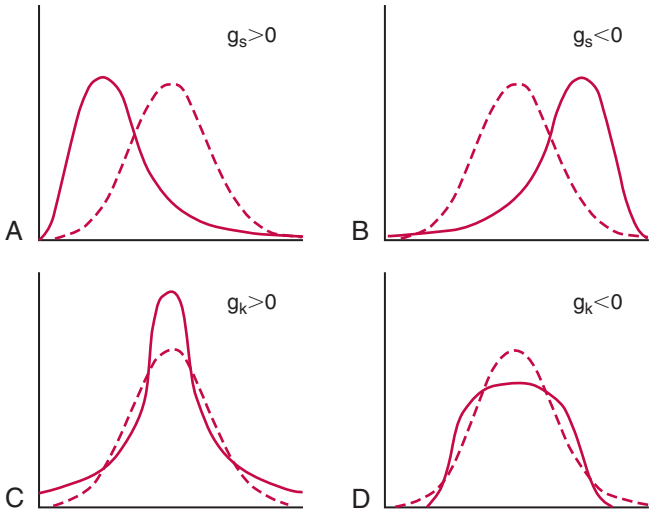

Figure 5-5 Skewness and kurtosis. The two *upper figures* show asymmetric distributions (A, positive skewness; B, negative skewness). The two *lower figures* show distributions with non-Gaussian peakedness (C, positive kurtosis; D, negative kurtosis). The Gaussian distribution *(dashed curve)* is shown in all graphs for comparison. Values of the coefficients of skewness (g_s) and kurtosis (g_k) are also shown.

complex parametric method is seldom necessary, but it will be presented here owing to its popularity and frequent misapplication. Other methods will be mentioned later in this chapter, but they require the use of computer techniques. When results obtained using proper application of any of these methods are compared, it is usually found that estimates of the percentiles are very similar. Detailed descriptions of nonparametric and parametric methods are given later in this chapter.

Sample Size

In general, the theoretical lower limit of the sample size required for estimation of the 100α and $100(1-\alpha)$ percentiles is equal to $1/\alpha$. Thus, estimation of the 2.5-percentile requires at least $1/0.025 = 40$ observations (per partition). For the nonparametric approach in particular, a sample size of at least 120 reference values has been recommended; otherwise, one cannot determine confidence intervals for the reference limits.[34,42]

It should be noted that for any method (parametric or nonparametric), the precision of the percentiles increases as the number of observations increases, as is shown by narrowing of their confidence intervals. Also, the more highly skewed a distribution is, the larger is the number of reference values needed to obtain reasonable confidence intervals.[51]

Partitioning of Reference Values

The best order of the first three actions outlined in Figure 5-2 (1—partitioning of reference values, 2—inspection of the distribution, and detection and/or 3—elimination of outliers) may in some cases be different from that shown in the figure. For example, it might be more appropriate to eliminate outliers before testing for partitioning. No strict rules for the order of these actions can be given as it depends on data and the statistical methods applied. With this caution in mind, the presentation in this chapter follows Figure 5-2.

The subset of reference individuals and corresponding reference values may be partitioned according to gender, age, and other characteristics (see Box 5-2). The process of partitioning is also called (1) stratification, (2) categorization, and (3) subgrouping, and its results are called (1) partitions, (2) strata, (3) categories, (4) classes, and (5) subgroups. In this chapter, the terms *partitioning* (for the process) and *(sub) classes* (for its result) are used.

The aim of partitioning is to provide a better basis for comparison of clinical laboratory results: *class-specific* reference intervals (e.g., age- and gender-specific reference intervals).

Various statistical criteria for partitioning have been suggested.[34,47] For example, an intuitive criterion states that partitioning is necessary if differences between classes are statistically significant (rejection of the "null" hypothesis of equal distributions). The distribution of reference values in the classes may show different locations (mean values vary) or different intraclass variations (standard deviations vary). These differences may be tested by statistical methods, which are not described here. The reader is referred to Chapter 2 and to standard textbooks of parametric[68,72] and nonparametric statistics.[12]

Differences in location or variation, however, may be statistically significant and still may be too small to justify replacing a single total reference interval with several class-specific intervals. Alternatively, statistically nonsignificant differences can lead to situations in which the proportions of each subclass above the upper or below the lower reference limits (without partitioning) are much different from the desired 2.5% on each side. Harris and Boyd[34] therefore suggested criteria based on the ratio between subclass standard deviations, a normal deviate test of means, and calculation of critical decision values dependent on the sample size.

Lahti and coworkers[47,48] focused on distances between reference limits instead of distances between means, and suggested new distance and proportion criteria for partitioning. Their model makes it possible to account for unequal subclass prevalences and is applicable to distributions of various types.

Partitioning requires large samples of reference values. If these are not used, subclass sizes may be too small for reliable estimates of reference intervals.

To solve the subclass size problem, it has been suggested to estimate regression-based reference intervals. Instead of dividing, for example, the total material into several age classes, one may construct continuous age-dependent reference limits and their confidence regions. Simulation studies have shown that this method produces reliable estimates with small sample sizes.[88]

When the intended purpose of the reference interval is to detect individual changes in biochemical status, subject-based reference values may be more appropriate than class-specific reference intervals for interpretation.[31,32,34]

tahir99-VRG & vip.persianss.ir

In the following sections, a homogeneous reference distribution and either the complete distribution (if partitioning has been shown to be unnecessary) or a subclass distribution (after partitioning) are assumed.

Inspection of Distribution

It is always advisable to display the reference distribution graphically and to inspect it. A *histogram,* as shown in Figure 5-3, is easily prepared and is the type of data display best suited for visual inspection. Examination of the histogram serves as a safeguard against misapplication or misinterpretation of statistical methods, and it may reveal valuable information about the data. Data should be evaluated for the following characteristics of the distribution:

1. Highly deviating values *(outliers)* may represent erroneous values.
2. *Bimodal* or *polymodal* distributions have more than one peak and may indicate that the distribution is nonhomogeneous because of mixing of two or more distributions. If so, the criteria used to select reference individuals should be reevaluated, or partitioning of the values according to age, gender, or other relevant factors should be attempted.
3. The shape of the distribution should be noticed. It may be asymmetrical, or it may be more or less peaked than the symmetrical and bell-shaped Gaussian distribution (see Figure 5-5). The asymmetry most frequently observed with clinical chemistry data is positive *skewness* (see Figure 5-5, *A*). A symmetric distribution with positive *kurtosis** has a high and slim peak and a greater number of values in both tails than the Gaussian type of distribution (see Figure 5-5, *C*). Conversely, negative kurtosis indicates that the distribution has a broad and flat top with relatively few observations in the tails (see Figure 5-5, *D*). Asymmetry and non-Gaussian peakedness may be combined.
4. The visual inspection may also provide initial estimates of the location of reference limits that are useful as checks on the validity of computations.

Identification and Handling of Erroneous Values

An *erroneous value* can be traced to a gross deviation from the prescribed procedure for establishment of reference values.[33] Such values may deviate significantly from proper reference values *(outliers)* or may be hidden in the reference distribution. Only a strict experimental protocol, with adequate controls at each step, can eliminate the latter type of erroneous values.

Visual inspection of a histogram is a reliable method for identification of possible outliers. It is important to keep in mind, however, that values far out in the long tail of a skewed distribution may easily be misinterpreted as outliers. If the distribution is positively skewed, inspection of a histogram displaying logarithms of the values may aid in the visual identification of outliers.

Some outliers may also be identified by *statistical tests* (see Chapter 2), but no single method is capable of detecting outliers in every situation that may occur. The number of techniques suggested or recommended is, for this reason, very large.[7,34,37] The two main problems encountered can be described as follows:

1. Many tests assume that the type of the true distribution is known before the test is used. Some of these specifically require that the distribution be Gaussian. However, biological distributions very often are non-Gaussian, and their types are seldom known in advance. Furthermore, statistical tests of types of distribution are unreliable in the presence of outliers. This unreliability poses a difficult dilemma: some tests for outliers assume that the type of distribution is known, but tests for determining the type of distribution require that outliers be absent! As a consequence, it may be difficult to transform the distribution to Gaussian form before outliers are identified by statistical tests. Some tests are relatively insensitive to departures from a Gaussian distribution. This is the case with Dixon's *range test,* in which a value is identified as an extreme outlier if the difference between the two highest (or lowest) values in the distribution exceeds one third of the range of all values (see Figure 5-3).[34,42,64]
2. Several tests for outliers assume that a data set contains only a single outlier. The limitation of these tests is obvious. Some tests may detect a specified number of outliers, or they may be run several times, discarding one outlier in each pass of data. The range test, however, usually fails in the presence of several outliers. It is possible to estimate the standard deviation using data remaining after *trimming* of both tails of the distribution by a specified percentage of observations.[34,38] Outliers could be identified by this method as the values lying 3 or 4 standard deviations from the arithmetic mean. This method assumes, however, that the true distribution is Gaussian.

Horn and coworkers[40] have published a novel method in two stages for outlier detection that seems to provide a promising solution to both of the problems just mentioned. With this method, one executes the following:

1. Mathematically transform the data to approximate a Gaussian distribution. Horn used the Box-Cox transformation,[10] but other transformations that correct for skewness (see later) probably would also work. As mentioned earlier, it is impossible to achieve exact symmetry by transformation in the presence of outliers, but this does not seem to be critical with Horn's method.
2. Identify (or eliminate) outliers using a criterion based on the central 50% of the distribution, thus reducing the masking effect of several outliers. Compute the interquartile range (IQR) between the lower and upper

*Kurtosis is a measure of the "peakedness" of the probability distribution of a real-valued random variable. A high kurtosis distribution has a sharper *peak* and longer, fatter *tails;* a low kurtosis distribution has a more rounded peak and shorter thinner tails.

tahir99-VRG & vip.persianss.ir

quartiles of the distribution (Q_1 and Q_3, respectively): $IQR = Q_3 - Q_1$. Then identify as outliers data lying outside the two fences

$$Q_1 - 1.5 * IQR \text{ and } Q_3 + 1.5 * IQR$$

Deviating values identified as possible outliers cannot always be discarded automatically. Values should be included or excluded on a rational basis. For example, records of the dubious values should be checked and errors corrected. In some cases, deviating values should be rejected because non-correctable causes have been found, such as in previously unrecognized conditions that qualify individuals for exclusion from the group of reference individuals.

Methods for Determining Reference Values

Nonparametric, parametric, bootstrap, and robust methods are used to determine reference intervals.

Nonparametric Method

This method consists essentially of cutting off a specified percentage of the values from each tail of the reference distribution. Three techniques may be used:

1. The percentiles may be determined *graphically* by plotting the cumulative distribution on Gaussian probability paper (see Figure 5-4, *B* and *D*).
2. A *mathematical function* may be fitted to the reference distribution.[34,66,70] The percentiles are then determined using the fitted function.
3. Very simple and reliable methods are based on *rank numbers.*[42,53,64] They also allow nonparametric estimation of the confidence intervals of the percentiles.[64] This method can easily be applied manually or with a spreadsheet program.

The rank-based method as recommended by the IFCC[42] and CLSI[15] requires the following steps:

1. First, the n reference values are sorted in ascending order of magnitude.
2. Next, the individual values are ranked. For example, the minimum value has rank number 1, the next value has rank number 2, and so on, until the maximum value, which has rank number n. Consecutive rank numbers should be given to two or more values that are equal ("ties").
3. The rank numbers of the 100α and $100(1 - \alpha)$ percentiles are computed as $\alpha(n + 1)$ and $(1 - \alpha)(n + 1)$, respectively. Thus the limits of the conventional 95%-reference interval have rank numbers equal to $0.025(n + 1)$ and $0.975(n + 1)$.
4. The percentiles are determined by finding the original reference values that correspond to the computed rank numbers, provided that the rank numbers are integers. Otherwise, one should interpolate between the two limiting values.
5. Finally, the confidence interval of each percentile is determined by using the binomial distribution.[64] Table 5-3 provides data for the 0.90-confidence interval of the 2.5- and 97.5-percentiles. For the relevant sample size n, rank numbers for the lower and upper limits should be found for the 2.5-percentile; those same values are subtracted from (n + 1) to find the rank numbers for the 97.5-percentile.

TABLE 5-3 Nonparametric Confidence Intervals of Reference Limits*

Sample Size	Rank Numbers	
	Lower	Upper
119-132	1	7

436-468	6	18
469-470	6	19
471-500	7	19

*The table shows the rank numbers of the 0.90-confidence interval of the 2.5-percentile for samples with 119 to 500 values. To obtain the corresponding rank numbers of the 97.5-percentile, subtract the rank numbers in the table from (n = 1), where n is the sample size.
From IFCC.[42]

Table 5-4 provides a detailed example of the nonparametric determination of 95%-reference limits using the serum GGT reference values first shown in Figure 5-3.

Parametric Method

The parametric method is much more complicated than the simple nonparametric method and requires computer software to process the data. The method is presented here under separate headings for testing of type of distribution, transformation of data, and estimation of percentiles and their confidence intervals.

It should be noted that commonly used statistical computer program packages[9,69,79] aid in the estimation of reference limits, but these packages may lack some of the techniques described in this chapter. The RefVal,[77] CBstat,[52] and Medcalc (http://www.medcalc.be/manual/referenceinterval.php) programs implement these methods.

Testing Fit to Gaussian Distribution

The parametric method for estimating percentiles assumes that the true distribution is Gaussian. This fact was frequently ignored in the past and caused Elveback[20] to warn against "the

TABLE 5-5 Summary of GGT Reference Interval Determination by Three Methods

Method	Lower Limit (Confidence Interval)	Upper Limit (Confidence Interval)	Values Below Lower Limit	Values Above Upper Limit
Nonparametric	7 (6 to 8)	47 (39 to 50)	1	2
Parametric—untransformed data	0 (−2 to 2)	36 (34 to 38)	0	7
Parametric—transformed data	7 (6 to 8)	40 (35 to 44)	1	6

The table summarizes the 95%-reference intervals and associated 90%-confidence limits generated by each of three methods for the same data set. The numbers of observed values deemed lower and higher than the corresponding interval for each method are given in the last two columns. Because the original data are positively skewed, note that the parametric techniques generate intervals that are biased low. Note too that the parametric technique on untransformed data has a lower confidence interval, which is actually less than 0.

ghost of Gauss." Negligence often results in seriously biased estimates of reference limits. After elimination of the outlier from the GGT reference values in Figure 5-3, the mean and standard deviation of the remaining 123 serum GGT reference values are 18.1 and 9.1 (see Figure 5-4, *A*), from which the reference interval is calculated as $0 \pm 1.960\ S_x$, or 0 to 36 IU/L (vs. the nonparametric values of 7 and 47 IU/L; Table 5-5). More highly positively skewed distributions may even result in negative values for the lower reference limit.

Therefore, a critical phase in the parametric method is testing the goodness-of-fit of the reference distribution to a hypothetical Gaussian distribution. If the Gaussian hypothesis must be rejected at a specified significance level, one is left with two alternatives (see Figure 5-2): either the nonparametric method can be used, or a mathematical transformation of data can be applied to approximate the Gaussian distribution. Only when the Gaussian hypothesis is not rejected by the test can one pass directly to parametric estimation of percentiles and their confidence intervals (see Figure 5-2).

Goodness-of-fit tests have been reviewed by Mardia.[56] These tests can be broadly classified as (1) graphical

tahir99-VRG & vip.persianss.ir

procedures, (2) coefficient-based tests, and (3) tests that are based on shape differences between observed and theoretical distributions.

1. *The graphical procedure* consists of plotting the cumulative distribution on probability paper, which has a nonlinear vertical axis based on the Gaussian distribution (see Figure 5-4, *B* and *D*). The plot should be close to a straight line if the distribution is Gaussian.
2. *Coefficient-based tests* use statistical measures of skewness and kurtosis (see Figure 5-5). Formulas for calculating these parameters are available elsewhere.[17,42,72,75,78] For Gaussian (and other symmetric distributions), the *coefficient of skewness* is zero; the sign of a nonzero coefficient indicates the type of skewness present in the data (see Figure 5-5, *A* and *B*). The *coefficient of kurtosis* is approximately zero for the Gaussian distribution. The sign of a nonzero coefficient indicates the type of kurtosis present in the data (see Figure 5-5, *C* and *D*). The statistical significance of these two coefficients may be found by referring to tables for testing skewness and kurtosis.[72]
3. Tests of *shape differences* that have been used to evaluate goodness-of-fit include the (1) Kolmogorov-Smirnov, (2) Cramer-von Mises, and (3) Anderson-Darling tests.[42,56,75,78,82] The Anderson-Darling test is recommended by the IFCC.[42] Computer programs for all three tests are available.[77]

Transformation of Data: Simple Method

In the previous section, it was shown that $0 \pm 1.960\ S_x$ of the serum GGT data in Figure 5-4, *A*, resulted in biased reference limits (too low values), as was to be expected with this positively skewed distribution. However, it is often possible to transform data mathematically to obtain a distribution of transformed values that approximates a Gaussian distribution. With these new values, the 2.5- and 97.5-percentiles are localized at 2 standard deviations on both sides of the mean. The estimates may then be transformed back to the original measurement scale by using the inverse mathematical function.

It is frequently observed that *logarithmically transformed* values, $y = \log(x)$, of a positively skewed distribution fit the Gaussian distribution rather closely. In other cases, *square roots* of the values, $y = \sqrt{x}$, result in a better approximation to the Gaussian distribution. This is the basis for the common use of logarithmic and square root transformations when reference limits are estimated. The method is applicable only to positively skewed distributions and is easily performed with a spreadsheet program. The procedure is as follows:

1. Test the fit of the distribution of original data to the Gaussian distribution. If the distribution has approximately Gaussian shape, the 2.5- and 97.5-percentiles are calculated directly as $0 \pm 1.960\ S_x$. Otherwise, continue with the following steps.
2. Transform data by the logarithmic function $y = log\ (x)$ or by the square root function $y = \sqrt{x}$, then test the fit to the Gaussian distribution. If the transformed distribution is significantly different from Gaussian shape, try another transformation or estimate the percentiles by the nonparametric method (see earlier in this chapter). Continue with the next step if the transformation resulted in a Gaussian distribution.
3. Compute the mean y and the standard deviation s_y of transformed data. Then estimate the 2.5- and 97.5-percentiles in the transformed data scale as

$$\overline{y} \pm 1.960\ S_y$$

4. The final step is reconversion of these percentiles to the original data scale. The inverse functions of the two transformations described here are as follows:

$$\text{Inverse of logarithmic function: } x = 10^y$$
$$\text{Inverse of square root function: } x = y^2$$

It is also possible to estimate the confidence limits of percentiles determined by the parametric method. This method is presented in a later section.

Example: As noted earlier, the original GGT data reference distribution is not Gaussian but is, similar to many biological distributions, skewed to the right (see Figure 5-4, *A*). However, by using the logarithm of the serum GGT values, a distribution very close to Gaussian shape (see Figure 5-4, *C*) is obtained. This observation is confirmed in Figure 5-4, *B* and *D*, where the cumulative probabilities are shown graphed on Gaussian probability paper; the original data are not linear, but the transformed data form a reasonably good line. As shown, the mean and standard deviation of the transformed data are $\overline{y} = 1.212$ and $s_y = 0.193$, respectively, that is, the mean value is 1.212 (corresponding to $10^{1.212}$, or 16 in the original scale). The transformed 2.5-percentile is then $1.212 - (1.960 \times 0.193) = 0.835$. On reconversion to the original data scale, a value of $10^{0.835} = 6.84$ is obtained. The lower reference limit of serum GGT is thus 7 IU/L. Similarly, it is found that the upper reference limit is 39 IU/L. These values are in closer agreement with those found by the nonparametric method: 7 and 47 IU/L (see Tables 5-4 and 5-5).

Transformation of Data: Two-Stage Method

Because simple logarithmic and square root transformations often fail to produce the desired Gaussian shape of the distribution, Harris and DeMets[36] introduced the two-stage method: first, use a function that transforms the distribution to symmetry (zero coefficient of skewness), and then apply another function that removes any remaining non-Gaussian kurtosis. Several mathematical functions may serve the purpose.[34,78] The IFCC recommends[42] the two-stage procedure based on the exponential function[55] and the modulus function[43]; the procedure is implemented in the RefVal computer program.[77] Successive approximations to symmetry and to Gaussian kurtosis (i.e., the iterative determination of the function parameters) are monitored by the coefficient-based tests, whereas the final evaluation has to be done by an independent test (e.g., the Anderson-Darling test, as mentioned earlier in this chapter).

tahir99-VRG & vip.persianss.ir

Parametric Estimates of Percentiles and Their Confidence Intervals

General estimates for the 100α and 100(1 − α) percentiles and their 0.90-confidence intervals can be determined by the following method, provided that data (original or transformed) fit the Gaussian distribution[42]:

As noted earlier, the 100α and 100(1 − α) *percentiles* are calculated as follows:

$$(\text{mean}) \pm (c) * (\text{standard deviation})$$

where *c* is the (1 − α) standard Gaussian deviate, as can be found in statistical tables. For the 2.5-and 97.5-percentiles, the (1 − 0.025) = 0.975 standard Gaussian deviate, c, has a value of 1.960.

The 0.90-*confidence intervals* of these percentiles are then determined as follows[42,78]:

$$\text{percentile} = \pm 2.81 \frac{S_y}{\sqrt{n}}$$

where s_y is the standard deviation of the reference values (original or transformed) and *n* is the number of values. This formula is a special case of a general formula that can be used for confidence intervals of other sizes or for other percentiles.[42,78]

Example: The parametric estimate of the 2.5-percentile of serum GGT was determined previously by the logarithmic transformation as $10^{0.835} = 6.8$. The 0.90-confidence limits of the lower percentile are then

$$0.835 - 2.81 * (0.193/\sqrt{123}) = 0.786 \qquad 10^{0.786} = 6.1$$
$$0.835 + 2.81 * (0.193/\sqrt{123}) = 0.884 \qquad 10^{0.884} = 7.7$$

Thus the complete estimate of the 2.5-percentile (and its 0.90-confidence interval) is 7 (6 to 8) IU/L. The 97.5-percentile is, by the same method, found to be 39 (35 to 43) IU/L. Table 5-5 summarizes data from the three methods used to determine reference intervals from GGT data.

Other Methods for Calculating Reference Limits

Other methods have been recommended for calculating reference limits including the so-called bootstrap and robust methods. Neither of these methods makes assumptions about the underlying distribution; it need not be Gaussian. Both require the use of computer software, as they involve numerous iterations and somewhat complicated calculations.

Bootstrap Method

Bootstrap-based methods are reliable for estimating reference intervals.[34,53,70] The following version uses the rank-based nonparametric method; it is simple and reliable:

1. First, random samples, each of size *m,* are selected, with replacement, from the original set of *n* reference values. One selects "with replacement" if each value randomly selected from the original set remains available, so that it may be selected again in the random selection of the next value. In other words, even if there is only one occurrence of a specific value in the original set of n values, it may appear more than once in one, or more, random samples of size m.The number of resamples should be high (500 is a reasonable number of iterations).
2. For each resample, the upper and lower reference limits (percentiles) are next estimated by the rank-based nonparametric procedure described previously. These estimates from each iteration are saved.
3. Upon completion of all iterations, the final lower reference limit is calculated as the mean of the estimates of the lower reference limit; similarly, the final upper reference limit is calculated as the mean of the estimates of the upper reference limit.
4. Finally, the 0.90-confidence interval of each reference limit is calculated from the distribution of the percentile estimates, that is, with 500 iterations, the 25th rank order value represents the 5th percentile, and the 475th rank order value represents the 95th percentile.

Among available methods for estimating reference limits and their confidence intervals, the bootstrap method may be among the most reliable.[34,53] The location of estimated percentiles is always dependent on the characteristics of the particular subset of reference values. Only two methods may be used to obtain percentile estimates that approach population values: using a very large sample, or performing repeated sampling from the same parent population. Both methods are obviously expensive. In practice, the bootstrap method is a good alternative: (1) it is economical because it is based upon resampling from a single subset of reference values (but a minimum of 100 values is needed)[53]; (2) it provides robust percentile estimates (with the mentioned single-sample limitation); and (3) the widths of the confidence intervals approach asymptotically those that would have been obtained by repeated sampling from the parent population.[18] However, computer processing software is needed to run the large number of bootstrap iterations.

The reader should note that the bootstrap version described here uses rank-based nonparametric percentile estimates. However, the bootstrap principle may be employed with any kind of estimation, parametric or nonparametric.

Robust Method

The robust method has the form of the parametric method described earlier, but instead of using the mean and the standard deviation of the sample, it uses robust measures of location and spread. For example, instead of using the mean, it uses the median: in a series of 10 values, if the highest value is doubled, the mean changes appreciably, but the median does not change at all and thus is considered robust. Briefly, the steps involved are as follows:

1. Symmetry of the data is ensured, using transformations if necessary (e.g., Box-Cox transformation[10]).
2. Initial robust measures of location (median) and spread (median absolute deviation) are found.
3. Using a *biweight estimation* technique, in which more weight is given to observations closer to the center and progressively less to values farther from the center, new estimates of location and spread are found until successive results are satisfactorily close.

tahir99-VRG & vip.persianss.ir

4. With final robust values of location and spread, the upper and lower limits are calculated, in a manner analogous to that described for the parametric technique.
5. Confidence intervals are then estimated using the bootstrapping technique described in the previous section.

Similar to the bootstrap method, this method does not require a Gaussian distribution. It is resistant to outliers and may be applied to very small numbers of observations. Details on the method are available.[41]

TRANSFERABILITY OF REFERENCE VALUES

Determination of reliable reference values for each test in the laboratory's repertoire is a major task that is often far beyond the capabilities of the individual laboratory. Therefore, it would be convenient if reference values generated in another laboratory could be used. This is especially important when ethical considerations limit the number of available individuals (e.g., when pediatric reference values are produced). Then, cooperative establishment of reference values may be necessary.

A major prerequisite for transfer of reference values is that the populations must be comparable (i.e., no major ethnic, social, or environmental differences should be noted between them). If they are not, a separate reference interval study must be done.

Analytical Issues

In practice, even if the populations are comparable, the problem of analytical transferability remains. The optimal, but usually very unrealistic, situation assumes that analytical methods, including their calibration and quality assurance, are identical in the laboratories. A more pragmatic approach involves (1) standardization of analytical protocols, (2) common calibration, (3) design of a sufficiently efficient external quality control scheme, and (4) the use of mathematical transfer functions if results still are not directly comparable.

The parameters of transfer functions may be estimated from results obtained by analysis of a sufficient number of patient specimens spanning the relevant range of concentrations in all participating laboratories.[15] Sometimes, functions obtained by simple linear regression suffice: using $y = a_0 + a_1{}^*x$, the constant term a_0 compensates for systematic shifts among methods, whereas the coefficient term a_1 adjusts for proportional differences. In other cases, a more elaborate system for transfer of laboratory data is necessary.[83] It should be noted that the mentioned transfer functions account only for analytical bias; however, adjustments for differences in imprecision may also be designed.

Multicenter Trials

Another way to assist individual laboratories in generating reference values is to pool data from multiple sites to obtain the requisite minimum 120 samples (per partition). *Multicenter production of reference values* is gaining acceptance, both as a theoretical concept and as a practical approach. A Spanish study[24] introduced a cooperative model, simulating a virtual laboratory for 15 biochemical quantities. A project in the Nordic countries (NORIP) has produced common reference intervals for 25 analytes.[62,67]

On a less rigorous but more pragmatic level is the so-called Reference Range Service of the College of American Pathologists (CAP).[16] Each participating laboratory submits data for each analyte under consideration from 20 reference individuals, including each individual's gender, age, and race/ethnic background. In addition, each laboratory indicates the specific analytical method it uses (e.g., instrument, reagents). CAP pools the data for each specific method and then applies the nonparametric technique described previously to generate reference intervals for that method. With sufficient numbers of participating laboratories, it becomes possible to generate reasonable 95%-reference intervals, with 90%-confidence limits, for multiple partitions. As more laboratories, with more diverse reference individuals, participate, it becomes possible to generate more information. In addition, as methods become more standardized, pooling data from different methods may become possible, thereby increasing even further CAP's ability to partition the data. The main advantage of the service is that each laboratory is required to submit data on just 20 samples.

Verification of Transfer

Whether a laboratory adopts reference values from (1) a package insert, (2) another laboratory, or (3) a multicenter trial, it is important that the laboratory verifies the appropriateness of those values for its own use.[34] This verification is the final check that the laboratory has implemented the analytical method correctly, and that the laboratory's own population is comparable with that used for the original reference value study.

Comparison of a locally produced, small subset of values with the large set produced elsewhere using traditional statistical tests often is not appropriate, because the underlying statistical assumptions are not fulfilled and the sample sizes are unbalanced. Relatively sophisticated methods using nonparametric tests[87] or Monte Carlo sampling[39] have been described. Notwithstanding these caveats, a reasonably practical alternative has been recommended by CLSI: with a sample size of 20 reference values, one verifies the appropriateness of a proposed reference interval so long as no more than two values are outside the proposed limits.[15] One obvious deficiency of this test is that it does not detect the situation where the reference interval of the local group is narrower than that of the study group. Nonetheless, it does provide reasonable reassurance that a proposed reference interval is used.

PRESENTATION OF AN OBSERVED VALUE IN RELATION TO REFERENCE VALUES

An observed value (patient's value) may be compared with reference values. This comparison is often similar to hypothesis testing, but it is seldom statistical testing in the strict

tahir99-VRG & vip.persianss.ir

sense. Ideally, the patient and the reference individuals should match [i.e., the hypothesis is stated that they were all picked from the same set (population)]. Often, however, this is not the case. Thus it is advisable to consider the reference values as the yardstick for a less formal assessment than hypothesis testing.

The clinician should always be supplied with as much information about the reference values as is needed for their interpretation. Reference intervals for all laboratory tests may be presented to clinicians in a booklet, together with information about (1) analysis methods, (2) their imprecision, and (3) descriptions of the reference values. The goal is to present enough information to clinicians for rational clinical judgments.

In addition, a convenient presentation of an observed value in relation to reference values may be a great help for the busy clinician.[19,28,42,74]

Presentation of the observed value, together with a *listing of all reference values* for the corresponding test, is a feasible procedure only when few reference values are available. When there are many reference values, it is more convenient to present the *reference distribution* in a table, graphically in the form of a histogram (see Figure 5-4, *A* and *C*), or by a plot of the cumulative distribution (see Figure 5-4, *B* and *D*). A very informative presentation of the observed value involves showing its location on a graph. A more condensed technique is to present the observed value and the *reference interval* on the same report sheet. The reference intervals may be preprinted on report forms, or the computer system may select the appropriate age- and gender-specific reference interval from a file and print it next to the test result. This type of presentation is often graphical.[28]

It is also possible to compute various *mathematical indices* or to *flag* the results on reports using convenient symbols. When such presentation methods are used, the original observed value should also be reported to allow comparison with results of other laboratory tests and metabolic calculations.

An observed value may be classified as low, usual, or high (three classes), depending on its *location in relation to the reference interval.* On reports, it is convenient to flag unusual results (e.g., by using "L" and "H" for "low" and "high," respectively).[28]

A more detailed division of the value scale has also been advocated.[19] Regions outside the reference interval may be subdivided to indicate how unusual the observed value is. The reference interval may also be subclassified. The advantages are doubtful, however, because the shape of the reference distribution is not taken into account.

Another popular method is to express the observed value by a *statistical distance measure.* All such distances are ratios of the following type:

$$\frac{\text{observed value} - \text{measure of location}}{\text{measure of dispersion}}$$

The *SD unit,* or normal equivalent deviate, is such a measure. It is calculated as the difference between the observed value and the mean of the reference values divided by their standard deviation.[30] Several similar ratios have been suggested[22]; all produce very confusing values if the reference distribution is very skewed. An observed value (e.g., with an SD unit of 2.2) would be above the 97.5-percentile if the reference distribution had a Gaussian shape, but it might be well below the upper reference limit of a positively skewed distribution. If this occurs, mathematical transformation of the reference distribution to the Gaussian shape may be used to resolve this problem.[73]

Reporting the observed value as a *percentile* of the reference distribution provides a very accurate measure of the relation.[19,66] An observed serum GGT value of 48 IU/L may, for example, be reported as 48 IU/L (99th percentile). Alternatively, the probability of finding a value closer to the mean than the observed value, the *index of atypicality,* can be estimated.[2,74]

When observed values of several analytes are reported simultaneously, it is possible to use multivariate analogs of the SD unit and the index of atypicality (see later).[1,2]

ADDITIONAL TOPICS

Multivariate, Population-Based Reference Regions

The topic of previous sections of this chapter has been univariate population-based reference values and quantities derived from them. However, such values do not fit the common clinical situation in which observed values of several different laboratory tests are available for interpretation and decision making. For example, the average number of individual clinical chemistry tests requested on each specimen received in the author's laboratory is roughly six; in many laboratories, this number is even larger. Two models are used for interpretation by comparison in this situation. Each observed value can be compared with the corresponding reference values or interval (i.e., a *multiple, univariate comparison is performed*); or the set of observed values can be considered as a single multivariate observation and can be interpreted as such by a *multivariate comparison.* In this section, the relative merits of these two approaches are discussed, and methods for the latter type of comparison are presented.

The Multivariate Concept

A univariate observation, such as a single laboratory result, may be represented graphically as a point on a line—the axis. Results obtained by two different laboratory tests performed on the same specimen (a bivariate observation) are then displayed as a point in a plane defined by two perpendicular axes. With three results, a trivariate observation and a point in a space are defined by three perpendicular axes, and so forth. The possibility of visualization of a multivariate observation is lost when there are more than three dimensions. Still, one can consider the multivariate observation as a point in a multidimensional hyperspace with as many mutually perpendicular axes as there are results of different tests. The

prefix *hyper-* signifies, in this context, "more than three dimensions." Such multivariate observations are also called *patterns* or *profiles*. A multivariate distribution thus is represented by a cluster of points on a plane, in a space, or in a hyperspace, depending on the dimensionality of the observation.[1,7,73,89] Several statistical methods are based on multivariate methods, some of which are straightforward extensions of well-known univariate methods.[58]

The Multiple, Univariate Reference Region

The univariate reference interval is bounded by two reference limits (lower and upper) on the result axis. Figure 5-6 shows the univariate reference intervals for two laboratory tests: one depicted on the *x*-axis, and the other, on the *y*-axis. Together, they describe a square in the plane of the two axes. Similarly, three or more univariate reference intervals define boxes or hyperboxes in the (hyper)space. By multiple, univariate comparison, it can be decided whether a multivariate observation point lies inside or outside this square, box, or hyperbox. However, this method has two very serious deficiencies[91]: an observation may lie outside the limits of the region without being unusual (see Figure 5-6, point *a*), or it may be found on the inside and still be an atypical observation (see Figure 5-6, point *b*). If the central 95%-interval is used, 5% of the values by definition are expected to be located in the two tails of the univariate reference distribution. However, more than 5% of the values would be located outside the square or (hyper)box created by several 95%-intervals. To be exact, $100(1 - 0.95^m)$ percent of multivariate reference values would be excluded by the method of multiple, univariate comparison (*m* being the number of different tests, or the dimensionality). For example, one would expect to find $100(1 - 0.95^{10}) = 40\%$ of false positives when 10 laboratory tests are used. This discouraging result has been verified in several multiphasic screening programs. Therefore, a better method is needed.

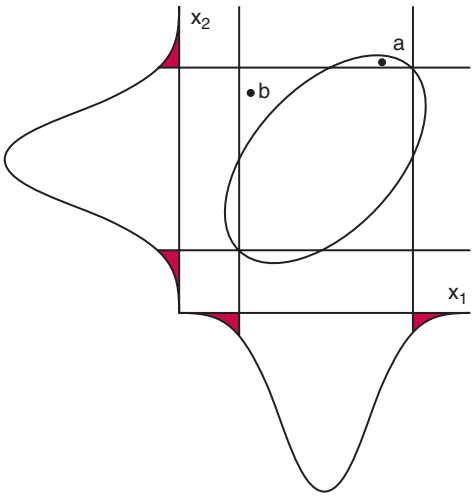

Figure 5-6 Bivariate reference region *(ellipse)* compared with the region defined by the two univariate reference intervals *(box)*.

The Multivariate Reference Region

It is possible to define a common multivariate reference region[1,2,11,34,89,91] on the basis of joint distribution of reference values for two or more laboratory tests. This multivariate region is not a right-angled area, or hyperbox, but is more like an ellipse in the plane (see Figure 5-6) or an ellipsoid hyperbody in hyperspace. This region may be a straightforward extension of the univariate 95% interval to the multivariate situation; it may be set to enclose 95% of central multivariate reference data points. In this case, one would expect to find only 5% false positives.

The use of multivariate reference regions usually requires the assistance of a computer program, which takes a set of results obtained by several laboratory tests on the same clinical specimen and calculates an index. Interpretation of a multivariate observation in relation to reference values is then the task of comparing the index with a threshold value estimated from the reference values. Obviously, this is much simpler than comparing each result with its proper reference interval.

This index is essentially a distance measure and is known as *Mahalanobis' squared distance* (D^2). It is analogous to the square of the standard deviation for single reference values. It expresses the multivariate distance between the observation point and the common mean of the reference values, taking into account the dispersion and the correlation of the variables.[1,2,11,34,89,91] More interpretational guidance may be obtained from this distance by expressing it as a percentile analogous to the percentile presentation of univariate observed values.[11] Also, the index of atypicality has a multivariate counterpart.[1,2]

Although the theory of multivariate reference regions has been known for a while, surprisingly few applications of it have been reported in the literature. An important report reviews the topic and presents the results of a very careful study on the multivariate 95% region for a 20-test chemistry profile.[11] Some of the most important findings can be summarized as follows:

1. Sixty-eight percent of subjects had at least one test result outside univariate reference intervals, which was close to what was theoretically expected: $100(1 - 0.95^{20}) = 64\%$.
2. By contrast, only 5% of patterns were outside the multivariate reference region (as expected).
3. Transformation to approximately Gaussian shape of the univariate distributions was necessary.
4. A test profile may be distinctly unusual in the multivariate sense even though each individual result is within its proper reference interval (e.g., see point *b* in Figure 5-6).
5. The multivariate reference region could detect minor deviations of multiple analytes.
6. Conversely, it could also be insensitive to highly deviating results for a single analyte.
7. Sensitivity could be increased by defining multivariate reference regions for subsets of physiologically related tests.

Subject-Based Reference Values

Figure 5-7 depicts the inherent problem associated with population-based reference values. It shows two hypothetical reference distributions. One represents the common reference distribution based on single specimens obtained from a group of different reference individuals. It has a true (hypothetical) mean μ and a standard deviation σ. The other distribution is based on several specimens collected over time in a single individual, the *i*th individual. Its hypothetical mean is μ_i and its standard deviation σ_i.

If an observed value is located outside the subject's 2.5- and 97.5-percentiles, the personal or *subject-based reference interval,* the cause may be a change in biochemical status, suggesting the presence of disease. Figure 5-7 shows that such an observed value may still be within the population-based reference interval. The sensitivity of the latter interval to changes in a subject's biochemical status depends accordingly on the location of the individual's mean μ_i relative to the common mean μ and to the relative magnitudes of the corresponding standard deviations σ_i and σ. A mean μ_i close to μ and a small σ_i relative to σ may conceal the individual's changes entirely within the population-based reference interval.

Harris[31,32] analyzed this topic and found that the ratio R of intraindividual (personal) variation over interindividual (among subjects) variation provides a criterion for the usefulness of the population-based reference interval. The population-based reference interval has less than the desired sensitivity to changes in biochemical status if the ratio value is $R \leq 0.6$. This interval is a more trustworthy reference if $R > 1.4$, at least for the individual whose standard deviation σ_i is close to the average value. Published data[31,90] usually show that homeostatically tightly controlled quantities, such as serum electrolytes, have high ratio values. Population-based reference intervals of such analytes suffice for clinical use. In contrast, serum proteins and enzymes have very low ratios because they are not under the same degree of metabolic control. Here, subject-based reference intervals seem more appropriate.

Two specific examples mentioned earlier may help to clarify this concept further. Figure 5-8 depicts immunoglobulin (Ig)M values from several healthy individuals over the course of several days. As illustrated, the intraindividual differences are small as compared with interindividual differences. Even though the population-based reference interval might extend from 200 to 1600 mg/dL, it would be most unusual (abnormal) for any patient's IgM value to change by more than 200 mg/dL, even if the value remained within the population-based reference interval. Similarly, it is well known that any given patient's serum creatinine value is reasonably constant,[25] which is related both to glomerular filtration rate (GFR) and to lean muscle mass. If the latter is constant, then changes in GFR are inversely proportional to the serum creatinine (see Chapters 25 and 48). That is, even though a typical (population-based) reference interval for serum creatinine might extend from 62 to 106 µmol/L (0.7 to 1.2 mg/dL), a change from 65 to 105 µmol/L in a given patient would be distinctly abnormal, representing the loss of almost half of the GFR.

Two solutions can be proposed to the problem of the clinical insensitivity of population-based reference intervals:

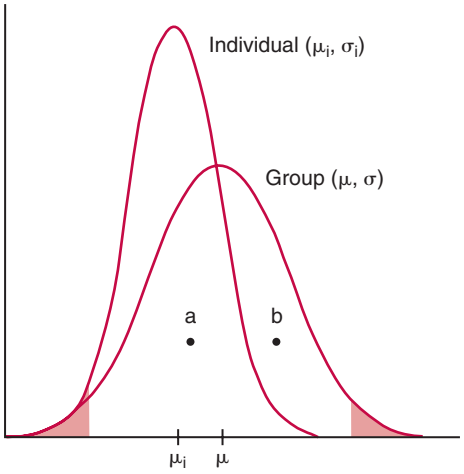

Figure 5-7 Relationship between population-based and subject-based reference distributions and reference intervals. The example is hypothetical, and the two distributions are, for simplicity, Gaussian. Note that points *a* and *b* are within the population-based reference interval, but only point *a* would be "normal" for this particular subject. *(Modified from Harris EK. Effects of intraindividual and interindividual variation on the appropriate use of normal ranges. Clin Chem 1974;20:1536.)*

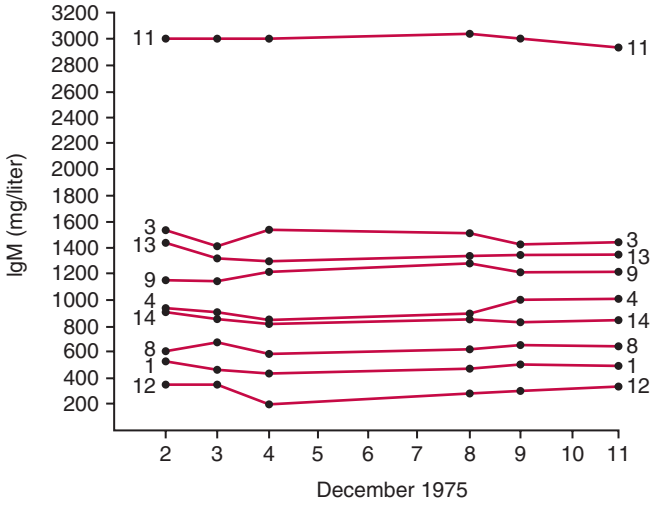

Figure 5-8 Serial immunoglobulin (Ig)M values over several days from reference individuals. Note that intraindividual variability is very small compared with interindividual variability. *(From Statland BE, Winkel P, Killingsworth LM. Factors contributing to intra-individual variation of serum constituents: 6. Physiological day-to-day variation in concentrations of 10 specific proteins in sera. Clin Chem 1976;22:1635-6.)*

1. One can try to reduce variation in reference values by *partitioning* into more homogeneous subclasses, as was discussed in a previous section. However, increasing the ratio, R, for example, from 0.6 to 1.4 by partitioning requires that one can obtain the rather dramatic reduction of 37% in standard deviation.[31] This often is difficult to attain in practice.
2. The other possibility is to use the patient's previous values, obtained when the patient was in a defined state of health, as the reference for any future value. Application of *subject-based reference values* becomes more feasible as health screening by laboratory tests and computer storage of results become available to large segments of the general population.

Two not completely separated classes of models may be used for construction of subject-based reference intervals: statistical and physiologic models.[34]

1. Harris has developed several models based on statistical *time series analysis.*[31-35] At one extreme, a stationary or *homeostatic model* is suitable for analytes showing relatively fast, random fluctuations around a constant mean (set point). The set point is estimated from past values that are given equal weights. Another model, the nonstationary *random-walk model,* allows a changing set point over time in healthy subjects. Then, more recent values are given heavier weights during estimation of the current set point. Intermediate and more or less complex models exist. Some of these data-following methods are suitable for adaptive forecasting in situations in which the time intervals are short (e.g., during hospitalization).[33] They might thus be implemented on a computer as part of a laboratory cumulative reporting system. The reader is referred to papers by Harris for details on statistical time series models.[31-35]
2. It is also possible to construct *physiologic models* that use known physiologic and biochemical time-dependent relationships. Winkel has developed a time series model for monitoring plasma progesterone in pregnancy using the assumption of a simple exponential growth curve for the size of the placenta.[90]

Dynamic versus Static Interpretation of Clinical Chemistry Data

Interpretation of observed values by comparison with population-based reference values or intervals is not the only way that clinical data may be used. Often, dynamic approaches to data interpretation are more appropriate. Time-dependent variation may provide important information. Time series analysis of consecutive values from the same individual is one example. Other examples include dynamic analysis of kinetic processes in the organism, such as intermediary metabolism and the exchange of substances between metabolic pools. For example, it is possible to design a model for urea turnover in the body.[26] The model defines (1) rates of urea input from various sources to the extracellular fluid, (2) exchange of urea across cell membranes, (3) urea degradation in the gut, (4) handling of urea by the kidneys, and so forth. Such a model may facilitate interpretation of serum urea values with the purpose of detecting hemorrhage or necrosis after major surgery and evaluating the magnitude of these complications. Biochemical model building, estimation of model parameters from observed values, and computer simulation of the models may add greatly to our understanding.

CHAPTER 6

Preanalytical Variables and Biological Variation

Donald S. Young, M.B., Ph.D.

The human body is composed of many different compounds and elements; the concentration or activity of these analytes in body fluids may reflect an individual's health or pathophysiological state. Many factors other than disease may affect the concentration or activity of these analytes.[31,49]

PREANALYTICAL VARIABLES

Preanalytical variables fall under two categories: those that are controllable and those that are not. Those that can be controlled have short-lived effects. Duration of the other factors is much longer. Standardization of specimen collection practices minimizes the variables that cause changes in test values within 1 day or from one day to another, thereby reducing the difficulty in interpretation of values. However, in clinical practice, standardization is rarely possible. Thus one must understand the influences of controllable and uncontrollable variables on the composition of body fluids.

Controllable Variables

Controlling variations begins with specimen collection. Collecting appropriate blood specimens involves both proper preparation of the individual and attention to the details of the technique of specimen collection. Controllable variables include physiologic variables such as posture, prolonged bed rest, exercise, physical fitness and training, circadian variation, and travel. Diet, life-style, stimulants, drugs, herbal preparations, and recreational drug ingestion are additional examples of variables that can be controlled. A few of the more important influences are discussed in this chapter.

In clinical practice, it is rarely possible to standardize specimen collection conditions to the extent that is ideal for proper interpretation of results. However, certain actions should be taken in an attempt to ensure proper specimens for testing. An essential element is proper identification of the patient and his/her specimen. At least two permanent identifiers [i.e., patient names (last and first), date of birth, medical record number] need to be used, with the same information contained on the test requisition form and on the specimen label. If specimens are collected for medicolegal purposes, a chain of custody system must be established to ensure that all persons handling or processing the specimen are identified. To protect both the patient and the phlebotomists when blood specimens are collected, the phlebotomist should wear gloves and protective impervious clothing. To draw specimens from infectious patients, the phlebotomist should also wear a facemask and goggles.

If pertinent for the requested tests, the phlebotomist should verify that the patient is fasting. Ideally, a patient should have remained in the same position for 30 minutes before a specimen is collected, and in the same position as likely to be appropriate for the next specimen to be collected (e.g., supine if an inpatient, sitting if an outpatient). A tourniquet should be used to facilitate location of a vein for venipuncture, but application for longer than 1 minute begins to induce hemoconcentration. An appropriately sized needle should be used to lessen the possibility of hemolysis. Other precautions must also be taken to prevent hemolysis—no shaking of tubes or vigorous mixing of blood or puncturing of skin before the alcohol used to clean the skin has evaporated.[105] Hemolysis may lead to false results through leakage of analytes from erythrocytes or through interference with certain photometric methods.[104] The extent of the interference is typically related to the degree of hemolysis. Use of an evacuated blood tube system to collect blood is preferred to use of a syringe to minimize hemolysis, and blood collected into one type of tube should never be transferred into another tube. Each laboratory must define which types of specimens are appropriate for the analytical methods that it uses. Generally, plasma allows more rapid processing of specimens for chemistry tests, but anticoagulants may interfere with some analytical methods.[104] However, serum concentrations of potassium and phosphate may be as much as 8.4% and 7.0% higher, respectively, than in plasma, and other analytes may be affected to a lesser extent.[58] The composition of blood from different vascular locations (e.g., capillary, artery, vein) may be slightly different, so consistent use of the same source of blood is desirable.[105]

Although testing of urine is common, the types of specimens needed for different tests can be quite different. For example, the first morning specimen is usually the most

concentrated and is most appropriate for microscopic examination, whereas specimens collected over 24 hours are most appropriate for quantitative measurements. The appropriate preservative for urine specimens depends on the analytes to be measured (e.g., alkalinized specimens are most appropriate for porphyrins and uric acid, whereas no preservative or acidification is more appropriate for other analytes). Cerebrospinal fluid and abnormal fluids such as pleural or ascitic fluid must be collected under sterile conditions because microbiological testing is frequently required at the same time as chemistry tests. In such situations, chemistry tests should be performed on the specimen in the first tube, and the second tube should be used for culture to eliminate contamination from tissue debris or skin bacteria.

Once specimens have been collected, they should be transported rapidly to a laboratory for testing. If a blood collection site is distant from a laboratory, specimens should be collected into evacuated blood tubes containing a thixotropic polymer gel and should be centrifuged on site. The gel forms an effective barrier between the separated serum or plasma and cells, so no leakage of cellular constituents occurs into the plasma or serum above the gel. Centrifugation of specimens should be done within 2 hours of blood collection, and within the laboratory, if specimens cannot be tested in a timely manner, they must be held under appropriate storage conditions—at room temperature, refrigerated, or frozen, depending on the analyte—until testing takes place.[105]

Physiologic Variables

Physiologic variables that are controllable that affect analytical results include (1) posture, (2) prolonged bed rest, (3) exercise, (4) physical training, (5) circadian variation, and (6) travel.

Posture

In an adult, a change from a lying to an upright position results in a reduction of the person's blood volume of about 10% (≈600 to 700 mL). Because only protein-free fluid passes through the capillaries to the tissue, this change in posture results in a reduction of the plasma volume of the blood and an increase (≈8 to 10%) in the plasma protein concentration. Normally, the decrease with the change from lying to standing is complete in 10 minutes. However, an interval of 30 minutes is required for the reverse change to occur when one goes from standing to lying.

The typical pressure at the arterial end of a capillary is 24 mm Hg (3.2 kPa), and at the venous end 10 mm Hg (1.3 kPa), although this varies with the distance of the capillary from the heart.[74] Transfer of fluid and solute across a capillary wall depends on a complex interaction of hydrostatic and osmotic pressures of capillary and interstitial fluids. Fluid moves into the interstitial space at the arteriolar end of the capillary and returns to the capillary at the venular end. A greater volume of fluid leaves the capillary at the arteriolar end than is returned to the venous end. Excess fluid drains into the lymphatic system. When an individual lies down, fluid return to the capillaries is increased, because capillary pressure is reduced. The volume of fluid returning to capillaries progressively declines when an individual is recumbent for a long time. Heart rate and systolic and diastolic blood pressures are greater in the upright than in the recumbent individual. Change in posture from lying to standing increases the secretion of catecholamines, aldosterone, angiotensin II, renin, and antidiuretic hormone (vasopressin). Epinephrine and norepinephrine concentrations in plasma may double within 10 minutes, but no change in their urinary excretion is noted. The increase in plasma aldosterone and plasma renin activity is slower, but their concentrations may still double within 1 hour. Concentrations of other hormones may also increase as a result of the relative hemoconcentration induced by standing. Typically, a 5 to 15% increase in the concentrations of most cellular elements and protein-bound molecules is also noted with a change from lying to an erect position.

Substantial changes also take place with a change from lying to a sitting position, or from standing to a supine or sitting position.[16] Reduction of the extracellular fluid volume with standing reduces the renal blood flow and causes a reduction in the glomerular filtration rate (GFR) and in urine production. Changes are apparent in 1 hour. Within 2 hours of becoming recumbent, an individual's hemoglobin and hematocrit may decrease by as much as 6.5% as the result of hypervolemia. This is associated with a reduction in the concentration of plasma protein on the order of 8% and of protein-bound constituents.[38] Although postural changes affect urinary sodium excretion, its plasma concentration is only slightly affected. Urinary excretion of sodium and lithium (used to treat some forms of schizophrenia) is reduced in response to increased aldosterone secretion, but the normal diurnal variation persists.[41] When an individual stands, his urinary pH decreases and excretion of bicarbonate is reduced as hydrogen ions are exchanged for sodium. Excretion of protein is reduced in most individuals with reduction of the glomerular filtration rate that occurs with standing. Orthostatic proteinuria is a condition in which protein is present when individuals are standing but is essentially absent when they are recumbent. This phenomenon may be caused by increased glomerular permeability from increased venous pressure. The incidence of orthostatic proteinuria is probably less than 5%.

Changes in concentration of proteins and protein-bound constituents in serum with postural changes are greater in hypertensive patients than in normotensive patients, in individuals with a low plasma protein concentration than in those with a normal concentration, and in the elderly compared with the young.[25,26] Most of the plasma oncotic pressure is attributable to albumin because of its high concentration, so that protein malnutrition—with its associated reduction in plasma albumin concentration—reduces the retention of fluid within the capillaries. Conversely, the impact of postural changes is less in individuals with abnormally high concentrations of protein, such as those with a monoclonal gammopathy (multiple myeloma). In general, the concentrations of freely diffusible constituents with molecular weights of less

TABLE 6-1 Change in Concentration of Serum Constituents With Change from Lying to Standing

Constituent	Average Increase, %

From Felding P, Tryding N, Hyltoft Petersen P, Hørder M. Effects of posture on concentrations of blood constituents in healthy adults: practical application of blood specimen collection procedures recommended by the Scandinavian Committee on Reference Values. Scand J Clin Lab Invest 1980;40:615-21.

than 5000 Da are unaffected by postural changes. However, a significant increase in potassium (≈0.2 to 0.3 mmol/L) occurs after an individual stands for 30 minutes.[27] This increase in K^+ has been attributed to the release of intracellular potassium from muscle. Changes in the concentration of some major serum constituents with changes in posture are listed in Table 6-1.

Application of a tourniquet at the time of blood collection mimics the effect of a change from a lying to a standing position, raising the plasma concentrations of proteins and protein-bound constituents, the activities of enzymes and the counts of blood cells, and the blood hematocrit and hemoglobin concentrations.

Prolonged Bed Rest

Plasma and extracellular fluid volumes decrease within a few days of the start of bed rest. Consequently, the blood hematocrit may increase by as much as 10% within 4 days. Usually a slight reduction in total body water is noted, but with 2 weeks' bed rest the plasma volume reverts to its pre-bed rest value.[38]

Concentrations of protein-bound constituents are also reduced, although mobilization of calcium from bones with an increased free ionized fraction compensates for the reduced protein-bound calcium, so serum total calcium is less affected. Indeed, a paradoxical increase in the total plasma calcium concentration may occur. Plasma 1,25-dihydroxyvitamin D and 25-hydroxyvitamin D concentrations may decrease by as much as 20%. Plasma aspartate aminotransferase activity is usually slightly less in individuals confined to bed than in those undertaking normal physical activity. Initially and paradoxically, CK activity is increased as a result of its release from skeletal muscles, but ultimately, CK activity may be less than in active, healthy individuals. Serum potassium may be reduced by up to 0.5 mmol/L over 3 weeks in association with a reduction in skeletal muscle mass.

Prolonged bed rest is associated with increased urinary nitrogen excretion, which increases by up to 15% after 2 weeks. Calcium excretion steadily increases up to 7 weeks of rest, increasing by a maximum of about 60%. Excretion of sodium, potassium, phosphate, and sulfate is also increased but to a much smaller extent; hydrogen ion excretion is reduced, and this is presumably caused by decreased metabolism of skeletal muscle.[22] The amplitude of circadian variation of plasma cortisol is reduced by prolonged immobilization, and urinary excretion of catecholamines may be reduced to one third of the concentration in an active individual. Vanillylmandelic acid (VMA) excretion is reduced by one fourth after 2 to 3 weeks of bed rest.

When an individual becomes active after a period of bed rest, longer than 3 weeks is required before calcium excretion reverts to normal, and another 3 weeks before positive calcium balance is achieved. A period of several weeks is required before positive nitrogen balance is restored.

Exercise

In considering the effects of exercise, the nature and extent of the exercise should be taken into account.[86] Static or isometric exercise, usually of short duration but of high intensity, uses previously stored ATP and creatine phosphate, whereas more prolonged exercise must use ATP generated by normal metabolic pathways. Changes in concentrations of analytes that result from exercise are largely due to shifts of fluid between intravascular and interstitial compartments and changes in hormone concentrations stimulated by the change in activity and by the loss of fluid due to sweating. Plasma concentrations of β-endorphin and catecholamines may more than double within a minute of initiation of strenuous exercise. Hemoconcentration, affecting high molecular weight constituents, follows strenuous exercise. The physical fitness of an individual may also affect the extent of change in the concentration of a constituent; the length of time after exercise when a specimen was collected also influences the concentrations of measured analytes. Such factors account for sometimes conflicting reports in the literature.

With *moderate exercise,* the provoked stress response causes an increase in blood glucose, which stimulates insulin secretion. The arteriovenous difference in glucose concentration is increased more than 5-fold from about 14 mg/dL (0.8 mmol/L) at rest, depending on the duration and intensity of exercise in association with greater tissue demand for glucose.[97] Plasma pyruvate and lactate are increased by increased metabolic activity of skeletal muscle. Even mild exercise may increase the plasma lactate twofold. Arterial pH and PCO_2 are reduced by exercise. Reduced renal blood flow causes a slight increase in the serum creatinine concentration. Competition for renal excretion between urate, lactate, and products of increased tissue catabolism causes the plasma urate concentration to increase. Exercise causes a reduction in cellular ATP, which increases cellular permeability. Increased permeability causes slight increases in the serum

activities of enzymes originating from skeletal muscle, such as AST, LD, CK, and aldolase.[94] The increase in CK is largely attributable to its CK-MM isoform, although small increases in CK-MB may also be observed. The increase in enzyme activity tends to be greater in unfit than in fit individuals. Performing normal daily activities over 4 hours may increase serum CK activity by as much as 50% in some healthy individuals.[48] Mild exercise produces a slight decrease in serum cholesterol and triglyceride concentrations that may persist for several days. Those who walk for about 4 hours each week have an average cholesterol concentration 5% lower and HDL concentration 3.4% higher than inactive individuals.

In general, the effects of *strenuous exercise* are exaggerations of those occurring with mild exercise. Thus hypoglycemia and increased glucose tolerance may occur. Plasma lactate may be increased tenfold during exercise but soon returns to normal in fit individuals. Severe exercise increases the concentration of plasma proteins owing to an influx of protein from interstitial spaces, which occurs after an initial loss of both fluid and protein through the capillaries. Plasma concentrations of total proteins increase by about 9% and renal glomerular permeability increases, leading to increased proteinuria.[75] Plasma fibrinolytic activity is also increased. Strenuous exercise may more than double CK activity, but the activity of enzymes with primarily liver or kidney origin is little changed, although hepatic and renal blood flow is reduced.

Strenuous exercise for 10 minutes increases plasma renin activity by 400%. Cortisol secretion is stimulated, and the normal diurnal variation may be abolished.[21] Urinary free cortisol excretion and plasma concentrations of cortisol, aldosterone, growth hormone (somatotropin), and prolactin are also increased by exercise. Plasma insulin concentration is decreased by exercise. Strenuous exercise increases both plasma and urinary concentrations of catecholamines. Changes in concentrations of cortisol and other stress-stimulated increased hormone concentrations are presumed to release leukocytes, primarily neutrophils, from the bone marrow into the peripheral circulation. Following strenuous exercise, the leukocyte count has been observed to increase to about 25,000 cells/μL.[41]

Blood pH, oxygen saturation, and venous bicarbonate concentrations are decreased by strenuous exercise. The concentration of triglycerides is reduced briefly by exercise, but the free fatty acid concentration is greatly increased; serum creatinine and urea nitrogen concentrations are also increased. Although the creatinine concentration returns rapidly to normal on cessation of exercise, the increased urea nitrogen concentration persists for some time. Reversible, benign hematuria and proteinuria with increased excretion of leukocytes and erythrocytes occur commonly with exercise and worsen in proportion to the extent of exercise. These may persist for 3 days following strenuous sports, but this does not warrant investigation. Urinary steroid excretion increases in response to the stress of exercise.

Some representative changes in concentration or activity of serum constituents induced by exercise are listed in Table 6-2.

Physical Training

Athletes generally have a higher serum activity of enzymes of skeletal muscular origin at rest than do nonathletes. However, the response of these enzymes to exercise is less in athletes than in other individuals. Reduced release of enzymes from skeletal muscle in well-trained individuals has been attributed to an increase in the number and size of mitochondria, allowing the muscle to better metabolize glucose, fatty acids, and ketone bodies. The proportion of CK that is CK-MB is much greater in trained than in untrained individuals.[14] Serum concentrations of urea, urate, creatinine, and thyroxine are higher in athletes than in comparable untrained individuals. Urinary excretion of creatinine is also increased. These changes are probably related to increased muscle mass and greater turnover of muscle mass in athletes.

TABLE 6-2 Effects of Strenuous Exercise on Selected Serum Constituents*

Constituent Value	% Increase	Constituent Value	% Decrease
Acid phosphatase	11	Albumin	4

From Statland BE, Winkel P, Bokelund H. Factors contributing to variation of serum constituents in healthy subjects. In: Siest G, ed. Organisation des laboratoires: biologie perspective. Paris: L'Expansion Scientifique Francaise, 1975:717-50.

*Changes were determined 15 minutes after conclusion of 20 minutes of exercise.

Body fat is reduced by physical training. This is associated with increased HDL-cholesterol and decreased LDL-cholesterol and triglyceride concentrations, the extent of which varies with the intensity and duration of training.

Circadian Variation

Many constituents of body fluids exhibit cyclical variation throughout the day.[95,100] Factors contributing to such variation include posture, activity, food ingestion, stress, daylight or darkness, and sleep or wakefulness. The cyclical pattern tends to be similar among individuals who work during the day and sleep at night, although it is different in night workers. These cyclical variations may be quite large; therefore the timing of specimen collection must be strictly controlled. For example, the concentration of serum iron may increase by as much as 50% from 0800 to 1400, and that of cortisol by a similar amount between 0800 and 1600. Serum potassium has been reported to decline from 5.4 mmol/L at 0800 to 4.3 mmol/L at 1400.[88,89] The typical total variation in several commonly measured serum constituents over 6 hours is illustrated in Table 6-3. Total variation is contrasted with analytical error.

Hormones are secreted in bursts, and this, together with the cyclical variation to which most hormones are subject, may make it very difficult to interpret their plasma concentrations properly.[99] Corticotropin secretion is influenced by cortisol-like steroids, but it is also affected by posture and by light, darkness, and stress. Its secretion is increased threefold to fivefold from its minimum between afternoon and midnight to its maximum around waking. Growth hormone and epinephrine concentrations exhibit similar change throughout the day. Cortisol concentrations are greatest around 0600 to 0800 hours, and one study reported mean minima and maxima of 15.8 µg/dL and 111 µg/dL, respectively, at different times during the day.[52]

Maximum renin activity normally occurs early in the morning during sleep; its minimum occurs late in the afternoon. The plasma aldosterone concentration shows a similar pattern. GFR varies inversely with the secretion of renin, probably through constriction of renal efferent arterioles.[42] GFR is least at the time of maximum renin secretion and is 20% greater in the afternoon, when renin activity is at a minimum. Excretion of 17-ketosteroids and 17-hydroxycorticosteroids is low at night and reaches a maximum about midafternoon.

No circadian variation in plasma concentrations of FSH and LH is noted in men, but a 20 to 40% increase in plasma testosterone occurs during the night. Prolactin is secreted, similar to other hormones such as LH and FSH, in multiple bursts; prolactin concentration is greatest during sleep.[99] The pituitary gland regulates hormone secretion primarily through negative feedback generated by increased circulating concentrations of circulating hormones. To perform a precise assessment of the concentration of a hormone, several measurements may be required.

Serum TSH is at a maximum between 0200 and 0400, and is at a minimum between 1800 and 2200. The variation is on the order of 50 to 206%.[52] Variations in serum thyroxine concentrations also occur, but these appear to be related to changes in the concentration of binding protein brought about by changes in posture. These variations are maximal at

TABLE 6-3 Total and Analytical Variation for Serum Tests on Specimens Obtained at 0800 and 1400*

Constituent	Mean	Total Variation, %	Analytical Variation, %
Sodium, mmol/L	141	1.9	1.8
Potassium, mmol/L	4.4	7.1	2.8
Calcium, mg/dL	10.8	3.2	2.7
Chloride, mmol/L	102	3.8	3.4
Phosphate, mg/dL	3.8	10.7	2.4
Urea nitrogen, mg/dL	14	22.5	2.5
Creatinine, mg/dL	1.0	14.5	6.3
Uric acid, mg/dL	5.6	11.5	2.6
Iron, µg/dL	116	36.6	3.4
Cholesterol, mg/dL	193	14.8	5.7
Albumin, g/dL	4.5	5.5	3.9
Total protein, g/dL	7.3	4.8	1.7

Alkaline phosphatase, U/L	63	20	3
Lactate dehydrogenase, U/L	195	16	12

*11 male subjects, age 21 to 27 years, studied at 0800, 1100, and 1400.

From Winkel P, Statland BE, Bokelund H. The effects of time of venipuncture on variation of serum constituents. Am J Clin Pathol 1975;64:433-47. Copyright © 1975 by the American Society of Clinical Pathologists. Reprinted with permission.

between 1000 and 1400. Total protein concentration may vary by as much as 10% over 24 hours, but variation in individual proteins may be even greater.

Growth hormone secretion is greatest shortly after sleep commences. Conversely, basal plasma insulin is higher in the morning than later in the day, and its response to glucose is also greatest in the morning and least at about midnight. When a glucose tolerance test is given in the afternoon, higher glucose values occur than when the test is given early in the day. Higher plasma glucose occurs in spite of a greater insulin response, which is nevertheless delayed and less effective.

Urinary excretion of catecholamines and their metabolites is less at night than during the day. The effect is related to activity, because in night workers, excretion is less during the day.

Peak urinary excretion of sodium and potassium occurs about noon, whereas excretion of calcium and magnesium is greatest during the night. Urinary phosphate excretion is low at night, with the result that serum phosphate is as much as 30% higher at night than during the morning. Urinary volume and creatinine excretion are low during the night. Creatinine clearance may be reduced by up to 10% during the night. Night urine contains excess ammonia, and its titratable acidity is high.[90]

Blood cell concentrations are affected by circadian rhythms, with neutrophil and lymphocyte counts increasing by 61% and 67%, respectively, at their peaks from their nadir concentrations.[52]

Travel

Travel across several time zones affects the normal circadian rhythm. Five days is required to establish a new stable diurnal rhythm after travel across 10 time zones. Changes in laboratory test results are attributable to altered pituitary and adrenal function. Urinary excretion of catecholamines is usually increased for 2 days, and serum cortisol is reduced. During a 20-hour flight, serum glucose and triglyceride concentrations increase, while glucocorticoid secretion is stimulated. During such a prolonged flight, fluid and sodium retention occurs, but urinary excretion returns to normal after 2 days.[11]

Space travel is associated with a decrease in blood and plasma volumes and is further associated with increases in plasma antidiuretic hormone, atrial natriuretic peptide, growth hormone, cortisol, and corticotropin concentrations.[60] In contrast, the plasma renin activity may be decreased by as much as 50%. Plasma aldosterone may also decrease but to a lesser extent. In spite of the stress of space travel, plasma concentrations of catecholamines are usually unaffected. Space travel leads to bone demineralization and a negative calcium and phosphate balance, primarily caused by increased excretion of these minerals. However, concentrations of commonly measured analytes generally do not exceed the reference range when astronauts adapt to space travel.[102]

Diet

Diet has considerable influence on the composition of plasma. Studies with synthetic diets have shown that day-to-day changes in the amount of protein are reflected within a few days in the composition of nitrogenous components of plasma and in the excretion of end products of protein metabolism.

Four days after the change from a normal diet to a high-protein diet, doubling of the plasma urea concentration occurs, along with an increase in its urinary excretion.[9] Serum cholesterol, phosphate, urate, and ammonia concentrations are also increased. High protein intake increases both serum and urinary urea and urate. A high-fat diet, in contrast, depletes the nitrogen pool because of the requirement for excretion of ammonium ions to maintain acid-base homeostasis. A high-fat diet increases the serum concentration of triglycerides but reduces serum urate. Reduction of fat intake reduces serum lactate dehydrogenase activity. Ingestion of very different amounts of cholesterol has little effect on its serum concentration; an increase in intake of 50% may affect the serum concentration by only 5 to 10 mg/dL (0.13 to 0.26 mmol/L).[54] Ingestion of monounsaturated fat instead of saturated fat reduces cholesterol and LDL-cholesterol concentrations. When polyunsaturated fat is substituted for saturated fat, the concentrations of triglycerides and HDL-cholesterol are reduced. Notwithstanding the conclusions of previous studies, a 2009 report suggests that different types of diets have a similar influence on the plasma concentrations of lipids, and that total caloric ingestion is the primary influence on an individual's body mass and blood lipid concentrations, with total and LDL-cholesterol and triglyceride concentrations decreasing and HDL-cholesterol increasing similarly when volunteers were fed different weight-loss diets.[81]

When dietary carbohydrates consist mainly of starch or sucrose rather than other sugars, the serum activities of ALP and LD are increased. AST and ALT activities are also influenced by the type of sugar ingested, being higher with a sugar diet than with a starch-based diet.[51] Plasma triglyceride concentration is reduced when sucrose intake is decreased. Peak glucose concentration tends to be less during a glucose tolerance test in individuals habitually ingesting a bread diet than when a high-sucrose diet is ingested. A high-carbohydrate diet decreases the serum concentrations of LDL-cholesterol, triglycerides, cholesterol, and protein. Individuals who eat many small meals throughout the day tend to have total LDL- and HDL-cholesterol concentrations that are lower than when food of the same type and amount is eaten in three meals.[2]

In addition to the types of foods and drinks ingested, specific food-related situations influence plasma composition. These include vegetarianism, obesity, malnutrition, fasting, and starvation.

Food Ingestion

The concentration of certain plasma constituents is affected by the ingestion of a meal, with the time between ingestion of a meal and collection of blood affecting the plasma concentrations of many analytes. For example, fasting overnight for 10 to 14 hours before blood collection noticeably decreases the variability in concentration of many analytes and is seen

as the optimal time for fasting around which to standardize blood collections.[24] The biggest increases in serum concentration that occur after a meal are noted for glucose and triglycerides.[13] The increase in ALP (mainly intestinal isoenzyme) is greater when a fatty meal is ingested and is influenced by the blood group of the individual and the substrate used for the enzyme assay. Activities of alanine and aspartate aminotransferases may increase by 10 to 20% following a meal.[49] In addition, lipemia following a meal may affect some analytical methods used to measure serum constituents. Ultracentrifugation or the use of serum blanks can reduce the adverse analytical effects of lipemia.

The effects of a meal may be long lasting. Thus ingestion of a protein-rich meal in the evening may cause increases in concentration of serum urea nitrogen, phosphorus, and urate that are still apparent 12 hours later.[1] Nevertheless, these changes may be less than the typical intraindividual variability. Large protein meals at lunch or in the evening increase serum cholesterol and growth hormone concentrations for at least 1 hour after a meal. The effect of carbohydrate meals on blood composition is less than that of protein meals. No change in the cortisol concentration is noted when breakfast is taken, probably because cortisol completely occupies all cortisol binding sites on its binding protein in the early morning. Glucagon and insulin secretions are stimulated by a protein meal, and insulin is also stimulated by carbohydrate meals.

In response to a meal, the stomach secretes hydrochloric acid, causing a reduction in the plasma chloride concentration. Venous blood from the stomach contains an increased amount of bicarbonate. This condition reflects a mild metabolic alkalosis ("alkaline tide") and increased PCO_2. The metabolic alkalosis is sufficient to reduce serum-free ionized calcium by 0.2 mg/dL (0.05 mmol/L). After ingestion of a meal, the liver becomes the prime site for metabolism of ingested substances. Ingestion of therapeutic drugs with meals may have considerable influence on the characteristic absorption and metabolism of each drug.

The effects of ingestion of a 700-kcal (2.93-MJ) meal on some commonly measured blood constituents are illustrated in Table 6-4. These effects differ with different meals. Thus the glucose increase is often greater and phosphate is usually decreased after a carbohydrate meal.[90]

Ingestion of one glass of water leads to statistically, but not clinically, significant alterations in the concentration of several commonly measured test constituents. When 75 g glucose is ingested with water, as in a glucose tolerance test, the concentration of glucose is increased. This stimulates the secretion of insulin. Insulin causes the release of sodium from cells and stimulates the transport of potassium into cells.

TABLE 6-4 Influence of a Standard 700-kcal Meal on Serum Constituents*

Constituent	Before Meal	2 h After† Meal
Alanine aminotransferase, U/L	31	33
Albumin, g/dL	4.5	4.6
Alkaline phosphatase, U/L	46	46
Aspartate aminotransferase, U/L	22	28
Bilirubin, total, mg/dL	0.7	0.8
Calcium, mg/dL	9.9	10.0
Cholesterol, mg/dL	220.0	220.0
Glucose, mg/dL	71	82*
Lactate dehydrogenase, U/L	198	198
Phosphate, mg/dL	3.1	3.6*
Potassium, mmol/L	3.8	4.0*
Sodium, mmol/L	140	141
Protein, total, g/dL	7.8	7.9
Urea nitrogen, mg/dL	16	16
Uric acid, mg/dL	6.0	6.2

*Results are mean values in 200 healthy individuals.
†Note that other studies have reported different changes based on different content and amounts of food.

Basel: Karger, 1973:193-200; Cohn JS, McNamara JR, Cohn SD, et al. Postprandial plasma lipoprotein changes in human subjects of different ages. J Lipid Res 1988;29:469-79. (These investigators have reported increases in plasma triglyceride concentrations greater than 150% after a high-fat meal.)

Ingestion of Specific Foods and Beverages

Constituents of food and drink affect the composition of plasma. Bran, serotonin, and caffeine are examples of such constituents.

Bran. Habitual ingestion of bran, which is widely promoted to improve the concentration of lipids, impedes absorption of certain compounds, including calcium, cholesterol, and triglycerides, from the gastrointestinal tract. The concentration of calcium may be reduced by as much as 0.3 mg/dL (0.08 mmol/L) and that of triglycerides by 20 mg/dL (0.23 mmol/L), especially if triglycerides were high initially.[46] Pectin and dietary fibers reduce serum apolipoprotein B and cholesterol concentrations.

Food Constituents. The composition of common foods is often overlooked. Many fruits, such as bananas, and vegetables that contain 5-hydroxytryptamine (serotonin) cause increased excretion of 5-HIAA. Avocados impair glucose tolerance by affecting insulin secretion. Onions reduce plasma glucose and the insulin response to glucose. Garlic ingestion may reduce serum cholesterol concentrations by about 9%.[104]

Caffeine. Caffeine is contained in many beverages, including coffee, tea, and colas, and has a considerable effect on the concentration of blood constituents. Caffeine stimulates the adrenal medulla, causing increased secretion of epinephrine, reflected in a two- to threefold increase in the plasma epinephrine concentration. Excretion of the catecholamines and their metabolites is increased and a slight increase in plasma glucose concentration occurs as a result of increased gluconeogenesis with concomitant impairment of glucose tolerance.[5] The adrenal cortex is also affected; plasma cortisol is increased, and this is accompanied by increased excretion of free cortisol, 11-hydroxycorticoids, and 5-HIAA. The effect

of caffeine may be so great that the normal diurnal variation of plasma cortisol may be suppressed. Plasma renin activity may also be increased following caffeine ingestion. Caffeinated, but not decaffeinated, coffee causes diuresis with a transient increase in excretion of sodium and potassium. It does this by inhibiting the reabsorption of electrolytes in the ascending loop of Henle of the renal nephrons.[66]

Caffeine has a marked effect on lipid metabolism. Ingestion of two cups of coffee may increase the plasma free fatty acid concentration by as much as 30% and those of glycerol, total lipids, and lipoproteins to a lesser extent. Activation of triglyceride lipase causes an increase in nonesterified fatty acid concentration. Prolonged ingestion of caffeine (e.g., over several weeks) causes a slight reduction in the serum cholesterol concentration but an increase in the serum triglyceride concentration. Because the effect on plasma LDL-cholesterol and apolipoprotein B is greater in individuals drinking decaffeinated coffee than in those drinking regular coffee, the effects may be unrelated to caffeine.[92]

Caffeine is also a potent stimulant of the secretion of gastric juice, hydrochloric acid, and pepsin. The serum gastrin concentration may be increased by as much as five times after three cups of coffee are ingested. Coffee has a diuretic effect, and it increases the excretion of erythrocytes and renal tubular cells in the urine. Caffeine increases the absolute amounts of sodium, potassium, calcium, and magnesium in urine—an effect that is not observed with decaffeinated coffee.

Vegetarianism

In long-standing vegetarians, the concentration of VLDL-cholesterol is reduced, typically by 12%, compared with nonvegetarians. Total lipid and phospholipid concentrations are reduced, and concentrations of cholesterol and triglycerides may be only two thirds of those in individuals on a mixed diet. Both HDL- and LDL-cholesterol concentrations are affected. In strict vegetarians, the LDL-cholesterol concentration may be 37% less and the HDL-cholesterol concentration 12% less than in nonvegetarians. The cholesterol:HDL-cholesterol ratio is decreased. Effects are less notable in individuals who have been on a vegetarian diet for only a short time. Lipid concentrations are also less in individuals who eat only a vegetable diet than in those who consume eggs and milk as well. Little difference is seen in the concentration of protein or the activities of enzymes in the serum of long-standing vegetarians and individuals on a mixed diet. A vegetarian diet does not appear to affect liver function in that liver function tests are similar in vegans and nonvegans.[37] The serum creatinine concentration may be slightly reduced in vegetarians because of reduced ingestion of protein, but urinary excretion of creatinine and its clearance may be almost 40% less than in meat-eaters.[61] Plasma concentrations of trace elements tend to be reduced in vegans. For example, serum copper may be reduced by 20%, selenium by 10%, and zinc by more than 10% after individuals have consumed a lactovegetarian diet for 3 months.[87] Although the plasma concentration of many vitamins is increased, that of vitamin B_{12} may be reduced in vegetarians to a concentration approaching that observed in deficiency. An explanation for the low vitamin B_{12} and the high bilirubin still has to be established. Differences in the composition of serum of vegetarians and nonvegetarians are shown in Table 6-5. Urinary pH is usually higher in vegetarians than in meat-eaters as the result of reduced intake of precursors of acid metabolites.

TABLE 6-5 Comparison of Blood Constituents Between Vegetarians and Nonvegetarians

Constituent	Vegetarians	Nonvegetarians
S-Albumin, g/dL	4.2	4.3
P-Calcium, mg/dL	9.4	9.7
P-Cholesterol, mg/dL	213	252
P-HDL cholesterol, mg/dL	66	66
B-Glucose, mg/dL	90	101
B-Hemoglobin, g/dL	13.9	14.3
P-Triglycerides, mg/dL	106	124
B-Urea nitrogen, mg/dL	14	16
P-Uric acid, mg/dL	5.3	5.8

Malnutrition

In malnutrition, the plasma concentrations of most proteins, including total protein, albumin, prealbumin, and β-globulin, are reduced. The frequently increased concentration of γ-globulin does not fully compensate for the decrease in other proteins. Concentrations of complement C3, retinol-binding globulin, transferrin, and prealbumin decrease rapidly with the onset of malnutrition and are measured to define the severity of the condition.[72] Plasma concentrations of lipoproteins are reduced, and serum cholesterol and triglycerides may be only 50% of the concentrations in healthy individuals. In spite of severe malnutrition, glucose concentration is maintained close to that in healthy individuals. However, the concentrations of serum urea nitrogen and creatinine are greatly reduced as a result of decreased skeletal mass, and creatinine clearance is decreased.

The plasma cortisol concentration is increased, largely as the result of an increase in the free cortisol moiety, but also possibly because of decreased metabolic clearance. Plasma concentrations of total T_3 and T_4 are considerably reduced, with the thyroxine concentration being most affected. This is due in part to reduced concentrations of TBG and prealbumin.

Erythrocyte and plasma folate concentrations are reduced in protein-calorie malnutrition, but the serum vitamin B_{12}

concentration is unaffected or may even be slightly increased.[55] Plasma concentrations of vitamins A and E are reduced, but the extent depends on the cause and duration of the malnutrition (e.g., dietary or iatrogenic, such as bariatric surgery). The blood hemoglobin concentration is reduced, but the serum iron concentration initially is little affected by malnutrition, although decreased plasma transferrin concentrations ultimately lead to reduced iron concentrations.

The activity of most of the commonly measured enzymes is reduced but increases with restoration of good nutrition.

Long-Term Fasting and Starvation

Withdrawal of most caloric intake has been used to treat certain cases of obesity. Such withdrawal provokes many metabolic responses. The body attempts to conserve protein at the expense of other sources of energy, such as fat. The blood glucose concentration decreases by as much as 18 mg/dL (1 mmol/L) within 3 days of the start of a fast, in spite of the body's attempts to maintain glucose production.[67] Insulin secretion is greatly reduced, whereas glucagon secretion may double in an attempt to maintain normal glucose concentration. Lipolysis and hepatic ketogenesis are stimulated. Amino acids are released from skeletal muscle, and the plasma concentration of branched-chain amino acids may increase by as much as 100% with 1 day of fasting, but the urea concentration decreases. Ketoacids and fatty acids become the principal sources of energy for muscle. This results in an accumulation of organic acids that leads to a metabolic acidosis with reduction of blood pH, PCO_2, and plasma bicarbonate concentrations. In addition, the concentrations of ketone bodies (acetoacetic acid, β-hydroxybutyric acid, and acetone), fatty acids, and glycerol in serum rise considerably. When individuals are fasted for 60 hours compared with the usual 12 hours typically used in clinical practice to obtain baseline laboratory values, plasma insulin concentrations are reduced by half and those of C-peptide by more than one third. In contrast, concentrations of glucagon, epinephrine, and norepinephrine are doubled, and that of growth hormone is increased fivefold.[10]

The breakdown of fat leads to a transient increase in body water. Typically, however, an osmotic diuresis soon reduces the blood volume. Fasting for 6 days increases plasma concentrations of cholesterol and triglycerides but causes a decrease in HDL-cholesterol concentration.[82] After individuals lived for 4 weeks on a 400-kcal diet, the concentrations of urea and triglycerides and the activity of gamma-glutamyltransferase decreased by 20 to 50%, whereas concentrations of urate, derived from nucleoprotein, and creatinine and the activity of AST increased by 20 to 40%.[96] Reduced GFR and competition for excretion from lactate and ketoacids contribute to the increased urate concentration.

Hepatic blood supply may be reduced with starvation. BSP retention is increased, and serum bilirubin rises; unconjugated bilirubin more than doubles within 48 hours.[3] Slight increases in the serum activities of aspartate and alanine aminotransferase and of lactate dehydrogenase are observed within 2 weeks of the start of a fast, but return to baseline within 4 to 6 weeks.[34] Enzyme changes may be linked more to focal necrosis of the liver than to general circulatory impairment.

In spite of the catabolism of tissue induced by starvation, the serum protein concentration is little affected initially; ultimately, a reduction occurs. With the onset of starvation, aldosterone secretion increases, leading to increased urinary excretion and decreased plasma concentration of potassium. Magnesium, calcium, and phosphate are affected similarly, although the urinary excretion of phosphate gradually declines. Although the plasma urea concentration is not significantly affected by 10 days of starvation, the absolute urinary excretion of urea, total nitrogen, and creatinine is increased over the first few days of starvation.[15]

Plasma growth hormone concentration may rise by as much as 15 times at the start of a fast but may return to normal after 3 days. Reduced energy expenditure is associated with decreased concentrations of thyroid hormones. Free and total triiodothyronine is decreased by up to 50% within 3 days of the start of a fast. Free thyroxine concentration is also affected, but to a lesser extent; total thyroxine is little changed. Urinary free cortisol is decreased by fasting, and the plasma cortisol concentration (free and total) shows a slight increase, together with loss of the normal diurnal variation.

Early in refeeding, sodium retention occurs as a result of decreased sodium and chloride excretion in the urine.[77] The reduction in potassium excretion takes longer. These events are associated with an even greater secretion of aldosterone than occurs during the period of fasting. Abnormal concentrations of most constituents rapidly revert to normal with refeeding. Nitrogen balance soon becomes positive, especially if the nonprotein calories are derived mainly from carbohydrate.

Life-Style

Life-style factors that affect the concentrations of commonly measured analytes include smoking and alcohol ingestion.

Smoking

Smoking, through the action of nicotine, may affect several laboratory tests. The extent of the effect is related to the number of cigarettes smoked and to the amount of smoke inhaled.

Through stimulation of the adrenal medulla, nicotine increases the concentration of epinephrine in the plasma and the urinary excretion of catecholamines and their metabolites.[18] Glucose concentration may be increased by 10 mg/dL (0.56 mmol/L) within 10 minutes of smoking a cigarette. The increase may persist for 1 hour. Plasma lactate is increased by about 0.3 µmol/L and because the pyruvate concentration is reduced by about 20 µmol/L the lactate : pyruvate ratio increases significantly within 10 minutes. Plasma insulin concentration shows a delayed response to the increase in blood glucose, rising about 1 hour after a cigarette is smoked. Typically, the plasma glucose concentration is higher in smokers than in nonsmokers, and glucose tolerance is mildly impaired

TABLE 6-6 Reported Increased Concentrations in Serum in Smokers

Constituent	% Change
Albumin	3
Cholesterol	3-4
Glucose	10
LDL-cholesterol	2
Phospholipids	5
Triglycerides	9-20
Urea nitrogen	10
VLDL-cholesterol	10

From Siest G, Henny J, Schiele F, (eds). Interpretation des examens de laboratoire. Basel: Karger, 1981; Craig W, Palomaki GE, Haddow JE. Cigarette smoking and serum lipid and lipoprotein concentrations: an analysis of published data. Br Med J 1989;298:784-8.

in smokers. The plasma growth hormone concentration is particularly sensitive to smoking. It may increase 10-fold within 30 minutes after an individual has smoked a cigarette.[64]

Plasma cholesterol, triglyceride, and LDL-cholesterol concentrations are higher (by about 3%, 9%, and 2%, respectively) in smokers than in nonsmokers. In contrast, serum apolipoprotein A-I and HDL-cholesterol concentrations are lower in smokers than in nonsmokers, by 8.9% and 5.7%, respectively.[17] Free fatty acid concentration tends to be variable, but inhalation during smoking produces an immediate increase in free fatty acids of about 30%. Serum C-reactive protein concentrations in current smokers may be almost twice as high as in nonsmokers (2.53 mg/L vs. 1.35 mg/L).[98] Some of the effects of smoking on serum constituents are listed in Table 6-6.

Smoking also affects the adrenal cortex; plasma 11-hydroxycorticosteroids may be increased by 75% with heavy smoking. In addition, the plasma cortisol concentration may increase by as much as 40% within 5 minutes of the start of smoking, although the normal diurnal rhythmicity of cortisol is unaffected. Smokers excrete more 5-hydroxyindoleacetic acid than do nonsmokers.

The blood erythrocyte count is increased in smokers. The amount of carboxyhemoglobin may exceed 10% of the total hemoglobin in heavy smokers, and the increased number of cells compensates for impaired ability of the red cells to transport oxygen. The blood PO_2 of the habitual smoker is usually about 5 mm Hg (0.7 kPa) less than in the nonsmoker, whereas the PCO_2 is unaffected. The blood leukocyte concentration is increased by as much as 30% in smokers, but the leukocyte concentration of ascorbic acid is greatly reduced. The lymphocyte count is increased as a proportion of the total leukocyte count.

Fluid retention caused by nicotine causes a mild decrease in the plasma protein concentration but without demonstrable effect on the calcium concentration or on the activity of serum enzymes. The plasma urate concentration is less in smokers than in nonsmokers, probably as a result of lessened intake of food by smokers. Both the serum urea and creatinine concentrations tend to be less in smokers than in nonsmokers.

Nicotine is a potent stimulant of the secretion of gastric juice. Volume and acid secretion are increased within 1 hour of smoking several cigarettes. In contrast, the bicarbonate concentration and the volume of pancreatic juice are reduced.

Smoking affects the body's immune response. For example, serum immunoglobulin (Ig)A, IgG, and IgM concentrations are generally lower in smokers than in nonsmokers, whereas the IgE concentration is higher. Smokers, more often than nonsmokers, may show the presence of antinuclear antibodies. The concentration of carcinoembryonic antigen has been reported to be as much as 70% higher in habitual smokers than in nonsmokers. The serum vitamin B_{12} concentration is often notably reduced in smokers, and the decrease is in inverse proportion to the serum concentration of thiocyanate.

The sperm count of male smokers is often reduced compared with that in nonsmokers: the number of abnormal forms is greater, and sperm motility is less.

Although an individual may have smoked previously, some residual influences may continue to be observed. Thus the erythrocyte folate concentration, on average, may be as much as almost 10% less compared with the concentration in nonsmokers. The reduction in serum concentration may be even greater. Plasma fibrinogen concentrations are increased by smoking, but it takes longer than 5 years after individuals stop smoking before fibrinogen concentrations revert to those in life-long nonsmokers.[65] Although the hematocrit reverts to nonsmoker levels within 5 years of cessation, it may take as long as 20 years before the leukocyte count becomes the same as in nonsmokers.[98]

Alcohol Ingestion

A single moderate dose of alcohol has few effects on laboratory tests. Ingestion of enough alcohol to produce mild inebriation may increase the blood glucose concentration by 20 to 50%. The increase may be even higher in persons with diabetes. More commonly, inhibition of gluconeogenesis occurs and becomes apparent as hypoglycemia and ketonemia as ethanol is metabolized to acetaldehyde and to acetate. Hypoglycemia is most common in children, alcoholics, and the malnourished. Lactate and acetate accumulate and compete with urate for excretion in the kidneys, so that the serum urate is also increased. Marked hypertriglyceridemia after alcohol ingestion is due to a combination of increased triglyceride formation in the liver and impaired removal of chylomicrons and VLDL from the circulation. The effect is most noticeable when alcohol is ingested with a fatty meal and may persist for longer than 12 hours. When moderate amounts of alcohol are ingested for 1 week, the serum triglyceride concentration is increased by more than 20 mg/dL (0.23 mmol/L). The plasma concentration of aldosterone may be increased by as much as 150% and that of prolactin by 40 to 50% within 2 to 4 hours of alcohol ingestion. Acute alcohol

ingestion has been reported to increase the activity of several serum enzymes, including GGT, isocitrate dehydrogenase, and ornithine carbamoyltransferase.[33] A single acute ingestion of alcohol (1 g/kg body weight) has been shown to be enough to increase the serum activity of GGT by almost 10% 4 hours later, and by about 100% 24 hours later—a manifestation of hepatic microsomal enzyme induction.[71]

Prolonged moderate ingestion of alcohol may increase the HDL-cholesterol concentration, which is associated with reduced plasma concentration of cholesterol ester transfer protein (CETP). Phenols in wine with potent antioxidant activity are probably responsible for reducing the oxidation of LDL-cholesterol.

Intoxicating amounts of alcohol stimulate the release of cortisol, although the effect is related more to the intoxication than to the alcohol per se. Sympatheticomedullary activity is increased by acute alcohol ingestion but without detectable effect on the plasma epinephrine concentration and with only a mild effect on norepinephrine. With intoxication, plasma concentrations of catecholamines are substantially increased. Acute ingestion of alcohol leads to a sharp reduction in plasma testosterone in men, with an increase in the plasma luteinizing hormone concentration. Acute ethanol ingestion also leads to a mild diuresis by inhibiting antidiuretic hormone secretion.[80]

Chronic alcohol ingestion affects the activity of many serum enzymes. GGT activity has been extensively studied, and increased activity of the enzyme is used as a marker of persistent drinking. The increase may be as much as 1000-fold. Chronic alcoholism is associated with many characteristic biochemical abnormalities, including abnormal pituitary, adrenal cortical, and medullary function. AST and ALT activities may be increased by 250% and 60%, respectively, in habitual alcohol users. Alcohol ingestion also has considerable influence on serum HDL-cholesterol and total cholesterol concentration.[104] Measurement of carbohydrate-deficient transferrin is becoming increasingly popular as a means of identifying habitual alcohol ingestion. Desialylation of proteins occurs because of inhibition of enzymatic glycosylation in the liver by alcohol. Increased mean cell volume (MCV) has also been used as a marker of habitual alcohol use and may be related to folic acid deficiency or a direct toxic effect of alcohol on red blood cell precursors.

Drug Administration

It is rare for a patient to be hospitalized without receiving medication. For certain medical conditions, more than 10 drugs may be administered at one time. Even many healthy individuals take several drugs regularly, such as vitamins, oral contraceptives, or sleeping tablets. Individuals with chronic diseases often ingest drugs on a continuing basis. The effects of drugs on laboratory tests may be manifest through their therapeutic intent, but also through side effects and patient idiosyncratic responses to their administration. Effects on the composition of body fluids are likely to be more apparent when large doses of a drug are administered for a long time than when administration of a single dose occurs on an isolated occasion. Coadministration of certain drugs may influence the metabolism of one or the other to alter their plasma concentrations and pharmacologic effects.[70] Drugs may also have in vitro effects on laboratory tests, often through spectral interferences with colorimetric methods. A comprehensive listing of the effects of drugs on laboratory tests is available.[103] Only a few representative effects are discussed here.

Many drugs, when administered intramuscularly, cause sufficient muscle irritation to increase amounts of enzyme released into the serum. Activities of CK, aldolase, and the skeletal muscle component of lactate dehydrogenase are increased in the serum. The increased activities may persist for several days after a single injection, and consistently high values may be observed during a course of treatment. *Penicillin* derivatives given intramuscularly are particularly likely to increase the activity of these enzymes, although any drug given intramuscularly appears capable of increasing enzyme activity.

Opiates, such as morphine or meperidine, can cause spasm of the sphincter of Oddi. The spasm transmits pressure back to the liver, causing release of liver and pancreatic enzymes into the serum.

Oral contraceptives affect many different constituents measured in the clinical laboratory. Tests are affected by both progestin and estrogen components. The overall effect depends on the proportion and amount of the two components. Many of the effects are related to estrogen-induced synthesis of hormone-binding proteins in the liver. This leads to increased plasma concentrations of thyroid hormones, glucocorticoids, and sex steroids, although concentrations of the free hormones are unaffected. Contraceptives containing only progestin may be associated with reduced plasma HDL-concentrations and increased LDL-cholesterol concentrations. With modern low-dose contraceptives, effects on lipid metabolism may be clinically insignificant, although the ethinyl estradiol component may increase the concentration of some coagulation factors.[62]

Diuretic drugs often cause a mild reduction of the plasma potassium concentration; hyponatremia may be observed. Hypercalcemia may occur with hemoconcentration, but occasionally the free ionized and protein-bound fraction is increased. Thiazides may cause hypokalemia, which is often associated with hyperglycemia and reduced glucose tolerance, especially in those with diabetes. Thiazides may cause prerenal azotemia with hyperuricemia as a result of decreased renal blood flow and GFR as a result of reduced blood volume. Thiazides, similar to other diuretics, by causing hemoconcentration increase the plasma concentration of lipids. Many thiazides induce microsomal enzymes and thus affect lipoprotein concentrations with increased concentrations of LDL-cholesterol and total cholesterol and triglycerides, the extent being dependent on the type, dose, and frequency of use of the diuretic.

The broad variety of possible effects of a single drug on clinical laboratory tests is exemplified by phenytoin, which is used to treat some cases of epilepsy. With long-term

treatment, many patients have reduced serum calcium and phosphate concentrations and increased ALP activity. Phenytoin induces the synthesis of bilirubin-conjugating enzymes in the liver. Consequently, the serum total bilirubin concentration is reduced, serum GGT activity is increased, and urinary glucaric acid excretion is augmented. A few cases of increased serum aminotransferase activity have been reported, together with prolongation of the prothrombin time. Occasionally, cholestatic, cytotoxic, or mixed hepatic injury may occur. The overall incidence of slight alteration of liver function is about 25%.

Phenytoin may cause hyperglycemia and glycosuria by inhibiting insulin secretion.[62] It decreases the urinary excretion of some steroids by stimulating the conversion of cortisol to 6-β-hydroxycortisol; it also diminishes serum FSH and the sperm count in semen, and thereby reduces fertility. Phenytoin also lowers the serum thyroxine concentration, probably by competitive displacement of thyroxine from its protein-binding sites; free thyroxine also tends to be low. Serum triiodothyronine is low, probably as a result of stimulated metabolism in the liver, but the concentration of TSH is unaffected by the altered thyroxine metabolism. Phenytoin administration may lead to osteomalacia with reduced plasma calcium concentration and increased serum alkaline phosphatase activity. This is probably attributable to the combined effects on vitamin D metabolism and reduced absorption of calcium. Concurrent administration of drugs that are metabolized by the P450 cytochrome system may decrease the rate of metabolism of phenytoin and increase its plasma concentration. Phenytoin may reduce the concentration of other drugs.[70] Barbiturates also induce the hepatic cytochrome enzyme system and may affect the concentrations of coadministered drugs.

Some drugs interfere with analytical methods.[103] Many studies have been done at supraphysiologic concentrations so the reported effects can be discounted, but at physiologic concentrations, spironolactone may appear to increase the concentration of analytes measured by fluorometric methods. Fluorescein, used topically for the diagnosis of various ocular disorders, may be present at a sufficiently high concentration in the plasma to cause a positive interference with analytical methods using fluorescence, particularly fluorescent polarization immunoassays. Icodextrin and mannitol, used with hemodialysis, may cause positive interference with point-of-care glucose testing devices that use coupled glucose-6-phosphate dehydrogenase methods.

Radiographic contrast agents not only may cause renal damage in some patients, but some, such as gadodiamide, which is used to enhance magnetic resonance images and is a powerful chelating agent, may interfere with the measurement of calcium, iron, and magnesium when blood specimens are collected shortly after administration of the dye.[76]

Ingestion of ascorbic acid can raise its plasma concentration to 30 mmol/L. With ascorbic acid ingestion, the vitamin may be present in sufficiently high amounts in urine and feces to render negative positive dipstick tests for hemoglobin in urine and for occult blood in feces.

Herbal Preparations

Herbal preparations are now commonly ingested in by many Americans. Lack of regulatory standardization means that the composition of mixtures with the same name may vary markedly and the purity of individual components cannot be assured. Thus observed effects may vary considerably from one preparation to another. The major concern with ingestion of herbs is their effect on the metabolism of therapeutic drugs.[56] St. John's Wort *(Hypericum perforatum)* acts primarily by increasing the expression of the cytochrome P450-3A *(CYP3A)* gene in the liver, which accelerates the breakdown of many drugs, reducing their plasma concentrations and effectiveness. When coadministered with cyclosporine or tacrolimus, their circulating concentrations have been reported to be reduced by more than 50%. St. John Wort decreases the circulating concentration of digoxin, the norethindrone component of many oral contraceptives, the antifungal drug vericonazole, the antiviral agent indinavir, and a variety of other drugs. Several studies have recorded marked reductions in the half-life and plasma concentration of warfarin (Coumadin) when it is coadministered. Ginseng ingestion may also reduce the plasma prothrombin time and international normalized ratio (INR) in patients who are taking warfarin. Ginseng also reduces the plasma glucose concentration in persons with type 2 diabetes. Grapefruit juice may be ingested and contains inhibitors of intestinal cytochrome P450-3A4, thereby increasing the bioavailability of drugs such as methadone, amiodarone, and simvastatin.

Garlic ingestion may cause an approximate 10% reduction in serum cholesterol concentration; it also significantly reduces the plasma concentration of the HIV protease inhibitor saquinavir. Both ginkgo biloba and ginseng have been reported to lessen hyperglycemia in patients with type 2 diabetes mellitus. Aloe vera, senna, and cascara sagrada have a laxative effect through anthraquinone derivatives that they contain, but their prolonged use may lead to hypokalemia, provoking hyperaldosteronism. Abuse of other laxatives may cause the same problems.

Many herbal preparations affect liver function. Germander has been reported to cause liver cell necrosis, and bishop's weed infrequently causes cholestatic jaundice. Tonka beans can cause reversible liver damage. Comfrey has been associated with at least one death from liver failure. Liver damage may be caused by impure constituents of herbal mixtures, and physicians should always question patients who present with apparent liver damage about their use of herbal preparations.

Noncontrollable Variables

Examples of noncontrollable preanalytical variables include those related to biological, environmental, and long-term cyclical influences and those related to underlying medical conditions.

Biological Influences

Better agreement has been noted between the serum concentrations or activities of several constituents in monozygotic twins than in dizygotic twins.[104] Evidence underscores the

importance of genetics in determining the concentration of blood constituents. An influence of heredity on the plasma concentrations of cholesterol, glucose, urea nitrogen, urate, and bilirubin has been substantiated.

An association of blood type with concentration of certain constituents (uric acid, α_1-antitrypsin, cholesterol, and ALP) has been established. In women with blood group O, the blood hemoglobin concentration is generally less than in women with other blood groups. Histocompatibility antigens have an underlying genetic basis but can be markedly influenced by prior blood transfusions.

The age, sex, and race of the patient influence the results of individual laboratory tests.[73,84] They are discussed individually in various chapters of this book, and reference intervals for various analytes as a function of some of these biological influences are listed in Chapter 60.

Age

Age has a notable effect on reference intervals; typical changes in serum composition that occur with age are listed in Table 6-7, although the degree of change differs in various reports. In general, individuals are considered as belonging to one of four groups: the newborn, the older child to puberty, the sexually mature adult, and the elderly adult.

Newborn. The body fluids of the newborn infant reflect both the trauma of birth and changes related to the infant's adaptation to an independent existence. The composition of the blood is affected by the maturity of the infant at birth. The erythrocyte count and the hemoglobin concentration in the neonate at birth are much higher than those of the adult, but within a few days of birth erythrocytes degrade in response to the higher oxygen concentration than that to which the fetus was exposed in utero. In the mature infant, most of the hemoglobin is present in the adult form, hemoglobin A, whereas in the immature infant, much of the hemoglobin may be found in the fetal form, hemoglobin F. In both mature and immature infants, the arterial blood oxygen saturation is very low initially. A metabolic acidosis develops in newborns as the result of accumulation of organic acids, especially lactic acid. The acid-base status, however, reverts to normal within 24 hours.

Within a few minutes of an infant's birth, fluid passes from the blood vessels into the extravascular spaces. This fluid is similar to plasma, except that fluid lost from the intravascular space contains no protein. Consequently, the plasma protein concentration increases. The serum activities of several enzymes, including CK, AST, and LD, are high after birth, with CK activity being almost three times higher than cord blood activity 12 hours after birth, and with AST activity doubling and LD activity increasing by more than 50%.[57]

In infants, even in the absence of disease, the concentration of bilirubin rises after birth because of enhanced erythrocyte destruction. Its concentration peaks about the third to fifth day of life. Conjugation of bilirubin is relatively poor in the neonate as a result of immature liver function. The physiologic jaundice of the newborn rarely produces serum bilirubin values greater than 5 mg/dL (85 µmol/L). Distinguishing this naturally occurring phenomenon from other conditions that produce neonatal hyperbilirubinemia may be difficult, and the chronological course of hyperbilirubinemia is important.

The blood glucose concentration is low in newborns because of their small glycogen reserves, although some attribute the low glucose to adrenal immaturity. Blood lipid concentrations are low but reach 80% of adult values after 2 weeks. The plasma sodium concentration in an infant at birth is slightly higher than in an adult; at 12 hours, it decreases to below the adult value before rising to a value slightly greater than in the adult. The chloride concentration changes similarly, and these changes are largely related to fluid transfer in

TABLE 6-7 Influence of Age on Mean Concentration of Serum Constituents in Males

		Change Compared With <29-Year Value			
	Measured Value <30 y	30-39 y	40-49 y	50-59 y	60-69 y

Uric acid, mg/dL	5.9	0	0.2	−0.1	−0.2

From Leonard PJ. The effect of age and sex on biochemical parameters in blood of healthy human subjects. In: Siest G, ed. Reference values in human chemistry. Basel: Karger, 1973:134-40.

and out of the blood capillaries. The plasma potassium concentration may be as high as 7 mmol/L at birth, but it falls rapidly thereafter. Plasma calcium is also high initially but falls by as much as 1.4 mg/dL (0.35 mmol/L) during the first day of life.

The plasma urea nitrogen concentration decreases after birth as the infant synthesizes new protein, and the concentration does not begin to rise until tissue catabolism becomes prominent. The plasma amino acid concentration is low as a result of synthesis of tissue protein, although urinary excretion of amino acids may be high because of immaturity of the tubular reabsorptive mechanisms. The plasma urate concentration is high at birth, but the high clearance of urate soon reduces the plasma concentration to below the adult value.

The serum thyroxine concentration of the healthy newborn, similar to that in the pregnant woman, is considerably higher than in the nonpregnant adult. After birth, an infant secretes TSH, which causes a further increase in the serum thyroxine concentration. The physiologic hyperthyroidism gradually declines over the first year of life.

It should be noted that the maturity of a baby at birth may have a marked effect on the concentration of some of his or her blood constituents. For example, plasma aldosterone may be as much as five times higher in premature infants as in mature babies for up to 7 days after birth.

Childhood to Puberty. Many changes in the composition of body fluids take place between infancy and puberty. Most of these changes are gradual, and abrupt changes to adult concentrations rarely occur.

The plasma protein concentrations increase after infancy, and adult concentration values are attained by the age of 10 years. Serum IgG increases slightly out of proportion to the increase in concentration of α_2-globulin. The serum activity of most enzymes decreases during childhood to adult values by puberty or earlier, although the activity of ALT may continue to rise, at least in men, until middle age. Serum ALP activity is high in infancy but decreases during childhood and rises again with growth before puberty. Indeed, during puberty GGT values can be fourfold higher than in adults. The activity of the enzyme is better correlated with skeletal growth and sexual maturity than with chronological age; it is greatest at the time of maximum osteoblastic activity occurring with bone growth. Activity decreases rapidly after puberty, especially in girls. Total and LDL-cholesterol concentrations also increase during the rapid growth spurt.

The serum creatinine concentration increases steadily from infancy to puberty, parallel to the development of skeletal muscle; until puberty, little difference in the concentration is noted between sexes. The serum urate concentration decreases from its high at birth until age 7 to 10 years, at which time it begins to increase, especially in boys, until about age 16 years.

The Adult. Adult values are usually taken as the reference for comparison with those of the young and the elderly. Concentrations of most test constituents remain constant between puberty and menopause in women, and between puberty and middle age in men.

During the midlife years, serum total protein and albumin concentrations decrease slightly. A slight decrease in serum calcium concentration may be noted in both sexes. In men, serum phosphate decreases greatly after age 20 years; in women, phosphate also decreases until menopause, when a sharp increase takes place. Serum urate concentrations peak in men in their twenties and in women during middle age. Urea concentration increases in both sexes in middle age. Age does not affect the serum creatinine concentration in men but does increase the concentration in women. Serum total cholesterol and triglyceride concentrations increase in both men and women at a rate of 2 mg/dL (0.02 mmol/L) per year to a maximum between ages 50 and 60 years. The activity of most enzymes in serum is greater during adolescence than during adult life. This enhanced enzyme activity presumably reflects the greater physical activity of the adolescent.

The Elderly Adult. The plasma concentrations of many constituents are increased in women after menopause (Table 6-8).[101]

Renal concentrating ability is reduced in the elderly adult, so that creatinine clearance may decline by as much as 50% between the third and ninth decades. This decreased clearance is caused more by a decrease in urinary creatinine excretion as a result of decreased lean body mass than by altered renal function. The proximal tubular maximum capacity for glucose reabsorption declines steadily from about 360 mg/min/1.73 m^2 at age 20 to 29 years to 230 mg/min/1.73 m^2 at age 80 to 89 years.[28] The plasma urea concentration rises with age, as does the urinary excretion of protein. Serum median IgG and IgM concentrations are reduced in the elderly, although serum IgA concentrations in men are increased slightly in the elderly. Serum ALP begins to rise in women at menopause, so that in elderly women activity of this enzyme may actually be higher than in men. The concentration of glucose in plasma 1 hour after a loading dose rises by 8 mg/dL (0.44 mmol/L) per decade.

TABLE 6-8 Changes in Composition of Serum with Menopause

Constituent	% Increase

Uric acid	10

From Wilding P, Rollason JG, Robinson D. Pattern of change for various biochemical constituents detected in well population screening. Clin Chim Acta 1972;41:375-87.

Hormone concentrations are also affected by aging. However, changes in concentration are much less pronounced than an endocrine organ's response to stimuli. Triiodothyronine concentration decreases by up to 40% in persons older than 40 years of age. Although thyroxine secretion is reduced, the thyroxine concentration is not changed, because its degradation is also reduced, with a mean of almost 90 μg/d thyroxine iodine at about age 20 years and 45 μg/d at about age 45 years.[40] The plasma parathyroid hormone concentration does decrease with age. Cortisol secretion is reduced, although the serum concentration may not be affected. Reduced secretion leads to a reduction in the urinary excretion of 17-hydroxycorticosteroids. 17-Ketosteroid excretion in the elderly adult is about half that in the younger adult. The secretion and metabolic clearance of aldosterone are decreased, with a reduction of 50% in the plasma concentration. The aldosterone response to sodium restriction is diminished. Basal insulin concentration is unaffected by aging, but its response to glucose is reduced. In men, the secretion rate and concentration of testosterone are reduced after age 50 years. In women, the concentrations of FSH and LH are increased in the blood and urine, with concentrations increasing progressively with increasing age.[83]

Estrogen secretion in women begins to decrease before menopause and continues at a greater rate after menopause, whereas gonadotropins show a feedback-mediated reciprocal rise. Serum concentrations of estrogens decrease by 70% or more, and urinary excretion of estrogens is decreased comparably. The decreased estrogen secretion may be responsible for the increase in serum cholesterol that occurs up to age 60 years in women. Estrogen secretion in men also declines with age.[59]

Sex

Until puberty, few differences in laboratory data are noted between boys and girls. After puberty, characteristic changes in the concentrations of sex hormones, including prolactin in women, become apparent. After puberty, the serum activities of ALP, ALT, AST, CK, and aldolase are greater in men than in women (see Chapter 60). The higher activity of enzymes originating from skeletal muscle in men is related to their greater muscle mass. After menopause, the activity of ALP increases in women until it is higher than in men. Although total LD activity is similar in men and women, the activities of the LD-1 and LD-3 isoenzymes are higher, and LD-2 is less in young women than in men. These differences disappear after the menopause.

The blood hemoglobin concentration is lower in women; thus, serum bilirubin concentrations are also slightly lower. Increased turnover of erythrocytes in women leads to their having a higher reticulocyte count than men. Serum iron is low during a woman's fertile years, and her plasma ferritin may be only one third of the concentration in men. The reduced iron concentration in women is attributable to menstrual blood loss. In contrast, the serum copper concentration tends to be higher in women than in men. Total cholesterol and LDL-cholesterol concentrations are typically higher in men than in women, whereas the α-lipoprotein, apolipoprotein A-1, and HDL-cholesterol concentrations are less. Plasma concentrations of creatinine, urea, and urate are higher in men than in women, and urinary excretion of amino acids is greater.[103] Creatinine clearance is greater in men than in women. The effect of age on the difference in concentration of some serum constituents between men and women is illustrated in Table 6-9.

Race

Differentiation of the effects of race from those of socioeconomic conditions is often difficult. Nevertheless, the total serum protein concentration is known to be higher in blacks than in whites. This is largely attributable to a much higher γ-globulin, although concentrations of α_1- and β-globulins

TABLE 6-9 Influence of Sex on Composition of Serum at Different Ages*

*Male values are higher than female values, except where indicated by a minus sign.

From Leonard PJ. The effect of age and sex on biochemical parameters in blood of healthy human subjects. In: Siest G. Reference values in human chemistry. Basel: Karger, 1973:134-40.

usually are also increased. Serum albumin is typically less in blacks than in whites. In black men, serum IgG is often 40% higher and serum IgA may be as much as 20% higher than in white men.[11]

The activity of CK and LD is usually much higher in both black men and women than in whites. This effect presumably is related to the amount of skeletal muscle, which tends to be greater in blacks than in whites. Because of their greater skeletal development, black children usually have a higher serum ALP at puberty than do white children. γ-Glutamyltransferase activity may be as much as twice as high in black men and women than in whites.[63] Amylase activity also tends to be higher in blacks than in whites.[79]

Carbohydrate and lipid metabolism differs in blacks and whites.[6] Glucose tolerance is less in blacks, Polynesians, Native Americans, and Inuits than in comparable age- and sex-matched whites. This is substantiated by a plasma glucose 1 hour after glucose challenge that may be as much as 15 to 25 mg/dL (0.8 to 1.4 mmol/L) higher in blacks than in whites. After age 40 years, serum cholesterol and triglyceride concentrations are consistently higher in both white men and women than in blacks. The lipoprotein (Lp) (a) concentration in blacks may be twice as high as in whites. These may be dietary rather than racial factors, because the concentration of plasma lipids has been shown to be different for the same racial group in different parts of the world. Black Americans of both sexes have lower leukocyte counts than white Americans, largely caused by a lower number of granulocytes, but their monocyte count is also less. Some indigenous groups of the Pacific (e.g., Maoris of New Zealand) have notably higher mean serum urate concentrations than white populations.

Environmental Factors

Environmental factors that affect laboratory results include altitude, ambient temperature, and place of residence.

Altitude

In individuals living at a high *altitude,* blood hemoglobin and hematocrit are greatly increased because of reduced atmospheric PO_2.[23] Erythrocyte 2,3-diphosphoglycerate is also increased, and the oxygen dissociation curve is shifted to the right. Increased erythrocyte concentration leads to increased turnover of nucleoproteins and excretion of urate. The fasting, basal concentration of growth hormone is high in individuals living at a high altitude, but concentrations of renin and aldosterone are decreased in healthy individuals. Different studies have reported no change in plasma sodium and potassium concentrations by high altitude, although others have reported increased concentrations and osmolality with a change from a mean of 290 mosmol/kg (mmol/kg) at sea level to 302 mosmol/kg (mmol/kg) at 6300 m.[7] Serum concentrations of C-reactive protein, transferrin, and β_2-globulin are notably increased with transition to a high altitude. Urinary creatinine concentration and clearance are decreased at high altitudes. Plasma and urine concentrations of catecholamine are increased with increased altitude. The increase is on the order of twofold, largely caused by norepinephrine.[19] Complete adaptation to a high altitude takes many weeks, whereas adjustment to lower altitudes takes less time.

Ambient Temperature

Ambient temperature affects the composition of body fluids. Acute exposure to heat causes the plasma volume to expand by an influx of interstitial fluid into the intravascular space, and by reduction of glomerular filtration. The plasma protein concentration may decrease by up to 10%. Sweating may cause salt and water loss, but usually no changes are seen in the plasma sodium and chloride concentrations. Plasma potassium concentration may decrease by as much as 10% as potassium is taken up by the cells. If sweating is extensive, hemoconcentration rather than hemodilution may occur.

Place of Residence

The geographic location where individuals live may affect the composition of their body fluids. Thus a significant increase in serum concentrations of cholesterol, triglycerides, and magnesium has been observed in people living in areas with hard water. Trace element concentrations are also affected by locale, for example, in areas where much ore smelting occurs, serum concentrations of the trace elements involved may be increased. Carboxyhemoglobin concentrations are higher in areas where there is much heavier automobile traffic than in rural areas (as was true for blood lead in the 1970s in the United States). Individuals who are exposed to ultraviolet light from sunshine typically have higher concentrations of 25-hydroxyvitamin D than those with minimal exposure, but concentrations are also affected by dietary vitamin D, season, age, and gender.[93]

Long-Term Cyclical Changes

Long-term cyclical changes affect laboratory results. Seasonal influences and the menstrual cycle are examples of such changes.

Seasonal Influences

Seasonal influences on the composition of body fluids are small compared with those related to changes in posture or misuse of a tourniquet. Probable factors are dietary changes as different foods come into season, and altered physical activity as more or different forms of exercise become feasible. Evaluation of seasonal variations is difficult because they depend on the definition of a season and on the magnitude of temperature change from one season to another. Day-to-day variability in the composition of body fluids is greater in summer than in winter.

In summer in the Northern hemisphere, the blood volume increases in association with the higher temperature. In winter, the plasma protein increases by as much as 10%. Serum urate concentrations appear to be 5 to 7% higher in summer than in winter. Urea concentrations are affected similarly. Serum triglyceride concentrations are up to 10% higher in summer, whereas the serum cholesterol has been reported to be higher in winter than in summer and has been negatively correlated with ambient temperature. The increased

winter cholesterol concentration has been attributed to less physical exercise, greater food intake, and lesser amounts of sunshine. However, similar changes in animals suggest that humoral factors may also be involved. Activities of serum enzymes arising from skeletal muscle are higher in summer than in winter, presumably as a result of increased physical activity. The increase in serum lactate dehydrogenase activity may be as much as 20%.

Calcium metabolism is affected by an individual's exposure to sunlight. Dehydrocholecalciferol in the skin is converted by ultraviolet irradiation to cholecalciferol, which is further metabolized in the liver and kidney to 1,25-dihydroxycholecalciferol. The calcium concentration in serum is decreased in summer to a mean of 10.0 mg/dL (2.5 mmol/L) from a mean of 10.7 mg/dL (2.7 mmol/L) in winter.[50] Calcium elimination in urine may be increased by as much as 30% from winter to summer.[39] Seasonal changes appear to affect other endocrine systems as well. A lower plasma glucose concentration may be observed and glucose tolerance is improved during summer. Serum concentrations of thyroid hormones are generally unaffected, but the serum concentration of triiodothyronine is decreased by 20% in summer, and its urinary excretion is increased. The TSH response to thyroid-releasing hormone is increased during summer. Excretion of metabolites of adrenal hormones usually is greater in summer than in winter. This could be attributable to greater physical activity.

Exposure to sunshine for as little as one weekend during summer may cause enough photodegradation of bilirubin to reduce the serum concentration by 20%. Protracted exposure to sun during the summer leads to a consistently lower bilirubin concentration than during the winter. Some seasonal effects on the composition of body fluids are listed in Table 6-10.

Influence of Menstrual Cycle

The plasma concentrations of many female sex hormones and other hormones are affected by the menstrual cycle (see also Chapters 53 through 56).[104] Thus the plasma corticosterone concentration is as much as 50% higher in the luteal phase than in the follicular phase. The urinary excretion of 17-hydroxycorticosteroids reaches a peak at midcycle. Plasma androstenedione concentration and plasma aldosterone concentration increase from the follicular phase to the luteal phase of the menstrual cycle. On the preovulatory day, the aldosterone concentration may actually be twice that of the early part of the follicular phase. The change in renin activity is almost as great. These changes are usually more pronounced in women who retain fluid before menstruation. Urinary catecholamine excretion increases at midcycle and remains high throughout the luteal phase. These changes within the menstrual cycle make it essential to do repetitive measurements on women at the same time during the cycle.

Plasma cholesterol and triglyceride concentrations tend to be highest at midcycle, corresponding to the time of maximum estrogen secretion. The cyclical variation in cholesterol is not observed with anovulatory cycles. The plasma albumin concentration decreases significantly in the luteal phase of the menstrual cycle compared with the concentration at the time of menstruation (by about 0.6 g/L).[53] The plasma fibrinogen concentration decreases greatly at menstruation. The serum calcium correlates with changes in albumin. The plasma parathyroid hormone concentration is significantly higher during the follicular phase than the luteal phase.[36] Creatinine and urate concentrations are highest at the time of menstruation and are lowest toward the end of the intermenstrual period.

The plasma iron concentration may be very low with the onset of menstruation; the magnesium concentration is least at this point of the cycle. Plasma sodium and chloride concentrations increase up to the onset of menstruation but may fall by 2 mmol/L with the postmenstrual diuresis.

The plasma ascorbic acid concentration is low at the time of ovulation, whereas that of folate is unaffected by the menstrual cycle. Serum CK activity may be slightly reduced at the time of ovulation, but the activities of other enzymes appear to be unaffected by the menstrual cycle.

TABLE 6-10 Seasonal Effects on Composition of Serum

	Concentration		
Constituent	**Highest**	**Lowest**	**% Difference Between High and Low**
Alanine aminotransferase	Winter	Spring, summer	5.0
Albumin	Fall	Summer	1.2
Aspartate aminotransferase	Spring	Fall	11.7
Calcium	Fall	Winter	1.0
Creatinine	Summer	Winter	4.7
Glucose	Fall	Spring	1.5

Underlying Medical Conditions

Some general clinical conditions have an effect per se on the composition of body fluids. These conditions may exist in addition to the primary complaint that prompted a patient's admission to the hospital. For example, obesity, blindness, fever, shock and trauma, and transfusions and infusions all affect one or more laboratory results.

Obesity

Serum concentrations of cholesterol, triglycerides, and β-lipoproteins are positively correlated with obesity.[41] One study in twins has shown that for an average increase of 7.3% in body mass index, increases of 2.5% in total cholesterol concentration, 3% in LDL-cholesterol concentration, and 18.2% in triglyceride concentration were observed.[16] The increase in the concentration of cholesterol is attributable to LDL-cholesterol because HDL-cholesterol is typically reduced. The serum urate concentration is also correlated with body weight, especially in individuals weighing more than 80 kg.[69] Serum LD activity and glucose concentration are increased in both sexes with increasing body weight.[85] In men, serum AST, creatinine, total protein, and blood hemoglobin concentration increase with increasing body weight. In women, serum calcium increases with increasing body weight. In both sexes, serum phosphate decreases with increased body mass.

Cortisol production is increased in obese individuals. However, increased metabolism maintains the serum concentration unchanged so that urinary excretion of 17-hydroxycorticosteroids and 17-ketosteroids is increased. Because the growth hormone concentration is reduced in obese individuals, it responds poorly to normal stimulation challenges such as glucose, arginine, or acute glucocorticoid administration. Plasma insulin concentration is increased, but glucose tolerance is impaired in the obese (see Chapter 26). Plasma glucose concentrations are increased. Although the serum thyroxine concentration is unaffected by obesity, serum triiodothyronine correlates significantly with body weight and increases further with overeating. In obese men, the plasma testosterone concentration is reduced.

Plasma concentrations of acute-phase reactants tend to be higher in obese than in lean individuals. Fasting concentrations of pyruvate, lactate, citrate, and unesterified fatty acids are higher in obese individuals than in those of normal body weight. Serum iron and transferrin concentrations are low. Plasma adiponectin and ghrelin concentrations are significantly reduced in obese individuals compared with those in lean individuals, whereas concentrations of leptin, especially free leptin, soluble leptin receptor, resistin, C-peptide and estrogens tend to be increased (see Chapter 46).

Blindness

With blindness, normal stimulation of the hypothalamic-pituitary axis is reduced. Consequently, certain features of hypopituitarism and hypoadrenalism may be observed.[8] In some blind individuals, the normal diurnal variation of cortisol may persist; in others it does not. Generally, plasma cortisol concentrations are reduced in blind people. Urinary excretion of 17-ketosteroids and 17-hydroxycorticosteroids is reduced. Plasma sodium and chloride are often low in blind individuals, probably as a result of reduced aldosterone secretion. Plasma glucose may be reduced in blind people, and insulin sensitivity is often decreased. The excretion of urate is reduced. Renal function may be slightly impaired, as evidenced by slight increases in serum creatinine and urea nitrogen.

Negative nitrogen balance may occur in blind people, and the serum protein concentration may be reduced. The serum cholesterol is frequently increased, and the bilirubin concentration may exceed the upper limit of normal. The diurnal variation of serum iron is often lost.

Pregnancy

Many changes in the concentrations of analytes occur during pregnancy, and proper interpretation of test results is dependent on knowledge of the duration of pregnancy (see Chapter 57).

Substantial hormonal changes occur during pregnancy, including several not normally associated with reproduction. Many of these changes are related to the great increase in blood volume that occurs during pregnancy, from about 2600 mL early in pregnancy to 3500 mL at about 35 weeks. This hemodilution reduces the concentration of plasma proteins. The total protein concentration is most reduced by the decrease in albumin concentration. However, the concentration of some transport proteins, including ceruloplasmin and thyroxine-binding globulin, is increased as a consequence of estrogen-stimulated hepatic synthesis. This results in increased concentrations of copper, cortisol, and thyroxine, for example. The concentrations of cholesterol and triglycerides are notably increased in association with increased concentrations of apolipoprotein A and B. In contrast, pregnancy creates a relative deficiency of iron and ferritin.

Urine volume increases during pregnancy, so that it is typically 25% greater in the third trimester than in the nonpregnant woman. The glomerular filtration rate increases by 50% during the third trimester. This results in increased urinary excretion of hydroxyproline and increased creatinine clearance.

Pregnancy triggers many physiologic stress reactions and is associated with increased concentrations of acute-phase reactant proteins. The erythrocyte sedimentation rate increases fivefold during pregnancy, largely as a result of an increase in the fibrinogen concentration.

Stress

Physical and mental stress influences the concentrations of many plasma constituents. Anxiety stimulates increased secretion of aldosterone, angiotensin, catecholamines, cortisol, prolactin, renin, growth hormone, TSH, and antidiuretic hormone. Plasma concentrations of albumin are decreased by up to 5%, and cholesterol may be increased to a greater extent, but fibrinogen, glucose, insulin, and lactate concentrations

may increase to a much greater degree. The magnitude of the changes is dependent on the nature and duration of the stress.

Fever

Fever provokes many hormonal responses.[78] Hyperglycemia occurs early and stimulates the secretion of insulin, which improves glucose tolerance; however, insulin secretion does not necessarily reduce the blood glucose concentration because increased secretion of growth hormone and glucagon also occurs. Fever appears to reduce the secretion of thyroxine, as do acute illnesses even without fever. In response to increased corticotropin secretion, the plasma cortisol concentration is increased, and its normal diurnal variation may be abolished. Urinary excretion of free cortisol and other steroids is increased. As acute fever subsides, or if it lessens but still persists for a prolonged period, hormone responses diminish.

Glycogenolysis and a negative nitrogen balance occur with the onset of fever. These are prompted by the typically decreased food intake and wasting of skeletal muscle that may accompany fever. Although an increase in blood volume is usually noted with fever, the serum concentrations of creatinine and urate are usually increased. Aldosterone secretion is increased with retention of sodium and chloride. Secretion of antidiuretic hormone also contributes to retention of water by the kidneys. Increased synthesis of protein occurs in the liver, and the plasma concentrations of acute-phase reactants and glycoproteins are increased. Plasma concentrations of cytokines may be substantially increased.

Fever accelerates lipid metabolism. Serum concentrations of cholesterol, nonesterified fatty acids, and the other lipids may decrease initially, but within a few days the free fatty acid concentration may increase. Fever is often associated with a respiratory alkalosis caused by hyperventilation. This pH increase causes a reduction in the plasma phosphate concentration, with increased excretion of phosphate and other electrolytes.[4] Serum iron and zinc concentrations decline with accumulation of both elements in the liver. The copper concentration increases because of increased production of ceruloplasmin by the liver. Some representative changes in serum composition induced by fever are listed in Table 6-11.

TABLE 6-11 Effects of Fever on Composition of Serum

Constituent	Baseline Value	Concentration After Induction of Fever			
		18 h	48 h	72 h	96 h
Sodium, mmol/L	141	130	130	132	135
Chloride, mmol/L	99	91	89	92	94
Potassium, mmol/L	3.6	3.5	3.0	3.4	3.6
Calcium, mg/dL	9.7	8.4	8.5	9.0	9.1
Phosphate, mg/dL	3.3	2.3	3.2	3.2	3.7
Magnesium, mg/dL	1.85	1.62	1.73	1.78	1.70
Creatinine, mg/dL	1.10	1.03	1.04	1.00	1.09
Urea nitrogen, mg/dL	13.4	14.0	15.2	18.5	17.4
Uric acid, mg/dL	5.0	5.5	5.7	6.2	6.2

From Beisel WR, Goldman RF, Joy RJT. Metabolic balance studies during induced hyperthermia in man. J Appl Physiol 1968;24:1-10.

Shock and Trauma

Regardless of the cause of shock or trauma, certain characteristic biochemical changes may result.[20] For example, corticotropin secretion is stimulated to produce a three- to fivefold increase in the serum cortisol concentration. 17-Hydroxycorticosteroid excretion is greatly increased, although excretion of 17-ketosteroids and metabolites of adrenal androgens may be unaffected. Aldosterone secretion is stimulated. Plasma renin activity is increased, as are secretions of growth hormone, glucagon, and insulin. Anxiety and stress increase the excretion of catecholamines. The stress of surgery has been shown to reduce serum triiodothyronine by 50% in patients without thyroid disease.

The general metabolic response to shock includes the normal response to stress with mobilization of lipids, although the serum triglyceride concentration is not usually affected. Following acute myocardial infarction and other cardiac events, notable decreases tend to occur in LDL- and HDL-cholesterols and in apolipoprotein B and A-I concentrations, with an increase in the triglyceride concentration. Surgical procedures and intercurrent illnesses produce similar effects. Thus, it is not recommended to assess serum lipids for future cardiac risk during the acute phase of such events. Even minor illnesses, such as colds, can affect lipid concentrations. The concentrations of lipids revert to normal within 1 month of the event. Plasma glucose concentration is increased in response to stress, and glucose tolerance is reduced.

Immediately after an injury, fluid is lost to extravascular tissue, with a resulting decrease in plasma volume. If the decrease is enough to impair circulation, glomerular filtration is diminished. Diminished renal function leads to the accumulation of urea and other end products of protein metabolism in the circulation. In burned patients, serum total protein concentration falls by as much as 0.8 g/dL because of both loss to extravascular spaces and catabolism of protein. Serum α_1-, α_2-, and γ-globulin concentrations are increased, but not enough to compensate for the reduced albumin concentration. The plasma fibrinogen concentration responds dramatically to trauma and may double within 2 to 8 days after surgery. The concentration of C-reactive protein rises at the same time.

TABLE 6-12 Incidence of Increased Activity of Serum Enzymes and Isoenzymes After Surgery

Enzyme	%
CK	76
CK-2 isoenzyme	6
Aspartate aminotransferase	50
α-Hydroxybutyrate dehydrogenase	28
LD-1 isoenzyme	18
LD-1 > LD-2	10
LD-5 isoenzyme	20

From Krafft J, Fink R, Rosalki SB. Serum enzymes and isoenzymes after surgery. Ann Clin Biochem 1977;14:294-6.

The muscle damage associated with the trauma of surgery increases the serum activity of enzymes originating in skeletal muscle, and this increased activity may persist for several days. Typical alterations in activity of serum enzymes following surgery are illustrated in Table 6-12. Increased tissue catabolism requires increased oxygen consumption and also leads to the production of acid metabolites. Thus blood lactate may increase two- to threefold. With tissue anoxia and impairment of renal and respiratory function, a metabolic acidosis develops. With tissue destruction, urinary excretion of the major biochemical components of skeletal muscle is increased.

Transfusion and Infusions

The protein-rich fluid lost from the intravascular space after trauma is replaced with protein-poor fluid from the interstitial spaces. Subsequently, this is replaced by a fluid similar in composition to plasma. Transfusion of whole blood or plasma raises the plasma protein concentration; the extent of this increase depends on the amount of blood administered. Serum LD activity, primarily LD-1 and LD-2 isoenzymes, is increased by the breakdown of transfused erythrocytes. Transfusions to replace blood lost because of injury reduce sodium, chloride, and water retention precipitated by the injury. Serum iron and transferrin concentrations are reduced immediately after an injury, but extensive blood transfusions can lead to siderosis and an increased serum iron concentration. Serum potassium may increase with transfusion of stored blood.

Infusions of glucose solutions usually result in a reduction in both plasma phosphate and potassium concentrations because these compounds are taken up by erythrocytes. Infusions of solutions of albumin may increase plasma ALP activity if the albumin has been prepared from placenta. Because of the possible influence of infused components on the concentration of circulating constituents, it is inadvisable to collect blood for analysis less than 8 hours after infusion of a fat emulsion or 1 hour after infusion of carbohydrates, amino acids, and protein hydrolysates or electrolytes.

BIOLOGICAL VARIABILITY*

Data from studies of biological variation may be used to assess the importance of changes in test values within an individual from one occasion to another, determining the appropriateness of reference intervals and, in conjunction with data from analytical variation, establishing laboratory analytical goals.[29-31] Application by clinicians of information on biological variability could enhance their ability to precisely identify important changes in test results in their patients. Properly determined reference intervals are used most appropriately in outpatient practice to provide a rough guide as to whether an individual is healthy with respect to an individual analyte. Other concepts, outlined in the following sections, have greater application for hospital inpatient practice, where day-to-day changes in laboratory test values are important for monitoring a patient's response to treatment.

Overview

Categories of biological variation include (1) within an individual and (2) between individuals. The change in laboratory data around a hemostatic set point from one occasion to another within one person is called within-subject or intraindividual variation (Table 6-13). The difference between set points of different individuals is called interindividual variation. Average intraindividual variability varies greatly for different analytes, even within the same biochemical class of compounds (e.g., 6.1% for total cholesterol, 7.4% for HDL-cholesterol, 9.5% for LDL-cholesterol, 22.6% for triglycerides). Major factors influencing reported intraindividual and interindividual variability primarily include the number of individuals in a study, the standardization (or lack thereof) of patient preparation and specimen collection conditions, the number of measurements per individual, and the homogeneity of the studied population.

Often, biological variability influences clinical decisions. For example, Mogadam and associates showed that intraindividual variability in LDL concentrations led to 10% of subjects moving from high risk for cardiovascular events status to normal, or vice versa.[68] Where clinicians rely inappropriately on the upper and lower limits of the reference interval as finite decision points for treatment, this will result in some patients receiving unnecessary treatment, and others, who should be candidates for treatment, going untreated and potentially lost to follow-up because their test values suggested that they were healthy. Emphasis on target values for lipid concentrations, for example, in effect only establishes different decision points than those historically inferred from reference intervals.

Test values in a healthy population used to derive a conventional reference interval are subject to a variety of

*Note: The author has based much of the discussion of biological variability on C.G. Fraser's book, entitled *Biological Variation: From Principles to Practice* (Washington, DC: AACC Press, 2001:1-151). This source should be consulted for further details.

TABLE 6-13 Comparison of Intraindividual and Interindividual Variations and Indices of Individuality

Analyte	Intraindividual Variation, %	Interindividual Variation, %	Index of Individuality
Alanine aminotransferase	24.3	41.6	0.58
Albumin	3.1	4.2	0.74
Alkaline phosphatase	32.6	39.0	0.84
Bilirubin	25.6	30.5	0.85
Calcium	1.9	2.8	0.68
Chloride	1.2	1.5	0.80
Creatine kinase	22.8	40.0	0.57
Creatinine	4.3	12.9	0.33
Lactate dehydrogenase	6.6	14.7	0.45
Magnesium	3.6	6.4	0.56
Phosphate	8.5	9.4	0.90
Potassium	13.6	13.4	1.02
Protein	2.7	4.0	0.68
Sodium	0.7	1.0	0.70
Urea nitrogen	12.3	18.3	0.67
Uric acid	8.6	17.2	0.50

influences, including endogenous, exogenous, genetic or ethnic, and laboratory factors. The statistical approach used to calculate the interval also has considerable influence on the derived reference interval (see Chapter 5). No individual has test results that would span the entire reference interval. Indeed all results within a healthy individual typically encompass only a small part of most reference intervals. Stratification into more appropriate intervals for subpopulations is sometimes required. The most typical stratifications are based on sex and age. Stinton and colleagues[91] have advocated that separate reference intervals are justified when the difference between the means of potentially different populations (e.g., men and women, blacks and whites) is greater than 25% of the 95%-reference interval of the entire population. An alternative approach to defining whether stratification is appropriate is that of Harris and Boyd, which involves calculation of the standard deviations of all results from each of the potentially different populations; if the standard deviation of 1 is more than 1.5 times another, stratification is justified.[44]

Inherent in any reported laboratory test results on patients are influences of (1) biological variation, (2) analytical variation or error, (3) preanalytical and postanalytical sources of variation, and (4) possible pathophysiologic alterations. When repeated measurements are made over time in one individual, even under standardized conditions, considerable variability in the test results is noted. Variability within the individual is attributable to both analytical and intraindividual factors, but intraindividual (within-subject) variability is typically less than the variability seen among a group of individuals. This means that when analytical variability is constant, a statistically significant change in the test results in one individual might occur, yet all results still could lie within the reference interval established by the results obtained from many individuals. Many studies have demonstrated remarkable constancy over the years in terms of intraindividual variability. For those analytes that are influenced by the endocrine system, variation tends to be even less than for those that have no hormonal regulation, especially those that are affected by dietary factors. In general, biological variability is only slightly affected by age or by diseases that do not directly cause abnormal concentrations of a specific analyte.[32]

Calculating Total Variation

To determine what confidence should be placed in a test result, it is useful to evaluate the variability of test values. Factors influencing a test value are preanalytical, analytical, and within an individual. Because sources of variation (squares of the standard deviations) are additive, the total variation (SD_T^2) for any one laboratory result is

$$SD_T^2 = SD_P^2 + SD_A^2 + SD_I^2$$

where

SD_P = Standard deviation of preanalytical variation
SD_A = Standard deviation of analytical variation
SD_I = Standard deviation of within-individual biological variation

It is possible to substitute the coefficient of variation for the standard deviation in the above equation. If the conditions of patient preparation, sample collection, and sample handling are standardized, preanalytical variation is minimized and total variation is then determined by the combined influence of analytical and intraindividual variations, thus:

$$CV_T = (CV_A^2 + CV_I^2)^{1/2}$$

Reference Change Values

To determine whether the difference between consecutive results for a single analyte in a patient might have clinical significance, Harris and Yasaka developed the concept of *reference change values*.[45] An *RCV,* also known as *critical difference,* is the value that must be exceeded before a change in consecutive test results is statistically significant at a predetermined probability. The concept introduces a scientific approach to an area where clinicians have largely relied on their intuition and experience. Historically, clinicians' impressions of clinically significant differences between results have varied markedly. Fraser and coworkers showed that systematically calculated critical differences for many analytes tend to be less than physicians' assumptions of clinically significant differences.[32]

RCV takes into account both analytical and within-individual variations discussed earlier. It is calculated using the following equation:

$$RCV = 2^{1/2} \times Z \times (CV_A^2 + CV_I^2)^{1/2}$$

where Z = Z-score (also called *standard normal deviate*). Z-scores vary with the desired probability for the change. The Z-scores for different probabilities may be derived from statistical tables. For the widely used probability of 95% for clinical laboratory decisions, the Z-score is 1.96. When inserted in the formula above, the formula becomes

$$RCV = 2.77 \times (CV_A^2 + CV_I^2)^{1/2}$$

In practice, a Z-score of 1.96 for a 95% probability is used to identify a significant RCV. A Z-score of 2.58 is used for a 99% probability to ensure an even more significant RCV. The higher the probability used in the calculation, the greater is the likelihood that all identified changes will be true changes. Yet greater certainty with the higher probability may make some physicians believe that the change is obvious, and that such large RCVs may mask trends in test values. The CV_A used for the calculation should be appropriate for the range of test values, as low analytical variability enhances the likelihood that calculated changes will be statistically significant. The probability of change is then largely influenced by intra-individual variation, CV_I. To enhance the utility of the RCV, intraindividual variability should also be minimized, with standardization of patient preparation and specimen collection and processing practices. Standardization is more readily achieved in hospital practice, where uniform timing of collections by trained phlebotomists is often possible, than in outpatient practices.

The change in values between successive measurements in a hospitalized patient is generally greater than the change in values reported in the literature as derived from studies of healthy individuals, because of the change in the patient's medical condition and its response to treatment. RCVs are not constant, and a significant change is likely to be smaller over the short term than over a longer time span. Thus application of RCVs derived from healthy individuals over a short time will identify an inappropriately large number of apparently significant changes in hospitalized patients. CV_I varies between individuals, so that calculations using the mean CV_I flag a disproportionately large number of significant changes. Table 6-14 shows the effects of using different probabilities of significant changes.

Index of Individuality

Although it would be preferable if the range of values in an individual when healthy could be used as the reference for the same individual when he or she is ill, this is largely impractical. The less specific reference interval derived from many individuals must be used as a guide to determine whether a specific result is abnormal. The *index of individuality* (II) allows a comparison of total within-subject (intraindividual) variation to between-subject (interindividual) variation. It is calculated as the ratio of total intraindividual variation to interindividual biological variation as follows:

$$II = \frac{[CV_A^2 + CV_I^2]^{1/2}}{CV_G}$$

where CV_A is the analytical variability, CV_I the intraindividual variability, and CV_G the interindividual variability. In clinical

TABLE 6-14 Significance of Changes in Serial Results: Probability That Changes Between Successive Values Are Significant, %

		Probability

practice for most analytes, CV_A is small in comparison with CV_I or CV_G and can be ignored; the formula for II is thus simplified to

$$II = \frac{CV_I}{CV_G}$$

A low index of individuality indicates that an analyte has marked individuality, and a high index indicates that an analyte has little individuality. Harris has demonstrated that it is appropriate to use the reference interval for an analyte to make clinical decisions only when $CV_I : CV_G$ is greater than 1.4.[43] When II is less than 0.6, conventional population reference values are of little value and may be misleading. Little variation in test values for an analyte within one person (i.e., a high index of individuality) means that an individual could have considerable changes in laboratory data that might have clinical significance for him or her, yet all these values could fall within the population reference interval. In theory, such analytes are of little use for the diagnosis of disease unless the changes are markedly abnormal.

Index of Heterogeneity

The *index of heterogeneity* (IH) provides a means of determining whether individuals within a population have similar within-individual variation for a given analyte. It is defined as the ratio of CV of $(SD^2_A + SD^2_I)^{1/2}$ to $[2/(n-1)]^{1/2}$, where A and I are the analytical and within-subject variations, and n is the number of specimens per subject. The higher the index of heterogeneity, the greater is the intraindividual variation.

Reliability Coefficient

The *reliability coefficient* (R) is the ratio of between-subject variation to total variation. This is another measure of individuality. It is calculated as the between-individual variance divided by the total variation.

$$R = \frac{CV_G^2}{CV_A^2 + CV_I^2 + CV_G^2}$$

The reliability coefficient will always be between 0 and 1. If it approaches 1, this means that there is very little variation in results over time within one individual, indicating that great confidence can be placed in a single result, and that repeated measurements are unnecessary.

Quality Specifications for Total Error Allowable

Analytical variations may increase the number of results in a healthy population outside a previously established reference interval. A positive analytical bias increases the number of high values, and a negative bias decreases the number to below the lower reference limit. It is possible to link the maximum tolerable analytical bias to biological variability.[32] The relationship below is derived on the assumption that the maximum acceptable bias is less than one quarter of the sum of intraindividual and interindividual variations within a population.

$$\text{Analytical bias} = < 0.25 \times (CV_I^2 + CV_G^2)^{1/2}$$

By substituting different factors in the above formula, different targeted analytical biases can be identified. If less analytical bias is deemed to be appropriate (e.g., one fifth of the total biological variation instead of one quarter), 0.20 would be substituted for 0.25. It has been suggested that analytical precision should be less than one half of the mean intraindividual variation ($CV_A = 0.50\ CV_I$). Total error is derived from the sum of imprecision and bias. From the formula above,

$$\text{Total allowable analytical error} < 1.65 \times 0.50 \times CV_I + 0.25 \times (CV_I^2 + CV_G^2)^{1/2}$$

The factor 1.65 is derived from 90% of the distribution of results excluding the highest and lowest 5% of values. Again, substituting different values for 0.50 and 0.25 above allows different goals to be established.

Other formulas have been used to determine quality specifications for bias. Generally, analytical bias should be less than one quarter of interindividual biological variation:

$$B_A < 0.250 \times (CV_I^2 + CV_G^2)^{1/2}$$

But optimum performance is also defined by substituting 0.125 for 0.250 in the above formula, and minimum performance is defined by substituting 0.375 for 0.250. When the factor 0.125 is used, 1.8% of values are outside one reference limit and 3.3% outside the other. When 0.375 is used, 1.0% of values are outside one reference limit and 5.7% are outside the other.[31] Fraser has stated that the lower number should be used when desirable performance standards are easily attained, and 0.375 should be used when performance goals are not readily attainable with current procedures.[32] Most of the literature has reported total error in terms of the sum of bias plus 1.65 times the precision (TE_A = Bias + 1.65 SD or CV of interindividual variation).

Biological variation has been included in a goal to determine analytical interference.[35] This goal specifies that

$$\text{Interference (\%)} < CV_I - (1.96 CV_A + SE)$$

where SE represents the percentage systematic error (inaccuracy).

Assessment of Mode of Reporting Test Results

The RCV concept is used to determine the most appropriate mode to report several analytes where several possibilities exist. For example, the amount of an analyte in urine could be reported in terms of concentration, absolute amount per unit of time, or amount relative to that of creatinine. The mode with the smallest relative change value is the most informative. Data on analytical and intraindividual variation together with RCV can pinpoint the most appropriate type of specimen for certain analyses. Howey and associates[47] studied random, early morning, and 24-hour urine specimens to determine the most appropriate means to monitor microalbuminuria. The first morning specimen became the preferred specimen because of its smallest within-individual variation,

smallest heterogeneity in intraindividual variances, and smallest RCV between consecutive measurements.

Data on biological variability are used to assist in selection of the most appropriate test in a given situation. For example, creatinine clearance and urine creatinine have less intraindividual variation than serum creatinine, so that creatinine clearance is a better choice than serum creatinine for initial assessment of renal function in an individual, but the lower RCV for serum creatinine makes this test better for monitoring individuals. However, the need for urine collection reduces the practicality of using clearance in the initial assessment of renal function. Findings of studies to determine whether the GFR calculated from the serum creatinine concentration might enhance the utility of the serum measurement still have to be thoroughly assessed.

CHAPTER 7

Specimen Collection and Processing

Doris M. Haverstick, Ph.D., D.A.B.C.C., and Amy R. Groszbach, M.E.D., M.L.T., M.B.(A.S.C.P.)[C.M.] *

Proper collection, identification, processing, storage, and transport of common sample types associated with requests for diagnostic testing are critical to the provision of quality test results. Many errors can occur during these steps. Minimizing these errors through careful adherence to the concepts discussed here and to individual institutional policies will result in more reliable information for use by healthcare professionals in providing quality patient care.

This chapter provides a review and discussion of common types of specimens and samples used for diagnostic testing.

TYPES OF SPECIMENS

Types of biological specimens that are analyzed in clinical laboratories include (1) whole blood; (2) serum; (3) plasma; (4) urine; (5) feces; (6) saliva; (7) spinal, synovial, amniotic, pleural, pericardial, and ascitic fluids; and (8) various types of solid tissue. The Clinical and Laboratory Standards Institute (CLSI) has published several procedures for collecting many of these specimens under standardized conditions.[4-16]

Blood

Blood for analysis may be obtained from veins, arteries, or capillaries. Venous blood is usually the specimen of choice, and venipuncture is the method for obtaining this specimen. Arterial puncture is used mainly for blood gas analyses. In young children and for many point-of-care tests, skin puncture is frequently used to obtain what is mostly capillary blood. The process of collecting blood is known as phlebotomy (from *phleb,* which means vein, and *tome,* to cut or incise) and should always be performed by a trained phlebotomist.

Venipuncture

In the clinical laboratory, venipuncture is defined as all of the steps involved in obtaining an appropriate and identified blood specimen from a patient's vein.[12]

Preliminary Steps

Before any specimen is collected, the phlebotomist must confirm the identity of the patient.[4] Two or three items of identification should be used (e.g., [1] name, [2] medical record number, [3] date of birth, [4] address if the patient is an outpatient). In specialized situations, such as paternity testing or other tests of medico-legal importance, establishment of a chain of custody for the specimen may require additional patient identification, such as a photograph, provided as part of the identification process or taken to confirm the identity of the patient.

Identification must be an active process. Where possible, the patient should state his or her name, and the phlebotomist should verify information on the patient's wrist band if the patient is hospitalized. If the patient is an outpatient, the phlebotomist should ask the patient to state his or her name and should confirm the information on the test requisition form with identifying information provided by the patient. In the case of pediatric patients, the parent or guardian should be present and should provide active identification of the child. In many institutions at this point in the process, the patient should be asked about latex allergies. If latex allergy is present and if latex gloves or a latex tourniquet may be used, the phlebotomist should secure an alternative tourniquet and put on gloves that are latex free. Finally, for some tests for genetic diseases, the performing laboratory may request a signed consent form from the patient; this should be completed at this time if it was not provided by the requesting physician.

Before collection of a specimen, a phlebotomist should dress in personal protective equipment (PPE), such as an impervious gown and gloves applied immediately before approaching the patient, to adhere to standard precautions against potentially infectious material and to limit the spread of infectious disease from one patient to another.[14] If the phlebotomist is to collect a specimen from a patient in isolation in a hospital, the phlebotomist must put on a clean gown and

**The authors gratefully acknowledge the original contributions by Drs. Donald S. Young and Edward W. Bermes, on which portions of this chapter are based.*

gloves and a face mask and goggles before entering the patient's room. The face mask limits the spread of potentially infectious droplets, and the goggles limit the possible entry of infectious material into the eye. The extent of the precautions required will vary with the nature of the patient's illness and the institution's policies and bloodborne pathogen plan, to which a phlebotomist must adhere. If airborne precautions are indicated, the phlebotomist must wear an N95 TB respirator.

If appropriate, the phlebotomist should verify that the patient is fasting, what medications are being taken or have been discontinued as required, and so forth. The patient should be comfortable, seated or supine (if sitting is not feasible), and should have been in this position for as long as possible before the specimen is drawn. For an outpatient, it is generally recommended that patients be seated before completion of the identification process to maximize their relaxation. At no time should venipuncture be performed on a standing patient. Either of the patient's arms should be extended in a straight line from the shoulder to the wrist. An arm with an inserted intravenous line should be avoided, as should an arm with extensive scarring or a hematoma at the intended collection site. If a woman has had a mastectomy, arm veins on that side of the body should not be used, because the surgery may have caused lymphostasis (blockade of normal lymph node drainage), affecting the blood composition. If a woman has had double mastectomies, blood should be drawn from the arm of the side on which the first procedure was performed. If the surgery was done within 6 months on both sides, a vein on the back of the hand or at the ankle should be used.

Before performing a venipuncture, the phlebotomist should estimate the volume of blood to be drawn and should select the appropriate number and types of tubes for the blood, plasma, or serum tests requested. In many settings, this will be facilitated by computer-generated collection recommendations and should be designed to collect the minimum amount necessary for testing. The sections below on "Order of Draw for Multiple Collections" and "Collection With Evacuated Blood Tubes" discuss in greater detail the recommended order of draw for multiple specimens and types of tubes. In addition to tubes, an appropriate needle must be selected. The most commonly used sizes are 19 to 22 gauge. (The larger the gauge number, the smaller the bore.) The usual choice for an adult with normal veins is 20 gauge; if veins tend to collapse easily, a size 21 is preferred. For volumes of blood from 30 to 50 mL, an 18-gauge needle may be required to ensure adequate blood flow. A needle is typically 1.5 inches (3.7 cm) long, but 1-inch (2.5-cm) needles, usually attached to a winged or butterfly collection set, are also used. All needles must be sterile, sharp, and without barbs. If blood is drawn for trace element measurements, the needle should be stainless steel and should be known to be free from contamination.

Location

The median cubital vein in the antecubital fossa, or crook of the elbow, is the preferred site for collecting venous blood in adults because the vein is large and is close to the surface of the skin.[12,20] Veins on the back of the hand or at the ankle may be used, although these are less desirable and should be avoided in people with diabetes and other individuals with poor circulation. In the inpatient setting, it is appropriate to collect blood through a cannula that is inserted for long-term fluid infusions at the time of first insertion to avoid the need for a second stick. For severely ill individuals and those requiring many intravenous injections, an alternative blood-drawing site should be chosen. Selection of a vein for puncture is facilitated by palpation. An arm containing a cannula or an arteriovenous fistula should not be used without consent of the patient's physician. If fluid is being infused intravenously into a limb, the fluid should be shut off for 3 minutes before a specimen is obtained and a suitable note made in the patient's chart and on the result report form. Specimens obtained from the opposite arm are preferred.[12] Specimens below the infusion site in the same arm may be satisfactory for most tests, except for those analytes that are contained in the infused solution (e.g., glucose, electrolytes).

Preparation of Site

The area around the intended puncture site should be cleaned with whatever cleanser is approved for use by the institution. Three commonly used materials are a prepackaged alcohol swab, a gauze pad saturated with 70% isopropanol, and a benzalkonium chloride solution (Zephiran chloride solution, 1:750). Cleaning of the puncture site should be done with a circular motion and from the site outward. The skin should be allowed to dry in the air. No alcohol or cleanser should remain on the skin because traces may cause hemolysis and invalidate test results. Once the skin has been cleaned, it should not be touched until after the venipuncture has been completed.

Timing

The time at which a specimen is obtained is important for those blood constituents that undergo marked diurnal variation (e.g., corticosteroids, iron) and for those used to monitor drug therapy (see Chapter 34). For most current molecular diagnostic tests, the time of day is unlikely to contribute to altered or invalid test results. Furthermore, timing is important in relation to specimens for alcohol or drug measurements in association with medico-legal considerations.

Venous Occlusion

After the skin is cleaned, a blood pressure cuff or a tourniquet is applied 4 to 6 inches (10 to 15 cm) above the intended puncture site (distance for adults). This obstructs the return of venous blood to the heart and distends the veins (venous occlusion). When a blood pressure cuff is used as a tourniquet, it is usually inflated to approximately 60 mm Hg (8.0 kPa). Tourniquets typically are made from precut soft rubber strips or from Velcro. It is rarely necessary to leave a tourniquet in place for longer than 1 minute, but even within this short time the composition of blood changes. Although the changes that occur in 1 minute are slight, marked changes

TABLE 7-1 Changes in Composition of Serum When Venous Occlusion Is Prolonged from 1 Minute to 3 Minutes*†

Increase	%	Decrease	%
Total protein	4.9	Potassium	6.2
Iron	6.7		
Total lipids	4.7		
Cholesterol	5.1		
Aspartate aminotransferase	9.3		
Bilirubin	8.4		

*To estimate the probable effect of a factor on results, relate percent increase or decrease shown (or intimated) in table to analytical variation (±% CV) routinely found for analytes.
†Mean values obtained from 11 healthy individuals.
From Statland BE, Bokelund H, Winkel P. Factors contributing to intraindividual variation of serum constituents: effects of posture and tourniquet application on variation of serum constituents in healthy subjects. Clin Chem 1974;20:1513-9.

have been observed after 3 minutes for many chemistry analytes (Table 7-1). No known changes affect molecular diagnostics.

The composition of blood drawn first—that is, the blood closest to the tourniquet—is most representative of the composition of circulating blood. The first-drawn specimen should therefore be used for those analytes such as calcium that are pertinent to critical medical decisions.[25] Blood drawn later shows a greater effect from venous stasis. Thus the first tube may show a 5% increase in protein, whereas the third tube may show a 10% change.[22] The concentration of protein-bound constituents is also influenced by stasis. Prolonged stasis may increase the concentration of protein or protein-bound constituents by as much as 15%. A uniform procedure for the order of draw for tests should therefore be established (see later). If it is possible to collect only a small volume of blood, the priority of which tests to perform should be established.

The increase in activity of creatine kinase and aspartate aminotransferase in serum seen after venipuncture may be caused by hemoconcentration, by slight trauma to tissue as the needle pierces the skin, and by stasis of blood in the tissue.

Pumping of the fist before venipuncture should be avoided because it causes an increase in plasma potassium, phosphate, and lactate concentrations. Lowering of blood pH by accumulation of lactate causes the plasma ionized calcium concentration to increase.[24] The ionized calcium concentration reverts to normal 10 minutes after the tourniquet is released.

Stress associated with blood collection can have effects on patients at any age. As a consequence, plasma concentrations of cortisol and growth hormone may increase. Stress occurs particularly in young children who are frightened, struggling, and held in physical restraint. Collection under these conditions may cause adrenal stimulation leading to an increased plasma glucose concentration or may create increases in the serum activities of enzymes that originate in skeletal muscle.

TABLE 7-2 Recommended Order of Draw for Multiple Specimen Collection

Stopper Color	Contents	Inversions
Yellow	Sterile media for blood culture	8
Royal blue	No additive	0
Clear	Nonadditive; discard tube if no royal blue used	0
Light blue	Sodium citrate	3-4
Gold/red	Serum separator tube	5
Red/red, orange/yellow, royal blue	Serum tube, with or without clot activator, with or without gel	5
Green	Heparin tube with or without gel	8
Tan (glass)	Sodium heparin	8
Royal blue	Sodium heparin, sodium EDTA	8
Lavender, pearl white, pink/pink, tan (plastic)	EDTA tubes, with or without gel	8
Gray	Glycolytic inhibitor	8
Yellow (glass)	ACD for molecular studies and cell culture	8

Wayne, Pa: Clinical and Laboratory Standards Institute, 2010; Kiechle FL, ed. So you're going to collect a blood specimen: an introduction to phlebotomy, 11th edition. Northfield, Ill: College of American Pathologists, 2005.

Order of Draw for Multiple Blood Specimens

In a few patients, backflow from blood tubes into veins occurs owing to a decrease in venous pressure. The dangerous consequences of this occurrence may be prevented if only sterile tubes are used for collection of blood. Backflow is minimized if the arm is held downward and blood is kept from contact with the stopper during the collection procedure. To minimize problems if backflow should occur, and to optimize the quality of specimens—especially to prevent cross-contamination with anticoagulants—blood should be collected into tubes in the order outlined in Table 7-2. This table also provides the recommended number of inversions for each tube type because it is critical that complete mixing of any additive with the blood collected be accomplished as quickly as possible.

Collection With Evacuated Blood Tubes

Evacuated blood tubes are usually considered to be less expensive and are more convenient and easier to use than syringes, and thus are the collection device of choice in many

institutions. Evacuated blood tubes may be made of soda-lime or borosilicate glass or plastic (polyethylene terephthalate). Because of the decreased likelihood of breakage and subsequent exposure to infectious materials, many laboratories have converted from glass tubes to plastic tubes. Several types of evacuated tubes may be used for venipuncture collection.[12] They vary by the type of additive added and the volume of the tube. The different types of additives are identified by the color of the stopper used (Table 7-3). Serum or plasma separator tubes are available that contain an inert, thixotropic, polymer gel material with a specific gravity of approximately 1.04. Aspiration of blood into the tube and subsequent centrifugation displace the gel, which settles like a disk between cells and supernatant when the tube is centrifuged. A minimum relative centrifugal force (RCF) of 1100 ×g is required for gel release and barrier formation in most tubes. Release of intracellular components into the supernatant is prevented by the barrier for several hours or, in some cases, for a few days. These separator tubes may be used as primary containers from which serum or plasma can be directly aspirated by a number of analytical instruments. Additional tubes, not listed, are sold for special applications,

TABLE 7-3 Coding of Stopper Color to Indicate Additive in Evacuated Blood Tube

Tube Type	Additive	Stopper Color	Alternative
Gel separation tubes	Polymer gel/silica activator	Red/black	Gold
	Polymer gel/silica activator/lithium heparin	Green/gray	Light gray
Serum tubes (nonadditive)	Silicone-coated interior	Red	Red
	Uncoated interior	Red	Pink
Serum tubes (with additives)	Thrombin (dry additive)	Gray/yellow	Orange
	Particulate clot activator	Yellow/red	Red
	Thrombin (dry additive)	Light blue	Light blue
Whole blood/plasma tubes	K_2 EDTA (dry additive)	Lavender	Lavender
	K_3 EDTA (liquid additive)	Lavender	Lavender
	Na_2 EDTA (dry additive)	Lavender	Lavender
	Citrate, trisodium (coagulation)	Light blue	Light blue
	Citrate, trisodium (erythrocyte sedimentation rate)	Black	Black
	Sodium fluoride (antiglycolic agent)	Gray	Light/gray
	Heparin, lithium (dry or liquid additive)	Green	Green
	Potassium oxalate/sodium fluoride	Light gray	Light gray
	Lithium heparin/iodoacetate	Light gray	Light gray
Specialty Tubes (Microbiology)			
Blood culture	Sodium polyanethol sulfonate (SPS)	Light yellow	Light yellow
Specialty Tubes (Chemistry)			
Lead	Heparin, potassium (liquid additive)	Tan	Tan
	Heparin, sodium (dry additive)	Royal blue	Royal blue
Trace elements	Silicone-coated interior (serum tube)	Royal blue	Royal blue
Stat chemistry	Thrombin	Gray/yellow	Orange
Specialty Tubes (Molecular Diagnostics)			
Plasma	K_2 EDTA (dry additive)/polymer gel/silica activator	Opalescent white	Opalescent white
	ACD solution A (Na_3 citrate, 22.0 g/L; citric acid, 8.0 g/L; dextrose, 24.5 g/L)	Bright yellow	Bright yellow
	ACD solution B (Na_3 citrate, 13.2 g/L; citric acid, 4.8 g/L; dextrose, 14.7 g/L)	Bright yellow	Bright yellow
Mononuclear cell preparation tube	Sodium citrate with density gradient polymer fluid	Blue/black	Blue/black
	Sodium heparin with density gradient polymer fluid	Green/red	Green/red

such as RNA isolation. These less common tubes must be validated by each laboratory before use if not approved by the manufacturer for the specific analysis to be conducted.

Stoppers may contain zinc, invalidating the use of evacuated blood tubes for zinc measurement, and TBEP [tris(2-butoxyethyl) phosphate], a constituent of rubber, which may interfere with the measurement of certain drugs. With time, the vacuum in evacuated tubes is lost and their effective draw diminishes. The silicone coating also decays with age. Therefore the stock of these tubes should be rotated and careful attention paid to the expiration date. Blood collected into a tube containing one additive should never be transferred into other tubes, because the first additive may interfere with tests for which a different additive is specified. Additionally, transfer of the additive from one tube to another should be minimized (or adverse effects reduced) through strict adherence to recommendations for order of tube use (see Table 7-2).

A typical system for collecting blood in evacuated tubes is shown in Figure 7-1.[17] This is an example of a commonly used single-use device that incorporates a cover that is designed to be placed over the needle when collection of the blood is complete, thereby reducing the risk of puncture of the phlebotomist by the now contaminated needle. A needle or winged (butterfly) set is screwed into the collection tube holder, and the tube is then gently inserted into this holder. The tube should be gently tapped to dislodge any additive from the stopper before the needle is inserted into a vein; this prevents aspiration of the additive into the patient's vein.

After the skin has been cleaned, the needle should be guided gently into the patient's vein (Figure 7-2); once the needle is in place, the tube should be pressed forward into the holder to puncture the stopper and release the vacuum. **As soon as** blood begins to flow into the tube, the tourniquet should be released without moving the needle (see earlier discussion on venous occlusion). The tube is filled until the vacuum is exhausted. It is critically important that the evacuated tube be filled completely. Many additives are provided in the tube based on a "full" collection; deviation or short draws can be a source of preanalytical error because they can significantly affect test results.[7] Once the tube is filled completely, it should be withdrawn from the holder, mixed gently by inversion, and replaced by another tube, if this is necessary. Other tubes may be filled using the same technique with the holder in place. When several tubes are required from a single blood collection, a shut-off valve—consisting of rubber tubing that slides over the needle opening—is used to prevent spillage of blood during exchange of tubes.

Blood Collection With Syringe

Syringes are customarily used for patients with difficult veins. If a syringe is used, the needle is placed firmly over the nozzle of the syringe, and the cover of the needle is removed. If the syringe has an eccentric nozzle, the needle should be arranged with the nozzle downward but the bevel of the needle upward. The syringe and the needle should be aligned with the vein to be entered and the needle pushed into the vein at an angle to the skin of approximately 15 degrees. When the initial resistance of the vein wall is overcome as it is pierced, forward pressure on the syringe is eased, and the blood is withdrawn by gently pulling back the plunger of the syringe. Should a second syringe be necessary, a gauze pad may be placed under the hub of the needle to absorb the spill; the first syringe is then quickly disconnected, and the second put in place to continue the blood draw. Using the same needle or a new needle, the cap of the evacuated tube should be punctured and the evacuated tube allowed to fill passively. Uncapping the evacuated tube is not recommended. Vigorous withdrawal of blood into a syringe during collection or forceful transfer from the syringe to the receiving vessel may cause hemolysis of blood. Hemolysis is usually less when blood is drawn through a small-bore needle than when a larger-bore needle is used.

Completion of Collection

When blood collection is complete and the needle withdrawn, the patient should be instructed to hold a dry gauze pad over the puncture site, with the arm raised to lessen the likelihood of leakage of blood. The pad may then be held in place by a bandage or by a nonadhesive strap (which avoids pulling hairs on the arm when it is removed); these are removed after 15 minutes. With a collection device, such as that shown in Figure 7-1, the needle is covered, and the needle and the tube holder are immediately discarded into a sharps container. In the event that a winged (butterfly) set is used, the wings are pushed forward to cover the needle, or with newer available equipment, a button is pressed, releasing a spring that retracts the needle. If a syringe was used, the needle and syringe (still attached) should be discarded in a hazardous waste receptacle.

All tubes should then be labeled per institutional policy. Most institutions have a written procedure prohibiting the advance labeling of tubes because this is seen as providing the potential for mislabeling, one of the most common sources of preanalytical error. Some institutions recommend showing the labeled tube to the patient to further confirm correct identification. Gloves should be discarded in a hazardous waste receptacle if visibly contaminated, or in noncontaminated trash if not visibly contaminated. Before applying new gloves and proceeding to the next patient, and depending on institutional policy, clinicians should use an alcohol-based cleanser or soap and water to wash their hands.

Venipuncture in Children

The techniques for venipuncture in children and adults are similar. However, children are likely to make unexpected movements, and assistance in holding them still is often desirable. A syringe or an evacuated blood tube system may be used to collect specimens. A syringe should be the tuberculin type or should have a 3-mL capacity, except when a large volume of blood is required for analysis. A 21- to 23-gauge needle or a 20- to 23-gauge butterfly needle with attached tubing is appropriate to collect specimens. In general, in the pediatric population, alternative collection through skin puncture is often used.

Skin Puncture

Skin puncture is an open collection technique in which the skin is punctured by a lancet and a small volume of blood is collected into a microdevice. Skin puncture blood is more like arterial blood than venous blood. In practice, it is used in situations in which (1) sample volume is limited (e.g., pediatric applications), (2) repeated venipunctures have resulted in severe vein damage, or (3) patients have been burned or bandaged and veins therefore are unavailable for venipuncture. This technique is also commonly used when the sample is to be applied directly to a testing device in a point-of-care testing situation or to filter paper. It is most often performed on (1) the tip of a finger, (2) an earlobe, and (3) the heel or big toe of infants. For example, in an infant younger than 1 year, the lateral or medial plantar surface of the foot should be used for skin puncture; suitable areas are illustrated in Figure 7-3.[1] In older children, the plantar surface of the big toe may also be used, although blood collection from anywhere on the foot should be avoided on ambulatory patients. The complete procedure for collecting blood from infants using skin puncture is described in a CLSI document.[10]

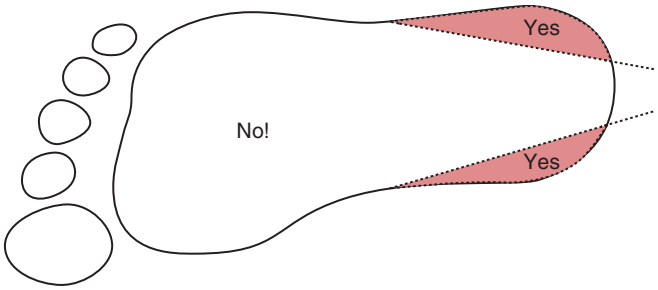

Figure 7-3 Acceptable sites for skin puncture to collect blood from an infant's foot. *(Modified from Blumenfeld TA, Turi GK, Blanc WA. Recommended site and depth of newborn heel punctures based on anatomical measurements and histopathology. Lancet 1979;1:230-3. Reprinted with permission from Elsevier.)*

To collect a blood specimen by skin puncture, the phlebotomist first thoroughly cleans the skin with a gauze pad saturated with an approved cleaning solution, as outlined earlier for venipuncture. If an alcohol swab is used, the alcohol must be allowed to evaporate from the skin so that hemolysis does not occur. When the skin is dry, it is quickly punctured by a sharp stab with a lancet. The depth of the incision should be less than 2.5 mm to prevent contact with bone. To minimize the possibility of infection, a different site should be selected for each puncture. The finger should be held in such a way that gravity assists collection of blood at the fingertip and the lancet held to make the incision as close to perpendicular to the fingernail as possible.[20] Massage of the finger to stimulate blood flow should be avoided because it causes the outflow of debris and tissue fluid, which does not have the same composition as plasma. To improve circulation of the blood, the finger (or the heel in the case of heelsticks) may be warmed by application of a warm, wet washcloth or a specialized device, such as a heel warmer, for 3 minutes before the lancet is applied. The first drop of blood is wiped off, and subsequent drops are transferred to the appropriate collection tube by gentle contact. Filling should be done rapidly to prevent clotting, and introduction of air bubbles should be prevented.

As the name suggests, blood is collected into capillary blood tubes by capillary action. A variety of collection tubes are commercially available (Figure 7-4). Containers are commercially available that contain different anticoagulants, such as sodium and ammonium heparin, and some are available in brown glass for collection of light-sensitive analytes, such as bilirubin (see later section on anticoagulants). As with evacuated blood tubes, to prevent the possibility of breakage and the spread of infection, capillary devices frequently are

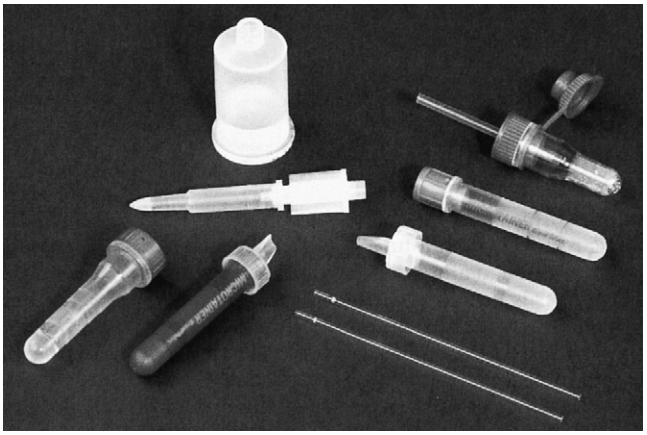

Figure 7-4 Microcollection tubes. *(From Flynn JC. Procedures in phlebotomy, 3rd edition. St Louis: Saunders, 2005.)*

plastic or coated with plastic. A disadvantage of some of the collection devices shown in Figure 7-4 is that blood tends to pool in the mouth of the tube and must be flicked down the tube, creating a risk of hemolysis. Drop-by-drop collection should be avoided because it increases hemolysis. The correct order of filling of these devices is the same as for evacuated blood tubes (see Table 7-2).

For collection of blood specimens on filter paper for molecular genetic testing and neonatal screening,[5] the skin is cleaned and punctured as described previously. The first drop of blood should be wiped away. Then the filter paper is gently touched against a large drop of blood that is allowed to soak into the paper to fill the marked circle. Only a single application per circle should be made to prevent nonuniform analyte concentration.[5] The paper is examined to verify that there has been complete penetration of the paper. The procedure is repeated to fill all the circles. Avoid milking or squeezing the finger or foot because this procedure contributes tissue fluids. The filter papers should be air-dried (generally for 2 to 3 hours to prevent mold or bacterial overgrowth) before storage in a properly labeled paper envelope. Blood should never be transferred onto filter paper after it has been collected in capillary tubes because partial clotting may have occurred, compromising the quality of the specimen. However, blood collected into an evacuated tube containing an anticoagulant may be applied directly to the filter paper. This is a convenient way to store a sample for possible future molecular testing (with patient consent). These blood spots are handled in the same manner as neonatal screening specimens, with air drying and storage in a dry protected environment.

Arterial Puncture

Arterial puncture requires considerable skill and is usually performed only by physicians or specially trained technicians or nurses. Preferred sites of arterial puncture are, in order, the (1) radial artery at the wrist, (2) brachial artery in the elbow, and (3) femoral artery in the groin. Because leakage of blood from the femoral artery tends to be greater, especially in the elderly, sites in the arm are used most often. The proper technique for arterial puncture is described in a CLSI document.[11]

In the neonate, an indwelling catheter in the umbilical artery is best to obtain specimens for blood gas analysis. In the older child or adult in whom it is impossible to perform an arterial puncture, a capillary puncture may be performed to obtain arterialized capillary blood. Such a specimen yields acceptable values for pH and PCO_2, but not always for PO_2. In the older child or adult, the preferred puncture site is the earlobe; in the young child or infant, it is the heel. Capillary blood specimens are particularly inappropriate when blood circulation is poor and thus should be avoided when a patient has reduced cardiac output, hypotension, or vasoconstriction. For each capillary puncture, the skin should be warmed first with a hot, moist towel to improve the circulation. The puncture itself should be performed as described previously; a free flow of blood is essential. Heparinized capillary tubes containing a small metal bar are used to collect the blood. Tubes should be sealed quickly and the contents mixed well by using a magnet to move the metal bar up and down in the tube so that a uniform specimen is available for analysis.

Anticoagulants and Preservatives for Blood

Serum is defined as the watery portion of blood that remains after coagulation has occurred and is the specimen of choice for many analyses, including viral screening and protein electrophoresis. Samples are collected into tubes with no additive or with a clotactivator and must be allowed to complete the coagulation process before further processing. Plasma is defined as the noncellular component of anticoagulated whole blood and is increasingly being used for routine chemistry testing to decrease turnaround time. Sometimes considerable differences may be observed between the concentrations of analytes in serum and in plasma, as shown in Table 7-4. For molecular diagnostics, anticoagulated whole blood or plasma is more likely to be the specimen of choice. A number of anticoagulants are available, including heparin, ethylenediaminetetraacetic acid (EDTA), sodium fluoride, citrate, acid citrate dextrose (ACD, oxalate, and iodoacetate.

Heparin

Heparin is the most widely used anticoagulant for chemistry and hematology testing. It is a mucoitin polysulfuric acid and is available as sodium, potassium, lithium, and ammonium salts, all of which adequately prevent coagulation. This anticoagulant accelerates the action of antithrombin III, which neutralizes thrombin and thus prevents the formation of fibrin from fibrinogen. Most blood tubes are prepared with approximately 0.2 mg heparin for each milliliter of blood (1000 units/mL) to be collected. The heparin is usually present as a dry powder that is hygroscopic and dissolves rapidly. Heparin has the disadvantages of high cost and a more temporary action of anticoagulation than is attained by chemical means, such as those discussed below. It produces a blue background in blood smears that are stained with Wright's stain. In addition, heparin is said to inhibit acid phosphatase

TABLE 7-4 Differences in Composition Between Plasma and Serum*

Plasma Value > Serum Value, %		No Difference Between Serum and Plasma Values	Plasma Value < Serum Value, %	
Calcium	0.9	Bilirubin	Albumin	1.3
Chloride	0.2	Cholesterol	Alkaline phosphatase	1.6
Lactate dehydrogenase	2.7	Creatinine	Aspartate aminotransferase	0.9
Total protein	4.0		Bicarbonate	1.8
			Creatine kinase	2.1
			Glucose	5.1
			Phosphorus	7.0
			Potassium	8.4
			Sodium	0.1

activity and to interfere with the binding of calcium to EDTA in analytical methods for calcium involving complexing with EDTA.

It should be noted that heparin is unacceptable for most tests performed using the polymerase chain reaction (PCR) because of inhibition of the polymerase enzyme by this large molecule. In some special circumstances, a heparin tube can be shared with a molecular diagnostic laboratory if a non-heparinized tube is not available. DNA can be extracted from heparinized samples, but amplification may be reduced.

Ethylenediaminetetraacetic Acid

EDTA is a chelating agent of divalent cations such as Ca^{2+} and Mg^{2+} that is particularly useful for (1) hematologic examinations, (2) isolation of genomic DNA, and (3) qualitative and quantitative virus determinations by molecular techniques, because it preserves the cellular components of blood. It is used as the disodium, dipotassium, or tripotassium salt, the last two being more soluble. It is effective at a final concentration of 1 to 2 g/L of blood. Higher concentrations hypertonically shrink the red cells. EDTA prevents coagulation by binding calcium, which is essential for the clotting mechanism. Newer advances using EDTA include the inclusion of a gel barrier to separate plasma from cells (white tubes; see Table 7-3). In blue/black tubes (see Table 7-3), incorporation of a density gradient allows recovery of nucleated cells after centrifugation, thus increasing the yield of DNA.

EDTA, probably by chelation of metallic cofactors, inhibits alkaline phosphatase, creatine kinase, and leucine aminopeptidase activities. Because it chelates calcium and iron, EDTA is unsuitable for specimens for calcium and iron analyses using photometric or titrimetric techniques. As an anticoagulant, it has little effect on other clinical tests, although the concentration of cholesterol has been reported to be decreased by 3 to 5%.

Sodium Fluoride

Sodium fluoride is a weak anticoagulant that is often added as a preservative for blood glucose. As a preservative, together with another anticoagulant such as potassium oxalate, it is effective at a concentration of approximately 2 g/L blood. It exerts its preservative action by inhibiting the enzyme systems involved in glycolysis, although such inhibition is not immediate[23] and a certain amount of degradation occurs during the first hour after collection. Most specimens are then preserved at 25 °C for 24 hours or at 4 °C for 48 hours. Without an antiglycolytic agent, the blood glucose concentration decreases approximately 100 mg/L (0.56 mmol/L) per hour at 25 °C. The rate of decrease is faster in newborns because of the increased metabolic activity of their erythrocytes and in leukemic patients because of the high metabolic activity of the white cells. Sodium fluoride is poorly soluble, and blood must be well mixed before effective antiglycolysis occurs.

If sodium fluoride is used alone for anticoagulation, three to five times greater concentrations than the usual 2 g/L are required. This high concentration and inhibition of the glycolytic cycle are likely to cause fluid shifts and a change in the concentration of some analytes. Fluoride is also a potent inhibitor of many serum enzymes and in high concentrations also affects urease, used to measure urea nitrogen in many analytical systems.

Citrate

Sodium citrate solution, at a concentration of 34 to 38 g/L in a ratio of 1 part to 9 parts of blood, is widely used for coagulation studies,[7] although the correct ratio of blood to anticoagulant is critical because the effect is easily reversible by addition of standard amounts of Ca^{2+} that are based on a proper collection volume. Because citrate chelates calcium, it is unsuitable as an anticoagulant for specimens for measurement of this element. It also inhibits aminotransferases and alkaline

phosphatase but stimulates acid phosphatase when phenylphosphate is used as a substrate. Because citrate complexes molybdate, it decreases the color yield in phosphate measurements that involve molybdate ions and produces low results.

Acid Citrate Dextrose

As indicated previously, the collection of specimens into EDTA is often used for isolation of genomic DNA from the patient. However, additional and complementary diagnostic tests, such as cytogenetic testing, may be requested at the same time. For this reason, samples for molecular diagnostics are often collected into ACD anticoagulant, so as to preserve both the form and the function of the cellular components. There are two ACD tube designations: ACD A and ACD B. These differ only by the concentrations of the additives (see Table 7-3). Both enhance the vitality and recovery of white blood cells for several days after collection of the specimen, thus they are suitable for both molecular diagnostic testing and cytogenetic testing.

Solution A is used for an 8.5-mL blood draw (10 mL total volume), whereas solution B is used for a 3-mL or a 6-mL blood draw (7 mL total volume). The specific test(s) requested will determine the size of tube necessary for specimen collection.

Oxalates

Sodium, potassium, ammonium, and lithium oxalates inhibit blood coagulation by forming rather insoluble complexes with calcium ions. Potassium oxalate ($K_2C_2O_4 \bullet H_2O$), at a concentration of approximately 1 to 2 g/L of blood, is the most widely used oxalate. At concentrations of greater than 3 g oxalate per liter, hemolysis is likely to occur.

Combined ammonium and/or potassium oxalate does not cause shrinkage of erythrocytes. However, other oxalates have been known to cause shrinkage by drawing water into the plasma. Reduction in hematocrit may be as much as 10%, causing a reduction in the concentration of plasma constituents of 5%. As fluid is lost from the cells, an exchange of electrolytes and other constituents across the cell membrane occurs. Oxalate inhibits several enzymes, including acid and alkaline phosphatases, amylase, and lactate dehydrogenase, and may cause precipitation of calcium as the oxalate salt.

Iodoacetate

Sodium iodoacetate at a concentration of 2 g/L is an effective antiglycolytic agent (with the caveats mentioned earlier) and a substitute for sodium fluoride. Because it has no effect on urease, it is often used when glucose and urea tests are performed on a single specimen. It inhibits creatine kinase but appears to have no notable effects on other clinical tests.

Influence of Site of Collection on Blood Composition

Blood obtained from different sites differs in composition. Skin puncture blood is more like arterial blood than venous blood. Thus there are no clinically significant differences between freely flowing capillary blood and arterial blood in pH, PCO_2, PO_2, and oxygen saturation. The PCO_2 of venous blood is up to 6 to 7 mm Hg (0.8 to 0.9 kPa) higher. Venous blood glucose is as much as 70 mg/L (0.39 mmol/L) less than capillary blood glucose.

TABLE 7-5 Difference in Composition of Capillary and Venous Serum*

Capillary Value Greater Than Venous Value, %		No Difference Between Capillary and Venous Values	Capillary Value Less Than Venous Value, %	
Glucose	1.4	Phosphate	Bilirubin	5.0
Potassium	0.9	Urea	Calcium	4.6
			Chloride	1.8
			Sodium	2.3
			Total protein	3.3

From Kupke IR, Kather B, Zeugner S. On the composition of capillary and venous blood serum. Clin Chim Acta 1981;112:177-85.

Blood obtained by skin puncture is contaminated to some extent with interstitial and intracellular fluids. The major differences between venous serum and capillary serum are illustrated in Table 7-5.

Collection of Blood from Intravenous or Arterial Lines

When blood is collected from a central venous catheter or arterial line, it is necessary to ensure that the composition of the specimen is not affected by the fluid that is infused into the patient. The fluid is shut off using the stopcock on the catheter, and 10 mL of blood is aspirated through the stopcock and discarded before the specimen for analysis is withdrawn. This is particularly important for molecular diagnostics because the stopcock is often heavily saturated with heparin to prevent clotting. Blood properly collected from a central venous catheter and compared with blood drawn from a peripheral vein at the same time shows notable differences in composition. A comparison of arterial blood with central and peripheral venous blood is illustrated in Table 7-6.

In theory, blood may be collected from the veins of an arm below an intravenous line without interference from the fluid being infused, because retrograde blood flow does not occur in the veins, and the fluid that is infused must first circulate through the heart and return to the tissue before it reaches the sampling site. However, as stated previously, collection from the arm without the intravenous line is recommended.[12]

Hemolysis

Hemolysis is defined as the disruption of the red cell membrane resulting in the release of hemoglobin and may be the consequence of intravascular events (in vivo hemolysis) or

TABLE 7-6 Influence of Collection Site on Composition of Plasma*

	Arterial	Central Venous	Peripheral Venous
Alanine aminotransferase, U/L	62	61	81
Albumin, g/L	36	37	39

From Rommel K, Koch C-D, Spilker D. Einfluss der Materialgewinnung auf klinisch-chemische Parameter in Blut, Plasma und Serum bei Patienten mit stabilem und zentralisiertem Kreislauf. J Clin Chem Clin Biochem 1978;16:373-80.
*To estimate the probable effect of a factor on results, relate percent increase or decrease shown (or intimated) in table to analytical variation (±% CV) routinely found for analytes.

may occur subsequent to or during blood collection (in vitro hemolysis). Serum and plasma show visual evidence of hemolysis when the hemoglobin concentration exceeds 50 mg/dL. Once the level exceeds 150 to 200 mg/dL, the plasma will appear bright red to most observers. Slight hemolysis has little effect on most test values. However, a notable effect may be observed on those constituents that are present at a higher concentration in erythrocytes than in plasma. Thus plasma activities or concentrations of aldolase, total acid phosphatase, lactate dehydrogenase, isocitrate dehydrogenase, potassium, magnesium, and phosphate are particularly increased by hemolysis. The inorganic phosphate in serum increases rapidly as the organic esters in the cells are hydrolyzed. An additional band caused by hemoglobin may be observed on serum protein electrophoresis. Most manufacturers now provide data on the effects of hemolysis on the analytical performance of individual tests, and this should be evaluated in the selection of individual methods.

Although the amount of free hemoglobin could be measured and a calculation made to correct test values affected by hemoglobin, this practice is undesirable because factors other than hemoglobin could contribute to the altered test values, and it would be impossible to assess their impact. Hemolysis may affect many unblanked or inadequately blanked analytical methods.[27]

In molecular diagnostic testing, hemoglobin may interfere with the amplification reaction, particularly when reverse transcriptase (RT)-PCR is the first step in the analysis of RNA. In some situations, the isolation of nucleic acid is sufficiently selective that free hemoglobin from the ruptured cells is removed and will not cause a problem. However, with hemolyzed blood, alternative or additional extraction methods are usually needed to ensure that RNA is fully and accurately transcribed, and that the greatest amplification of DNA is achieved.

Urine

The type of urine specimen to be collected is dictated by the tests to be performed. Untimed or random specimens are suitable for only a few chemical tests; usually, urine specimens must be collected over a predetermined interval of time, such as 4, 12, or 24 hours. A clean, early morning, fasting specimen is usually the most concentrated specimen, and thus is preferred for microscopic examinations and for the detection of abnormal amounts of constituents, such as proteins, or of unusual compounds, such as chorionic gonadotropin. The clean timed specimen is one obtained at specific times of the day or during certain phases of the act of micturition. Bacterial examination of the first 10 mL of urine voided is most appropriate to detect urethritis, whereas the midstream specimen is best for investigating bladder disorders. The double-voided specimen is the urine excreted during a timed period after complete emptying of the bladder; it is used, for example, to assess glucose excretion during a glucose tolerance test. Its collection must be timed in relation to the ingestion of glucose. Similarly, in some metabolic disorders, urine must be collected during or immediately after symptoms of the disease appear (see Chapter 33 on porphyrins).

When they are to be tested for their alcohol and drugs of abuse content, urine specimens are collected under rigorous conditions requiring chain of custody documentation. (See Chapter 35 for details of such a collection.)

Catheter specimens are used for microbiological examination in critically ill patients or in those with urinary tract obstruction, but should not normally be obtained just for examination of chemical constituents. The suprapubic tap

specimen is a useful alternative, because the tap is unlikely to cause infection. After appropriate cleaning of the skin over the full bladder, a 22-gauge spinal needle is passed through a small wheal made by a local anesthetic. The bladder is penetrated and the urine withdrawn into the syringe.

Even though tests in the clinical laboratory are not usually affected by lack of sterile collection procedures, the patient's genitalia should be cleaned before each voiding to minimize the transfer of surface bacteria to the urine. Cleansing is essential if the true concentration of white cells is to be obtained.

Currently, urine is an uncommon specimen type in the molecular diagnostic laboratory for genomic testing, although some laboratories use urine samples for bladder cancer screening and monitoring of therapy for bladder cancer. However, urine is frequently used for molecular testing for infectious agents, such as *Chlamydia,* a common sexually transmitted organism, or BK virus, associated with potential rejection and/or failure of transplanted kidneys. Because most requests involve a specific organism, an untimed or random urine specimen collected into a sterile container with no preservative is usually acceptable.

Timed Urine Specimens

The collection period for timed specimens should be long enough to minimize the influence of short-term biological variations. When specimens are to be collected over a specified period of time, the patient's close adherence to instructions is important. The bladder must be emptied at the time the collection is to begin and this urine discarded. Thereafter all urine must be collected until the end of the scheduled time. If a patient has a bowel movement during the collection period, precautions should be taken to prevent fecal contamination of the urine. If a collection has to be made over several hours, urine should be passed into a separate container at each voiding and then emptied into a larger container for the complete specimen. This two-step procedure prevents the danger of patients splashing themselves with a preservative, such as acid. The large container should be stored at 4 °C during the entire collection period.

Before beginning a timed collection, a patient should be given written instructions with regard to diet or drug ingestion, if appropriate, to avoid interference of ingested compounds with analytical procedures. Thus instructions for collection of specimens for 5-hydroxyindoleacetic acid measurements should specify avoidance of avocados, bananas, plums, walnuts, pineapples, eggplant, acetaminophen, and cough syrups containing glyceryl guaiacolate (guaifenesin). These dietary components are sources of 5-hydroxytryptamine and should be avoided for this reason; the other compounds interfere with certain analytical procedures but may not interfere with highly specific analytical methods. Each laboratory should determine its own requirements. See also specimen information for specific analytes in the respective chapters.

For 2-hour specimens, a prelabeled 1-L bottle is generally adequate. For a 12-hour collection, a 2-L bottle usually suffices; for a 24-hour collection, a 3- or 4-L bottle is appropriate for most patients. A single bottle allows adequate mixing of the specimen and prevents possible loss of some of the specimen if a second container does not reach the laboratory. Urine should not be collected at the same time for two or more tests requiring different preservatives. Aliquots for an analysis such as a microscopic examination should not be removed while a 24-hour collection is in process. Removal of aliquots is not permissible even when the volume removed is measured and corrected, because excretion of most compounds varies throughout the day, and test results will be affected. Appropriate information regarding the collection, including warnings with respect to handling of the specimen, should appear on the bottle label.

When a timed collection is complete, the specimen should be delivered without delay to the clinical laboratory, where the volume should be measured. This may be done by using graduated cylinders or by weighing the container and the urine when preweighed or uniform containers are used. The mass in grams may be reported as if it were the volume in milliliters. There is rarely a need to measure the specific gravity of a weighed specimen because errors in analysis usually exceed the error arising from failure to correct the volume of urine for its mass.

Before a specimen is transferred into small containers for each of the ordered tests, it must be thoroughly mixed to ensure homogeneity, because the specific gravity, volume, and composition of the urine all may vary throughout the collection period. The small container into which an aliquot is transferred should not be a plastic bottle if toluene or another organic compound has been used as a preservative; metal-free containers must be used for trace metal analyses.

Collection of Urine from Children

Collection of a timed specimen from an infant is difficult, but fortunately such specimens are rarely required. The scrotal or perineal area is cleaned and dried first, and any natural or applied skin oils are removed. For an untimed specimen, a plastic bag (U-Bag, Hollister Inc, Chicago Ill; or Tink-Col, C.R. Bard Inc, Murray Hill, NJ) is placed around the infant's genitalia and is left in place until urine has been voided.

A metabolic bed is used to collect timed specimens from infants. The infant lies on a fine screen above a funnel-shaped base containing a drain, under which a container is placed to receive urine. The fine screen retains fecal material. Nevertheless, the urine is likely to be contaminated, to some extent, by such material.

To obtain a sterile urine specimen for culture from an infant, a suprapubic tap is performed. The collection of specimens from older children is done as in adults, using assistance from a parent when this is necessary.

Urine Preservatives

The most common preservatives and the tests for which preservatives are required are listed in Table 7-7. Preservatives have different roles but usually are added to reduce bacterial action or chemical decomposition, or to solubilize

TABLE 7-7 Commonly Used Urine Preservatives

Preservative	Concentrations/Volumes
HCl	6 mol/L; 30 mL per 24 hour collection
Acetic acid	50%; 25 mL per 24 hour collection
Na_2CO_3	5 g per 24 hour collection
HNO_3	6 mol/L; 15 mL per 24 hour collection
Boric acid	10 g per 24 hour collection
Toluene	30 mL per 24 hour collection
Thymol	10% in isopropanol; 10 mL per 24 hour collection

Adapted from information provided in CLSI. Routine urinalysis and collection, transportation, and preservation of urine specimens: CLSI-approved guideline GP16-A3. Wayne, Pa: Clinical and Laboratory Standards Institute, 2009.

constituents that otherwise might precipitate out of solution. Another application is to decrease atmospheric oxidation of unstable compounds. Some specimens should not have *any* preservatives added because of the possibility of interference with analytical methods.

One of the most acceptable forms of preservation of urine specimens is refrigeration immediately after collection; it is even more successful when combined with chemical preservation. Urinary preservative tablets that contain a mixture of chemicals, such as potassium acid phosphate, sodium benzoate, benzoic acid, hexamethylene tetramine, sodium bicarbonate, and mercuric oxide [Starplex Scientific Inc (www.starplexscientific.com)], have been used for chemical and microscopic examination. Because these tablets contain sodium and potassium salts among others, they should not be used for analysis of these analytes. The preservative tablets act mainly by lowering the pH of the urine and by releasing formaldehyde. Formalin has also been used for preserving specimens, but in large amounts it precipitates urea and inhibits certain reactions (e.g., the dipstick esterase test for leukocytes). Acidification to below pH 3 is widely used to preserve 24-hour specimens and is particularly useful for specimens for determination of calcium, steroids, and vanillylmandelic acid (VMA). However, precipitation of urates will occur, thereby rendering a specimen unsuitable for measurement of uric acid.

Sulfamic acid (10 g/L urine) has also been used to reduce pH. Boric acid (5 mg/30 mL) has been used, but it too causes precipitation of urates. Although thymol and chloroform were widely used in the past to preserve specimens for chemical and microscopic urinalysis, it is now recognized that specimens for these tests should be analyzed immediately, and that the addition of preservatives is both largely ineffective and a source of interference with several analytical methods. Toluene is the only organic solvent that is still used as a preservative. When present in a large enough amount, it acts as a barrier between the air and the surface of the specimen. Toluene, however, does not prevent the growth of anaerobic microorganisms and, because of its flammable nature, is a safety hazard. A mild base, such as sodium bicarbonate or a small amount of sodium hydroxide, is used to preserve porphyrins, urobilinogen, and uric acid. A sufficient quantity should be added to adjust the pH to between 8 and 9.

Feces

Small aliquots of feces are frequently analyzed to detect the presence of "hidden" blood—also known as "occult" blood. Detecting this blood is considered an effective means to discover "the presence of a bleeding ulcer or malignant disease in the gastrointestinal tract. The utility of screening for occult blood is that it is included as part of many periodic health examinations. Tests for occult blood should be done on aliquots of excreted stools rather than on material obtained on the glove of a physician doing a rectal examination, because this procedure may cause enough bleeding to produce a positive result. In other instances, the small amount of stool present on the glove may not be representative of the whole, so that bleeding may not be recognized.

In the newborn, the first specimen from the bowel (meconium) may be used for detection of maternal drug use during the gestational period, which requires specific attention to the details of collection and identification (see Chapter 35). Feces from infants and children may be screened for tryptic activity to detect cystic fibrosis. In the infant, fecal material for these tests is usually recovered from the child's diaper. See Chapter 21 for a discussion of the measurement of trypsin in feces.

In adults, measurement of fecal nitrogen and fat in 72-hour specimens is used to assess the severity of malabsorption; measurement of fecal porphyrins is occasionally required to characterize the type of porphyria (see Chapter 33). Usually, no preservative is added to the feces, but the container should be kept refrigerated throughout the collection period, and care should be taken to prevent contamination from urine. When the collection is complete, the container and feces are weighed, and the mass of excreted feces is calculated. The specimen is homogenized and aliquoted so that the amount of fat or nitrogen excreted per day and the proportion of dietary intake excreted can be calculated.

For metabolic balance studies, collections of stool are usually made over a 72-hour period. Many balance studies are carried out in conjunction with research on the metabolism of such elements as calcium. It is important for such studies that a patient be on a controlled diet for a sufficiently long time before commencement of the study, so that a steady state has been attained.

Testing of patient DNA in stool is uncommon, but DNA isolated from fecal samples is representative of the genetic composition of the colonic mucosa at the time of stool collection. The differential and quantitative analysis of stool DNA integrity has been proposed as a sensitive and specific biomarker useful for the detection of colorectal cancer.[2]

Cerebrospinal Fluid

Cerebrospinal fluid (CSF) is normally obtained from the lumbar region, although a physician may occasionally request

analysis of fluid obtained during surgery from the cervical region or from a cistern or ventricle of the brain. CSF is examined when there is a question as to the presence of (1) a cerebrovascular accident, (2) meningitis, (3) demyelinating disease, or (4) meningeal involvement in malignant disease. Lumbar punctures should always be performed by a physician. The physician thoroughly cleans the skin of the lumbar region below the termination of the spinal cord where the cauda equina goes through the spinal canal. The physician then makes a small bleb in the skin over the space between the third and fourth or fourth and fifth lumbar vertebrae with 2% procaine and introduces a spinal needle [22-gauge, 3.5 inches (9 cm) long] through the bleb into the spinal canal. The pressure is then measured with a manometer and 3 to 4 mL of fluid allowed to drip into plain tubes. The tubes should be sterile, especially if microbiological tests are required. Because the initial specimen may be contaminated by tissue debris or skin bacteria, the first tube should be used for chemical or serological tests, the second for microbiological tests, and the third for microscopic and cytologic examination. The same procedure is used for infants and children, but the volume of fluid withdrawn should be the minimum for the requested tests.

Up to 20 mL of spinal fluid can be safely removed from an adult, although this amount is not usually required. Antiglycolytic agents usually are not added to the tube for glucose measurement; rapid processing of specimens, a clinical requirement for tests on spinal fluid, ensures that little metabolism of glucose occurs even in the presence of many bacteria. To allow proper interpretation of spinal fluid glucose values, a simultaneous blood specimen should be obtained. The most common use of spinal fluid in molecular diagnostics is for the rapid identification of an infectious agent and for T- and B-cell gene rearrangements associated with hematologic malignancies.

Synovial Fluid

Synovial fluid is a clear thixotropic fluid that serves as a lubricant in a joint, tendon sheath, or bursa. The technique used to obtain it for examination is called *arthrocentesis.* Synovial fluid is withdrawn from joints to aid characterization of the type of arthritis and to differentiate noninflammatory effusions from inflammatory fluids. Normally, only a very small amount of fluid is present in any joint, but this volume is usually very much increased in the presence of inflammatory conditions. Arthrocentesis should be performed by a physician using sterile procedures, and the technique must be modified from joint to joint depending on the anatomic location and the size of the joint. The skin over the joint is cleaned with an antiseptic, such as iodine, and then is anesthetized with an agent like ethyl chloride. A needle of appropriate size is introduced into the joint, and the required amount of fluid is aspirated into the syringe. The physician should establish priorities for the tests to be performed in case the available volume is insufficient for all tests. Sterile plain tubes should be used for culture and for glucose and protein measurements; an EDTA tube is necessary for total leukocyte, differential, and erythrocyte counts. Microscopic slides are prepared for staining with Gram's or other stains indicated, and for visual inspection.

The most common use of synovial (joint) fluid in molecular diagnostics is to assess the presence of infectious microorganisms that lead to complications of great severity. Examples of organisms that the laboratory may test for include (1) *Borrelia burgdorferi,* the causative agent in Lyme disease; (2) *Staphylococcus aureus* for the presence of a staph infection; and (3) aerobic gram-negative bacilli for the presence of *Salmonella, Pasteurella,* or *Pseudomonas,* which can lead to loss of limbs if left untreated.

Amniotic Fluid

Collection of amniotic fluid is a technique known as amniocentesis. It is performed by a physician (1) for prenatal diagnosis of congenital disorders, (2) to assess fetal maturity, or (3) to look for Rh isoimmunization or intrauterine infection. Virtually any molecular diagnostic assay can be applied to the DNA from an amniotic fluid specimen. Some of the more common molecular diagnostic assays include tests for cystic fibrosis, sickle cell anemia, Tay-Sachs disease, and thalassemia.

Gestational timing for sample collection is dependent upon the clinical question. Although ultrasound is not essential, amniocentesis is best performed with its assistance to aid localization of the placenta and to determine the presentation of the fetus. The best sites for obtaining amniotic fluid are behind the neck of the fetus or below its head, or may include other unoccupied areas of the amniotic cavity.

The skin is cleaned and anesthetized as for other similar procedures, and 10 mL of fluid is aspirated into a syringe connected to the spinal needle that is typically used. Sterile containers, such as polypropylene test tubes or urine cups, are used to transport the fluid to the laboratory. Few complications result from amniocentesis. Occasionally a bloody tap is made, but normally the fluid is clear and yellow. The blood may come from the uterine wall, the placenta, or even the fetus. Determination of fetal hemoglobin can be used to help ascertain the source, if it is important to do so.

For prenatal determination of genetic disorders, the cellular content of the amniocentesis sample may not provide sufficient nucleic acid for analysis. To perform cytogenetic studies and to obtain more DNA, the fluid is usually cultured under highly specialized conditions to expand the number of cells. Nine to 12 days of culturing is used to obtain a sufficient number of cells for DNA extraction. The cells are gently removed from the surface of the flask through the use of the enzyme trypsin, mixed, and placed into a collection tube. The sample is then ready for DNA extraction.

Chorionic Villus Sampling

Chorionic villus sampling (CVS) allows for earlier diagnosis of inherited genetic disorders than is possible with amniotic fluid analysis. With CVS, testing can be performed at a gestation period of 10 to 12 weeks, whereas with amniotic fluid, testing generally is not performed until week 15 to 20 of gestation. CVS is the technique of inserting a catheter or needle into the placenta and removing some of the chorionic

villi, or vascular projections, from the chorion. This tissue has the same chromosomal and genetic makeup as the fetus and can be used to test for disorders that may be present in the fetus. When chorionic villus is sampled, ultrasound is performed to assess the placenta and determine its position. The sample of the placenta is obtained through the vagina or through the abdomen, depending on the location of the placenta. The specimen is examined under a microscope by a physician at the time of collection to determine the quality, quantity, and integrity of the chorionic villi. Once it is received by the laboratory, the quality of the specimen is further assessed by examination for branching, budding, and veining. The specimen is then placed in culture medium and is allowed to grow for up to 3 weeks. Once the cells are fully confluent, they are treated in the way that cells from amniotic fluid (earlier) are treated for DNA extraction.

Maternal cell contamination testing is used to definitively identify the source of isolated cells in an amniotic fluid sample and in CVS. Such confirmation of the source of the sample is strongly recommended for any prenatal diagnostic testing and may be required as a quality monitor in some laboratories.

Pleural, Pericardial, and Ascitic Fluids

The pleural, pericardial, and peritoneal cavities normally contain a small amount of serous fluid, which lubricates the opposing parietal and visceral membrane surfaces. Inflammation or infection affecting the cavities causes fluid to accumulate. The fluid may be removed to determine whether it is an effusion or an exudate—a distinction made possible by protein or enzyme analysis. The fluid may also be examined for cellular elements.[6] The primary uses of these fluids in the molecular diagnostic laboratory are for infectious agent identification and possibly for the detection of cancer cells.[24]

The collection procedure is called *paracentesis.* When specifically applied to the pleural cavity, the procedure is a *thoracentesis;* if applied to the pericardial cavity, a *pericardiocentesis.* Paracentesis should be performed only by skilled and experienced physicians. Pericardiocentesis has now been largely supplanted by echocardiography.

The skin over the intended puncture site should be cleaned with 70% isopropanol and then allowed to dry in the air. A spinal needle is inserted into the body cavity through a small bleb in the skin raised by injection of a local anesthetic. Fluid is then withdrawn by a syringe and is transferred to appropriate tubes for analysis. Paracentesis is rarely associated with complications. Occasionally, blood-stained fluid is obtained through puncture of a small blood vessel. If adhesions are present between the intestine and the abdominal wall, a part of the intestine could be perforated by a peritoneal tap. With thoracentesis, pneumothorax and bronchopleural fistulas are potential complications.

Saliva

Although measurement of the concentrations of certain analytes in saliva has been advocated,[3] clinical application of methods that use saliva has been limited. Exceptions include measurement of blood group substances to determine secretor status and genotype. Measurement of a drug in saliva has been suggested to estimate the free, pharmacologically active concentration of the drug in serum. There is, however, a considerable difference in pH between saliva and serum, and ratios of bound-to-free drug may not be the same. Fortunately, ultrafiltration techniques are now available that facilitate the processing of serum for free drug analysis.

Several slightly different techniques have been devised for the collection of saliva. Usually an individual is asked to rinse out his or her mouth with water and then chew an inert material, such as a piece of rubber or paraffin wax, from 30 seconds to several minutes. The first mouthful of saliva is discarded; thereafter the saliva is collected into a small glass bottle. Newer devices require the patient to put a small amount of table sugar in the palm of the hand and then touch the table sugar with the tongue. Table sugar promotes the production of saliva. Depending on the collection tube, saliva can be used as a source of DNA or RNA.

Buccal Cells

Collection of buccal cells (cells of the oral cavity of epithelial origin) has been identified as providing an excellent source of genomic DNA. Collection of buccal cells is often viewed as less invasive than collection of blood. It is particularly useful for collecting cells with the patient's genomic DNA when the patient has had blood transfusions and thus has blood with another person's (or persons') DNA. Similarly, it is useful after bone marrow transplantation when the circulating blood cells are derived wholly or partially from the donor of the bone marrow. Two methods are used commonly to collect buccal cells: rinsing with mouthwash and using swabs or cytobrushes.

Rinsing of the oral cavity generally provides a higher yield of cells than can be obtained by using swabs. For these collections, the patient is provided with a small amount of mouthwash and is instructed to rinse well for a minimum of 60 seconds, then return the mouthwash to a collection tube. There is no harm in doing this longer than 60 seconds, but shortening the time may decrease the yield of buccal cells. Mouthwash solutions high in phenol and ethanol are destructive to recovered cells and should be avoided. It is necessary for each laboratory to validate a list of acceptable solutions.

Swabs or cytobrushes have also been used to collect buccal cells for molecular genetics testing. For swabs, a sterile Dacron or rayon swab with a plastic shaft is preferred because calcium alginate swabs or swabs with wooden sticks may contain substances that inhibit PCR-based testing. After collection, the swab or cytobrush should be stored in an air-tight plastic container or immersed in liquid, such as phosphate-buffered saline (PBS) or viral transport medium. In general, the yield of cells and nucleic acid is lower with physical scraping using swabs or cytobrushes than with rinsing.

Solid Tissue

Traditionally, the solid tissue most often analyzed in the clinical laboratory was malignant tissue from the breast for

estrogen and progesterone receptors. During surgery, at least 0.5 to 1 g of tissue is removed and trimmed of fat and nontumor material. This tissue is quickly frozen, within 20 minutes, preferably in liquid nitrogen or in a mixture of dry ice and alcohol. A histologic section should always be examined at the time of analysis of the specimen to confirm that the specimen is indeed malignant tissue.

The same procedure may be used to obtain and prepare solid tissue for toxicologic analysis; however, when trace element determinations are to be made, all materials used in the collection or handling of the tissue should be made of plastic or materials known to be free of contaminating trace elements (see also Chapter 31).

Somatic gene analyses, such as T-cell receptor rearrangement and clonal expansion, are now providing important information for clinicians. Additionally, mutations in malignant tissues may be used to direct therapy (see Chapter 43). For these studies, the molecular diagnostic laboratory often receives tissue that has been formalin-fixed and paraffin-embedded (FFPE). In general, neutral buffered formalin, containing no heavy metals, will not interfere with amplification reactions. However, recovery of nucleic acids is greatly decreased if the tissue has been overfixed. DNA can still be extracted from tissue embedded in paraffin, but the DNA will be degraded to low molecular weight fragments. In most cases, segments of DNA will amplify in a PCR reaction, but Southern blot methods will be problematic, as most require high molecular weight DNA.

Tissue structure can be retained without permanent fixation by freezing specimens in an optimal cutting temperature compound (OCT). OCT is a mixture of polyvinyl alcohol and polyethylene glycol that surrounds but does not infiltrate the tissue. The sample is then frozen at ≈−80 °C, and sections are prepared for review by a pathologist. OCT is fully water soluble and should be completely removed from a tissue specimen before it is used as a source of DNA. In general, DNA of higher molecular weight can be extracted from OCT-fixed tissues compared with that extracted from FFPE samples.

Hair and Nails

Currently, the use of hair or nail in molecular diagnostics is limited to forensic analysis (genomic DNA identification). Hair and fingernails or toenails have been used for trace metal and drug analyses. However, collection procedures have been poorly standardized, and quantitative measurements are better obtained from blood or urine.

HANDLING OF SPECIMENS FOR ANALYSIS

Steps that are important for obtaining a valid specimen for analysis include (1) identification, (2) preservation, (3) separation and storage, and (4) transport.

Maintenance of Specimen Identification

Proper identification of the specimen must be maintained at each step of the testing process.[4] The minimum information on a label should include a patient's name, location, and identifying number, and the date and time of collection. All labels should conform to the laboratory's stated requirements to facilitate proper processing of specimens. No specific labeling should be attached to specimens from patients with infectious diseases to suggest that these specimens should be handled with special care. All specimens should be treated as if they are potentially infectious.[14]

In practice, every specimen container must be adequately labeled even if the specimen must be placed in ice, or if the container is so small that a label cannot be placed along the tube, as might happen with a capillary blood tube. Direct labeling of a capillary blood tube by folding the label like a flag around the tube is preferred. For small volumes of urine submitted in a screw-cap urine cup and any specimen submitted in a screw-cap test tube or cup, the label should be placed on the cup or tube directly, not on the cap.

Preservation of Specimens

The practitioner must ensure that specimens are collected into the correct container and are properly labeled; in addition, specimens must be properly treated both during transport to the laboratory and from the time the serum, plasma, or cells have been separated until analysis. For some tests, specimens must be kept at 4 °C from the time the blood is drawn until the specimens are analyzed, or until the serum or plasma is separated from the cells. Examples are specimens for ammonia and blood gas determinations, such as PCO_2, PO_2, and blood pH (see Chapter 28). Transfer of these specimens to the laboratory must be done by placing the specimen container in ice water. Specimens for acid phosphatase, lactate and pyruvate, and certain hormone tests (e.g., gastrin and renin activity) should be treated the same way. A notable decrease in pyruvate and increase in lactate concentration occurs within a few minutes at ambient temperature (see Chapter 28).

For all test constituents that are thermally labile, serum and plasma should be separated from cells in a refrigerated centrifuge. Specimens for bilirubin or carotene and for some drugs, such as methotrexate, must be protected from both daylight and fluorescent light to prevent photodegradation.

Hemolysis may occur in pneumatic tube systems unless the tubes are completely filled and movement of the blood tubes inside the specimen carrier is prevented.[26] The pneumatic tube system should be designed to eliminate sharp curves and sudden stops of specimen carriers, because these factors are responsible for much of the hemolysis that may occur. With many systems, however, the plasma hemoglobin concentration may be increased, and the serum activity of red cell enzymes, such as lactate dehydrogenase, may also be increased. Nonetheless, the amount of hemolysis is usually so small that it can be ignored. In special cases, such as a patient's undergoing chemotherapy whose cells are fragile, samples should be centrifuged before they are placed in the pneumatic tube system or identified as "messenger delivery only."

For the molecular diagnostic laboratory, it's challenging to recover RNA from transported specimens. Depending on

the tissue source, RNA yields will vary, primarily because of the amount of RNA present at the time of collection. Specimens from liver, spleen, or heart have large amounts of RNA, but specimens from skin, muscle, and bone have lower RNA content. Increasingly, creative solutions to this issue continue to be produced (e.g., see www.dnagenotek.com) with collection kits that contain stabilizers and even the first reagents required for extraction, all of which have the effect of maximizing the recoverable nucleic acid. Tissue samples should be frozen immediately. Alternatively, a blood specimen should never be frozen before separation of the cellular elements because of hemolysis and released heme that may interfere with subsequent amplification processes. For tissue samples, it is critical to choose the disruption method best suited for the specific type of tissue. Thorough cellular disruption is critical for high RNA quality and yield. RNA that is trapped in intact cells is often removed with cellular debris by centrifugation.[18]

For specimens that are collected in a remote facility with infrequent transportation by courier to a central laboratory, proper specimen processing must be done in the remote facility so that appropriately separated and preserved plasma or serum is delivered to the laboratory. This necessitates that the remote facility has ready access to all commonly used preservatives and wet ice.

Separation and Storage of Specimens

Plasma or serum should be separated from cells as soon as possible and certainly within 2 hours.[21] Premature separation of serum, however, may permit continued formation of fibrin, which can clog sampling devices in testing equipment. If it is impossible to centrifuge a blood specimen within 2 hours, the specimen should be held at room temperature rather than at 4 °C to decrease hemolysis. For most plasma samples used for molecular diagnostics, the plasma should be removed from the primary tube promptly after centrifugation and held at −20 °C in a freezer capable of maintaining this temperature. Frost-free freezers should be avoided because they have a wide temperature swing during the freeze-thaw cycle. Note, however, that 4 °C or −20 °C is not the optimum storage temperature for all tests; some lactate dehydrogenase isoenzymes, for instance, are more stable at room temperature than at 4 °C. Although changes in concentration of test constituents have been observed when serum or plasma is stored in a gel separator tube in a refrigerator for 24 hours, these changes do not appear to be large enough to be of clinical significance.

Specimen tubes should be centrifuged with stoppers in place. Closure reduces evaporation, which occurs rapidly in a warm centrifuge with the air currents set up by centrifugation. Stoppers also prevent aerosolization of infectious particles. Specimen tubes containing volatiles, such as ethanol, *must* be stoppered while they are spun. Centrifuging specimens with the stopper in place maintains anaerobic conditions, which are important in the measurement of carbon dioxide and ionized calcium. Removal of the stopper before centrifugation allows loss of carbon dioxide and an increase in blood pH. Control of pH is especially important for the enzymatic measurement of acid phosphatase, which is labile under alkaline conditions engendered by CO_2 loss.

Cryopreservation of white blood cells and DNA is one method to store and maintain samples for extended periods of time. Whole blood specimens can be centrifuged, and white cells removed and cryopreserved at −20 °C until these cells are required for DNA extraction. For even longer periods of storage, isolated DNA can be stored at −70 °C. The extracted DNA should not be exposed to repetitive cycles of freezing and thawing because this can lead to shearing of the DNA. After these extracted DNA samples have completely thawed, it is important to fully mix the sample to ensure a homogeneous specimen.

Transport of Specimens

Although the remaining discussion uses the specific example of referral laboratory testing by another laboratory, many of the issues discussed, such as regulations related to shipping,[13] are also relevant to a laboratory that receives specimens from outlying clinics via a (laboratory-owned and/or operated) courier service. This may involve validating specific transport/storage conditions that are in conflict with existing CLSI recommendations.[9,19]

Before a referral laboratory is used for any tests, the quality of its work should be verified by the referring laboratory. Guidelines for selection and evaluation of a referral laboratory have been published.[15] For laboratories accredited by the College of American Pathologists (CAP), it is a requirement that the referring laboratory validate that the referral laboratory is CLIA certified by obtaining a copy of the CLIA certificate before specimens are shipped. For molecular diagnostic testing, this is of particular importance, because often the latest genetic test being requested by a physician has not yet been moved from research interest status to patient care status and may not be available in a CLIA-certified laboratory.

Specimen type and quantity and specimen handling requirements of the referral laboratory must be observed, and in laboratories operating under CLIA ’88 regulations, test results reported by a referral laboratory must be identified as such when they are filed in a patient’s chart. The director of a referring laboratory has the responsibility to ensure that specimens will be adequately transported to the referral laboratory. Also, the director should determine the benefits of different services and should keep in mind that the fastest service is usually the most expensive. The director should also know that specimens should not be sent to a referral laboratory at the end of the week, because more delays in transit occur during weekends than during the working week, and deterioration of specimens is more likely.

It should be assumed that transport from a referring laboratory to a referral laboratory may take as long as 72 hours. Under optimal conditions, a referring laboratory should retain enough specimen for retesting should an unanticipated problem arise during shipment. The tube used for holding a specimen (primary container) should be so constructed that the contents do not escape if the container is exposed to

extremes of heat, cold, or sunlight. Reduced pressure of 0.50 atmosphere (50 kPa) may be encountered during air transport, together with vibration, and specimens should be protected from these adverse conditions by a suitable container. Variability in temperature is a significant factor causing instability of test constituents.

Polypropylene and polyethylene containers are usually suitable for specimen transport. Glass should be avoided. Polystyrene is unsuitable because it may crack when frozen. Containers must be leakproof and should have a Teflon-lined screw cap that does not loosen under the variety of temperatures to which the container may be exposed. The materials of both stopper and container must be inert and must not have any effect on the concentration of the analyte.

In situations in which sample delivery for molecular analysis will be delayed, extracted nucleic acid, usually DNA only, can be transported in a buffer solution or water, or it can be dried down and shipped as a loose powder. With either method, DNA should be transported at ambient temperatures and should not be exposed to extremely high temperatures for an extended period of time because it will begin to degrade, and testing may be compromised.

The shipping or secondary container used to hold one or more specimen tubes or bottles must be constructed to prevent the tubes from banging against each other. Corrugated, fiberboard, or Styrofoam boxes designed to fit around a single specimen tube are commonly used. A padded shipping envelope provides adequate protection for shipping single specimens. When specimens are shipped as drops of blood on filter paper (e.g., for neonatal screening), the paper should be enclosed in a paper envelope to ensure that the sample remains dry. The initial paper envelope can be placed in a shipping envelope and transported to the testing facility; rapid shipping is rarely required for dried blood on paper.

For transport of frozen or refrigerated specimens, a Styrofoam container should be used. The container walls should be 1 inch (2.5 cm) thick to provide effective insulation. The container should be vented to prevent buildup of carbon dioxide under pressure and a possible explosion. Solid carbon dioxide (dry ice) is the most convenient refrigerant material for keeping specimens frozen, and temperatures as low as –70 °C can be achieved. The amount of dry ice required in a container depends on the size of the container, the efficiency of its insulation, and the length of time for which the specimens must be kept frozen. One piece of solid dry ice (about 3 inches × 4 inches × 1 inch) in a container with 1-inch Styrofoam walls and a volume of 125 cubic inches (2000 cm^3) will maintain a single specimen frozen for 48 hours.

Various laws and regulations apply to the shipment of biological specimens.[4,8,14] Although they theoretically apply only to etiologic agents (known infectious agents), all specimens should be transported as if the same regulations applied. Airlines have rigid regulations covering the transport of specimens. Airlines deem dry ice a hazardous material; therefore the transport of most clinical laboratory specimens is affected by the regulations, and those who package the specimens should be trained in the appropriate regulations, such as those put forth by the U.S. Air International Transport Association (IATA).

The various modes of transport of specimens influence the shipping time and cost, and each laboratory will need to make its own assessment as to adequate service. The objective is to ensure that the properly collected, processed, and identified specimen arrives at the testing facility in time and under the correct storage conditions so that the analytical phase can then proceed.

CHAPTER 8

Quality Management

George G. Klee, M.D., Ph.D., and James O. Westgard, Ph.D.

The principles of quality management, assurance, and control have become the foundation by which clinical laboratories are managed and operated. This chapter begins with a discussion of the fundamentals of total quality management followed by discussions of (1) total quality management of the clinical laboratory, (2) laboratory error and the Six Sigma process, (3) elements of a quality assurance program, (4) control of preanalytical variables, (5) control of analytical variables, (6) control of analytical quality using stable control materials, (7) control of analytical quality using patient data, (8) external quality assessment and proficiency testing programs, and (9) identification of sources of analytical errors. We conclude the chapter with a discussion on quality initiatives, including the ISO 9000 certification process.

FUNDAMENTALS OF TOTAL QUALITY MANAGEMENT[127]

Public and private pressures to contain healthcare costs are accompanied by pressures to improve quality. Seemingly contradictory pressures for both cost reduction and quality improvement (QI) require that healthcare organizations adopt new systems for managing quality. When faced with these same pressures, other industries implemented *total quality management,* or TQM.[116] TQM may also be referred to as (1) total quality control (QC), (2) total quality leadership, (3) continuous quality improvement, (4) quality management science, or, more generally, (5) industrial quality management. TQM provides both a management *philosophy* for organizational development and a management *process* for improving the quality of all aspects of work. Many healthcare organizations have adopted the concepts and principles of TQM.[12,101]

Fundamental Concepts

In this chapter, *quality* is defined as conformance with the requirements of users or customers. More directly, *quality* refers to satisfaction of the needs and expectations of users or customers. The focus on users and customers is important, particularly in service industries such as healthcare. Users of healthcare laboratories are often nurses and physicians; their customers are patients and other parties who pay the bills.

Cost must be understood in the context of quality. If *quality* means conformance with requirements, then *quality costs* must be understood in terms of "costs of conformance" and "costs of nonconformance," as illustrated in Figure 8-1. In industrial terms, costs of conformance are divided into prevention costs and appraisal costs. Costs of nonconformance consist of internal and external failure costs. For a laboratory testing process, calibration is a good example of a cost incurred to prevent problems. Likewise, quality control is a cost for appraising performance, a repeat run is an internal failure cost for poor analytical performance, and repeat requests for tests because of poor analytical quality are an external failure cost.

This understanding of quality and cost leads to a new perspective on the relationship between them. Improvements in quality can lead to reductions in cost. For example, with better analytical quality, a laboratory would be able to reduce waste; this, in turn, would reduce cost. The father of this fundamental concept was the late W. Edwards Deming, who developed and internationally promulgated the idea that quality improvement reduces waste and leads to improved productivity, which, in turn, reduces costs and provides a competitive advantage.[42] As a result, the organization stays in business and is able to continue providing jobs for its employees.

Fundamental Principles

Quality improvement occurs when problems are eliminated permanently. Industrial experience has shown that 85% of all problems are process problems that are solvable only by managers; the remaining 15% are problems that require the action and improvement in performance of individual workers. Thus quality problems are primarily management problems because only management has the power to change work processes.

This emphasis on processes leads to a new view of the organization as a system of processes (Figure 8-2). For example, physicians might view a healthcare organization as a provider of processes for patient examination (A), patient testing (B), patient diagnosis (C), and patient treatment (D). Healthcare administrators might view the activities in terms of processes for admitting patients (A), tracking patient services (B), discharging patients (C), and billing for costs of

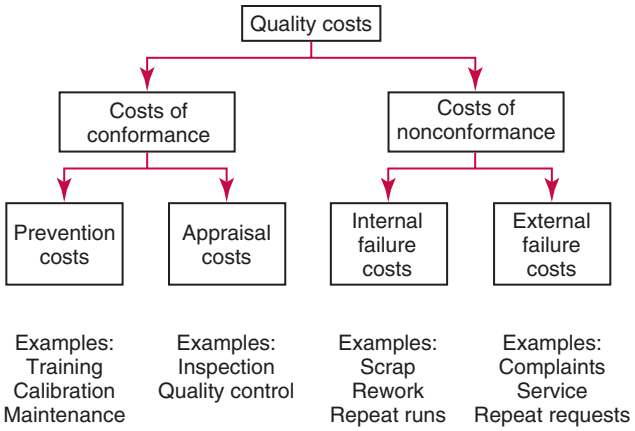

Figure 8-1 The cost of quality in terms of the costs of conformance and the costs of nonconformance with customer requirements. *(From Westgard JO, Barry PL. Cost-effective quality control: managing the quality and productivity of analytical processes. Washington, DC: AACC Press, 1986.)*

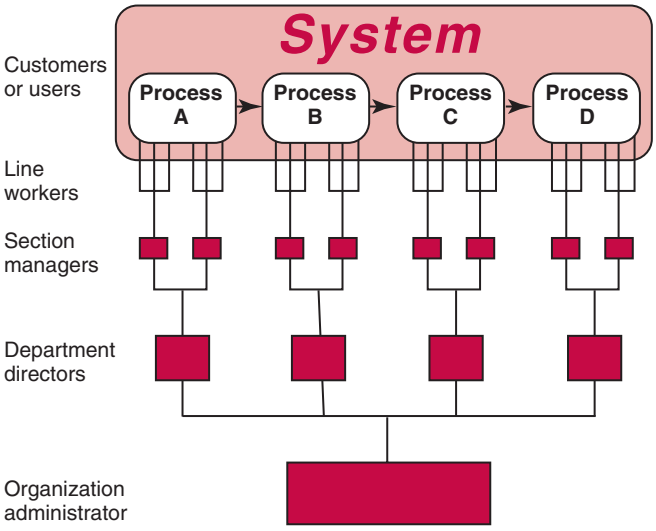

Figure 8-2 Total quality management (TQM) view of an organization as a system of processes.

service (D). Laboratory directors might understand their responsibilities in terms of processes for acquisition of specimens (A), processing of specimens (B), analysis of samples (C), and reporting of test results (D). Laboratory analysts might view their work as processes for acquiring samples (A), analyzing samples (B), performing quality control (C), and releasing patient test results (D). The total system for a healthcare organization involves the interaction of all of these processes and many others. Given the primary importance of these processes for accomplishing the work of the organization, TQM views the organization as a support structure rather than as a command structure. As a support structure, the most immediate processes required for delivery of services are those of frontline employees. The role of upper management is to support the frontline employees and to *empower* them to identify and solve problems in their own work processes.

The importance of empowerment is easily understood if a problem involves processes from two different departments. For example, if a problem occurs that involves the link between process A and process B in Figure 8-2, the traditional management structure requires that the problem be passed up from the line workers to a section manager or supervisor, a department director, and an organization administrator. The administrator then works back through an equal number of intermediaries in the other department. Direct involvement of line workers and their managers should provide more immediate resolution of the problem.

However, such problem solving requires a carefully structured process to ensure that root causes are identified and proposed solutions verified. Juran's "project-by-project" quality improvement process[53] provides detailed guidelines that have been widely adopted and integrated into current team problem-solving methods.[11,12,97] These methods outline distinct steps for (1) carefully defining the problem, (2) establishing baseline measures of process performance, (3) identifying root causes of the problem, (4) identifying a remedy for the problem, (5) verifying that the remedy actually works, (6) "standardizing" or generalizing the solution for routine implementation of an improved process, and (7) establishing ongoing measures for monitoring and controlling the process.

The quality improvement project team provides a new flexible organization unit. A *project team* is a group of employees appointed by management to solve a specific problem that has been identified by management or staff. The team comprises members from any department and from any level of the organization and includes anyone whose presence is necessary to understand the problem and identify the solution. Management initiates the project, and the team is empowered and supported to identify the root cause and verify a solution; management then becomes involved in replanning the process (i.e., planning the implementation of changes in a laboratory process, defining and standardizing the improved process, and establishing appropriate measures for ongoing evaluation and control of the process).[129]

TOTAL QUALITY MANAGEMENT OF THE CLINICAL LABORATORY

The principles and concepts of TQM have been formalized into a quality management process (Figure 8-3). The traditional framework for managing quality in a healthcare laboratory has emphasized the establishment of quality laboratory processes (QLPs), QC, and quality assessment (QA). A QLP includes analytical processes and the general policies, practices, and procedures that define how work is done. QC emphasizes statistical control procedures but also includes nonstatistical check procedures, such as linearity checks, reagent and standard checks, and temperature monitors. QA, as currently applied, is primarily concerned with broader measures and monitors of laboratory performance, such as (1) turnaround time, (2) specimen identification, (3) patient

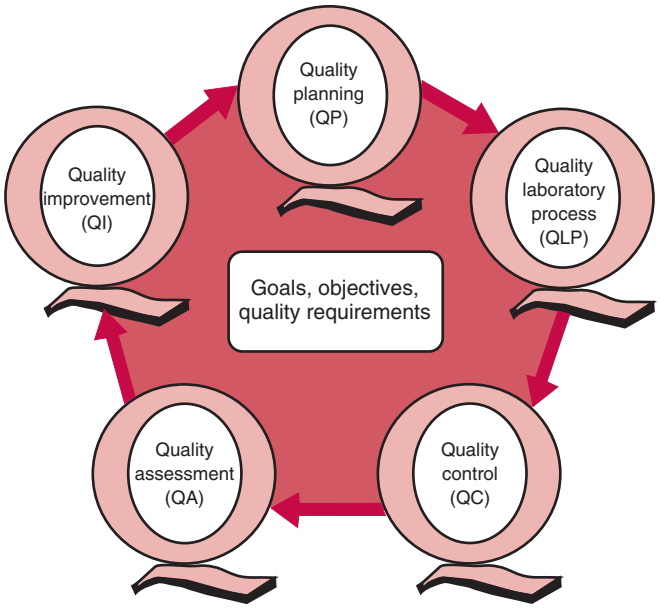

Figure 8-3 Total quality management (TQM) framework for managing quality in a healthcare laboratory. *(From Westgard JO, Burnett RW, Bowers GN. Quality management science in clinical chemistry: a dynamic framework for continuous improvement of quality. Clin Chem 1990;36:1712-6.)*

identification, and (4) test utility. Quality "assessment" is the proper name for these activities rather than quality "assurance." Measuring performance does not by itself improve performance and often does not detect problems in time to prevent negative outcomes. Quality assurance requires that causes of problems be identified through QI and eliminated through quality planning (QP), or that QC be able to detect problems early enough to prevent their consequences.

To provide a fully developed system and framework for managing quality, the QI and QP components must be established.[37,80,127] QI provides a structured problem-solving process for identifying the root cause of a problem and for identifying a remedy for the problem. QP is necessary to (1) standardize the remedy, (2) establish measures for monitoring performance, (3) ensure that the performance achieved satisfies quality requirements, and (4) document the new QLP. The new process is then implemented through QLP, measured and monitored through QC and QA, improved through QI, and replanned through QP. These five components, working together in a feedback loop, illustrate how continuous QI is accomplished and how quality assurance is built into laboratory processes.

The "five-Q" framework also defines how quality is able to be managed objectively using the "scientific method" or the *PDCA cycle* (**p**lan, **d**o, **c**heck, **a**ct). QP provides the planning step, QLP establishes standard processes for doing things, QC and QA provide measures for checking how well things are done, and QI provides a mechanism for acting on those measures. The method that we naturally apply in scientific experiments should also serve as the basis for objective management decisions.

ESTABLISHING QUALITY GOALS AND ANALYTICAL PERFORMANCE LIMITS

Fundamental requirements for all objective quality control systems are clearly defined quality goals. Laboratories must define their service goals and establish clinical and analytical quality requirements for testing processes. Without such quality goals, there is no objective way to determine whether acceptable quality is being achieved, or to identify processes that have to be improved, or to design new processes that ensure that a specified level of quality will be attained.

The establishment of medically relevant analytical performance limits is not an easy task. Each assay and each clinical application of each assay logically should have its own optimal and its own acceptable performance limits. Systematic and random errors generally affect applications differently; therefore independent assessment of the quality goals for these two types of errors may be most practical. Systematic errors have the most profound effect on medical diagnostic decisions, especially those involving specific diagnostic limits. Medical guidelines may specify numeric decision limits such as 200 mg/dL of cholesterol in the National Cholesterol Education Program (NCEP) guideline.[4,8] Analytical tolerance limits for systematic errors may be very tight near the decision limit and less stringent for measurements farther from the decision values. Performance limits for random errors can be bounded by biological variations as follows.

$$SD_{total} = \sqrt{SD^2_{analytical} + SD^2_{biological}}$$

If analytical imprecision is less than 25% of the biological variation [measured as standard deviation (SD) or coefficient of variation (CV)], then the total combined analytical and biological SD or CV will be increased by less than 3% compared with the biological variation [e.g., $\sqrt{(0.25)^2 + (1.00)^2} = \leq 1.03$]. If an assay is used to monitor test changes within an individual over time, the within person biological variation would be the appropriate bonding limit. Values for biological variation were published in a 1999 paper by C. Ricos.[90] Updated values are available at the website www.westgard.com (assessed March 22, 2011).[122]

The establishment of analytical performance goals may represent a compromise between what would be optimal for best medical practice and what is realistically achievable by current technology, given healthcare cost constraints. The optimal systematic error generally is zero, particularly around the decision levels. Consequences of systematic error depend on the uncertainties associated with the other decision variables and the degree of redundancy incorporated into the decision algorithms. When medical decisions are based on multiple independent measurements, the adverse effects of errors in any one measurement are less than when a critical decision is based on only one measurement.

Two types of system analysis are used to determine what analytical performance is achieved with a particular

laboratory system. The first is called a *bottom-up analysis,* and the second is a *top-down analysis.*[6,7] In the bottom-up analysis, the system is divided into multiple components. The uncertainties of all components are defined and statistically combined to obtain the total uncertainty of the complete system. The systematic errors add linearly, whereas the random errors add by the square root of the sum of squares.

Total systematic error (SE) and total random error (if independent) are defined as follows:

$$\text{Total Systematic Error (SE)} = \text{Systematic Error}_1 + \text{Systematic Error}_2 + \text{Systematic Error}_N$$

$$\text{Total Random Error} = \sqrt{(\text{Random Error}_1)^2 + (\text{Random Error}_2)^2 + \ldots\ldots (\text{Random Error}_N)^2}$$

(Note: If the component errors are not statistically independent, covariances must be accounted for when adding the random errors.)

Error limits for each of these components are obtained from (1) the manufacturers, (2) published literature, or (3) in-house validation studies.

The top-down analysis generally utilizes quality control measurements and/or proficiency testing results. In-house quality control measurements may underestimate the total errors, particularly if the target values for the controls are not independently assigned, or if the data are collected only over a short period of time. Potential differences across multiple calibrators and differences across multiple reagent lots should be accounted for in estimating total analytical variations. On the other hand, between-laboratory proficiency testing data may overestimate the analytical variation within an individual laboratory.

The performance characteristics obtained from assessment of laboratory processes have been used to back-calculate the system performance that a laboratory is able to realistically achieve. Maximum tolerance ranges utilized in QC programs (the specifications promised to clinicians) must be wider than the limits measured by bottom-up or top-down assessments to provide adequate statistical power to ensure that the laboratory consistently meets performance expectations. For example, if the analytical performance assessment of a laboratory process shows a CV of 5%, the maximum tolerance range for the QC may be set at ±30%, and clinicians should be advised that analytical variation will not exceed ±30% (based on ±6 sigma tolerance specifications). Even if only 4 sigma confidence limits are used, clinicians should be advised that variation may be up to ±20%. The concepts of Six Sigma reliability and the metrics for establishing effective operating QC limits are further explained later in this chapter. Therefore, if the medical utility of the assay can tolerate these wider limits, system integrity would be much better in maintaining this level of performance.

It should be noted that quality goals cannot be set on an absolute basis because they vary from laboratory to laboratory, depending on the medical missions of the healthcare facilities and the professional interests of the physicians using the laboratory tests. Quality goals must also be considered in relation to cost. A goal of achieving the highest possible quality is not appropriate or practical when costs are being curtailed. In establishing quality goals, it is therefore more realistic to specify the quality that is necessary or adequate for medical applications of the laboratory test results to be produced.

The balance of this chapter focuses primarily on analytical quality and the procedures by which it is monitored. Goals for analytical quality are established in the same way that they are established for purposes of method evaluation (see Chapter 2). The philosophy is to define an "allowable analytical error" based on "medical usefulness" requirements. A "total error" specification is useful because it will permit calculation of the sizes of random and systematic errors that have to be detected to maintain performance within the allowable error limit (see Chapter 2).[85] Medical decision concentrations (i.e., the concentrations at which medical interpretation of laboratory test results is particularly critical) are important in establishing the analytical concentrations at which analytical performance has to be most carefully monitored. Thus analytical goals are established by specifying the allowable analytical error and the critical medical decision concentration. Method evaluation is only the first step in validating that analytical performance satisfies those goals. Quality control procedures should provide for continuing verification that those goals are being achieved during routine service.

LABORATORY ERROR AND THE SIX SIGMA PROCESS

A study by the Institute of Medicine found that more than 1 million preventable injuries and 44,000 to 98,000 preventable deaths occur annually in the United States.[60,64] Additional publications have offered suggestions for minimizing medical errors in general.[13,40,64-66,94] The magnitude of laboratory errors and the use of the Six Sigma process in controlling them are discussed in the following sections.

Number of Errors Made in the Clinical Laboratory

A study of 363 incidents captured by a laboratory's quality assurance program in a hospital enumerated the sources and impact of errors.[92] Incidents included those in which (1) physicians' orders for laboratory tests were missed or incorrectly interpreted; (2) patients were not properly prepared for testing or were incorrectly identified; (3) specimens were collected in the wrong containers or were mislabeled or mishandled; (4) the analysis was incorrect; (5) data were entered improperly; or (6) results were delayed, not available, or incomplete, or they conflicted with clinical expectations. Upon evaluating the data, the authors found no effect on patient care for 233 patients; 78 patients were not harmed but were subjected to an unnecessary procedure not associated with increased patient risk; and 25 patients were not harmed but were subjected to an additional risk of inappropriate care. Of the total number, preanalytical mistakes accounted for 218

(45.5%), analytical for 35 (7.3%), and postanalytical for 226 (47.2%). Nonlaboratory personnel were responsible for 28.6% of the mistakes. An average of 37.5 patients per 100,000 treated were placed at increased risk because of mistakes in the testing process.

Witte and colleagues investigated rates of error within the analytical component and found that widely discrepant values were rare, occurring in only 98 of 219,353 analyses.[145] When these results were converted into a standard metric of errors per million episodes, an error rate of 447 ppm was calculated.[13] In another study, Plebani and Carraro identified 189 mistakes from a total of 40,490 analyses, with a relative frequency of 0.47% (4667 ppm). The distribution of mistakes was 68.2% preanalytical (3183 ppm), 13.3% analytical (620 ppm), and 18.5% postanalytical (863 ppm).[86] Most laboratory mistakes did not affect patients' outcomes, but in 37 patients, laboratory mistakes were associated with additional inappropriate investigations, thus resulting in an unjustifiable increase in costs. In addition, laboratory mistakes were associated with inappropriate care or inappropriate modification of therapy in 12 patients. The authors concluded that "promotion of quality control and continuous improvement of the total testing process, including pre-analytical and post-analytical phases, seems to be a prerequisite for an effective laboratory service."[86]

In a study of common immunoassays, Ismail and colleagues found only 28 false results from 5310 patients (5273 ppm).[51] However, as a result of incorrect immunoassay results attributable to interference, 1 patient had 15 consultations, 77 laboratory tests, and an unnecessary pituitary computed tomography scan. The authors stress (1) the necessity for good communication between clinician and laboratory personnel, (2) the importance of the clinical context, and (3) the necessity for use of multiple methods of identifying erroneous test results—a necessity for a rigorous and robust quality system. Heterophilic antibody blocking studies were most effective in identifying interference, but in 21% of patients with false results, dilution studies or alternative assays were necessary to identify the problem. In a similar study, Marks enlisted participation from 74 laboratories from a broad international spectrum of settings and found that 6% of analyses gave false-positive results and, as in the Ismail study, found that use of a heterophilic blocking reagent corrected approximately one third of these.[72] Further evaluation of the data showed no consistent pattern for false results: errors were distributed across donors, laboratories, and systems of analysis. In reviewing the data from these last two studies, Leape suggested setting up a system that would ensure that every result was given a rigorous review before being reported.[64]

Bonini et al conducted several MEDLINE studies of laboratory medical errors and found large heterogeneity in study design and quality and lack of a shared definition of *laboratory error.*[17] However, even with these limitations, they concluded that most such errors occur in the preanalytical phase and suggested that these could be reduced by the implementation of a more rigorous method for error detection and classification and the adoption of proper technologies for error reduction. Thus current QA programs that monitor only the analytical phase of the total process have to be expanded to include both preanalytical (see Chapter 6) and postanalytical phases (www.westgard.com/essay34/assessed March 22, 2011). Through expanded monitoring, the total process would then be managed so as to reduce or eliminate all defects within the process.[86]

Six Sigma Principles and Metrics

Six Sigma,[41A,46A,48] is an evolution in quality management that is being widely implemented in business and industry in the new millennium.[89] Six Sigma metrics are being adopted as the universal measure of quality to be applied to their processes and the processes of their suppliers. The principles of Six Sigma go back to Motorola's approach to TQM in the early 1990s and the performance goal that "6 sigma's or 6 standard deviations of process variation should fit within the tolerance limits for the process," hence, the name Six Sigma (http://mu.motorola.com/accessed March 22, 2011). For this development, Motorola won the Malcolm Baldridge Quality Award in 1988.

Six Sigma provides a more quantitative framework for evaluating process performance and more objective evidence for process improvement. The goal for process performance is illustrated in Figure 8-4, which shows the tolerance specifications or quality requirements for that measurement set at −6S and +6S. Any process can be evaluated in terms of a sigma metric that describes how many sigma's fit within the tolerance limits. The power of the sigma metric comes from its role as a universal measure of process performance that facilitates benchmarking across industries.

Two methods can be used to assess process performance in terms of a sigma metric (Figure 8-5). One approach is to measure outcomes by inspection. The other approach is to measure variation and predict process performance. For processes in which poor outcomes can be counted as errors or defects, the defects are expressed as defects per million (DPM), then are converted to a sigma metric using a standard table available in any Six Sigma text.[48] This conversion from defects per million to sigma levels is an

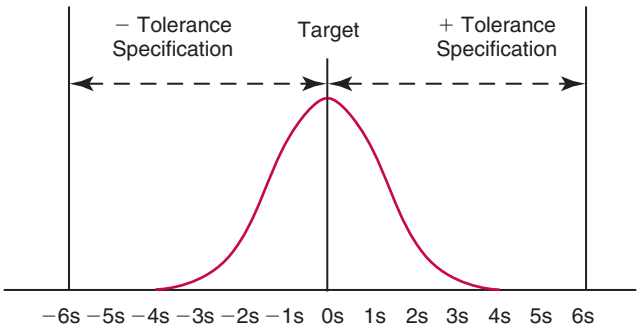

Figure 8-4 Six Sigma goal for process performance "tolerance specification" represents the quality requirement.

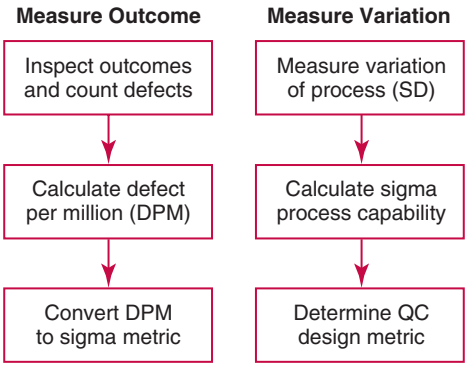

Figure 8-5 Six Sigma methods for measuring process performance. The method of measuring process variation is applicable to analytical testing processes.

enumeration of the area under the error curve plus or minus the tolerance limits (±2 S = 308,500 DPM; ±3 S = 66,800 DPM; ±4 S = 4350 DPM; ±5 S = 230 DPM; ±6 S = 3.4 DPM). In practice, Six Sigma provides a general method by which to describe process outcomes on the sigma scale.

To illustrate this assessment, consider the rates of malfunction for cardiac pacemakers. Analysis of approved annual reports submitted by manufacturers to the Food and Drug Administration (FDA) between 1990 and 2002 revealed that 2.25 million pacemakers were implanted in the United States. Overall, 17,323 devices were explanted because of confirmed malfunction.[70] The defect rate then is estimated at 7699 DPM (17,323/2,250,000), or 0.77%, which corresponds to a sigma of 3.92 using a DPM-to-sigma conversion calculator (http:www.isixsigma.com/sixsigma/six_sigma_calculator.asp?m=basic/accessed March 22, 2011). For comparison or benchmarking purposes, airline baggage handling has been described as 4.15 sigma performance, and airline safety (0.43 deaths per million passenger miles) as better than Six Sigma performance. A defect rate of 0.033% would be considered excellent in any healthcare organization, where error rates from 1 to 5% are often considered acceptable.[13] A 5.0% error rate corresponds to a 3.15 sigma performance, and a 1.0% error rate corresponds to 3.85 sigma. Six Sigma shows that the goal should be error rates of 0.1% (4.6 sigma) to 0.01% (5.2 sigma) and ultimately 0.001% (5.8 sigma).

The first application describing sigma metrics in a healthcare laboratory was published by Nevalainen et al[79] in the year 2000. This application focused on preanalytical and postanalytical processes. Order accuracy, for example, was observed to have an error rate of 1.8%, or 18,000 DPM, which corresponds to 3.6 sigma performance. Hematology specimen acceptability showed a 0.38% error rate, or 3800 DPM, which is a 4.15 sigma performance. The best performance observed was for the error rate in laboratory reports, which was only 0.0477%, or 477 DPM, or 4.80 sigma performance. The worst performance was therapeutic drug monitoring timing errors of 24.4%, or 244,000 DPM, which is 2.20 sigma performance.

Of the studies discussed in the previous section, it is possible to convert the error rates computed in DPM to sigma metrics. For example, for the Ross-Boone study,[92] the computed DPM corresponds to a 3.3 sigma long-term performance. For the Plebani et al study[86] a DPM of 620 DPM corresponds to a 3.2 sigma long-term performance. In the Ismail et al study,[51] a DPM of 5273 corresponds to a 2.6 sigma long-term performance. On average, this indicates about 3.0 sigma long-term performance.

The application of sigma metrics for assessing analytical performance depends on measuring process variation and determining *process capability* in sigma units.[95,110,126] This approach makes use of the information on precision and accuracy that laboratories acquire initially during method validation studies and have available on a continuing basis from internal and external quality control. An important aspect of this method is that the capability, or predictive performance, of the process must be ensured by proper quality control; therefore the ease of assessment comes with the responsibility to design and implement QC procedures that will detect medically important errors.

To apply this method, the tolerance limits are taken from performance criteria for external quality assessment programs or regulatory requirements [such as the U.S. Clinical Laboratory Improvement Amendment (CLIA) criteria for acceptable performance in proficiency testing]; process variation and bias can be estimated from method validation experiments, peer-comparison data, proficiency testing results, and routine QC data. For laboratory measurements, it is straightforward to calculate the sigma performance of a method from the imprecision: SD or CV and inaccuracy (bias) observed for a method and the quality requirement (allowable total error, TE_a) for the test [Sigma = (TE_a – bias)/SD]. For a cholesterol test with an NCEP total error of 9%, method bias of 1.0%, and method CV of 2.0%, the sigma metric is 4.0 [(9.0 – 1.0)/2]. If the method had a CV of 3.0% and a bias of 3.0% (the maximum allowable figures according to NCEP guidelines), the sigma metric is 2.0. Sigma metrics from 6.0 to 3.0 represent the range from "best case" to "worst case." Methods with Six Sigma performance are considered "world class"; methods with sigma performance less than 3 are not considered acceptable for production.

Those conclusions can be readily understood by considering the amount of quality control that is necessary for measurement processes having different performance metrics. Figure 8-6 shows a *power function graph* that describes the probability of rejecting an analytical run on the *y*-axis versus the size of the systematic error that has to be detected on the *x*-axis. The bold vertical lines correspond to methods having 3, 4, and 5 sigma performance (left to right). The different lines or power curves correspond to the control rules and the number of control measurements given in the key at the right (top to bottom). These different QC procedures have different sensitivities or capabilities for detecting analytical errors. Practical goals are to achieve a probability of error detection of 0.90 (i.e., a 90% chance of detecting the critically sized systematic error), while keeping the probability of false

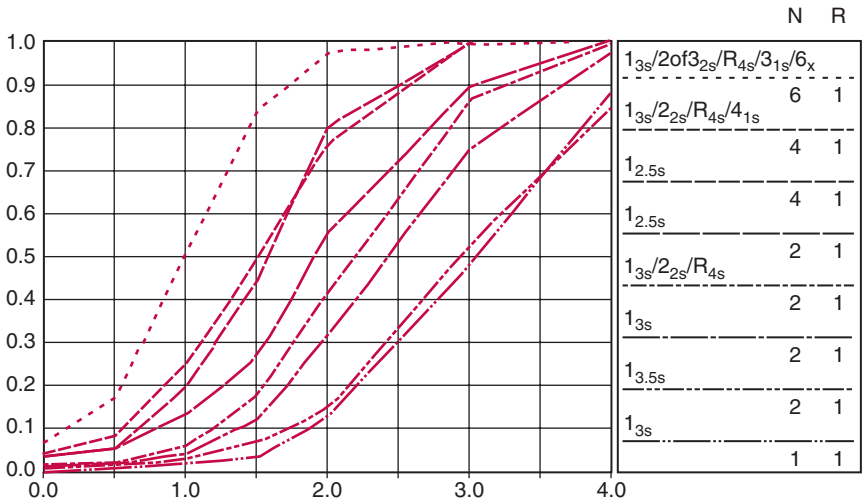

Figure 8-6 The probability for rejection is shown on the y-axis versus the size of the systematic error on the *x*-axis *(bottom scale)* or the sigma-metric of the measurement procedure *(top scale)*. The *vertical lines* represent measurement procedures having 3-sigma, 4-sigma, and 5-sigma performance. The key at the right identifies quality control (QC) procedures. The curves in the graph, top to bottom, match the list in the key, top to bottom. *N*, Total number of control measurements; *Pfr*, probability for false rejection; *R*, number of runs to which the QC procedure is applied.

rejection at 0.05 or less (i.e., 5% or lower chance of false alarms). This is easy to accomplish for processes with 5 to 6 sigma performance; it requires more careful selection and increased QC efforts for processes from 4 to 5 sigma, and it becomes very difficult and expensive for processes less than 4 sigma.

As demonstrated previously, the application of Six Sigma principles and metrics is very valuable for all phases of the laboratory testing process.[41A,46B] Because the core business of the laboratory is to produce accurate test results, it makes sense to first apply Six Sigma to the analytical processes. This also is the easiest application because there are tolerance limits in the form of acceptability criteria from peer-comparison and proficiency-testing programs, QC data available for estimating method precision, and peer data available for estimating method bias. Laboratories should next expand their efforts to the preanalytical and postanalytical processes, knowing that their core processes are producing the necessary analytical quality.

Effect of Analytical Bias on Clinical Decisions

Changes in analytical bias directly shift the distribution of patient test values. If the elevated values on a test are associated with specific clinical actions, then the shifts in analytical bias can notably alter the number of patients having test values that exceed the action limit.[56] For example, for a serum calcium assay with an action limit of 10.1 mg/dL, an upward bias of 0.2 mg/dL changes the number of patients subjected to further investigation from 6.5 to 15.0%. Similarly, analytical shifts in other critical analytes can cause notable clinical problems, such as false elevations of prostate-specific antigen values, triggering prostate ultrasound examinations and biopsies, and false elevation of thyroid-stimulating hormone (TSH), triggering additional thyroid examinations. These small analytical shifts can have major downstream effects on healthcare costs.

LEAN PRODUCTION

Lean production is a quality process that is focused on creating more value by eliminating activities that are considered waste. For example, any inefficient activity or process that consumes resources or adds cost or time without creating value is revised or eliminated. In practice, it focuses on *system level* improvements (as opposed to *point improvements*). Because of its success in enhancing efficiency environments,[10] the lean approach has proven useful wherever a defined set of activities is working to produce a product or service. For example, a "lean team" at Saint Mary's Hospital, a Mayo Clinic hospital in Rochester, Minnesota, used lean production to improve the efficiency of its paper ordering system for laboratory work in its intensive care unit.[69] Because the goal of lean production is to enhance efficiency and the Six Sigma Process to improve quality, they have been combined and integrated into the management of several organizations, including healthcare facilities[84,115,144] and clinical[99,106] and molecular diagnostic[28] laboratories.[46]

ELEMENTS OF A QUALITY ASSURANCE PROGRAM

Attainment of quality goals in a clinical laboratory requires a comprehensive quality assurance program. *Quality assurance* is used here to represent practices that are generally

recommended for ensuring that desired quality goals are achieved. It is a broad spectrum of plans, policies, and procedures that together provide an administrative structure for a laboratory's efforts to achieve quality goals. The term *quality control* is often used to represent those techniques and procedures that monitor performance parameters. Generally, these are quantitative techniques that monitor particular sources of errors, estimate the magnitude of the errors, and alert laboratory personnel when indications suggest that quality has deteriorated. A quality assurance program involves virtually everything and everybody in the clinical laboratory. An error in any one step during the (1) acquisition, (2) processing, (3) analysis of a specimen, and (4) reporting of a laboratory test result affects the quality of the analysis and causes the laboratory to fall short of its quality goals.

Commitment

Dedication to quality service must be central and reflect a team effort. Otherwise, quality goals are not likely to be achieved. Quality must be a major consideration in all management decisions because any single decision may compromise other plans and practices for attaining quality goals. A true commitment is required by laboratory directors, managers, and supervisors if the efforts of other laboratory personnel are to be successful.

Facilities and Resources

Laboratories must have the administrative support necessary to provide the quality of services desired. This means having (1) adequate space, (2) equipment, (3) materials, (4) supplies, (5) staffing, (6) supervision, and (7) budgetary resources. These resources provide the basis upon which quality services are developed and maintained.

Personnel Competency and Training*

People are critical components of a total quality system, and training and education are vital to the performance of personnel. A key factor in successful training and assessment of laboratory staff is the planning and implementation of targeted education programs. Given the shortage of clinical laboratorians in many countries, laboratories are providing in-depth training for both new and existing staff and are assessing their competency on an ongoing basis. In the United States, CLIA requires competency assessment as part of the laboratory quality system. In other countries, ISO 15189 requires competency assessment as part of the technical requirements for medical laboratories.

CLIA identifies the following six elements as required components of a laboratory competency assessment program: (1) direct observation of routine patient test performance; (2) monitoring of the recording and reporting of test results; (3) review of intermediate test results, QC records, proficiency testing results, and preventive maintenance records; (4) direct observation and performance of instrument maintenance and function checks; (5) assessment of test performance through testing previously analyzed specimens, internal blind testing samples, or external proficiency testing samples; and (6) assessment of problem-solving skills.[87]

Assessment of competence in job tasks as required by CLIA must be conducted semiannually the first year of employment and annually thereafter, and upon implementation of new test methods before patient test results are reported. Guidelines to assist in the development and documentation of competency assessment are available from the Clinical and Laboratory Standards Institute (CLSI). The CLSI Guideline, *Training and Competence Assessment,* gives detailed instructions on how to develop and implement a training and competency assessment program that meets regulatory requirements, and provides examples of forms for documentation and record keeping.[38]

Design of an in-service training program based on instructional systems design includes the following elements: (1) analysis, (2) design, (3) implementation, and (4) evaluation. It begins with a needs assessment or gap analysis to determine employee performance requirements, to identify deficiencies, and to evaluate existing education and training resources. It requires the development of measurable instructional objectives that are based on the specific skills and competencies required of the employee to perform the job or task, and selection of an appropriate teaching strategy. The in-service training program also considers how an instructional program will be delivered and a range of organizational factors that may impact the successful delivery of the instruction. These include (1) employee participation, (2) scheduling, (3) availability of subject matter experts to teach, (4) budget constraints, and (5) assessment of learning outcomes. It provides evaluation of the effectiveness of the instructional program.[39]

A workforce deficiency sometimes found with laboratory personnel is lack of academic education in basic quality control practices and statistical methods of analysis. Without formal training in statistical quality control for the clinical laboratory, employees are often taught what to do, but may not understand the "why," which can impact their ability to troubleshoot and problem-solve. This background understanding is difficult to teach in short, "in-service" laboratory sessions and generally is better provided in a more structured program. Implementing an in-house education program in basic quality control practices that is dependent on the availability of subject matter experts to provide the instruction may not be feasible. A cost-effective, alternative approach is to access experts through existing Web-based training programs and complement this with local problem-oriented examples.

In the face of increased pressures to reduce operating costs, including expenses associated with attendance at and travel to conferences, Internet education programs provide an effective, cost-efficient way to implement in-service training. Web-based training programs in quality control concepts are available through both professional organizations and private

*This information was provided by Susan M. Lehman, Director, Clinical Laboratory Science Program, Mayo Clinic, Rochester, MN.

companies. As an example, the Mayo Clinic identified that a gap in academic education in basic quality control concepts existed based on the diversity of its workforce and the varying academic backgrounds required for its highly specialized laboratories. To provide the desired level of academic education to its employees in a way that could be readily accomplished, employees were enrolled in the course *Basic QC Practices* available on the Web through Westgard QC Inc. The e-learning content of the curriculum includes the following modules: (1) statistical quality control, (2) construction and interpretation of Levey-Jennings control charts, (3) electronic checks and sources of error, (4) CLIA '88 regulations for QC, (5) control materials and limitations of QC, (6) multirule and multilevel interpretation of QC data, (7) false rejection and error detection, (8) troubleshooting, (9) regulatory guidelines, (10) QC documentation and record keeping, and (11) external quality assessment programs. In addition, the online curriculum was customized to employees' specific needs by adding staff lectures, six 2-hour laboratory sessions, assignments tailored to the clinical laboratory practice at Mayo, and pretesting and post-testing to assess competency.

Implementation of this in-house training program in basic quality control by the Mayo Clinic followed the educational model designed for the Clinical Laboratory Science Program. The didactic component is provided in an e-learning platform and is underscored by transactional distance theory,[76] whereby the three modalities of learner interaction with content, instructor, and fellow learners were integrated into the online module. Each lesson plan also includes a supplemental laboratory module taught by traditional methods of interaction between instructor and learner, which is closely anchored in the context of the work performed. Finally, the curricular model implements the *reverse lecture-homework paradigm,* whereby learners complete the Web-supported didactic modules asynchronously as "homework" assignments (Figure 8-7, *A*) and complete the laboratory lessons in the classroom (work setting) under the guidance and direction of the instructor/supervisor (Figure 8-7, *B*).

The in-service training program in quality control concepts follows the CLSI academic curricular model and applies the reverse lecture-homework paradigm (see Figure 8-7). To implement the program, employees complete 14 online lessons asynchronously, as "homework," and participate in 6 scheduled laboratory sessions taught in the traditional format, over a period of 3 weeks. The electronic curriculum includes employee interaction with the written quality control course content ("learner-content"), threaded discussions ("learner-learner"), and email ("learner-instructor"). The online material is applied directly during "hands-on" instructor-facilitated laboratory sessions that are problem-based and consist of a combination of case studies, laboratory activities, and discussions.

Implementing an e-learning platform allows the curricular model to expand the number of students over time toward an improved economy of scale. For academic programs, this approach allows for a potential increase in class size with minimal additional expenses. For in-service training, an electronic curriculum provides the opportunity to share training across different physical sites in a healthcare delivery system. This sharing will eliminate the costs associated with duplication of effort, reduce the operating cost to cover additional employees, and decrease the startup costs for new academic and in-service programs at additional sites.

Technical Procedures

Technical procedures necessary for laboratory services include the following:

1. Control of preanalytical conditions or variables, such as test requests, patient preparation, patient identification, specimen acquisition, specimen transport, specimen processing, specimen distribution, preparation of work lists and logs, and maintenance of records (see Chapters 6 and 9).[149]

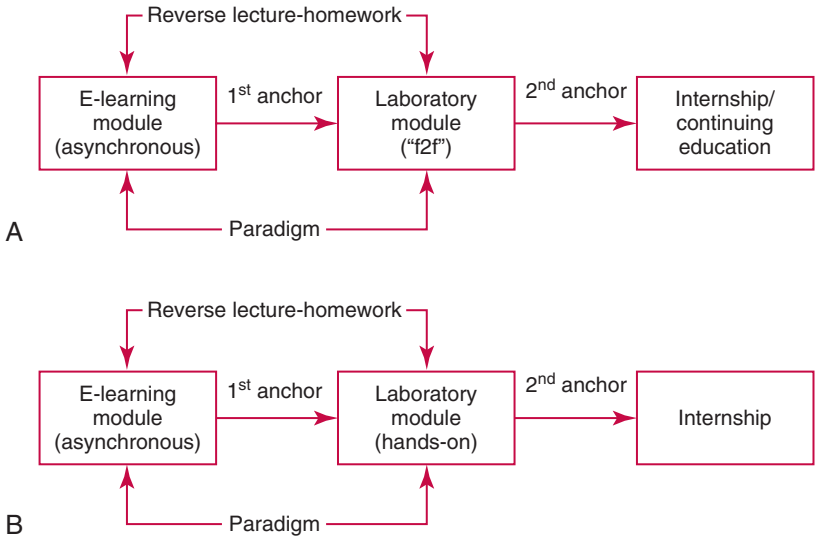

Figure 8-7 Examples of reverse lecture-homework paradigms.

2. Control of analytical variables, which include analytical methods, standardization and calibration procedures, documentation of analytical protocols and procedures, and monitoring of critical equipment and materials.
3. Monitoring of analytical quality through the use of statistical methods and control charts.
4. Control of postanalytical conditions or variables.

Problem-Solving Mechanism

Although it is a particularly critical element in a quality assurance program, the necessity for a mechanism for problem solving is often underemphasized. Such a mechanism provides the link between identification of a problem and implementation of a solution to the problem. It is a *feedback loop* that responds to an error signal by making adjustments to reduce the size of the error or to prevent its recurrence. For problems limited to individual methods or instrument systems, delegation of responsibility for the systems may provide the corrective mechanism. Specialized troubleshooting skills need to be developed and improved and preventive maintenance programs instituted. For problems that occur more generally, the in-service training program can be an important part of the mechanism but often requires additional input from a QC specialist or supervisor to initiate the use of this mechanism and to help define its objectives. A different approach to problem solving is the use of quality teams that meet regularly to analyze problems and identify solutions.[97] By involving personnel, quality teams heighten interest and commitment to quality and provide a creative feedback mechanism.

The comprehensive nature of quality assurance programs and their missions, goals, and activities have been discussed in greater detail by Eilers.[44] Detailed outlines of the elements of cost management for quality assurance are available,[45,54] as are detailed recommendations by professional organizations, such as the College of American Pathologists (CAP),[1] the CLSI,[33,35-37] and the International Federation of Clinical Chemistry,[22-27] and books devoted to quality assurance practices in clinical laboratories.[29,120]

CONTROL OF PREANALYTICAL VARIABLES

Systems Analysis

The operation of the clinical laboratory consists of a series of processes, each of which has potential sources of error. Table 8-1 shows the processes that take place from the time of the physician's initial request for a test to the time of final interpretation of the test result. This *systems analysis* identifies the critical processes for a typical laboratory; however, each laboratory situation is somewhat different, and additional processes and additional sources of error may be identified. It is important for each laboratory to perform a systems analysis of its own laboratory testing system to identify those areas where errors are likely to occur.

Once the processes have been documented, those that are most susceptible to error should be identified and should receive the most attention. Often, processes that lead to the greatest number of complaints, such as lost specimens or delayed results, are judged to be most important, even though other steps, such as appropriateness of test selection and the acceptability of a specimen, may be of greater importance for optimal medical care. Guidelines describing procedures for specimen handling are available from organizations such as the CLSI. Documents put forth by accrediting agencies, such as CAP,[1] Centers for Disease Control and Prevention, and state regulatory agencies, are also helpful in this regard.

TABLE 8-1 Laboratory Testing Processes and Their Potential Errors

Process	Potential Errors
Test ordering	Inappropriate test
	Handwriting not legible
	Wrong patient identification
	Special requirements not specified
	Cost or delayed order
Specimen acquisition	Incorrect tube or container
	Incorrect patient identification
	Inadequate volume
	Invalid specimen (e.g., hemolyzed, too dilute)
	Collected at wrong time
	Improper transport conditions
Analytical measurement	Instrument not calibrated correctly
	Specimen mixup
	Incorrect volume of specimen
	Interfering substance present
	Instrument precision problem
Test reporting	Wrong patient identification
	Report not posted in chart
	Report not legible
	Report delayed
	Transcription error
Test interpretation	Interfering substances not recognized
	Specificity of test not understood
	Precision limitations not recognized
	Analytical sensitivity not appropriate
	Previous values not available for comparison

Types of Preanalytical Variables

It is difficult to establish effective methods for monitoring and controlling preanalytical variables because many of these variables are outside of traditional laboratory areas (see Chapter 6). Monitoring of preanalytical variables requires the coordinated effort of many individuals and hospital departments, each of which must recognize the importance of these efforts in maintaining a high quality of service.

Accomplishing such monitoring may require support from outside the laboratory, particularly from the institution's clinical practice committee or some similar authority. Variables to consider are discussed in the following section.

Test Usage and Practice Guidelines

Traditionally, laboratory test utilization has been monitored or controlled to some degree, but current emphasis on the cost of medical care and government regulation of medical care has increased their importance. For example, clinical practice committees may decide that only certain tests are necessary for emergency care and therefore limit their availability. Peer review audits may lead to the development of other guidelines concerning the appropriate use of diagnostic tests in different clinical situations. Numerous patient care strategies and guidelines are being developed that directly impact laboratory usage.[55] For example, implementation guidelines for the use of bleeding times at the University of Massachusetts Medical Center resulted in a substantial reduction in test requests.[78] Careful monitoring of test requests and their appropriateness is likely to increase in importance, and the laboratory will likely have a role in identifying situations in which test utilization can be optimized and in providing in-service education to effect changes in ordering patterns.

Patient Identification

Correct identification of patients and specimens is a major concern for laboratories. The highest frequency of error occurs with the use of handwritten labels and request forms. One method for checking identification is to compare identifiers such as the patient's name and his or her unique hospital number. The identification on the specimen label should also correspond with the identification supplied with the test requisition. The use of plastic embossed patient identification cards to imprint the patient's name on test request forms and on blood collection labels can eliminate transcription and identification errors but does not guarantee that the patient name on the labels correctly identifies the donor of the specimen. Integration of bar code technology into the analytical systems used by clinical laboratories has significantly reduced within laboratory specimen identification problems (see Chapter 19).

Turnaround Time

Delayed and lost test requisitions, specimens, and reports have been major problems for laboratories. An essential feature in monitoring the cause of delays is the recording of actual times of specimen collection, receipt in the laboratory, and reporting of test results. This has been done manually by placing time stamps in key locations such as blood-drawing centers, specimen-processing stations, result-reporting areas, and wards or chart-posting areas. It also has been done more effectively by programming computer systems to automatically document the times of test requests, specimen acquisition, processing, analysis, and reporting.[91] Turnaround time has been monitored like any other QC variable, and limits established to flag "out-of-range" specimens. Lists of delayed specimens also provide a powerful mechanism for detecting lost specimens or reports. Resolution of problems in this area is aided by a systems analysis of laboratory operations, which helps to identify those steps and areas that cause delays and disruptions in service. A good system for monitoring patient, specimen, and information flow may be obtained through integration of the light wand and/or bar code or optical character identification system with a computer that could automatically track each specimen at each of the steps from test request to result posting.

Transcription Errors

In laboratories where electronic identification and tracking have not been implemented, a substantial risk of transcription error exists is associated with manual entry of data, even with double checking of results. Computerization will reduce this type of transcription error, as such systems often have error detection routines programmed into the terminal entry functions, such as check digits, limit checks, test correlation checks, and verification checks with master hospital files. Implementation of electronic data exchanges eliminates many of these transcription errors.

Patient Preparation

Laboratory tests are affected by many factors such as recent intake of food, alcohol, or drugs, and by smoking, exercise, stress, sleep, posture during specimen collection, and other variables (see Chapter 6). Proper patient preparation is essential for test results to be meaningful. Although responsibility for this usually resides with personnel outside the laboratory, the laboratory must define the instructions and procedures for patient preparation and specimen acquisition. These procedures should be included in hospital procedure manuals and should be transmitted to patients in both oral and written instructions. Compliance with these instructions is monitored directly when the laboratory employs its own phlebotomists. Specific inquiry should be made regarding patient preparation before specimens are collected, and efforts should be made to correct noncompliance. For tests in which standardization of the collection is very important (such as for plasma catecholamines), specimens should be collected in a controlled environment with appropriate supervision.

Specimen Collection

The techniques used to acquire a specimen affect many laboratory tests (see Chapter 7).[104] For example, prolonged tourniquet application causes local anoxia to cells and excessive venous back pressure. The anoxia causes small solutes (such as potassium) to leak from cells, and the venous pressure concentrates cells, proteins, and substances bound to proteins (such as calcium). Blood collected from an arm into which an intravenous infusion is running can be diluted or contaminated. Collection of blood through an indwelling catheter should be avoided because it is a major source of contamination. Hemolysis during and after collection alters the concentration of any analyte that has a red blood cell/plasma concentration differential. Improper containers and incorrect

preservatives greatly affect test results and make them inappropriate. One way to monitor and control this aspect of laboratory processing is to have a specially trained laboratory team assigned to specimen collection. All members of the team should be given explicit instruction in the proper methods of specimen collection. The identification of the person collecting a specimen should be maintained. Individuals who process the specimens should be trained to look for and document collection problems. Physicians should be encouraged to report clinically inconsistent results. Similarly, errors detected by limit checks, delta checks (differences between consecutive results on individual patients), or other algorithms should be recorded. Any collection problems should be reviewed with the individuals collecting the specimens. Pride of workmanship should be encouraged, and quality performance should be rewarded.

Specimen Transport

The stability of specimens during transport from the patient to the laboratory is seldom monitored; however, this aspect may be critical for some tests when performed locally and for most tests when sent to regional centers and commercial laboratories.[33] Most laboratories have recommendations for specimen storage and transport, but many of these are empirical and lack adequate scientific documentation. Even the definition of *stability* is not well agreed upon; some investigators accept changes less than 10%,[61,143] and others relate stability to medically significant changes[93] or a percentage of established analytical variability.[112]

In controlling specimen transport, the essential feature is the authority to reject specimens that arrive in the laboratory in an obviously unsatisfactory condition (such as a thawed specimen that should have remained frozen). As with other QC procedures, a small number of problems are expected, but if the error rate gets too large, systems analysis of transport procedures with resulting modifications may be necessary. In tests in which stability is a major problem, the design of specific control procedures appropriate for those tests may be necessary. Potential procedures would include the use of devices to record minimum and maximum temperatures and the use of refrigerated packs in shipping containers.

Accessioning and Documentation

When the serum aliquot tubes arrive in the laboratory, various logging and monitoring systems are necessary. In laboratories without computerized reporting, a request and/or report form generally accompanies the specimens. The specimen should be inspected to confirm adequacy of volume and freedom from problems that would interfere with the assay, such as lipemia or hemolysis. The specimens are then stored appropriately, and identification information and arrival time are recorded in a master log. If analyses are performed in batches, specimen identification generally is recorded in specific locations on the worksheets using the information on the tube labels. After analysis, results are recorded on the worksheet, and if both the assay and the individual test results pass the QC criteria, the test results are transferred to the result forms for reporting. However, before the results are reported, a second technologist should verify the adequacy of the QC and should check for transcription errors by comparing results on the report forms with those on the master log. Specimens that require further analysis because of dilution or assay problems should be indicated on the master log or on a delayed report log.

Specimen Separation and Aliquoting

Separating and aliquoting blood specimens are directly under the control of the laboratory. The main variables are the centrifuges, the containers used, and the personnel.

Centrifuge Performance

Centrifuges are discussed in Chapter 9. For QC purposes, centrifuges should be monitored by checking the speed, timer, and temperature.

Container Monitoring

Evaporation can substantially alter test results; therefore all containers should be sealed or the surface area of the liquids contained in them protected. Collection tubes, pipettes, stoppers, and aliquot tubes are sources of calcium and trace metal contamination. Also, glass beads and other materials added to blood specimens to aid in the separation of serum from cells may cause contamination. Manufacturers should provide reassurance that materials used are tested for contamination by calcium and possibly other elements. Cork stoppers should not be used on specimens intended for calcium determinations because false elevations of 10 to 50% may occur. Some of the plasticizers used in making plastic containers interfere with drug analyses. Also, some plastic materials adsorb trace amounts of some analytes and should not be used for substances in low concentration, such as parathyroid hormone.[52] Also, the effects of evaporation are important matters of concern during processing, storage, and analysis. Because of the intricate relationship between specimen processing and analytical testing, supplies and processing procedures should not be changed without consulting the personnel responsible for analytical testing (see also Chapter 7).

Clerical Errors

An elegant system for monitoring manual clerical functions was developed to detect errors in blood banking records.[109] In this system, known errors are discretely introduced into the system using fictitious patients. The types of errors introduced are chosen to represent errors likely to occur or errors that cause major problems. The fictitious reports are routed to dummy locations and eventually are returned to the QC technologist. One can calculate the efficiency of the laboratory error detection program by comparing the number of fictitious errors discovered versus the number introduced. This efficiency factor is then used to estimate the actual laboratory error rate based on the number of true errors discovered in the laboratory. Implementation of this scheme requires the cooperation of laboratory personnel and the involvement of a QC specialist. Through a combination of

paranoia and pride of workmanship, most personnel are more conscientious when they know they are being monitored. A substantial increase in the rate of error detection was observed shortly after this plan was implemented in the blood bank. Public display of individual error rates encourages pride in workmanship.

CONTROL OF ANALYTICAL VARIABLES

Reliable analytical methods are obtained by a careful process of selection, evaluation, implementation, maintenance, and control (see Chapter 2).

Certain variables—water quality, calibration of analytical balances, calibration of volumetric glassware and pipettes, stability of electrical power, and the temperature of heating baths, refrigerators, freezers, and centrifuges—should be monitored on a laboratory-wide basis because they will affect many of the methods used in the laboratory (see Chapter 9). In addition, certain variables will relate more directly to individual analytical methods, and these require that procedures be developed to deal specifically with the characteristics of those methods.

Choice of Analytical Method

Selection and evaluation of analytical methods are discussed in Chapter 2. It is important to recognize, however, that the initial evaluation of a method often takes place in a setting somewhat more idealized than the production setting. Therefore, it is desirable to have a startup period in the service laboratory before test results are to be reported. This period allows time to (1) discover any additional problems, (2) develop maintenance programs that alleviate those problems, and (3) train a sufficient number of analysts to support the routine service operation.

Reference Materials and Methods

Reference materials and methods used are major factors in determining the quality and reliability of the analytical values produced by a clinical laboratory. Uriano[113] and Tietz[111] have defined a hierarchy of analytical methods and reference materials that shows the relationship between them. For example, *definitive methods* are those of highest quality that are used to validate reference methods and primary reference materials. *Primary reference materials* are those of the highest quality that are used in the (1) development and validation of reference methods, (2) calibration of definitive and reference methods, and (3) production of secondary reference materials. *Reference methods* are used to validate field methods. *Secondary reference materials* are used to provide working calibrators for field methods and to assign values to control materials. *Control materials* are used only to monitor field methods.

Definitions of Relevance to Analytical Quality

Many organizations have developed definitions for terms of analytical relevance to the clinical laboratory. Depending on the organization that developed them and the circumstances and culture under which they were developed, definitions for the same term are often slightly different. As part of its global harmonization effort, the CLSI has developed the Harmonized Terminology Database, which is a compilation of internationally accepted terminology (http://www.clsi.org/Content/NavigationMenu/Resources/HarmonizedTerminologyDatabase/Harmonized_Terminolo.htm/accessed March 22, 2011). To use it, one clicks on the Website and then simply enters the term of interest, and definitions for that term are listed. Standard, internationally preferred terms and definitions are highlighted in **blue.** Terms and definitions in black are acceptable; but *only if* the standard internationally preferred terms and definitions are unacceptable for a certain context. Terms highlighted in **red** *are not* acceptable in the international standards community.

In general, the international standards community uses the definitions listed in the *Vocabulary of Basic and General Terms in Metrology* (VIM) document produced by the International Organization for Standardization (ISO). Several of these definitions that are of particular interest to clinical laboratorians are listed in Table 8-2.

ANALYTICAL TRACEABILITY

Considerable effort has been spent in developing a traceable accuracy base for measurands of clinical interest (Figure 8-8).[3,9,41,111,114] The driver to develop such a base was the European Directive 98/79/EC, which requires that "the traceability of values assigned to calibrators and/or control materials must be assured through available reference measurement procedures and/or available reference materials of a higher order" (www.ce-mark.com/ivd.pdf/accessed March 22, 2011). It became effective on December 7, 2003.

In 2002, the Joint Committee for Traceability in Laboratory Medicine (JCTLM) was created to provide a worldwide platform to promote and give guidance on internationally recognized and accepted equivalence of measurements in laboratory medicine and traceability to appropriate measurement standards (http://www.bipm.org/en/committees/jc/jctlm/accessed March 22, 2011), and to review and list reference methods, materials, and laboratories that provide higher order measurement methods. The original three principal participants in JCTLM were the International Bureau of Weights and Measures (BIPM), the International Federation for Clinical Chemistry and Laboratory Medicine (IFCC), and the International Laboratory Accreditation Cooperation. Other key participants include producers of certified reference materials [e.g., National Institute for Standards and Technology (NIST), the Institute for Reference Materials and Measurements (IRMM)]. In vitro diagnostic (IVD) manufacturers are represented by the Advanced Medical Technology Association (AdvaMed) and the European Diagnostic Manufacturers Association (EDMA); external quality assessment and proficiency testing organizations; standards organizations (e.g., CLSI, ISO/Technical Committee 212); and regulatory bodies [e.g., FDA, European Union (EU) authorities, European Commission].

Arrows pointing to the left indicate value assignment activity using the procedure; arrows pointing to the right indicate calibration activity using the material. *(Reproduced from Vesper HW, Thienpont LM. Traceability in laboratory medicine. Clin Chem 2009;55:1067-75. With permission from The American Association for Clinical Chemistry. Publishing for Clinical Chemistry Journal.)*

The JCTLM has created two working groups: (1) JCTLM WG-I, Reference Materials and Reference Procedures, and (2) JCTLM WG-II, Reference Laboratory Networks. They are responsible for providing practical support to the worldwide IVD industry in establishing metrological traceability for values assigned to calibrators and/or control materials as required by the European Directive on in vitro diagnostics and by comparable regulations in other countries. Also, the JCTLM is considering forming two additional working groups—one dealing with publications (WR-III), and one with master comparisons (WG-IV).

Role of International Organization for Standardization (ISO)

ISO is a worldwide federation of national standards bodies from more than 150 countries (http://www.iso.ch) accessed March 22, 2011. The work of the ISO results in international agreements, which are published as international standards. The ISO 9000 standards are examples of such standards, and they have been applied on a worldwide basis. The ISO has several technical committees that address quality issues of interest to clinical laboratorians.

ISO 9000

ISO 9000 is a set of standards for ensuring quality management and quality assurance in manufacturing and service industries. They were first published in 1987 and are used worldwide, with more than 80 countries adopting them as national standards. ISO 9000 certification is a tangible expression of an organization's commitment to quality that is recognized internationally. Many major diagnostic companies and healthcare facilities have received ISO 9000 certification.

The ISO 9000 standards include the following:

ISO 9000:2005: Quality management systems—Fundamentals and vocabulary

ISO 9001:2008: Quality management systems—Requirements

ISO 9004:2009: Managing for the sustained success of an organization—A quality management approach

ISO Technical Advisory Groups for Laboratory Standards

The ISO has a number of technical committees that relate to quality activities in the clinical laboratory. For example, in response to a CLSI [then National Committee for Clinical Laboratory Standards (NCCLS)] proposal, the ISO organized in 1995 a Technical Advisory Group (TC 212—Clinical Laboratory Testing and In Vitro Diagnostic Testing Systems). The ISO has delegated responsibility for managing TC 212 to the American National Standards Institute (ANSI), which, in turn, has delegated this responsibility to CLSI. Creation of this technical committee provides a focus for coordination of international standardization in the field of laboratory medicine and in vitro diagnostic test systems. Four working groups for TC 212 have been organized:

- WG 1—Quality management in the clinical laboratory
- WG 2—Reference systems
- WG 3—In vitro diagnostic products
- WG-4—Antimicrobial susceptibility testing

tahir99-VRG & vip.persianss.ir

These working groups have produced a number of documents (Table 8-3).

ISO 15189:2007 is an example of an ISO document; it was published by the ISO in 2007 and is based on ISO 9001:2000 and ISO 17025:2005, the latter being a standard for testing and calibration laboratories.

ISO 15189:2007 identifies specific management requirements, such as laboratory organization and management, a quality management system, document control, review of contracts, evaluation by referral laboratories, external services and supplies, advisory services, resolution of complaints, identification and control of nonconformities, corrective action, preventive action, continual improvement, quality and technical records, internal audit, and management review. Technical requirements cover personnel, accommodation and environmental conditions, laboratory equipment, preexamination procedures, examination procedures, assurance of quality of examination procedures, postexamination procedures, and reporting of results. Annexes provide tables that correlate the requirements between ISO 9001:2000 and ISO/IEC 17025:2005. In addition, there are annexes with recommendations for protection of laboratory information systems, ethics in laboratory medicine, and point-of-care testing (POCT).

Other ISO technical committees that relate to quality in healthcare include (1) TC 48—Laboratory Glassware and Related Apparatus; (2) TC 76—Transfusion, Infusion, and Injection Equipment for Medical Use; (3) TC 176—Quality Management and Quality Assurance; (4) TC 210—Quality Management and Corresponding General Aspects for Medical Devices; and TC 215—Health Informatics. ISO/TC 76 is particularly concerned with development of standards for glass containers for blood transfusions, plastic containers for blood collection and transfusion, and blood specimen containers for hematology and biochemistry.

Preparing for ISO Accreditation

In 2002, Burnett compared ISO standards and synthesized an "ideal standard" that became a practical guide for laboratories preparing for ISO accreditation.[21] In his comparison, he supplements the original ISO standards and illustrates their application and provides many examples of specific forms and policies that would be appropriate for a laboratory. He also provides additional technical information about the quality required for the "intended use" of laboratory tests, which is important if the goal of uniform quality is to be achieved for a patient who moves from place to place and from country to country.

Documentation of Analytical Protocols

Step-by-step procedures for performing analytical determinations are critical if the methods are to provide the same results when used by different analysts over a long period of time. Maintaining such consistency requires written protocols or methods and procedure manuals. Examples of process and procedure documents are available in a CLSI document,[35] which includes template documents for preanalytical, analytical, and postanalytical laboratory activities. Method procedures and manuals should be reviewed annually and revised whenever changes occur. It is also a good practice to retain outdated procedures in an archival file.

Establishment of Reference Intervals

Details for the establishment of reference values are presented in Chapter 5. A CLSI document is also available on the topic.[34]

Inventory Control of Materials

Stable operation of laboratory methods is critically dependent on the materials used with the methods. Storage temperatures for stability should be defined and monitored. Procedures are necessary to inventory materials and initiate orders when supplies are low. These procedures must be tailored to the particular reagents and supplies that are in use. In general, when materials are stable and changes in lot numbers cause problems, large stocks should be maintained, although this may be limited by economic considerations, shelf life, and storage space. Adequate inventory should be maintained to allow time for additional shipment and testing of additional supplies should the current shipment be unsatisfactory. Formal inventory control procedures will help minimize required storage by initiating orders when stock reaches a certain predetermined level. Many companies will ship reagents on a standing order once usage rates are established. In fact, with the arrival of rapid transportation and delivery capabilities, a laboratory is now able to order reagents and supplies and receive them in a very short period of time—a "just-in-time" approach to inventory control.

Input Control of Materials

Along with inventory management, the quality of materials should be monitored when they are received. Interruptions in service can be prevented by testing the adequacy of materials before their introduction for routine use. It is particularly important that patient results from new lots of reagents and calibrators be compared with those obtained with previous lots. It also is important to measure QC materials and reassign target values if they change with new lots of reagents. New lots of blood-drawing tubes, processing tubes, and the like should undergo some parallel or comparison testing before their routine use. In establishing pretesting procedures for monitoring incoming materials, it should be recognized that this kind of testing is costly, in terms of both time and money.

Another part of input control is the proper labeling of reagents and materials. Proper identification should include the name, lot number (particular manufacturing batch) and concentration, date received, date prepared, date opened, date of expiration, and recommended storage conditions. In practice, such information is provided by manufacturers via a human-readable bar code.

Monitoring Method Changes

An essential tool for solving analytical problems is a record or log of all changes and problems occurring with a method.

This should include the date, time, analyst, and any changes in lots of reagents, materials, or calibrators. All instrument maintenance should be recorded, including all work performed by service personnel from outside the laboratory. The occurrence of control problems should be indicated, along with actions taken to resolve the problems. Periodic review of these logs should lead to implementation of preventive maintenance programs, based on the frequency of occurrence of particular problems.

CONTROL OF ANALYTICAL QUALITY USING STABLE CONTROL MATERIALS AND CONTROL CHARTS

In the routine operation of clinical laboratories worldwide, the performance of analytical methods is routinely monitored by analyzing specimens whose concentrations or activities are known, followed by comparing observed values with known values. Known values are usually represented by an interval of acceptable values, or upper and lower limits for control (control limits). When observed values fall within the control limits, the analyst is assured that the analytical method is functioning properly. When observed values fall outside the control limits, the analyst should be alerted to the possibility of problems in the analytical determination. A number of books are available that discuss the application of QC in the operation of the clinical laboratory.[19,29,118,119,130] CLSI document C24 is a good consensus guideline for statistical QC.

Control Materials

Specimens that are analyzed for QC purposes are called *control materials.* They are required to be (1) stable, (2) available in aliquots or vials, and (3) amenable to analysis periodically over a long time. Little vial-to-vial variation should occur, so that differences between repeated measurements are attributed to the analytical method alone. The control material preferably should have the same matrix as the test specimens of interest (e.g., a protein matrix may be best when serum is the test material to be analyzed by the analytical method).[73] Materials from human sources have generally been preferred, but because there is some risk of hepatitis infection, bovine and synthetic materials offer a certain advantage in safety. The concentration of analyte should be in normal and abnormal intervals, corresponding to concentrations that are critical in the medical interpretation of test results.

In practice, clinical laboratories are able to purchase materials from one of several companies that manufacture control sera or "control products." These are generally supplied as liquid, frozen, or lyophilized materials that are reconstituted by adding water or a specific diluent solution. Also available are materials that have matrices representing urine, spinal fluid, and whole blood. Liquid control materials have the potential advantage of eliminating errors caused by reconstitution. However, the matrices of these control materials may contain other materials that are a potential source of error with some analytical methods and instruments.

When commercial control materials are selected, several other elements, in addition to the matrix of the product, should be considered. Stability is critical because it is often desirable to purchase a year's supply of one manufacturing lot or batch. Different batches (or lot numbers) of the same material will have different concentrations, which require new estimates of the mean and standard deviation. The size of the aliquots or vials should be convenient for analytical methods to be monitored. Larger vials are generally less expensive (on a per milliliter basis), but unused materials may eliminate any savings. Two or three different materials should be selected to provide concentrations that monitor performance at different medical decision levels. There may be some advantage in selecting materials from different manufacturers to minimize possible problems with a given manufacturing process. Alternatively, a series of materials designed by one manufacturer to have a certain relationship between concentrations can be used to gain additional information regarding linearity and accuracy.

Control products are purchased as assayed or unassayed materials. Assayed materials come with a list of values for the concentrations that are expected for that material. This list often includes both the mean and the standard deviation for several of the common analytical methods and preferably for a reference method used to measure a particular analyte. Because of the work required to determine these values, assayed materials in general are more expensive. Although the stated assay values are useful in selecting the desired materials, it is advisable to determine the mean and the standard deviation in the user's laboratory, because this process improves the performance characteristics of statistical control procedures.

General Principles of Control Charts

The most common method of comparing the values observed for control materials with their known values is the use of control charts. Control charts are simple graphical displays in which the observed values are plotted versus the time when the observations were made.* The known values are represented by an acceptable range of values, as indicated on the chart by lines for upper and lower control limits. When plotted points fall within control limits, this is generally interpreted to mean that the method is performing properly. When points fall outside the control limits, this may signify a problem with the analytical system or with the controls.

Control limits are usually calculated from the mean ($\bar{x}$) and standard deviation(s) obtained from repeated measurements on known specimens by the particular analytical method that is to be controlled. The mean ($\bar{x}$) and standard deviation(s) are calculated from the following equations:

*Although the discussions in this chapter imply that plots are manually prepared, in actual practice, a wide variety of computer software packages are available for statistically calculating and plotting QA data.

tahir99-VRG & vip.persianss.ir

$$\bar{x} = \frac{\sum x_i}{n}$$

$$s = \sqrt{\frac{n\sum_{i=1}^{n} x_i^2 - \sum_{i=1}^{n} (x_i)^2}{n(n-1)}}$$

where x_i is an individual control observation and n is the number of observations in the time period being monitored (see Chapter 2). The initial estimate should be based on measurements obtained over a period of at least 20 days when the method is working properly. These conditions are necessary because the measurements are used to characterize the distribution of values that is expected during stable routine operation of the analytical method.

Also, not all sources of variability may be encountered during this 20-day interval. For example, some sources of variability, such as reagent lot changes, changes with different matrix-related biases for the QC materials, calibrator lot changes with small shifts in results, maintenance cycles, etc, occur at periodic intervals. These sources of variability explain why the cumulative estimate of SD is more reliable as a measure of expected variability, because it includes more sources of variability. The initial estimate may not be entirely reliable owing to the low number of data points and possible outliers in the data. The estimates are revised when more data have been accumulated by recording n and the summations of x_i and x_i2, then using the cumulative totals in the previous equations to obtain cumulative means and standard deviations. The effects of outliers can be minimized by eliminating values exceeding the mean by more than ±3.1 to ±3.8 s (where the exact factor depends on the total number of data points: 3.14 for n = 30; 3.22, n = 40; 3.33, n = 60; 3.41, n = 80; 3.47, n =100; 3.66, n = 200; 3.83, n = 400).

It is assumed that the error distribution of the analytical method is Gaussian (see Chapter 2). The control limits are set to include most of the control values, usually 95 to 99.7%, which correspond to the mean ±2 or 3 SDs. Because it should be a relatively rare occurrence to observe a value in the tails of the distribution (only 1 out of 20 times for 2 s limits and 3 out of 1000 for 3 s limits), such an observation is suspect and suggests that something has happened to the analytical method. Such an occurrence could have caused a shift in the mean (an accuracy problem), which would result in a higher probability of exceeding the limits, or it could have caused an increase in the SD (a precision problem), which would widen the distribution and also result in a higher probability of exceeding the limits.

Figure 8-9, *A*, illustrates how the distributions of control values will appear for three different situations: (1) stable performance where only an occasional observation exceeds the control limits, (2) occurrence of a systematic error that shifts the mean of the distribution and causes a much higher expectation or probability of observing control values outside one of the control limits, and (3) occurrence of an increase in random error or imprecision, which widens the distribution and causes a much higher probability of observing a control value outside either of the control limits.

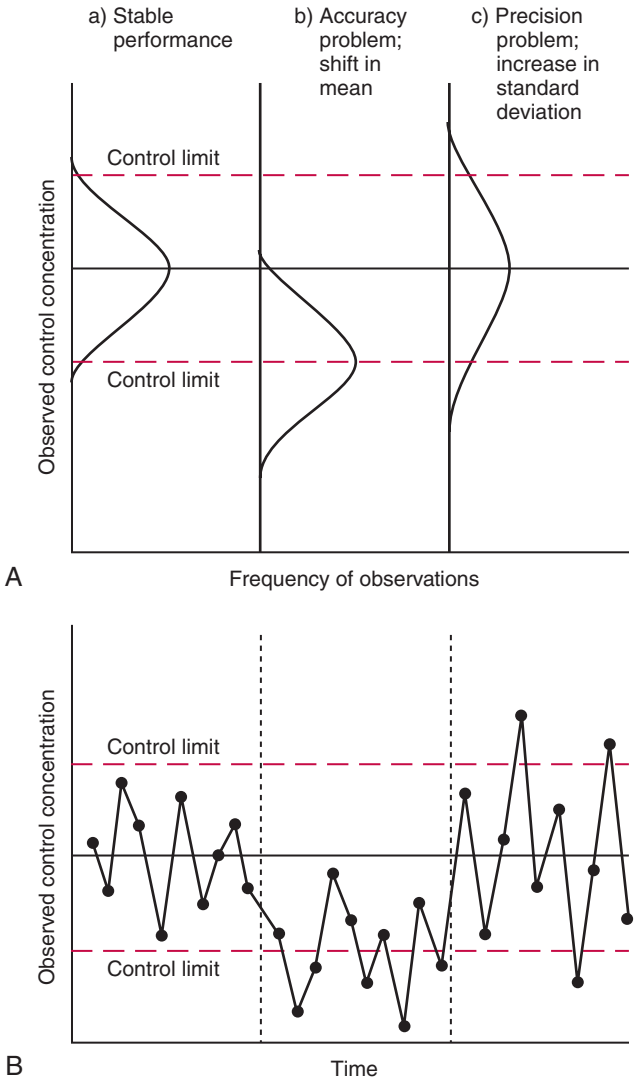

Figure 8-9 Conceptual basis of control charts. A, Frequency distributions of control observations for different error conditions. B, Display of control values representing those distributions when concentration is plotted versus time on a control chart.

Control charts are used to compare observed control values with control limits and to provide a visual display that can be quickly inspected and reviewed. These charts have the concentration or observed value plotted on the y-axis versus time of observation on the x-axis. It is common practice to plot 1 month's data on a chart—usually only one or two points a day—but the time axis should be chosen to be appropriate for the method being monitored. An example of a control chart is shown in Figure 8-9, *B*, where the control values represent the three situations in Figure 8-9, *A*, with 10 values per situation for a total of 30 values. When the analytical method is operating properly, the control values fall predominantly within the control limits. When there is an accuracy

tahir99-VRG & vip.persianss.ir

problem, the control values are shifted to one side, and several values in a row may fall outside one of the limits. When a precision problem occurs, the control values fluctuate much more widely, and values may exceed both upper and lower control limits.

Interpretation of the control data is guided by certain decision criteria or control rules, which define when an analytical run is judged "in control" (acceptable) or "out of control" (unacceptable). These control rules are given symbols, such as A_L, or n_L, where A is the abbreviation for a statistic, n is the number of control observations, and L refers to the control limits. For example, 1_{3s} refers to a control rule where 1 observation exceeding the mean ±3 s control limits is the criterion for rejecting the analytical run.

Analytical run is used here to refer to that segment of data for which a decision on acceptability is to be made. This is the group of patient results that is to be reported based on control results available for inspection at that time.

The total number of control observations available for inspection when a decision is to be made on the acceptability of an analytical run is designated as "*N*." For example, when one control observation precedes and one follows a group of 10 patient samples whose results are to be reported, two control observations are included in this analytical run.

The different control procedures discussed here have different performance capabilities, depending on the control rules and the number of control observations chosen. These choices should be related to the quality goals set by the laboratory. Many of the procedures in use today have been chosen not for best performance, but rather for ease of use in manual implementation or rule availability in the QC software of instruments and laboratory information systems. Tetrault and Steindel contend that the best set of control rules will vary from method to method.[109] Knowledge of the performance characteristics of control procedures is necessary to select control rules and *n*'s that will detect relevant laboratory problems without causing too many "false alarms" (rejections when there are no analytical problems). Experienced analysts often employ a series of informal rules or judgments to reduce the number of false alarms without knowing their effects on the detection of real problems, or true alarms. There should be some quantitative assessment of these two characteristics—false alarms and true alarms—whenever capabilities of new control procedures are assessed or established control procedures are reviewed.

Performance Characteristics of a Control Procedure

The performance of a control procedure is described by its probability for rejection.[137] *Probability* refers to the likelihood that an event will occur; in this case, the event is the rejection of an analytical run. Ideally, there should be no rejections of analytical runs when the analytical method is performing properly. Alternatively, when analytical errors occur, the control procedure should provide a rejection signal. This corresponds to having a probability of 0.00 in the first situation and a probability of 1.00 in the second.

The term *probability for false rejection* (p_{fr}) is used to describe the first situation, in which no analytical errors are present except for the inherent imprecision or inherent random error of the analytical method. (Some random error is always associated with an analytical method, even when it is working properly. This is the random error that is estimated by the replication experiment during method evaluation studies.) When only this inherent random error is present, without any additional errors, the probability for false rejection should be zero. The frequency of false rejection is critical, because false rejections are like false alarms. Too many false alarms cause the analyst to disregard the alarm system, even when the alarm is occurring as a result of real errors that should be corrected.

Probability for error detection (p_{ed}) is the term used to describe the second case, in which there is an analytical error, in addition to the inherent or background random error. The probability for error detection should be high (near 1.00) when these errors are large enough to invalidate the quality goals for the analytical method. Unfortunately, this is difficult to achieve because the control procedure is attempting to detect a signal (additional error) in the presence of noise (inherent random error).

These critical performance characteristics—probability for false rejection and probability for error detection—are summarized by graphs of probability for rejection (*y*-axis) versus the size of analytical error (*x*-axis). Graphs such as that shown in Figure 8-10 are called *power functions* because they describe the statistical power of the control procedure.[135] The different lines on the graph represent different numbers of control observations (e.g., $n = 1$, 2, and 4 for the three lines on this graph). The probability for false rejection is given by the

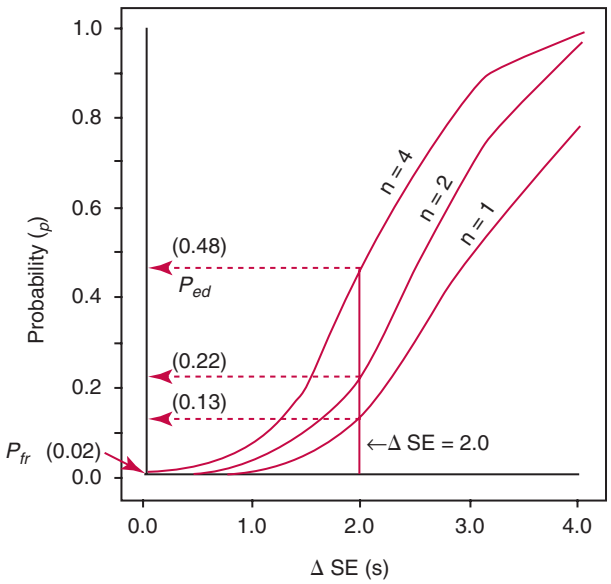

Figure 8-10 Power function graph presenting probability for rejection on the *y*-axis versus size of the error on the *x*-axis. The different lines represent numbers of control observations, in this case, $n = 1$, 2, and 4.

tahir99-VRG & vip.persianss.ir

y-intercept, the point where each line intersects the *y*-axis. For this control procedure with *n* from 1 to 4, p_{fr} is 0.01 to 0.02, or 1 to 2%. The probability for error detection can be determined for an error of any size by locating the size of the error on the *x*-axis, drawing a line up to intersect the power function curve, drawing a horizontal line from the point of intersection to the *y*-axis, and reading the probability for rejection from the scale on the *y*-axis. For this control procedure, p_{ed} is 0.13 for $n = 1$, 0.22 for $n = 2$, and 0.48 for $n = 4$. Thus there is a 13 to 48% chance of detecting an error of this size with this control procedure, depending on the number of control observations used.

Two power function graphs are necessary: one to describe the performance for random error (RE) and the other for the performance for systematic error (SE). For RE, as shown in Figure 8-11, *A*, the *x*-axis is labeled ΔRE. A value of 1.0 is consistent with the standard deviation of the analytical method; when the system is working properly, a value of 2.0 corresponds to a doubling of the initial standard deviation, 3.0 to a tripling, and so forth. For systematic error, the *x*-axis is labeled ΔSE (Figure 8-11, *B*). A value of 1.0 s corresponds to a systematic shift equivalent to the size of the standard deviation, a value of 2.0 s to a shift equivalent to two times s, and so forth.

Power functions are determined by mathematical calculations or by computer simulation studies, the latter having been used in clinical laboratories to characterize many of the commonly used control procedures.[47,135] Power functions are useful for evaluating the performance capabilities of individual control procedures, for comparing the performance of different control procedures, and for designing new procedures with improved performance characteristics. The best control procedure is the one with the lowest probability for false rejection and the highest probability for detecting those errors that are large enough to invalidate the analytical quality goals for the method.

The sizes of the analytical errors that must be detected if the control procedure is to maintain a specified quality can be determined from a general analytical model for translating quality requirements into laboratory process specifications.[142]

$$TE_a = bias_{meas} + \Delta SE_{cont} s_{meas} + z\Delta RE_{cont} s_{meas}$$

TE_a is the analytical quality requirement expressed as an allowable total error. Minimum total error requirements for between laboratory proficiency testing evaluations are defined by the CLIA proficiency testing criteria for acceptable performance (see later section). $Bias_{meas}$ is the analytical measurement bias (stable inaccuracy), s_{meas} is the analytical measurement standard deviation (stable imprecision), ΔSE_{cont} is the change in systematic error (unstable inaccuracy) to be detected by the control procedure, ΔRE_{cont} is the change in random error (unstable imprecision) to be detected by the control procedure, and *z* is related to the chance of exceeding the quality requirement. When *z* is 1.65, a maximum defect rate of 5% may occur before an analytical run is rejected.

This analytical model is solved for ΔSE_{cont} (by setting ΔRE_{cont} to 1.0) or for ΔRE_{cont} (by setting ΔSE_{cont} to 0.0) to determine the critical sizes of errors that must be detected to maintain performance within the specified quality:

$$\Delta SE_{crit} = [(TE_a - |bias_{meas}|)/s_{meas}] - 1.65$$
$$\Delta RE_{crit} = (TE_a - |bias_{meas}|)/1.65\, s_{meas}$$

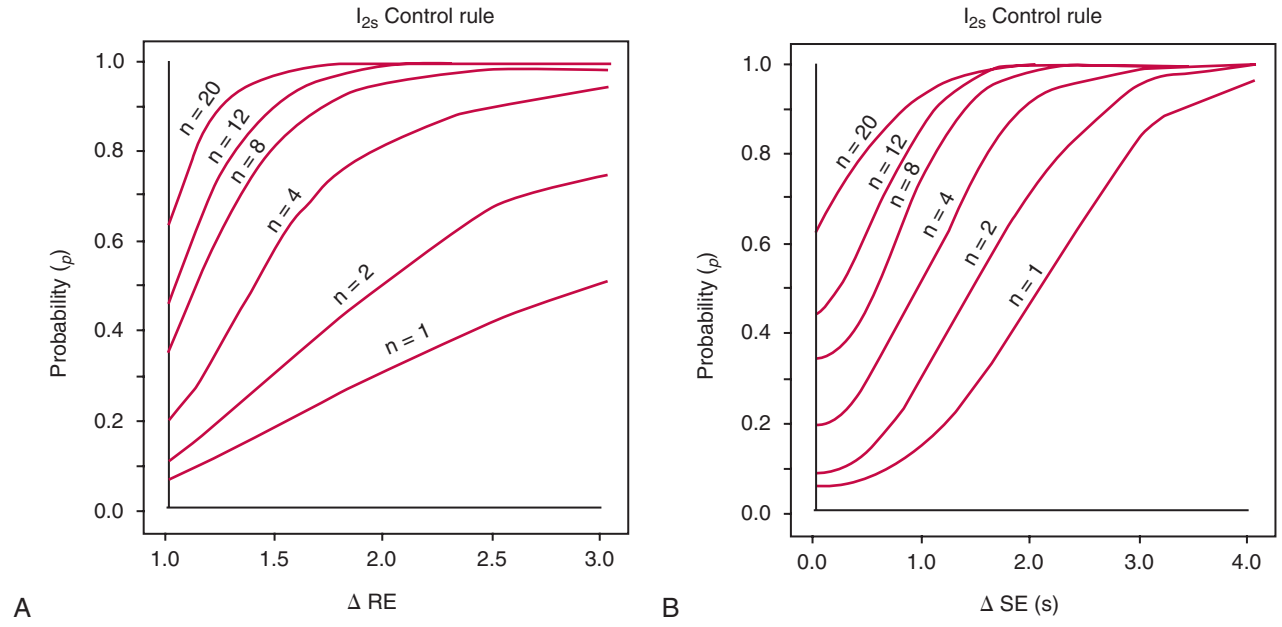

Figure 8-11 Power functions for 12s control rule. A, Random error. B, Systematic error. *(From Westgard JO, Groth T. Power functions for statistical control rules. Clin Chem 1979;25:863-9.)*

tahir99-VRG & vip.persianss.ir

ΔSE_{crit} is the critical systematic error that would shift the distribution enough to cause 5% of the test results to exceed TE_a; ΔRE_{crit} is the critical increase in random error that would widen the distribution enough to cause 5% of the test results to exceed TE_a ($z = 1.65$ for 5% on one side; $z = 1.96$ for 2.5% on each side).

For example, if TE_a were specified as 10 mg/dL at a concentration of 120 mg/dL, and s_{meas} were estimated as 2.0 mg/dL and $bias_{meas}$ as 0.0 mg/dL, ΔSE_{crit} would be 3.35, and ΔRE_{crit} would be 3.03. This indicates that the control procedure has to be able to detect a systematic shift equivalent to 6.7 mg/dL (3.35 s) and a random error equivalent to a standard deviation of 6.1 mg/dL (3.03 s).

With knowledge of these values for critical errors and the power functions for a control procedure, it is possible to make a critical assessment of the performance achievable by different statistical control procedures. The quality of the control procedures themselves can be evaluated and related to the quality goals defined for the laboratory.

The relationship between the quality requirement for a test, the imprecision and inaccuracy that are allowable, and the QC that is necessary is shown graphically by a chart of operating specifications (OPSpecs chart).[117,121] Figure 8-12 shows such a chart that has been prepared for a TE_a of 10%, single rules and multirules with *n*'s that are commonly used in laboratories, and a p_{ed} of 0.90 or 90% error detection for systematic errors. This OPSpecs chart is derived from the analytical quality planning model shown earlier, setting ΔRE to 1.0, then rearranging as follows:

$$bias_{meas} = TE_a - (\Delta SE_{cont} + 1.65)s_{meas}$$

Notice that this equation has the form of a straight line ($Y = a + bX$), where the *y*-intercept *(a)* is TE_a and the slope *(b)* depends on the sensitivity of the QC procedure. The value for ΔSE_{cont} is obtained from power curves for the control rules and *n*'s of interest and for specified probabilities, such as 90% and 50%.[117] A plot of $bias_{meas}$ versus s_{meas} will describe the allowable limits of imprecision and inaccuracy for different control rules and different numbers of control measurements. A QC procedure can be selected by plotting the observed inaccuracy and imprecision as the method's operating point, then identifying the control rules and *n*'s of the lines above the operating point.

For this example, where the observed imprecision is 2.0% and the observed inaccuracy is 1.0%, the four lines above the operating point correspond to the top four QC procedures listed in the key on the right. All four will provide at least 90% detection of critical systematic errors, but their false rejection rates will vary from 0.03 to 0.18, or 3 to 18%. Appropriate choices would be the $1_{2.5s}$ single rule with $n = 4$, or the $1_{3s}/2_{2s}/R_{4s}/4_{1s}$ multirule with $n = 4$, to keep false rejections low.

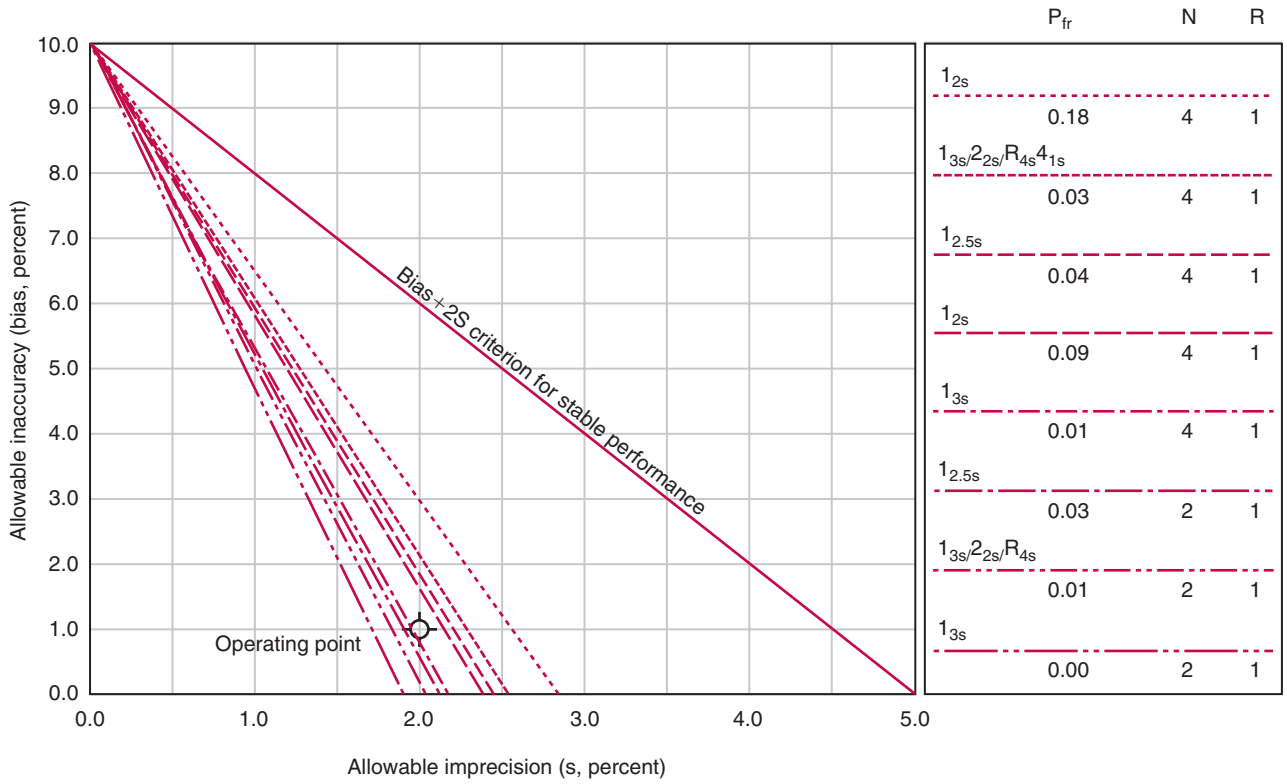

Figure 8-12 Operating specifications chart for an analytical quality requirement of 10% *(Te_a)* and an analytical quality assurance for systematic error of 90%. Allowable inaccuracy is plotted on the *y*-axis versus allowable imprecision on the *x*-axis.

tahir99-VRG & vip.persianss.ir

Step-by-Step Process for Selecting QC Procedures

Laboratories should establish a systematic process for selecting appropriate QC procedures. The necessity for this is illustrated by the statement in the U.S. CLIA regulations[101] that "the laboratory must evaluate instrument and reagent stability and operator variance in determining the number, type, and frequency of testing calibration or control materials and establish criteria for acceptability used to monitor test performance during a run of patient specimens." Given that most laboratories must also satisfy certain national proficiency testing requirements, analytical requirements for quality have been defined by regulatory or professional groups for many of the common tests.

1. Define the analytical quality requirement in the form of an allowable total error (TE_a). Ideally, these goals should be based on the impact of analytical uncertainty on medical decisions. However, in the absence of evidence-based clinical criteria, proficiency testing criteria provide a surrogate starting point for defining the minimum quality that must be achieved.
2. Evaluate method performance to obtain estimates of imprecision and inaccuracy. Obtain initial estimates from replication and comparison of methods experiments. Obtain ongoing estimates from routine QC and proficiency testing surveys.
3. Obtain power function graphs for the control rules and *n*'s of interest, or OPSpecs charts for the defined TE_a. Power function graphs and OPSpecs charts for commonly used QC procedures with *n*'s of 2, 3, 4, and 6 are available in the scientific literature,[134,135] in workbook format,[125] and also from computer programs (EZ Rules and QC Validator 2.0, Westgard QC Inc., Madison, Wis.; http://www.westgard.com/accessed March 22, 2011).
4. Calculate the critical systematic error and draw a vertical line showing its location on the power function graph, or plot the observed imprecision and inaccuracy of your method on the OPSpecs chart for the TE_a of interest.
5. Assess the probabilities for error detection and false rejection.
6. Select control rules and *n*'s that provide 90% detection of the critical systematic error and less than 5% false rejections. For less critical assays with stable methods, consider 50% error detection if necessary to keep the numbers of control measurements and false rejections low.
7. Select a total QC strategy to provide an appropriate balance between statistical and nonstatistical process improvement and preventive maintenance QC procedures. With 90% error detection, depend on the statistical QC component and perform the minimal preventive maintenance, instrument function checks, and method validation tests required by good laboratory practice, manufacturers' instructions, and regulatory and accreditation guidelines.

   With 50 to 90% error detection, balance the efforts between statistical and nonstatistical QC procedures; improve method performance by reducing the bias and reducing imprecision, especially with laboratory-developed procedures. With less than 50% error detection, increase the efforts for nonstatistical QC to prevent problems from occurring and improve method performance, or consider replacing the method to achieve better imprecision and inaccuracy and more cost-effective operation of the testing process.
8. Reassess for changes in method performance as necessary. Cost-effective QC depends on doing the right QC to ensure that the desired quality is achieved at minimum cost.[130] If method performance improves, less QC will be necessary; if method performance deteriorates, more QC will be necessary. Adjust the QC design as necessary for any changes in method performance.

Detailed applications based on calculated critical systematic errors have been presented for a multitest chemistry analyzer[57,139]; detailed applications using OPSpecs charts have been presented for automated immunoassays[77]; and illustrative examples using OPSpecs charts have also been provided for a variety of tests in chemistry, hematology, coagulation, endocrinology, toxicology, and immunology.[125] Manual application of this QC planning process is performed in just a minute using a workbook of OPSpecs charts that cover the range of analytical quality requirements from 1 to 50% and common single and multirules with *n*'s from 2 to 6.[125] Computer support is necessary to use clinical quality requirements stated in the form of a medically important change or a decision interval for test interpretation; clinical requirements are more complicated and require an expanded quality planning model that accounts for additional preanalytical factors, such as within run biological variation.[140]

With manual or computer-supported QC planning, laboratories are able to identify appropriate control rules and the minimum number of control measurements that will ensure that the desired quality is achieved at the minimum cost. These control rules and *n*'s are usually implemented by setting up a Levey-Jennings control chart or a Westgard multirule chart, and less often by a cumulative sum chart or mean and range charts.

Levey-Jennings Control Chart

Control charts were first introduced into the clinical chemistry laboratory by Levey and Jennings in 1950.[67] They demonstrated how the industrial control procedures developed by Shewhart[102] could be used with the mean and range of duplicate measurements from clinical chemical methods. In an alternate chart, single control values are plotted directly. This "single-value" chart was adopted by most laboratories because data calculations were not required before the control results were plotted. Today, this single-value chart is commonly known as a *Levey-Jennings chart,* even though Levey and Jennings recommended plotting the mean and range of replicate measurements. To use a Levey-Jennings control chart, follow these steps:

1. Analyze samples of the control material by the analytical method to be controlled on at least 20 different days during stable method performance. Calculate the mean and standard deviation for those results.

tahir99-VRG & vip.persianss.ir

2. Construct a control chart manually on graph paper or electronically using graphical software. Label the *y*-axis "control value" and set the range of concentrations to include the mean ±4 s. Draw horizontal lines for the mean and the upper and lower control limits. Set the control limits as the mean ±3 s when the number of control observations, *n,* is 2 or greater. When *n* is 1, control limits may be set as the mean ±2 s. (See the following discussion of performance characteristics.) Label the *x*-axis in terms of time, using day, run number, control observation number, or whatever is most appropriate for recording the relative time of the control observations.
3. Introduce control specimens into each analytical run, record the values, and plot each value on the control chart.
4. When the control values fall within the control limits, interpret the run as being "in control" and report the patient results. When a single control value exceeds control limits, stop the method; *do not* report patient results. Inspect the method to determine the cause for the errors. Resolve the problem, then repeat the entire run—specimens and control samples. Determine control status for the new run in the same manner.

An example of a Levey-Jennings chart is shown in Figure 8-13, where control limits have been set as the mean ±3 s. Power functions for a Levey-Jennings chart having 3 s control limits, or a 1_{3s} control rule, are shown in Figure 8-14. The probability for false rejection is seen to be less than 0.05 or 5% even when *n* is very large. The probability for error detection increases as *n* increases, but for an *n* of 2 to 4, the procedure is not very sensitive for random or systematic errors. Figure 8-11 shows the power functions for a Levey-Jennings chart having 2 s control limits, or the 1_{2s} control rule. Observe that the *y*-intercept increases rapidly as *n* increases. The probabilities for false rejection are as follows: $n = 1$, 0.05; $n = 2$, 0.09; $n = 4$, 0.18; $n = 8$, 0.33; $n = 12$, 0.46; and $n = 20$, 0.64. Because probabilities for false rejection greater than 0.05 or 5% are not desirable, use of the 1_{2s} rule is limited to the case where $n = 1$. In practice, the 1_{2s} rule has been widely used with a higher *n*. However, such use causes a false rejection problem that may compromise the usefulness of the control procedure. There is no easy way to tell whether the rejection signal is due to the background random error (false

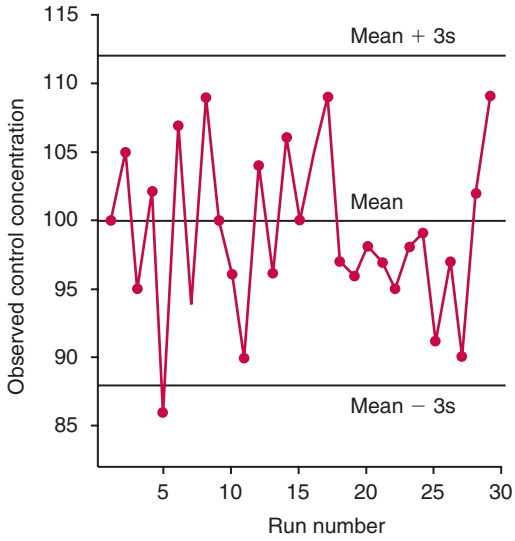

Figure 8-13 Levey-Jennings control chart having control limits set as the mean ±3 s. Concentration is plotted on the *y*-axis versus time (run number) on the *x*-axis.

tahir99-VRG & vip.persianss.ir

rejection), or whether an additional error has occurred (true rejection). This difficulty has led to a more qualitative interpretation of the control results and often to routine repetition of the control measurements (and sometimes patient sampling) whenever a control value exceeds a 2 s limit. When the second or repeated control value is observed to be outside the 2 s control limits, this provides evidence for a true rejection, and problem-solving procedures should be started. A similar false rejection problem arises when multichannel instrument systems are controlled using the 1_{2s} rule on each of several channels. For one control material being analyzed by 4, 8, 12, and 20 channels, the chances that the control value on at least one channel exceeds its 2 s limits are 18%, 33%, 46%, and 64%, respectively. Such a high rate of values exceeding control limits may cause the same percentage of work to be routinely repeated, obviously compromising the efficiency of the laboratory and increasing its costs. It is important to recognize the seriousness of the false rejection problem and its relationship to the control limits chosen for the Levey-Jennings chart. These false rejections are in effect an inherent property of the control procedure. They occur because of the control limits that have been selected—not because of any problems with the analytical method. Therefore the use of 2 s control limits cannot be generally recommended. With the use of 3 s control limits, the false rejection problem is eliminated, but unfortunately error detection is also reduced.

Westgard Multirule Chart

The *multirule* procedure developed by Westgard and associates[128] uses a series of control rules for interpreting control data. The probability of false rejections is kept low by selecting only those rules whose individual probabilities for false rejection are very low (0.01 or less). The probability for error detection is improved by selecting those rules that are particularly sensitive to random and systematic errors. The procedure requires a chart having lines for control limits drawn at the mean ± 1 s, 2 s, and 3 s, and is adapted to existing Levey-Jennings charts by the addition of one or two sets of control limits.

The following control rules are used.

Rule	Description
1_{2s}	One control observation exceeding the mean ± 2 s is used only as a "warning" rule that initiates testing of the control data by the other control rules.
1_{3s}	One control observation exceeding the mean ± 3 s is a rejection rule that is primarily sensitive to random error.
2_{2s}	Two consecutive control observations exceeding the same mean plus 2 s or mean minus 2 s limit is a rejection rule that is sensitive to systematic error.
R_{4s}	One observation exceeding the mean plus 2 s and another exceeding the mean minus 2 s is a rejection rule that is sensitive to random error.
4_{1s}	Four consecutive observations exceeding the mean plus 1 s or the mean minus 1 s is a rejection rule that is sensitive to systematic error.
10_0	Ten consecutive control observations falling on one side of the mean (above or below, with no other requirement on size of the deviations) is a rejection rule that is sensitive to systematic error.

Use of the multirule procedure is similar to use of a Levey-Jennings chart, but the data interpretation is more structured. To use the multirule procedure, follow these steps:

1. Analyze samples of the control material by the analytical method to be controlled on at least 20 different days during stable method performance. Two different materials having appropriate concentrations are recommended, but a single material can be used. Calculate the mean and standard deviation for the results for each control material being used.
2. Manually or electronically construct a control chart for each of the control materials being used. The observed concentration or control value should be plotted on the *y*-axis, setting the range of concentrations to include the mean ± 4 s. Draw horizontal lines for the mean, the mean ± 1 s, the mean ± 2 s, and the mean ± 3 s. It may be desirable to use different colors for these lines, perhaps green, yellow, and red for the 1 s, 2 s, and 3 s limits, respectively. The *x*-axis should be scaled for time, day, or run number, and labeled accordingly.
3. Introduce two control specimens into each analytical run, one for each of the two concentrations when two different materials have been selected. Record the control values and plot each on its respective control chart.
4. When both control observations fall within the 2 s limits, accept the analytical run and report the patient results. When one of the control observations exceeds a 2 s limit, this is a warning condition that warrants further investigation. Inspect the control data using the 1_{3s}, 2_{2s}, R_{4s}, and 10_0 rules. When any one of these rules indicates that the run is out of control, reject the analytical run and do not report the patient results. When all of these rules indicate that the run is in control, accept the analytical run and report the patient results.
5. When a run is out of control, determine the type of error occurring based on the control rule that has been violated. Look for sources of that type of error. Correct the problem, then reanalyze the entire run, including both control and patient samples.

An example application of the multirule procedure is shown in Figure 8-15, where the top chart is for a high-concentration control material and the bottom chart is for a low-concentration material. Table 8-4 summarizes the interpretation of the charted data, providing the run number, the accept and/or reject decision, control rules violated, and the type of error suspected based on the rule violations. It is important to note that the R_{4s} rule is applied only within a run, so that between run systematic errors are not wrongly interpreted as random errors. However, the rule may be applied "across" materials, meaning that one of the observations can be on the low material and the other on the high material, as long as they are within the same run. On the other hand, note that the 2_{2s}, 4_{1s}, and 10_0 rules can be applied across runs and materials. This effectively increases *n* and improves the error detection capabilities of the procedure.

Power functions for the multirule procedure are shown in Figure 8-16 for *n* from 2 to 6. The probability for false

tahir99-VRG & vip.persianss.ir

rejection will be much lower at these *n*'s than for the Levey-Jennings chart having 2 s control limits. However, the false rejections do increase as *n* increases, limiting *n* to a maximum of 4 to 6. For larger *n*'s, it would be necessary to modify the procedure by eliminating the R_{4s} rule, or by replacing this approximate range rule with an exact range rule (see discussion of Shewhart range procedure later in this chapter).

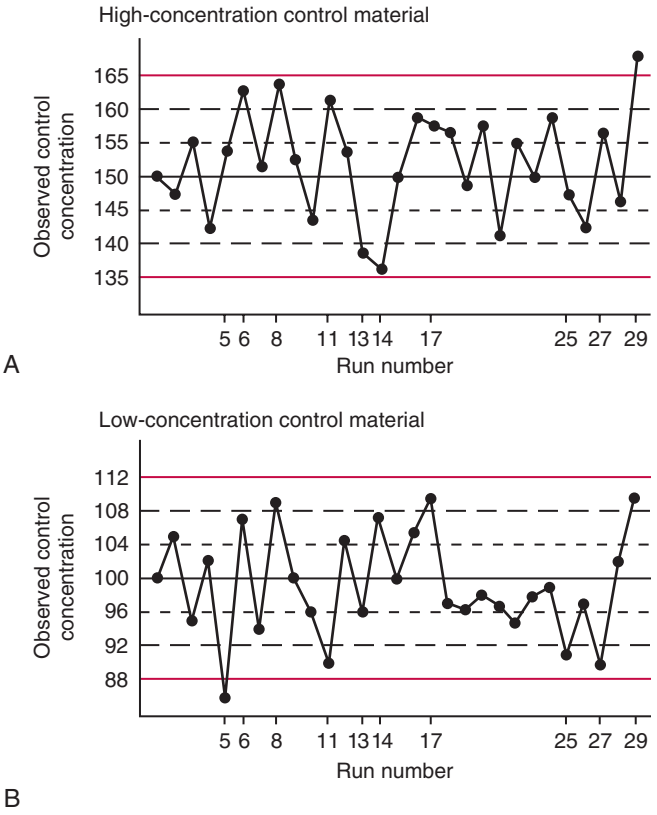

Figure 8-15 Westgard multirule control chart having control limits drawn at the mean ± 1 s, 2 s, and 3 s. Concentration is plotted on the *y*-axis versus time (run number) on the *x*-axis. A, Chart for high-concentration control material. B, Chart for low-concentration control material. *(From Westgard JO, Barry PL, Hunt MR, Groth T. A multi-rule Shewhart chart for quality control in clinical chemistry. Clin Chem 1981;27:493-501.)*

Comparison of the probability for error detection between the multirule procedure and the Levey-Jennings chart having 3 s limits shows improved error detection for the multirule procedure. The R_{4s} rule improves the detection of random error, and the 2_{2s}, 4_{1s}, and 10_0 rules improve the detection of systematic error. Elimination of the 10_0 rule does not cause much loss in error detection but does considerably reduce the quantity of control data that must be inspected; thus the simplification may make the multirule procedure easier to use.

Cumulative Sum (Cusum) Control Chart

The single-value control charts discussed in the previous sections provide a display of the differences between observed values and the expected mean. Control rules, such as 2_{2s}, 4_{1s}, and 10_0, provide one way of determining when these successive differences no longer appear to be random (too many in a row on one side of a limit). A more exact and quantitative method is the cumulative sum control procedure or cusum chart. To set up a cusum chart, follow these steps:

1. Analyze the control material by the analytical method to be controlled on at least 20 different days, and calculate the mean and standard deviation of those results. (This is the same as the initial step required for a Levey-Jennings chart or for a multirule chart.)
2. Manually or electronically construct a control chart. Label the *y*-axis "cusum." Draw a horizontal line at the midpoint of the *y*-axis to represent a cusum of zero. Set the range of values above and below to be about 10 times the standard deviation. Label the *x*-axis in terms of time, using day, run number, control observation number, or whatever is most appropriate for recording the relative time of the control observation.
3. Introduce control specimens into each analytical run and record the value obtained.
4. Calculate the difference between the value and the expected mean. Obtain the cusum by adding this difference to the cumulative sum of the previous differences. Plot the cusum on the control chart and inspect the plot.
5. Interpret the charted data by evaluating the slope of the cusum line. A steep slope suggests that a systematic error is present and that the run is out of control.

TABLE 8-4 Interpretation of Example Control Data Using the Westgard Multirule Procedure

Run Number	Decision on Run		Control Rule Violated					Type of Error

13	110	+10	+55
14	107	+7	+62
15	107	+7	+69
16	107	+7	+76

Example calculations are shown in Table 8-5. These cusum values are plotted versus observation numbers in Figure 8-17. When control values scatter on both sides of the mean, giving both positive and negative differences, the cusum will alternate in sign, and the plotted values will wander back and forth across the zero line on the control chart. When the control values fall mostly on one side of the mean so that most of the differences have the same sign, the cusum value increases in magnitude, and the plotted values will move away from the zero line of the control chart.

It is more difficult to judge the control status from cusum charts than from Levey-Jennings or multirule charts. The approach that has been used most extensively is to make the judgment based on the slope of the cusum line. In industry, this has often been done by constructing templates having a V-shaped section removed from a rectangular sheet of clear plastic. This V-shaped cutout establishes the angle that is the control limit and gives the technique its name of V-*mask cusum*. The apex of the V-mask is positioned on the control chart at a specified distance in front of the most recent

cusum observation. If all of the plotted values are contained within the angle of the V-mask, the method is judged to be in control. If any of the plotted values fall outside the angle of the V-mask, the method is judged to be out of control. Although this technique for interpreting cusum data is very objective, V-mask overlays have not been very widely used or recommended for clinical laboratories. Instead, interpretation has been based on visual inspection and on judgment of the angle of the cusum line, sometimes aided by the use of special graph paper having an underlying pattern of 45-degree angles (∠∠∠∠∠∠∠.) across the chart. When this special graph paper is used, the convention has been to scale the graph so that a change of 2 s on the *y*-axis is the same distance between two points on the *x*-axis. The 45-degree angle then represents the slope expected when the observed mean is approximately 2 s from the expected mean.

An alternative way of interpreting cusum data is to use a numerical limit for the cusum value itself, a technique known as *decision limit cusum.* Particular decision limit schemes are characterized by two parameters: *k,* a factor for calculating the threshold, and *h,* a factor for calculating the decision limit or control limit. The cusum calculations do not start until a control value exceeds a certain threshold above (k_u) or below (k_l), the expected mean (0). Once exceeded, the differences from the threshold are calculated and summed for successive observations to provide the cusum. This process continues until the cusum exceeds the upper and lower control limits (h_u and h_l) and the method is judged out of control, or until the cusum changes sign, in which case the cusum calculation is stopped and the method is judged to be in control. An example of the cusum calculations for the decision limit technique is given in Table 8-6.

These example data are plotted in Figure 8-18. One advantage of the decision limit cusum chart is that it has horizontal lines for control limits, permitting the cusum chart to be interpreted in a manner similar to a Levey-Jennings chart. This form of interpretation requires less experience and judgment, thus making possible more consistent interpretation when many analysts use the control procedure. Another advantage of the decision limit technique is that it can be implemented using only tabular operations (without charting), thus making it very easy to program for computerized handling of control data.

Although interpretation is easier and more objective, selecting the threshold and control limits is somewhat difficult. This selection is done with the aid of nomograms, which are complicated to understand and use; therefore it is initially perhaps best to use one of the decision limit schemes recommended in the clinical chemistry literature.[136] For manual implementation, set the threshold at the $x \pm 1.0$ s and the control limits at 2.7 s. For computer implementation, set the threshold at the $x \pm 0.5$ s and the control limits at 5.1 s. This latter procedure will be sensitive to smaller errors because of the choice of the lower threshold. However, the charting is not as convenient when performed manually, particularly when the cusum is used in combination with the 1_{3s} control rule to provide better detection of random errors.[136]

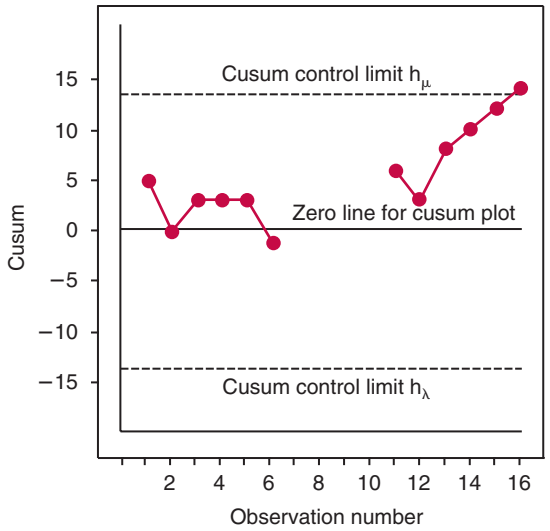

Figure 8-18 Decision limit cumulative sum control chart (e.g., data in Table 19-5). The cumulative sum of the differences from the threshold is plotted on the *y*-axis versus time (control observation number) on the *x*-axis.

TABLE 8-6 Example Cusum Calculations and Tabular Record for Decision Limit Cusum (for Control Material With $\bar{x}$ *(x bar)* = *100*, s = 5.0; for Control Chart With k_u = 105, k_l = 95, h_u = 13.5, h_l = 13.5)

Control Observation Number	Control Value	d_i	Cs_i	Comment
1	110	+5	+5	Start cusum calculation

12	102	−3	+3	
13	110	+5	+8	
14	107	+2	+10	
15	107	+2	+12	
16	107	+2	+14	

When compared with the Levey-Jennings chart with 3 s limits, the cusum procedure provides better detection of systematic errors but less sensitivity for random errors. Because of the low sensitivity to random errors, cusum should not be used alone, but rather should be included with a

Levey-Jennings procedure on a combined chart[136] or used as a separate chart along with a Levey-Jennings chart. Performance is similar to the multirule procedure for low *n*'s, at least as far as detecting systematic errors. However, the multirule procedure is more sensitive to random errors because of the added R_{4s} rule.

Alternative Calculations and Applications

Moving averages and moving standard deviations are used in industry and sometimes in clinical laboratories. With these procedures, *n* is chosen, measurements are collected until *n* is attained, and then the mean and the standard deviation are calculated. With each additional measurement, the oldest measurement is dropped, the newest is added, and new estimates of the mean and the standard deviation are obtained after each new control measurement, rather than waiting for new groups of *n* measurements. Parvin[82] has proposed the use of a multimean rule that combines the means of control values observed in consecutive runs. Similar updated means and standard deviations are obtained from exponential smoothing, a calculation procedure that provides an average that weighs recent observations more heavily than older observations.[134] The *smoothed mean* is sensitive to trends that are just beginning to develop, and therefore it is often referred to as a *trend analysis procedure.* The calculations are too complicated to be implemented manually, but the availability of computer software makes these calculations feasible in clinical laboratories.

Power functions for mean (or Z-test), range, and χ^2 (or standard deviation) control procedures, when compared with those for previous control procedures, show higher probabilities for error detection, particularly at larger *n*'s. The probability for false rejection can be set at a suitably low level by proper choice of control limits. Thus these control procedures appear to offer better performance characteristics than single-value control charts because they have higher error detection and lower false rejection as *n* increases.

The use of mean and standard deviation control procedures (or related procedures) to monitor accuracy and precision is a direct extension of the practices of method evaluation, the mean being used to monitor systematic error and the standard deviation to monitor random error. This relationship helps explain why control procedures having *n*'s from 1 to 4 have relatively low power or error detection capability. It is no surprise that it is more difficult to estimate precision and accuracy using quality control procedures with *n*'s of 1 to 4 than with method evaluation procedures using *n*'s of 20 to 40. For low *n*'s, all control procedures have relatively low power. As *n* increases, power will increase, particularly for procedures using mean, range, S-charts, Z-tests, and χ^2-tests, moving averages and moving standard deviations, and trend analysis. Future practices in statistical quality control in clinical laboratories will undoubtedly make greater use of these procedures.

The integration of powerful computer hardware and software into analytical systems has made it practical to use complicated control procedures on a routine basis in clinical laboratories. Calculations on control data, once properly programmed, are performed quickly and without mistakes. Graphical displays can be generated, with color added to aid the interpretation of control data. Specific control rules are programmed to provide "accept" and "reject" signals or printouts. Records are maintained to document instrument changes, preventive maintenance, and control problems. Monthly summary statistics and quality control reports are generated. Many of these features, along with many of the statistical control procedures that have been described, are found in quality control software programs that are commercially available today.

CONTROL OF ANALYTICAL QUALITY USING PATIENT DATA

QC mechanisms based on patient data provide additional information useful in monitoring the quality of laboratory analyses. These procedures are often time consuming and generally are not sensitive enough to serve as the only means of QC. However, many of the control problems detected with these techniques may not be evident with conventional QC systems. A quality assurance program should make appropriate use of "patient data procedures," and both individual and multiple patient results have been used for QC purposes.

Individual Patient Results

Patient test results are the final product of most laboratory procedures, and monitoring of these results is the most direct form of QC. Unfortunately, procedures for monitoring results are not very sensitive and have low probabilities for error detection. The most effective procedure is the clinical correlation of test results with other information related to the patient, especially surgical findings, response to therapy, and autopsy data. Less sensitive but easier to implement are comparisons with previous test values and correlation with related test results. The easiest procedure is the comparison of test results with physiologic or probabilistic limits.

Clinical Correlation

Operationally, it is impractical for high-volume, core laboratories to correlate all test results with the clinical status of the patient. In general, the clinician ordering the tests is in a better position to evaluate the appropriateness of test results. However, clinicians often order a test because they are uncertain of the exact clinical status of their patient and base their diagnoses heavily on the laboratory test results. In such cases, it is circular reasoning to correlate clinical diagnoses with laboratory test results. Clinical correlation studies are best done retrospectively when laboratory test results are directly related to other evidence, such as surgical findings. Unfortunately, most laboratory tests do not correlate perfectly with disease states, and one must evaluate multiple cases before determining the diagnostic efficiency of a given test (as discussed further in Chapter 3). In an individual patient, clinical correlation can identify impossible or highly unlikely test results that cannot be flagged in the laboratory, such as a

normal serum bilirubin concentration in a highly jaundiced patient. Clinicians should be encouraged to report these discrepancies to the laboratory, and a mechanism should be available to follow up with these problems. Also, after using a test for a period of time, many clinicians can detect alterations in test results, and although this is not reliable for documenting problems, informal discussions with clinicians frequently using the test can aid in identifying aspects of laboratory tests that should be further investigated.

A focus on linking laboratory tests with patient care outcomes (see Chapter 4) requires an integrated healthcare system in which all processes are operating properly.[49,146] This integrated system includes (1) correct assessment of the patient's problem, (2) ordering of the correct tests, (3) accurate and timely analytical performance, (4) correct interpretation of the test results, and (5) implementation of appropriate clinical actions that produce the expected response in the patients.

Correlation With Other Laboratory Tests

As in clinical correlation, a single test result can be judged to be implausible in a limited number of situations, but the combination of several test results is impossible or very unlikely. If the tests involved in these comparisons are performed at the same time, it is often possible to identify errors and correct problems before reporting the test results to the clinicians. Even though very few tests have exact clinical relationships, and one often must consider statistical percentages rather than the results of a single patient to identify malfunctions, several relationships provide some possibilities for monitoring an individual patient's results, at least for purposes of initiating further review:

1. *Blood typing.* There is a close association between the ABO blood antigens on erythrocytes and isoantibodies found in plasma. Exceptions are found in patients recently transfused with whole blood.
2. *Anion gap.* To maintain electrical neutrality, the sum of the charges of anions in a blood sample must equal the sum of the charges of cations when expressed in molar concentrations. With all units in mmol/L, an anion gap (AG) can be calculated as follows:

$$AG = (Na^+ + K^+) - (Cl^- + HCO_3^-)$$

   Values less than approximately 3 mmol/L or greater than about 21 mmol/L may indicate error. Elevated values may be found in patients with renal failure, diabetic acidosis, cardiac failure, anoxia, and other conditions (see Chapter 49). Low values occur in hypoproteinemia and with intravenous hydration. The capabilities of AG control procedures were studied by Cembrowski and coworkers,[32] who recommend that the average AG of groups of eight or more patients be used to provide a more sensitive statistical control.
3. *Acid-base balance.* The Henderson-Hasselbalch equation is also used to calculate theoretical bicarbonate and total CO_2 concentrations when pH and PCO_2 are measured. Theoretical and measured results generally agree within 2.0 mmol/L.
4. *Thyroxine-TSH.* Normally, thyroxine sends negative feedback to the pituitary and reduces the secretion of TSH. Patients with serum thyroxine concentrations above 8.0 µg/dL seldom have elevated concentrations of TSH. Exceptions occur in secondary and tertiary hyperthyroidism.

Intralaboratory Duplicates

In practice, samples often are divided into two aliquots and analyzed, and the duplicates used for control purposes. This is a simple quality control procedure that does not require stable control materials; therefore it is used when stable materials are not available, or as a supplemental procedure when stable control materials are available. The differences between duplicates are plotted on a range type of control chart that has limits calculated from the standard deviation of the differences.[130] When duplicates are obtained from the same method, this range chart monitors only random error and thus is not adequate for ensuring the accuracy of the analytical method. When duplicates are obtained from two different laboratory methods, then the range chart actually monitors both random and systematic errors but cannot separate the two types of errors. Such a procedure is very effective in identifying biases between methods that may indicate the need to recalibrate a method or instrument. Interpretation becomes more difficult, particularly when there are stable systematic differences or biases between the two analytical methods. Multiplicative factors may be necessary to deal with proportional differences, and additive factors may be necessary to allow for constant differences. Interpretation of observed differences becomes more qualitative; nevertheless, this procedure still provides a useful way of monitoring the consistency of data being generated by the laboratory.

Delta Checks With Previous Test Results

Certain errors, particularly errors in specimen identification, have been detected by comparing laboratory test results with values obtained on previous specimens from the same patient. The expected variability of test results depends on both the analyte and the time interval between determinations. Ladenson has defined delta check limits based on a 3-day interval in terms of a percentage change from the initial value.[62] His check limits for some common tests are shown in Table 8-7.

In identifying specimen-related errors, it is helpful to examine multiple test parameters, including hematologic tests, because differences in a profile of test results often are more obvious and more statistically significant than are changes in individual tests. For example, in a 1979 study, the performance of several delta check methods was evaluated, including two discriminant functions, for detecting mislabeled specimens; a false-positive rate of 5% and an error detection of about 50% for mislabeled specimens were observed.[138]

Limit Checks

A patient's test results should be reviewed to check that they are within the physiologic ranges compatible with life. These

TABLE 8-7 Recommended Limits for Delta Checks

Test	Delta Check Limit, %
Albumin	20
Bilirubin, total	50
Calcium, total	15

TABLE 8-8 Recommended Reference Values for Limit Checks

Test	Low Warning	High Warning
Albumin, g/dL	1.5	6
Alkaline phosphatase,* U/L	5	300
Amylase,* U/L	20	1000
Bilirubin, mg/dL	0.2	10.0
Calcium, mg/dL	6.5	13.0
Creatine kinase, U/L	5	1500
Creatinine, mg/dL	0.3	7.5
Phosphorus, mg/dL	1.0	8.0
Potassium, mmol/L	3.0	6.0
Sodium, mmol/L	120	150
Urea nitrogen, mg/dL	3	50
Uric acid, mg/dL	1.0	12.0

*Values are method dependent.
From Whitehurst P, DiSilvio TV, Boyadjian G. Evaluation of discrepancies in patients' results: an aspect of computer-assisted quality control. Clin Chem 1975;21:87-92.

limit checks are helpful for detecting clerical errors, such as transposed digits or misplaced decimal points. This checking can be combined with warning limit checks for detecting and verifying possible, but infrequently occurring, test results. These warning limits are dependent on the test methodology and on characteristics of the patient population being tested. Table 8-8 shows limits for some common tests. Many automated chemistry instruments have monitors that allow autorelease of test results within defined limits, which are wider than some of the values listed in this table. For example, the Roche Diagnostics Module and Cobas Systems have auto release limits of 23 to 1050 U/L for alkaline phosphatase and 0.1 to 30.0 mg/dL for total bilirubin.

Multiple Patients

Test Distribution Statistics

Statistics based on distributions of test results from large numbers of patients are useful for detecting systematic errors (shifts and drifts) but are of no value for detecting random errors (increased variability or scatter). They are useful adjuncts to the fundamental control procedures, which use stable control materials, but should not be substituted for them. Patient values include numerous sources of variation—demographic, biological, pathologic, and preanalytical (see Chapter 6)[149]—in addition to the analytical variation caused by the analytical method. As a result, individual test values have too much variability to have any utility for QC; however, the mean of multiple test values or groups of patients is more stable and therefore may be useful for control purposes.

Changes in the means of patient populations may be caused by multiple variables (see Chapters 3 and 5). Changes in the demographic and clinical characteristics of patients, such as the ratio of males to females, the ratio of hospitalized patients to outpatients, or the presence of many specimens from a specialty clinic, can alter the mean value. Similarly, changes in preanalytical conditions[149] such as tourniquet time and specimen storage alter patient population means and therefore can be monitored by the use of patient means. These variables are not monitored by those control procedures employing stable materials; thus *patient mean procedures* provide additional capabilities and should be used in conjunction with other control procedures. Population statistics are most useful when patients are segmented into groups such as different clinics, different phlebotomists, and so forth. These subgroups generally have smaller within group variations, which helps improve the detection of systemic changes. The smaller the within group variance, the better the ability to detect an analytical or preanalytical assay change.

Statistical Methods for Monitoring Patient Means

The *mean of normals* or *average of normals* (AON) approach calls for establishing limits, usually the limits for reference values, for "trimming" patient data.[141] Values outside these limits are eliminated from the calculations, thus reducing the response to outliers and subpopulations and also to real errors. An alternative approach has been to use the median as the control statistic; this may be a more sensitive indicator of change than the mean. More complicated estimates have been recommended to account for hospitalized patients having slightly different test values from those of ambulatory patients. A weighted mean based on the percentage of patients in each category has greater sensitivity for error detection, particularly for measurements of the serum concentrations of total protein, albumin, and calcium.

Bull's algorithm has been widely employed for online monitoring of automated hematologic cell counters.[108] Bull and colleagues[20] evaluated six statistics for monitoring erythrocyte indices: the sample mean, two moving average means, the mean of a truncated sample, John's mean, and the median. They assessed the usefulness of these different statistics by

mathematically introducing both abrupt bias changes and cyclic time changes. The moving average statistics were found to have superior error detection. The batch size used in calculating the moving average regulates smoothing of the data. Large batch sizes not only smooth out undesired individual patient effects, but also increase the number of specimens (and time) necessary to detect instrument malfunction. A weighted moving average based on a batch size of 20 specimens was recommended. Cembrowski has developed power function graphs to provide quantitative information on both single-rule and multirule variations of Bull's algorithm.[31,68]

Control statistics based on patient data have been readily implemented in computerized laboratories.[54] However, several authors have shown that these control procedures are not as sensitive as procedures using stable control material. All of these statistics are designed to detect systematic errors and have virtually no power for detecting random error. The relative sensitivity of these statistics for detection of systematic errors, as compared with stable control materials, is dependent on three factors: (1) variation in patient test values (and the test statistics derived from them), (2) analytical variation, and (3) the number of specimens relative to the number of controls. Low patient variability, high analytical variability, and a high ratio of specimens to controls favor patient-based QC procedures. Patient test result variability depends not only on the analyte measured, but also on the population being tested. Populations consisting mainly of healthy individuals generally have lower test variability than populations of inpatients and medical specialty clinics. Results from several quantitative studies of these variables and their effects on the statistical power of procedures using patient means have been reported by a number of investigators. Cembrowski and associates, Ye and colleagues,[30,54,147] and Smith and Kroft[103,104] have further evaluated the performance and relationship of AON and Bull's algorithms and have proposed an exponentially adjusted moving mean whose performance can be optimized for individual applications.

Combined Use of Liquid Controls and Moving Averages of Patient Values for Quality Control Monitoring

Distributions of measured test values have been used to supplement traditional liquid controls for monitoring analytical bias. These patient specimen measurements generally have much larger variances than liquid controls because they contain biological, pathophysiologic, and preanalytical sources of variation, in addition to the analytical variation. However, if some of these sources of variation are controlled, averaging techniques often are used to generate tracking parameters, which have variations of the same order of magnitude as liquid controls. Demographic information about specific patients such as age, sex, and medical provider service area have been used to adjust test values, resulting in smaller variances of group means for the monitoring parameters. The larger the number of patient results included in a mandatory group, the smaller the variations between averages of these groups; however, the use of larger groups delays the time to detection of changes. Variations of the group mean decrease approximately proportionately to the square root of the number of patient values included in the group. Various statistical techniques have been used to calculate a QC statistic from patient values, such as the exponentially adjusted moving mean proposed by Smith and Kroft.[103,104] In general, there is a trade-off between decreased variance versus increased time for error detection when larger numbers of patient values are used in these QC statistics. For most chemistry tests, 50 to 100 patient test values often are necessary.[54,57,147] An advantage of test value distributions over liquid controls is the inclusion of preanalytical variation caused by specimen collection, transport, and storage. This allows patient value–derived QC parameters to detect changes in these variables, in addition to changes in the analytical testing.

Figure 8-19 illustrates an algorithm for combining liquid controls with a patient value–derived parameter. The same multirule evaluation systems used for liquid controls have been used for tracking the patient value–derived QC statistic. Set points and threshold values are assigned to this derived parameter to optimize the power for error detection for systematic error. Note that the averaging algorithms used to generate these derived parameters average out random errors, so these derived parameters are not useful for detecting random errors. As illustrated in the figure, this combined control protocol is most accurate when both the liquid control and the patient-derived control move in the same direction (both high, or both low). When the controls move discordantly, further investigation is necessary to define whether the problem is related to instability of liquid controls, changes in patient characteristics (such as many sick patients seen at one time), preanalytical test changes, or other causes.

EXTERNAL QUALITY ASSESSMENT AND PROFICIENCY TESTING PROGRAMS

All of the control procedures described earlier in the chapter have focused on monitoring a single laboratory. These procedures constitute what is called *internal quality control*[124] to distinguish them from procedures used to compare the performance of different laboratories, the latter being known as *external quality assessment*. The two are complementary activities, internal QC being necessary for the daily monitoring of the precision and accuracy of the analytical method, and external quality assessment being important for maintaining long-term accuracy of the analytical methods.[22,23]

In practice, internal QC procedures detect changes in performance only between the present operation and the "stable" operation that was characteristic during the baseline period, when the analytical method was thought to be operating properly. Although the procedures detect systematic and random errors, the only systematic errors detected are those changes from the original baseline. If the method actually had some undetected systematic errors during the baseline period, those systematic errors would be included in the mean that was used to calculate control limits for the procedure. Thus only systematic changes from this original mean will be detected by internal QC procedures.

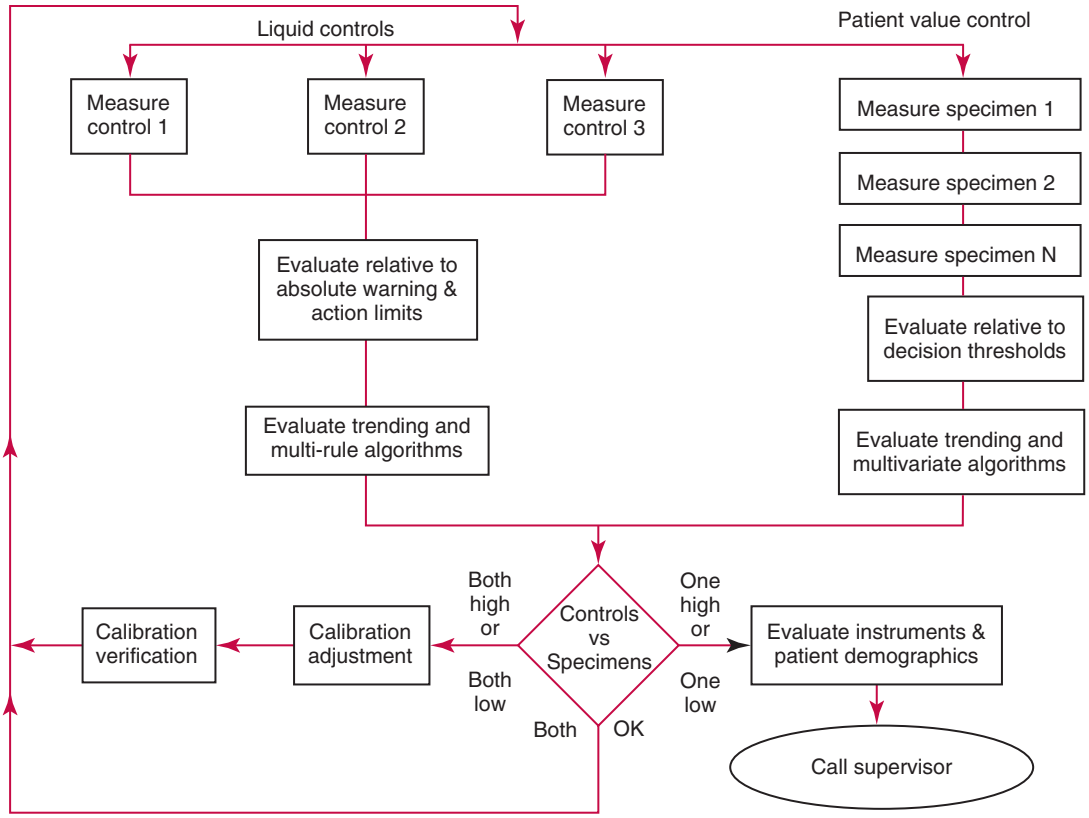

Figure 8-19 Protocol for combining liquid controls and a patient value–derived control.

Initial method evaluation studies are essential to ensure that systematic errors are not present before the baseline period and the determination of mean and control limits. The accuracy of the method should be initially established by comparison with other analytical methods (and recovery and interference studies) and should continue to be monitored by comparison with other analytical methods. Ongoing comparison-of-methods studies are desirable to ensure that systematic errors do not slowly increase and go undetected by internal QC procedures. These ongoing comparison studies are provided by external QA programs, which in turn form the basis for proficiency testing programs.

Quality Control Comparison Programs

Several external QA programs are available to laboratories, some sponsored by professional societies and others offered by manufacturers of control materials. The basic operation of these programs involves having all participating laboratories analyze the same lot of control material, usually daily as part of the internal QC activities. Results are sent to the sponsoring group for the data analysis. Summary reports are prepared by the program sponsor and are distributed to all participating laboratories. This reporting takes time for processing of all data from a large number of laboratories; thus the data analysis is not available in real time and is useful only for monthly reviews and periodic problem-solving activities. However, with advances in telecommunications and the arrival of the World Wide Web, real-time external QC is a possibility.

Reports often include extensive data analysis, statistical summaries, and plots. The mean of all results or the mean of results from peer laboratories (those performing the test with similar methods) is taken as the target value and is used for comparison with the individual laboratory's result. Different programs do this in different ways. For example, the statistical significance of any difference between an individual laboratory's observed result and the group mean can be tested by use of the *t*-test. When the difference is significant, the laboratory is alerted that its results are biased compared with the results of most of the other laboratories. Another approach is to divide the difference by the overall standard deviation of the group, and then to express the difference in terms of the number of standard deviations as follows:

$$\text{SDI} = \frac{\text{Laboratory Result} - \text{Group Mean}}{\text{Group SD}}$$

where *SDI* is the abbreviation for standard deviation interval or index, and *Group SD* is the standard deviation for the group or a selected subset of the group. Differences greater than 2 or 3 indicate that a laboratory is not in agreement with the rest of the laboratories in the program. These calculations reduce all test results to the same values, which makes it possible to interpret the data without reference to the exact mean and *s* for each analytical method. For example, a value of +2.0

has the same meaning for any test, indicating that the value is 2 s above its target mean.

Additional information about the nature of the systematic error is obtained when two different control materials are analyzed by each laboratory. For example, the laboratory's observed mean for material A is plotted on the *y*-axis versus its observed mean for material B on the *x*-axis; these graphs are called *Youden plots*.[148] Ideally, the point for a laboratory should fall at the center of the plot. Points falling away from the center but on the 45-degree line suggest a proportional analytical error. Points falling away from the center but not on the 45-degree line suggest an error that is constant for both materials or an error that occurs with just one material.

The operation of quality control comparison programs is greatly improved by using a PC and appropriate software. Operationally, comparisons are performed more quickly using the PC as a terminal for transmitting data via the Internet to the central computer. Processing of the data to compare the results from many different laboratories is then performed, and reports are returned to the laboratory. Because individual control observations are entered into the PC, control data are then immediately tested by internal control procedures to determine control status. Thus in practice, the PC integrates the internal QC and the external comparison procedures into a more efficient program for QA.

Proficiency Testing and Laboratory Accreditation

Proficiency testing (PT) programs are a type of external quality assessment in which simulated patient specimens made from a common pool are analyzed by the laboratories enrolled in the program. Results are returned to a central facility and are evaluated to determine the "quality" of each laboratory's performance. Government and licensing agencies are increasingly using PT as an objective method for accrediting laboratories, thereby giving them official authorization to operate.[96]

An example of using PT for such a purpose is the U.S. Government's mandate that clinical laboratories be accredited and licensed. Historically, this developed after a series of newspaper articles were published that focused on laboratory quality problems and led to a determined effort by the U.S. government to protect patients' interests and the public welfare.[15,16] In 1988, the U.S. Congress subsequently revised the Clinical Laboratory Improvement Act of 1967 (CLIA '67) and passed the Clinical Laboratory Improvement Amendment (CLIA '88); it mandates PT as a major part of the laboratory accreditation process.[2,101] The implementation rules for this legislation have been evolving, with the final legislative rule being published on January 24, 2006.[100] Additional interpretative guidelines were published by the Centers for Medicare and Medicaid Services (CMS) in January 2004 in the form of the *State Operations Manual.* Appendix C of that document refers specifically to guidelines for laboratories and laboratory testing services.[5]

The initial CLIA '88 regulations focused primarily on the analytical process. However, it was later stressed that the quality of the "total testing process" must be monitored, in addition to the precision and accuracy of the analytical phase.[83,86,92,145] Thus as mentioned earlier in this chapter, current QA programs that monitor only the analytical phase of the total process have to be expanded to include both preanalytical (see Chapter 6) and postanalytical phases (www.westgard.com/essay34/accessed March 22, 2011).

CLIA requires all U.S. laboratories to register with the government and to identify the tests they perform. Certain tests are "waived," meaning that any laboratory can perform those tests as long as they follow the manufacturers' directions. There are no other requirements for quality management of those tests. Laboratories that perform "nonwaived" tests are subject to the complete CLIA regulations and must be inspected periodically by the government or by certain professional organizations that are deemed to have standards at least as stringent as the CLIA requirements. Two such organizations are the College of American Pathologists (CAP) and the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). The CLIA implementation rules and interpretative guidelines outline the criteria for acceptable performance in laboratory inspection and accreditation.

CLIA requirements cover several broad classes: (1) Subpart J. Facility Administration; (2) Subpart K. Quality Systems; (3) Subpart M. Personnel; and (4) Subpart Q. Inspection. The final rule dealt mainly with changes to the subpart on Quality Systems, with particular attention to preanalytical, analytical, and postanalytical systems. It places increased emphasis on having quality systems to monitor preanalytical and postanalytical processes, yet the biggest impact of the final rule is on analytical quality assessment and analytical quality systems.[131]

In general, the performance characteristics of PT programs for detecting bias and imprecision are evaluated using methods similar to those listed for assessing internal QC.[63] A commonly used evaluation criterion has been the comparison of PT test results with those of peer groups, considering all values that exceed 3 SD to be "unacceptable." This rule fails to detect many of the laboratories that have poor performance, especially those that have precision problems.[43] The initial CLIA '88 proposal called for the PT of two specimens four times per year, but the final rule expanded this to the study of five samples three times per year, so as to improve the capability of detecting "unacceptable" performance.

CLIA '88 criteria grouped laboratory tests into "specialty" and "subspecialty" categories, and specifically representative tests to be monitored in each category.[101] To be totally "successful" in a given category, a laboratory must produce correct results on four out of five specimens for each of the analytes in that category and must have an overall score of at least 80% for three consecutive challenges. If there are more than two incorrect results for any analyte, the laboratory is considered "on probation." If a laboratory has two or more incorrect results for any analyte or has an overall score less than 80% on two of three consecutive surveys, it is classified as "suspended" and must cease testing all analytes in that specialty category until its status is reinstated.

The CLIA regulations have established fixed limits (percentages or absolute values from target) for evaluating PT performance. These test categories and limits are shown in Table 8-9. Target values for these analytes will be established by the agencies implementing PT programs under the federal guideline[101] that states, "Target value means either the mean of all responses after removal of outliers (those responses greater than 3 standard deviations from the original mean) or the mean established by definitive or reference methods acceptable for use in the National Reference System (NRS) for the Clinical Laboratory by the CLSI. In instances in which definitive or reference methods are not available, a comparative method may be used. If the method group is less than 20 participants, 'target value' means the overall mean after outlier removal (as defined above) unless acceptable scientific reasons are available to indicate that such an evaluation is not appropriate."

Accepted reference methods do not exist for many of these *controlled analytes,* and even when they do exist, the values obtained for PT specimens with some analytical systems may not match those obtained with the reference method owing to differences in matrices and analyte form.[110]

CLIA '88 regulations specify that PT specimens should be treated in the same manner as patient specimens and require that personnel performing the tests sign a statement attesting that they have complied with the regulations. In reality, PT specimens must be treated differently than those from patients, because many are lyophilized or sealed in containers, and reporting of their results requires different forms and generally is not computerized.

A new requirement of the final CLIA regulations is that laboratories must perform method validation studies on all new tests introduced after April 24, 2003. Before this, laboratories that implemented new methods and analytical systems that had been cleared by the FDA could simply follow manufacturers' directions for operation and assume that the manufacturers' performance claims were valid. With issuance of the final rule, the performance of all new tests must be validated in each laboratory to document the reportable range, precision, accuracy, and reference intervals. For some methods, it may also be necessary to determine the detection limit and to test for possible interferences.

Another major change in the final rule was the elimination of an earlier provision that would have required the FDA to review a manufacturer's QC instructions. This was a key provision for allowing laboratories to simply follow a manufacturer's directions. However, with elimination of that provision, laboratories now have greater responsibility for establishing effective QC systems that will monitor the complete analytical process, take into account the performance specifications of the method, detect immediate errors, and monitor long-term precision and accuracy.

The most controversial change in the final rule is the introduction of *equivalent QC procedures.* CLIA sets a minimum level of QC that must be performed by all laboratories. Typically, this requires two levels of controls to be analyzed every 24 hours, or for some tests, one level of control to be analyzed every 8 hours. The new guidelines for equivalent QC may allow laboratories to reduce daily QC to weekly or even monthly QC for analytical systems that have built-in procedural controls. The provision is obviously targeted for POCT or near-patient testing (NPT), where personnel lack the skills to perform QC and instead rely on instrument checks, most notably electronic checks or electronic QC. In spite of arguments about the inadequacy of electronic QC,[123] it has become widely accepted in POCT and NPT applications. Although at least one example of an analytical system with improved QC technology requires little or no operator initiation of QC,[133] most analytical systems have yet to demonstrate the performance that would justify a reduction of daily QC to only weekly or monthly QC.

In the United States, as a result of personnel standards of the CLIA and current staffing shortages, many laboratories have been left without the technical and analytical skills to manage quality effectively. Consequently, in the authors' opinion, the use of statistical QC is declining in many laboratories (www.westgard.com/essay34/accessed March 22, 2011). Thus QC has come to mean *quality compliance* rather than quality control. The consequences of a regulatory approach to quality have to be carefully assessed relative to other initiatives. Regulation does not appear to be an adequate substitute for professional responsibility for quality.

To summarize this section, PT programs are far from ideal monitors of laboratory performance. In a study of PT survey problems at the Mayo Clinic, more than half of the errors on surveys were directly related to deficiencies in the surveys (such as invalid specimens and inappropriate evaluation criteria), and only 28% could be linked to specific analytical problems.[58] A PT program piloted by the New York State Department of Health involves obtaining aliquots of patient specimens that are routinely processed by the laboratory at the time of its annual inspection.[88] These specimens are reanalyzed in the state's laboratories using reference methods, and the results are compared with those obtained during inspection. This prevents problems such as the presence of unnatural specimens and laboratory clerical errors related to reporting of PT results. Other specimen stability problems, methodologic interferences, and potential clerical errors at the reference laboratories probably continue to occur.

IDENTIFYING THE SOURCES OF ANALYTICAL ERRORS

The control procedures discussed in the previous sections provide a means of alerting the analyst to problems that may cause the quality of analytical performance to fall short of the goals set by the laboratory. However, these control procedures do not identify the sources of the analytical errors to solve the control problems. The following additional procedures are often necessary to identify these sources.

Physical Inspection

When alerted to a control problem, the first step should be to carefully inspect the analytical method, equipment,

TABLE 8-9 HCFA/CLIA Proficiency Testing Criteria for Acceptable Performance

Analyte or Test	Acceptable Performance
Routine Chemistry	
Alanine aminotransferase	Target value ±20%
Albumin	Target value ±10%
Alkaline phosphatase	Target value ±30%
Amylase	Target value ±30%
Aspartate aminotransferase	Target value ±20%
Bilirubin, total	Target value ±0.4 mg/dL or ±0% (greater)
Blood gas PCO_2	Target value ±55 mm Hg or ±8% (greater)
Blood gas pH	Target value ±0.04
Blood gas PO_2	Target value ±3 standard deviations (SD)
Calcium, total	Target value ±1.0 mg/dL
Chloride	Target value ±5%
Cholesterol, high-density lipoprotein	Target value ±30%
Cholesterol, total	Target value ±10%
Creatine kinase	Target value ±30%
Creatine kinase isoenzymes	MB elevated (presence or absence) or target value ±3 SD
Creatinine	Target value ±0.3 mg/dL or ±15% (greater)
Glucose	Target value ±6 mg/dL or ±10% (greater)
Iron, total	Target value ±20%
Lactate dehydrogenase (LD)	Target value ±20%
LD isoenzymes	LD 1/LD 2 positive or negative or target value ±30%
Magnesium	Target value ±25%
Potassium	Target value ±0.5 mmol/L
Sodium	Target value ±4 mmol/L
Total protein	Target value ±10%
Triglycerides	Target value ±25%
Urea nitrogen	Target value ±2 mg/dL or ±9% (greater)
Uric acid	Target value ±17%
Endocrinology	
Cortisol	Target value ±25%
Free thyroxine	Target value ±3 SD
Human chorionic gonadotropin	Target value ±3 SD or positive or negative
T_3 uptake	Target value ±3 SD
Triiodothyronine	Target value ±3 SD
Thyroid-stimulating hormone	Target value ±3 SD
Thyroxine	Target value ±20% or 1.0 µg/dL (greater)
Toxicology	
Alcohol, blood	Target value ±25%
Blood lead	Target value ±10% or ±4 µg/dL (greater)
Carbamazepine	Target value ±25%
Digoxin	Target value ±20% or 0.2 ng/mL (greater)
Ethosuximide	Target value ±20%
Gentamicin	Target value ±25%
Lithium	Target value ±0.3 mmol/L or ±0% (greater)
Phenobarbital	Target value ±20%
Phenytoin	Target value ±25%
Primidone	Target value ±25%
Procainamide (and metabolite)	Target value ±25%
Quinidine	Target value ±25%
Theophylline	Target value ±25%
Tobramycin	Target value ±25%
Valproic acid	Target value ±25%

TABLE 8-9 HCFA/CLIA Proficiency Testing Criteria for Acceptable Performance—cont'd

Analyte or Test	Acceptable Performance
Hematology	
Cell identification	90% or greater consensus on identification
White cell differentiation	Target ±3 SD based on percentage of different types of white cells
Erythrocyte count	Target ±6%
Hematocrit	Target ±6%
Hemoglobin	Target ±7%
Leukocyte count	Target ±15%
Platelet count	Target ±25%
Fibrinogen	Target ±20%
Partial thromboplastin time	Target ±15%
Prothrombin time	Target ±15%
General Immunology	
α_1-antitrypsin	Target value ±3 SD
α-fetoprotein	Target value ±3 SD
Antinuclear antibody	Target value ±2 dilution or positive or negative
Antistreptolysin O	Target value ±2 dilution or positive or negative
Anti–human immunodeficiency virus	Reactive or nonreactive
Complement C3	Target value ±3 SD
Complement C4	Target value ±3 SD
Hepatitis (HbsAg, anti-HBc, HbeAg)	Reactive (positive) or nonreactive (negative)
Immunoglobulin (Ig)A	Target value ±3 SD
IgE	Target value ±3 SD
IgG	Target value ±25%
IgM	Target value ±3 SD
Infectious mononucleosis	Target value ±2 dilution or positive or negative
Rheumatoid factor	Target value ±2 dilution or positive or negative
Rubella	Target value ±2 dilution or positive or negative

reagents, and specimens. Does everything look, feel, smell, and sound correct? An inspection may seem to be a very qualitative and subjective technique, but it can be exceedingly useful when performed with checklists developed for specific analytical methods. This inspection should include a review of records documenting changes that have occurred with the instrument and reagents. Brief instrument function checks are often performed to verify proper system performance and to separate chemical and instrumental sources of error. An experienced analyst can often spot the problem by making this kind of inspection, whereas inexperienced analysts will be aided by formal checklists.

Relationship of Type and Source of Error

The type of error itself provides a clue about the source of the error. For example, systematic errors are often related to calibration problems (impure calibration materials, improper preparation of calibrating solutions, erroneous set point and assigned values, unstable calibrating solutions, contaminated solutions, inadequate calibration techniques, nonlinear or unstable calibration functions, unstable reagent blanks, and inadequate sample blanks). Random errors are more likely caused by lack of reproducibility in the pipetting of samples and reagents, by the dissolving of reagent tablets and the mixing of sample and reagents, and by lack of stability of temperature baths, timing regulation, and photometric and other sensors. Individual analytical methods may not be subject to all of these possible sources of error; rather, there may be only a few plausible sources for a particular type of error. Experienced analysts often know what these common sources are for their particular analytical methods and quickly identify the sources once the type of error is known.

Some information about the type of error occurring is obtained by knowing to which errors the control procedures respond. As discussed earlier in this chapter, different control rules have different sensitivities to detect random and systematic errors. However, in practice, it is often possible to make a good judgment as to the type of error occurring based on the control procedure that provides the alert. Control procedures that employ patient samples rather than stable

control materials can help identify preanalytical sources of error, such as sample handling and processing.* External quality assessment procedures that employ frozen patient samples[14,59,74,75,81,98,107] may provide more extensive information about errors than what is available from internal procedures. Information from all of these procedures is complementary and, when used in combination, provides a more complete assessment of the types of errors occurring and their possible sources.

Method Evaluation Experiments

When the type of error cannot be easily identified and quantified from available control data, it may be necessary to use the experiments employed in method evaluation studies (see Chapter 3). A *comparison-of-methods experiment* may be used to estimate systematic errors when another routine method is available for measuring the analyte of interest. Interpretation of the results must consider that observed differences between the two methods could be caused by either method and therefore cannot be assigned to the method under investigation unless the quality of the "comparison" method is well documented. Recovery, interference, and linearity experiments may be more specific in estimating systematic errors, including the constant or proportional nature of systematic errors.

To identify sources of random error, a *replication experiment* is designed to estimate the contributions from several different components. For example, when duplicates are analyzed within a run for several different runs, the data are used to determine the components of within run and between run variations. This process isolates the errors that occur in different time periods, which in turn may help reveal the sources of the random error. Replication experiments of this type, using analysis of variance statistical techniques, are tailored to particular analytical systems to identify the major factors that contribute to the random error of those analytical methods. Performance of control procedures also depends on the different components of variance, and it is particularly important that the between run component be kept as small as possible.[132]

Although the discussions in this chapter imply that plots are manually prepared, in actual practice, a wide variety of computer software packages are available for statistically calculating and plotting QA data.

Optimization Techniques

More complicated experimental techniques, such as factorial experiments, *simplex optimization,* and *response surface optimization,* have been used to solve complex control problems. These techniques generally are used by laboratorians only for laboratory development of tests because only manufacturers typically have access to this information for FDA-approved assays.[18,50,71,105] Youden[148] described the use of a series of experiments in which several factors could be varied simultaneously, thus reducing the total number of experiments necessary to determine how these factors affect the performance of the analytical method. These "factorial" experiments have been used for testing the "ruggedness" of an analytical method (i.e., its responsiveness to any disturbance in chosen experimental conditions). A properly optimized method should be rugged—this means that small changes in the analytical conditions should not greatly affect analytical performance. Formal optimization strategies have been employed to decide on those analytical conditions. These techniques provide systematic approaches for selecting the analytical conditions that minimize errors and reduce control problems.

CHAPTER 9

Principles of Basic Techniques and Laboratory Safety

*Stanley F. Lo, Ph.D., D.A.B.C.C., F.A.C.B.**

To reliably perform qualitative and quantitative analyses on body fluids and tissue, the clinical laboratorian must understand the basic *principles and techniques* of analytical chemistry. Valcárcel has generically defined analytical chemistry as "a metrological science that develops, optimizes, and applies measuring processes intended to derive quality analytical information in order to solve the measuring problems posed."[25] Factors that affect the analytical process and operation of the clinical laboratory include knowledge of (1) the concept of solute and solvent; (2) units of measurement; (3) chemicals; (4) reference materials; (5) basic techniques, such as volumetric sampling and dispensing, centrifugation, measurement of radioactivity, gravimetry, thermometry, buffer solution, and processing of solutions; and (6) safety.

CONCEPT OF SOLUTE AND SOLVENT

Many analyses in the clinical laboratory are concerned with determination of the presence or measurement of the concentration of substances in solutions, the solutions most often being blood, serum, urine, spinal fluid, or other body fluids (see Chapter 7).

A *solution* is a homogeneous mixture of one or more *solutes* dispersed molecularly in a sufficient quantity of a dissolving *solvent*. In laboratory practice, solutes are typically measured and are frequently referred to as analytes or measurands. A solution may be gaseous, liquid, or solid. A clinical laboratorian is concerned primarily with the measurement of gases or solids in liquids, where there is always a relatively large amount of solvent in comparison with the amount of solute.

Expressing Concentrations of Solutions

The following equations define the expression of concentrations:

$$\text{Mole} = \frac{\text{mass (g)}}{\text{gram molecular weight (g)}}$$

$$\text{Molarity of a solution} = \frac{\text{number of moles of solute}}{\text{number of liters of solution}}$$

$$\text{Molality of a solution} = \frac{\text{number of moles of solute}}{\text{number of kilograms of solvent}}$$

$$\text{Normality of a solution} = \frac{\text{number of gram equivalents of solute}}{\text{number of liters of solution}}$$

$$\text{Gram equivalent weight (as oxidatant or reductant)} = \frac{\text{formula weight (g)}}{\text{difference in oxidation state}}$$

In the past, milliequivalent (mEq) was used to express the concentration of electrolytes in plasma. Now, the recommended unit for expressing the concentration of an electrolyte in plasma is millimoles per liter (mmol/L). For example, if a sample contains 322 mg of Na per deciliter then the serum contains 3220 mg/L. The molar concentration of Na is

$$\text{mmol/L} = \frac{\text{mg/L}}{\text{mg molecular mass}} = \frac{322 \times 10 \times 1}{23} = 140 \text{ mmol/L}$$

In clinical laboratory practice, a *titer* is thought of as the lowest dilution at which a particular reaction takes place. Titer is customarily expressed as a ratio, for example, 1:10 or 1 to 10.

Regarding gases in solution, Henry's law states that the solubility of a gas in a liquid is directly proportional to the pressure of the gas above the liquid at equilibrium. Thus as the pressure of a gas is doubled, its solubility is also doubled. The relationship between pressure and solubility varies with the nature of the gas. When several gases are dissolved at the same time in a single solvent, the solubility of each gas is

*The author gratefully acknowledges the original contributions of Drs. Edward W. Bermes, Stephen E. Kahn, Donald S. Young, Edward R. Powsner, and John C. Widman, on which portions of this chapter are based.

proportional to its partial pressure in the mixture. The solubility of most gases in liquids decreases with an increase in temperature, and indeed boiling a liquid frequently drives out all dissolved gases. Traditionally, the unit used to describe the concentration of gases in liquids has been percent by volume (vol/vol). Using the SI, gas concentrations are expressed in moles per cubic meter (mol/m^3).

UNITS OF MEASUREMENT

A meaningful measurement is expressed with both a number and a unit. The unit identifies the dimension—mass, volume, or concentration—of a measured property. The number indicates how many units are contained in the property.

Traditionally, measurements in the clinical laboratory have been made in metric units. In the early development of the *metric system,* units were referenced to length, mass, and time. The first absolute systems were based on the centimeter, gram, and second (CGS), and then the meter, kilogram, and second (MKS). The Système Internationale d'Unités (SI) is a different system that was accepted internationally in 1960. The *units of the system* are called SI units.

International System of Units

Base, derived, and supplemental units are the three classes of SI units.[20] The eight fundamental base units are listed in Table 9-1. A *derived unit* is derived mathematically from two or more base units (Table 9-2). A *supplemental unit* is a unit that conforms to the SI but has not been classified as either base or derived. At present, only the radian (for plane angles) and the steradian (for solid angles) are classified this way.

The Conférence Générale des Poids et Mésures (CGPM) recognizes that some units outside the SI continue to be important and useful in particular applications. An example is the liter as the reference volume in clinical analyses. Liter is the name of the submultiple (cubic decimeter) of the SI unit of volume, the cubic meter. Considering that 1 cubic meter represents some 200 times the blood volume of an adult human, the SI unit of volume is neither a convenient nor a reasonable reference volume in a clinical context. Nevertheless, the CGPM recommends that such exceptional units as the liter should not be combined with SI units and preferably should be replaced with SI units whenever possible.

The minute, hour, and day have had such long-standing use in everyday life that it is unlikely that new SI units derived from the second could supplant them. Some other non-SI units are still accepted, although they are rarely used by most individuals in their daily lives but have been very important in some specialized fields. Details of the SI system are found in an expanded version of this chapter.[2]

In practical application of units, certain values are too large or too small to be expressed conveniently. Numeric values are brought to convenient size when the unit is appropriately modified by official prefixes (Table 9-3).

Standardized Reporting of Test Results

To describe test results properly, it is important that all necessary information be included in the test description. Systems developed for expressing results produced by the clinical laboratory include the Laboratory Logical Observation Identifiers, Names, and Codes (Lab LOINC),[15-17] and the Nomenclature, Properties, and Units (NPU) developed by the

TABLE 9-1 SI Base Units

Quantity	Name	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second	S
Electrical current	ampere	A
Thermodynamic temperature	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	cd
Catalytic amount	katal	kat

TABLE 9-2 Examples of SI-Derived Units Important in Clinical Medicine, Expressed in Terms of Base Units

Quantity	Name	SI Symbol	Expression in Terms of SI Base Units	Expression in Terms of Other SI Units
Volume	cubic meter	m^3	m^3	
Mass density	kilogram per cubic meter	kg/m^3	kg/m^3	
Concentration of amount of substance	mole per cubic meter	mol/m^3	mol/m^3	
Frequency	hertz	Hz	s^{-1}	
Force	newton	N	$m \cdot kg \cdot s^{-2}$	
Pressure	pascal	Pa	$m^{-1} \cdot kg \cdot s^{-2}$	N/m^2
Energy, work, quantity of heat	joule	J	$m^2 \cdot kg \cdot s^{-2}$	$N \cdot m$
Power	watt	W	$m^2 \cdot kg \cdot s^{-3}$	J/s
Electric potential, potential difference, electromotive force	volt	V	$m^2 \cdot kg \cdot s^{-3} \cdot A^{-1}$	$W \cdot A^{-1}$

TABLE 9-3 Metric Prefixes of SI Units*

Factor	Prefix	Symbol
10^{24}	yotta	Y
10^{21}	zetta	Z
10^{18}	exa	E
10^{15}	peta	P
10^{12}	tera	T
10^{9}	giga	G
10^{6}	mega	M
10^{3}	kilo	k
10^{2}	hecto	h
10^{1}	deka†	da
10^{-1}	deci	d
10^{-2}	centi	c
10^{-3}	milli	m
10^{-6}	micro	μ
10^{-9}	nano	n
10^{-12}	pico	p
10^{-15}	femto	f
10^{-18}	atto	a
10^{-21}	zepto	z
10^{-24}	yocto	y

*The Eleventh Conférence Générale des Poids et Mésures (CGPM) (1960, Resolution 12) adopted a first series of prefixes and symbols of prefixes to form the names and symbols of the decimal multiples and submultiples of SI units. Prefixes for 10^{-15} and 10^{-18} were added by the 12th CGPM (1964, Resolution 8) and those for 10^{15} and 10^{18} by the 15th CGPM (1975, Resolution 10), and those for 10^{21}, 10^{24}, and 10^{-24} were proposed by the Comité International des Poids et Mésures (CIPM) (1990) for approval by the 19th CGPM (1991).

†Outside the United States, the spelling "deca" is used extensively.

From The International System of Units (SI). Washington, DC: National Institute of Standards and Technology, 1991.

International Federation of Clinical Chemistry/International Union of Pure and Applied Chemistry (IFCC/IUPAC).

Lab LOINC System

The Lab LOINC system is a universal coding system for reporting laboratory and other clinical observations to facilitate electronic transmission of laboratory data within and between institutions (http://www.loinc.org). It has several thousand observations in its database. For each observation, there is a code, a long formal name, a short 30-character name, and synonyms. A mapping program termed "Regenstrief LOINC Mapping Assistant" (RELMA) is available to map local test codes to LOINC codes and to facilitate searching of the Lab LOINC database. Both Lab LOINC and RELMA are available at no cost from http://loinc.org/relma (accessed March 16, 2011).

NPU

The NPU system recommends that the following items be included with each test result:

1. The name of the system or its abbreviation
2. A dash (two hyphens)
3. The name of the analyte (never abbreviated) with an initial capital letter
4. A comma
5. The quantity name or its abbreviation
6. An equal sign
7. The numeric value and the unit or its abbreviation

Applications

The Lab LOINC and NPU coding systems are used in context with existing standards, such as the Systematized Nomenclature of Medicine, Clinical Terms (SNOMED CT). Other such coding systems are the ASTM E1238 (American Society for Testing and Materials), HL7 version 2.2 (Health Level Seven; http://www.hl7.org; accessed March 16, 2011), and CEN ENV 1613—a standard developed by the European Committee for Standardization of the Comité Européen de Normalisation (CEN) Technical Committee 251 (http://www.cen.eu/ accessed March 16, 2011).

SNOMED CT is a comprehensive clinical terminology, originally created by the College of American Pathologists (CAP) and, as of April 2007, owned, maintained, and distributed by the International Health Terminology Standards Development Organisation (IHTSDO) in Denmark (http://www.ihtsdo.org; accessed March 16, 2011). IHTSDO is a not-for-profit association that develops and promotes use of SNOMED CT to support safe and effective health information exchange. In practice, the CAP continues to support SNOMED CT operations under contract to the IHTSDO and provides SNOMED-related products and services as a licensee of the terminology.

On April 1, 2009, the owners of LOINC, NPU, and SNOMED CT began an operational trial of prospective divisions of labor in the generation of laboratory test terminology content. This trial will provide practical experience and important information on opportunities to decrease duplication of effort in the development of laboratory test terminology and to ensure that SNOMED CT works effectively in combination with LOINC or NPU.

CHEMICALS

The quality of the analytical results produced by the laboratory is a direct indication of the purity of the chemicals used as analytical reagents. The availability and quality of the reference materials used to calibrate assays and to monitor their analytical performance also are important.

Laboratory chemicals are available in a variety of grades. The solutes and solvents used in analytical work are *reagent grade chemicals,* among which water is a solvent of primary importance.

Reagent Grade Water

Preparation of many reagents and solutions used in the clinical laboratory requires "pure" water. Single-distilled water fails to meet the specifications for Clinical Laboratory Reagent Water (CLRW) established by the Clinical Laboratory and Standards Institute (CLSI).[10] Because the terms *deionized*

TABLE 9-4 Clinical Laboratory and Standards Institute (CLSI) Specifications for Reagent Water

	CLRW
Microbiological content,* colony-forming units per mL, cfu/mL (maximum)	10
pH	Not applicable
Resistivity,† MΩ per centimeter (MΩcm), 25 °C	≥10 (in line)
Silicate, mg SiO_2/L (maximum)	0.05
Particulate matter‡	Water passed through 0.2-µm filter
Organics	Water passed through activated carbon

*Microbiological content. The microbiological content of viable organisms, as determined by total colony count after incubation at 36 ± 1 °C for 14 hours, followed by 48 hours at 25 ± 1 °C, and reported as colony-forming units per mL (cfu/mL).

†Specific resistance or resistivity. The electrical resistance in ohms measured between opposite faces of a 1-cm cube of an aqueous solution at a specified temperature. For these specifications, the resistivity will be corrected for 25 °C and reported in MΩ/cm. The higher the quantity of ionizable materials, the lower will be the resistivity and the higher the conductivity.

‡Particulate matter. When water is passed through a membrane filter with a mean pore size of 0.2 µm, it is considered to be free of particulate matter; when water is passed through a bed of activated carbon, it is considered to contain minimum organic material.

From CLSI. Preparation and testing of reagent water in the clinical laboratory, 4th edition. CLSI Document C3-A4. Wayne, Pa: CLSI, 2006.

water and *distilled water* describe preparation techniques, they should be replaced by reagent grade water, followed by the designation of CLRW, which better defines the specifications of the water and is independent of the method of preparation (Table 9-4).

Preparation of Reagent Grade Water

Distillation, ion exchange, reverse osmosis, and ultraviolet oxidation are processes used to prepare reagent grade water. In practice, water is filtered before any of these processes are used.

Distillation

Distillation is the process of vaporizing and condensing a liquid to purify or concentrate a substance or to separate a volatile substance from less volatile substances. It is the oldest method of water purification. Problems with distillation for preparing reagent water include the carryover of volatile impurities and entrapped water droplets that may contain impurities into the purified water. This will result in contamination of the distillate with volatiles, sodium, potassium, manganese, carbonates, and sulfates. As a result, water treated by distillation alone does not meet the specific conductivity requirement of type I water.

Ion Exchange

Ion exchange is a process that removes ions to produce mineral-free *deionized water.* Such water is most conveniently prepared using commercial equipment, which ranges in size from small, disposable cartridges to large, resin-containing tanks. Deionization is accomplished by passing feed water through columns containing insoluble resin polymers that exchange H^+ and OH^- ions for the impurities present in ionized form in the water. The columns may contain cation exchangers, anion exchangers, or a *mixed-bed resin exchanger,* which is a mixture of cation- and anion-exchange resins in the same container.

A single-bed deionizer generally is capable of producing water that has a specific resistance in excess of 1 MΩ/cm. When connected in series, mixed-bed deionizers usually produce water with a specific resistance that exceeds 10 MΩ/cm.

Reverse Osmosis

Reverse osmosis is a process by which water is forced through a semipermeable membrane that acts as a molecular filter. The membrane removes 95 to 99% of organic compounds, bacteria, and other particulate matter and 90 to 97% of all ionized and dissolved minerals, but fewer of the gaseous impurities. Although this process is inadequate for producing reagent grade water for the laboratory, it may be used as a preliminary purification method.

Ultraviolet Oxidation

Ultraviolet oxidation is another method that works well as part of a total system. The use of ultraviolet radiation at the biocidal wavelength of 254 nanometers eliminates many bacteria and cleaves many ionizing organics that are then removed by deionization.

Quality, Use, and Storage of Reagent Grade Water

Type III water may be used for glassware washing. (Final rinsing, however, should be done with the water grade suitable for the intended glassware use.) It may also be used for certain qualitative procedures, such as those used in general urinalysis.

Type II water is used for general laboratory testing not requiring type I water. Storage should be kept to a minimum; storage and delivery systems should be constructed to ensure a minimum of chemical or bacterial contamination.

Type I water should be used in test methods requiring minimal interference and maximal precision and accuracy. Such procedures include trace metal, enzyme, and electrolyte measurements, and preparation of all calibrators and solutions of reference materials. This water should be used immediately after production. No specifications for storage systems for type I water are given because it is not possible to maintain high resistivity while drawing off water and storing it.

Testing for Water Purity

At a minimum, water should be tested for microbiological content, pH, resistivity, and soluble silica,[10] and the maximum

interval in the testing cycle for purity of reagent water should be 1 week. It should be noted that measurements taken at the time of production may differ from those taken at the time and place of use. For example, if the water is piped a long distance, consideration must be given to deterioration en route to the site of use. To meet the specifications for high-performance liquid chromatography (HPLC), in some instances it may be necessary to add a final 0.1-µm membrane filter. The water can be tested by HPLC using a gradient program and monitoring with an ultraviolet (UV) detector. No peaks exceeding the analytical noise of the system should be found.

Reagent Grade or Analytical Reagent Grade (AR) Chemicals

Chemicals that meet specifications of the American Chemical Society (ACS) are described as reagent or analytical reagent grade. These specifications have also become the de facto standards for chemicals used in many high-purity applications. These are available in two forms: (1) lot-analyzed reagents, in which each individual lot is analyzed and the actual amount of impurity reported, and (2) maximum impurities reagents, for which maximum impurities are listed. The Committee on Analytical Reagents of the ACS periodically publishes "Reagent Chemicals" listing specifications (http://pubs.acs.org/reagents/index.html; accessed March 16, 2011). These reagent grade chemicals are of very high purity and are recommended for quantitative or qualitative analyses.

Ultrapure Reagents

Many analytical techniques require reagents whose purity exceeds the specifications of those described previously. Manufacturers offer selected chemicals that have been especially purified to meet specific requirements. There is no uniform designation for these chemicals and organic solvents. Terms such as *spectrograde, nanograde,* and *HPLC pure* have been used. Data of interest to the user (e.g., absorbance at a specific UV wavelength) are supplied with the reagent.

Other designations of chemical purity include chemically pure (CP), USP and NF grade [chemicals produced to meet specifications set down in the U.S. Pharmacopeia (USP) or the National Formulary (NF)]. Chemicals labeled *purified, practical, technical,* or *commercial grade* should not be used in clinical chemical analysis without prior purification.

REFERENCE MATERIALS

A *reference material* is a material or substance with one or more physical or chemical properties that is sufficiently well established to be used for (1) calibrating instruments, (2) validating methods, (3) assigning values to materials, and (4) evaluating the comparability of results. Reference materials are of prime importance in establishing *metrologic transferability* (http://www.bipm.org; accessed March 16, 2011),[1,26] a term defined as "the property of a measurement result whereby the result can be related to a reference through a documented unbroken chain of calibrations, each contributing to the measurement uncertainty."[13]

Primary, secondary, standard, and certified are types of reference materials.

Primary Reference Materials

Primary reference materials are highly purified chemicals that are directly weighed or measured to produce a solution whose concentration is exactly known. The IUPAC has proposed a degree of 99.98% purity for primary reference materials. These highly purified chemicals may be weighed out directly for the preparation of solutions of selected concentration or for the calibration of solutions of unknown strength. They are supplied with a certificate of analysis for each lot.

Secondary Reference Materials

Secondary reference materials are solutions whose concentrations cannot be prepared by weighing the solute and dissolving a known amount into a volume of solution. The concentration of secondary reference materials is usually determined by analysis of an aliquot of the solution by an acceptable reference method, using a primary reference material to calibrate the method.

Standard Reference Materials (SRMs)

Standard reference materials (SRMs) for clinical and molecular laboratories are available from the National Institute of Standards and Technology (NIST; http://ts.nist.gov; accessed March 16, 2011). Cholesterol, the first SRM developed by the NIST, was issued in 1967. It should be noted that not all SRMs have the properties and the degree of purity specified for a primary standard, but each has been well characterized for certain chemical or physical properties and is issued with a certificate that gives results of the characterization. These may then be used to characterize other materials.

Examples of SRMs that are available from the NIST for use in clinical and molecular diagnostics laboratories include (1) pure crystalline standards (Table 9-5), (2) human-based standards (Table 9-6), (3) animal blood standards (Table 9-7), (4) standards containing drugs of abuse in urine and human hair (Table 9-8), and (5) SRMs used for DNA profiling/crime scene investigations (Table 9-9).

Certified Reference Materials (CRMs)

Certified reference materials (CRMs) are available for clinical and molecular laboratories from the Institute for Reference Materials and Measurements (IRMM) in Geel, Belgium (http://www.irmm.jrc.be; accessed March 16, 2011). The IRMM is one of the seven institutes of the Joint Research Centre (JRC), a Directorate-General of the European Commission (EC). Other acronyms used to label IRMM reference materials include ERM (European Reference Materials), BCR (Community Bureau of Reference of the Commission of the European Communities), and the IFCC (International Federation of Clinical Chemistry).

Examples of available IRMM standards are listed in Tables 9-10 and 9-11. Reference materials also are available from the World Health Organization (WHO; http://www.who.int/biologicals; accessed March 16, 2011).

TABLE 9-5 Standard Reference Materials (SRMs)—Pure Crystalline Standards

SRM Number	Analyte
998	Angiotensin I (human)
916a	Bilirubin
915b	Calcium Carbonate
911c	Cholesterol
921	Cortisol (hydroxycortisone)
914a	Creatinine
917b	D-Glucose (dextrose)
920	D-Mannitol
937	Iron Metal (clinical)
928	Lead Nitrate
924a	Lithium Carbonate
929a	Magnesium Gluconate Dihydrate
918b	Potassium Chloride
919b	Sodium Chloride
1595	Tripalmitin
912a	Urea
913a	Uric Acid
925	VMA (4-Hydroxy-3-Methoxy-DL-Mandelic Acid)
8327	Peptide Reference Materials (For Molecular Mass and Purity Measurements)

Available from the National Institute of Standards and Technology (www.nist.gov; accessed March 16 2011).

TABLE 9-6 Standard Reference Materials (SRMs)—Human Serum Based

SRM Number	Description
909b	Human Serum (Contains 12 Analytes)
1951b	Lipids in Frozen Human Serum
956b	Electrolytes in Frozen Human Serum
965a	Glucose in Frozen Human Serum
967	Creatinine in Frozen Human Serum
970	Ascorbic Acid in Frozen Human Serum
1952a	Cholesterol in Frozen Human Serum
968c	Fat-Soluble Vitamins in Human Serum
1589a	PCBs, Pesticides, and Dioxins/Furans in Human Serum
1599	Anticonvulsant Drug Level Assay (Valproic Acid and Carbamazepine)
900	Antiepilepsy Drug Level Assay
1955	Homocysteine and Folate in Human Serum

PCBs, Polychlorinated biphenyls.
Available from the National Institute of Standards and Technology (www.nist.gov; accessed March 16, 2011).

Number	Plasmid DNA
IRMM/IFCC-490	Sequence of 609 bp DNA Fragment from Human Prothrombin Gene (G20210 Wildtype Sequence)
IRMM/IFCC-491	Sequence of 609 bp DNA Fragment from Human Prothrombin Gene (Point Mutation G20210A)
IRMM/IFCC-492	Sequence of 609 bp DNA Fragment from Human Prothrombin Gene (G20210 Wildtype and Point Mutation G20210A Sequences)

*Availability: Each polypropylene vial contains approximately 1 ng plasmid DNA in a volume of 50 µL of a tris/EDTA solution.
bp, Base pairs.

BASIC TECHNIQUES AND PROCEDURES

Basic practices used in clinical and molecular diagnostic laboratories include (1) optical, (2) chromatographic, (3) electrochemical, (4) electrophoretic, (5) mass spectrometric, (6) enzymatic, and (7) immunoassay techniques. These techniques are discussed in detail in Chapters 10 through 16. Here we discuss the basic techniques of volumetric sampling and dispensing, centrifugation, measurement of radioactivity, gravimetry, thermometry, controlling hydrogen ion concentration, and processing solutions.

Volumetric Sampling and Dispensing

Clinical chemistry procedures require accurate volumetric measurements to ensure accurate results. For accurate work, only Class A glassware should be used. Class A glassware is certified to conform to the specifications outlined in NIST circular C-602.

Pipettes

Pipettes are used for the transfer of a volume of liquid from one container to another. They are designed either (1) to contain (TC) a specific volume of liquid or (2) to deliver (TD) a specified volume. Pipettes used in clinical, molecular diagnostic, and analytical laboratories include (1) manual transfer and measuring pipettes, (2) micropipettes, and (3) electronic and mechanical pipetting devices. Developments in improved design of pipetting systems include robotic automation, the capability to provide electronic and personal computer (PC) control of pipetting devices, and careful attention to advanced ergonomic design features. Automatic photometric pipette calibration systems are also available that reduce the time needed to periodically check pipettes and potentially allow more efficient use of personnel.

Transfer and Measuring Pipettes

A transfer pipette is designed to transfer a known volume of liquid. Measuring and serologic pipettes are scored in units such that any volume up to a maximum capacity is delivered.

Transfer Pipettes. *Transfer pipettes* include both volumetric and Ostwald-Folin pipettes (Figure 9-1). They consist of a cylindrical bulb joined at both ends to narrower glass tubing. A calibration mark is etched around the upper suction tube, and the lower delivery tube is drawn out to a gradual taper. The bore of the delivery orifice should be sufficiently narrow to allow rapid outflow of liquid and incomplete drainage cannot cause measurement errors beyond tolerances specified.

A volumetric transfer pipette (Figure 9-1, *A*) is calibrated to deliver accurately a fixed volume of a dilute aqueous solution. The reliability of the calibration of the volumetric pipette decreases with decreased size, and therefore special micropipettes have been developed.

Ostwald-Folin pipettes (Figure 9-1, *B*) are similar to volumetric pipettes but have the bulb closer to the delivery tip and are used for accurate measurement of viscous fluids, such as blood or serum. In contrast to a volumetric pipette, an Ostwald-Folin pipette has an etched ring near the mouthpiece, indicating that it is a blow-out pipette. With the use of a pipetting bulb, the liquid is blown out of the pipette only after the blood or serum has drained to the last drop in the delivery tip. When filled with opaque fluids, such as blood, the top of the meniscus must be read. Controlled slow drainage is required with all viscous solutions so that no residual film is left on the walls of the pipette.

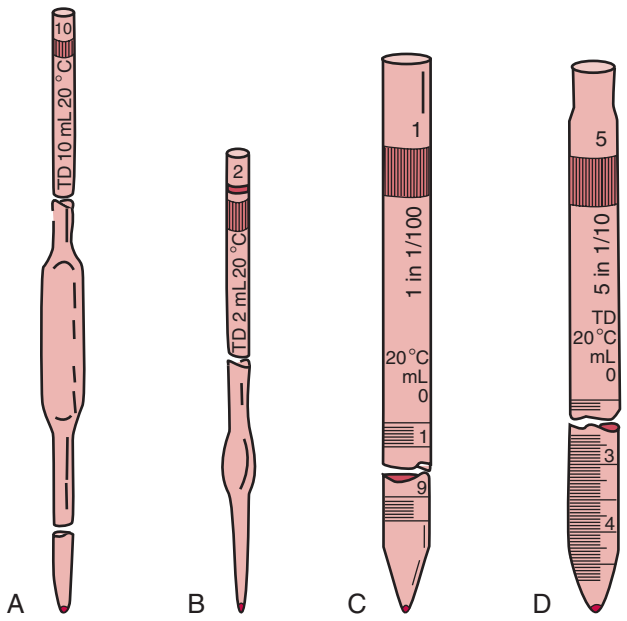

Figure 9-1 Pipettes. A, Volumetric (transfer). B, Ostwald-Folin (transfer). C, Mohr (measuring). D, Serologic (graduated to the tip).

Measuring Pipettes. The second principal type of pipette is the *graduated* or *measuring pipette* (Figure 9-1, *C*). This is a piece of glass tubing that is drawn out to a tip and graduated uniformly along its length. Two types are available. The Mohr pipette is calibrated between two marks on the stem, whereas the serologic pipette has graduated marks down to the tip. The serologic pipette (Figure 9-1, *D*) must be blown out to deliver the entire volume of the pipette and has an etched ring (or pair of rings) near the bulb end of the pipette signifying that it is a blow-out pipette. Mohr pipettes require controlled delivery of the solution between the calibration marks. Serologic pipettes have a larger orifice than do Mohr pipettes and thus drain faster. In practice, measuring pipettes are used principally for measurement of reagents and generally are not considered sufficiently accurate for measuring samples and calibrators.

Pipetting Technique

There are general pipetting techniques that apply to the pipettes described previously. For example, pipetting bulbs should always be used, and pipettes must be held in a vertical position when the liquid level is adjusted to the calibration line and during delivery. The lowest part of the meniscus, when it is sighted at eye level, should be level with the calibration line on the pipette. The flow of liquid should be unrestricted when volumetric pipettes are used, and the tips should be touched to the inclined surface of the receiving container for 2 seconds after the liquid has ceased to flow.

With graduated pipettes, the flow of liquid may have to be slowed during delivery. Serologic pipettes are calibrated to the tip, and the etched glass ring on top of the pipette signifies that it is to be blown out. First, the pipette is allowed to drain, and then the remaining liquid is blown out.

Micropipettes

Micropipettes are pipettes used for the measurement of microliter volumes. With such devices, the remaining volume that coats the inner wall of a pipette causes notable error. For this reason, most micropipettes are calibrated to contain (TC) the stated volume rather than to deliver it (TD). Proper use requires rinsing the pipette with the final solution after the contents are delivered into the diluent. Volumes are expressed in microliters (µL); the older term *lambda* is no longer recommended. Micropipettes generally are available in small sizes, ranging from 1 to 500 µL. Also, they are available for volumes as low as 0.2 µL.

Semiautomatic and Automatic Pipettes and Dispensers. Figure 9-2, *A* and *B*, illustrates two types of adjustable micropipetting devices that demonstrate unique ergonomic design features. These devices are programmable and are used for simultaneously dispensing aliquots of liquid into multiple wells. In practice, with the use of disposable plastic tips, they allow simultaneous aspiration and delivery of solutions to multiple sample micro wells. Each channel is piston driven to allow the user to pipette with as few or as many tips as necessary. Aliquots of liquid as small as 0.2 µL are dispensed at three different aspiration or dispense rates.

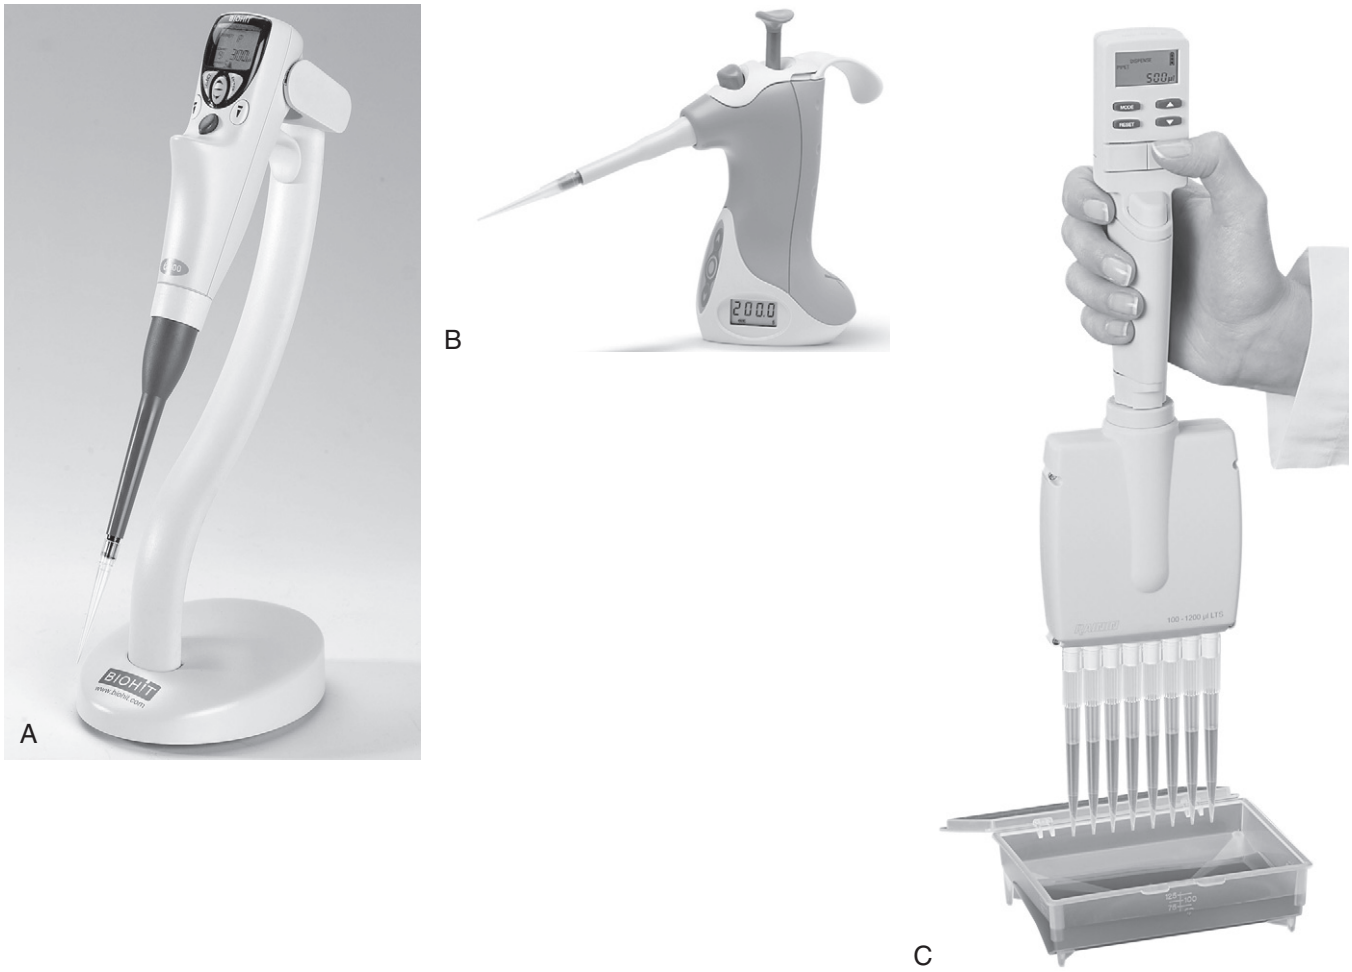

Figure 9-2 A, Adjustable volume micropipetting device with ergonomic design. B, Adjustable volume electronic micropipetting device with ergonomic design. C, Electronic programmable multichannel pipette. *(A, Courtesy Biohit Plc. B, Courtesy VistaLab Technologies, Inc. C, Courtesy Rainin Instrument LLC.)*

Semiautomatic manual and electronic versions of pipettes and dispensers are available in sizes ranging from 0.5 µL to 10 mL. Figure 9-2, *C*, illustrates an electronically operated, positive-displacement multichannel pipettor. This device aspirates and dispenses its predefined volumes (from 0.5 to 200 µL) when its plunger is moved through a complete cycle. Its disposable, fluid containment tips are made of a plastic material that tends to retain less inner surface film than does glass. Such pipettes (1) avoid the risk of cross-contamination among samples, (2) eliminate the necessity for washing between samples, and (3) improve the precision of measurements. Models that allow for digital adjustment of the volume aspirated and dispensed are available.

Figure 9-3, *A*, shows an automatic dispensing apparatus that aspirates and dispenses preset volumes of two different liquids by means of two motor-driven syringes, one for metering a volume of the sample and one for metering a volume of the diluent. It is possible to adjust this device to aspirate as little as 1 µL of one liquid and to deliver it with as much as 999 µL of the other. This type of device, available as a dilutor or dispenser, is obtainable as a manual, electronic, or computer-controlled device. The device is microprocessor controlled and is easily programmed. Twenty-one dispensing programs are stored in memory and retrieved. This type of liquid dispensing device is also obtainable as a computer-controlled system.

A more versatile piece of equipment is the robotic liquid handling workstation shown in Figure 9-3, *B*. This automated pipetting station is used with individual reaction tubes and also with 96- and 384-well microtiter plates. Depending on the design of the system, a single probe or multiple probes may be used to rapidly transfer programmed volumes of solution from one container to microtiter plates (e.g., so that the transfer to all 96 wells is complete in 1 minute). In some systems, liquid sensing is incorporated into the sample probes to minimize contact with sample and reagents even though automatic washing of the probes is performed between specimens. Two-dimensional (X-Y) movement of probes and tubes or microtiter plates is built into the pipetting stations to minimize the necessity for operator intervention. This

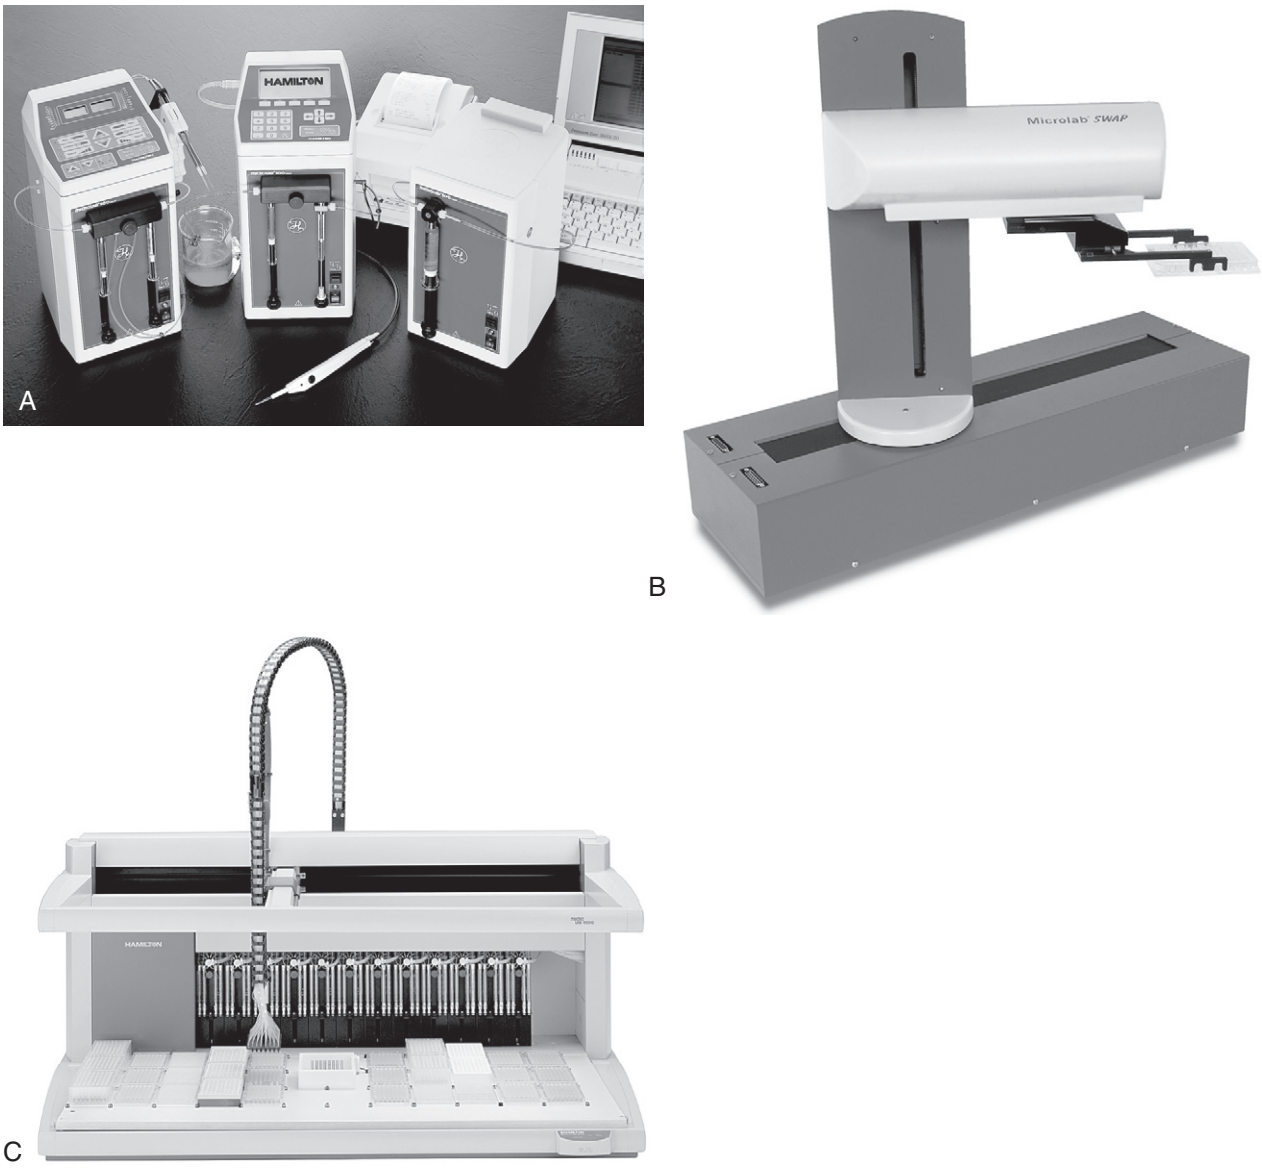

Figure 9-3 A, Personal computer (PC)-controlled diluting and/or dispensing apparatus that aspirates and dispenses preset volumes of one or two different liquids, such as a diluent and sample, by means of motor-driven syringes. B and C, Robotic liquid handling workstations. *(A and B, Courtesy Hamilton Co.)*

device dispenses programmed volumes from 0.5 to 1000 µL in serial dilutions from 4 to 16 channels employing an autoloaded system with barcodes for positive identification.

Volumetric Flasks

Volumetric flasks (Figure 9-4) are used to measure exact volumes; they are commonly found in sizes varying from 1 to 4000 mL. In practice, they are used primarily in preparing solutions of known concentration, and they are available in various grades. The most accurate are certified as meeting standards set forth by the NIST.

An important factor in the use of a volumetric apparatus is the requirement for an accurate adjustment of the meniscus. A small piece of card that is half black and half white is most useful. The card is placed 1 cm behind the apparatus with the white half uppermost and the top of the black area about 1 mm below the meniscus. The meniscus then appears as a clearly defined, thin black line. This device also is useful in reading the meniscus of a burette.

Volumetric equipment should be used with solutions equilibrated to room temperature. Solutions diluted in volumetric flasks should be repeatedly mixed during dilution so that the contents are homogeneous before the solution is made up to final volume. Errors caused by expansion or contraction of liquids on mixing are thereby minimized.

Volumetric flasks should be thoroughly cleaned and dried before calibration. The flask is then weighed and filled with carbon dioxide–free deionized water until just above the

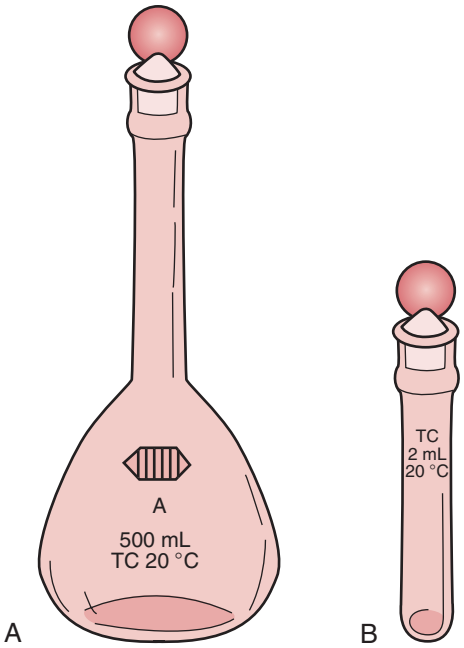

Figure 9-4 Volumetric flasks. A, Macro. B, Micro.

graduation mark. The neck of the flask just above the water level should be kept free of water. The meniscus mark is set at the graduation line by removing excess water, and the flask is reweighed. The final weight is corrected for the equilibrated water and air temperature to obtain the volume of the flask. Flasks also may be calibrated by the spectrophotometric technique described in the next section.

Centrifugation

Centrifugation is the process of using centrifugal force to separate the lighter portions of a solution, mixture, or suspension from the heavier portions. A *centrifuge* is a device by which centrifugation is effected.

In the clinical laboratory, centrifugation is used to

1. Remove cellular elements from blood to provide cell-free plasma or serum for analysis (see Chapter 7).
2. Concentrate cellular elements and other components of biological fluids for microscopic examination or chemical analysis.
3. Remove chemically precipitated protein from an analytical specimen.
4. Separate protein-bound or antibody-bound ligand from free ligand in immunochemical and other assays (see Chapter 16).
5. Extract solutes in biological fluids from aqueous to organic solvents.
6. Separate lipid components such as chylomicrons from other components of plasma or serum, and lipoproteins from one another (see Chapter 27).

Types of Centrifuges

Several types of centrifuges are used in the clinical laboratory including (1) horizontal-head, (2) swinging-bucket, (3) fixed-angle head, (4) angle-head, (5) ultracentrifuge, and (6) axial units. In addition, the development of automatic balancing centrifuges has enabled centrifugation to be incorporated as an integral step in the total automation of laboratory testing (see Chapter 19).

Principles of Centrifugation

The correct term to describe the force required to separate two phases in a centrifuge is *relative centrifugal force (RCF)*. Units are expressed as number of times greater than gravity (e.g., 500 ×g).

RCF is calculated as follows:

$$RCF = 1.118 \times 10^{-5} \times r \times rpm^2$$

where

1.118×10^{-5} is an empirical factor

r = radius in centimeters from the center of rotation to the bottom of the tube in the rotor cavity or bucket during centrifugation

rpm = the speed of rotation of the rotor in revolutions per minute

The RCF of a centrifuge may also be determined from a nomogram distributed by manufacturers of centrifuges. RCF is derived from the distance from the rotor center to the bottom of the tube, whether the tube is horizontal to, or at an angle to, the rotor center.

The time required to sediment particles depends on the (1) rotor speed, (2) radius of the rotor, and (3) effective path length traveled by the sedimented particles, that is, the depth of the liquid in the tube. Duplication of conditions of centrifugation is often desirable. The following is a useful formula for calculating the speed required of a rotor whose radius differs from the radius with which a prescribed RCF was originally defined:

$$\text{rpm (alternate rotor)} = 1000 \times \sqrt{\frac{RCF,\ original\ rotor}{11.18 \times r(cm),\ alternate\ rotor}}$$

The length of time for centrifugation is calculated so that running with an alternate rotor of a different size is equivalent to running with the original rotor:

$$\text{time (alternate rotor)} = \frac{\text{time} \times RCF\ \text{(original rotor)}}{\text{RCF (alternate rotor)}}$$

Note, however, that it may not be possible to reproduce conditions exactly when a different centrifuge is used. Descriptions of times of centrifugation include the time for the rotor to reach operating speed (which may vary from instrument to instrument) and do not include deceleration time, during which sedimentation is still occurring but less efficiently. Even with maximal braking, deceleration may take as long as 3 minutes in some centrifuges.

Operation of the Centrifuge

For proper operation of a centrifuge, only those tubes recommended by their manufacturer should be used. The material used for the tube must withstand the RCF to which the tube is likely to be subjected. Polypropylene tubes generally are capable of withstanding RCFs of up to 5000 ×g. The tubes

should have a tapered bottom, particularly if a supernatant is to be removed, and should be of a size to fit securely into the rack to be centrifuged. The top of the tube should not protrude so far above the bucket that the swing into a horizontal position is impeded by the rotor.

For smooth operation of the centrifuge, the rotor must be properly balanced. The weight of racks, tubes, and their contents on opposite sides of a rotor should not differ by more than 1% or by an acceptable limit established by the manufacturer. Centrifuges that automatically balance their rotors are now available.

Tubes of collected blood should be centrifuged before they are unstoppered to reduce the probability of an aerosol being produced when the tube is opened. The practice of using a wooden applicator to release a clot stuck to the top of the tube or to its stopper should be avoided; it is a potential cause of hemolysis. Centrifugation at an appropriate RCF usually ensures that the clot is released from the tube wall and is drawn to the bottom of the tube.

Despite years of experience with centrifuges, just a few specific recommendations can be made for RCF or time for centrifugation of blood specimens. For example, CLSI standard H18-A4[5] proposes an RCF of 1000 to 1200 ×g for 10 ± 5 minutes. Standards have not been established for centrifugation of other specimens, such as serum to which a protein precipitant has been added.

Operating Practice

Cleanliness of a centrifuge is important in minimizing the possible spread of infectious agents, such as hepatitis viruses. With proper operation of a centrifuge, few tubes break. In case of breakage, the racks and chamber of the centrifuge must be carefully cleaned. Any spillage should be considered a possible bloodborne pathogen hazard. Gray dust arising from sandblasting of the chamber by fragments of glass indicates tube breakage and possible contamination, necessitating cleaning of the chamber. Broken glass embedded in cushions of tube holders may be a continuing cause of breakage if cushions are not inspected and replaced as part of the cleanup procedure.

The speed of a centrifuge should be checked at least once every 3 months. The measured speed should not differ by more than 5% from the rated speed under specified conditions. All the speeds at which the centrifuge is commonly operated should be checked. The centrifuge timer should be checked weekly against a reference timer (such as a stopwatch) and should not be more than 10% in error. Commutators and brushes should be checked at least every 3 months. Brushes (where used) should be replaced when they show considerable wear. However, in many modern induction-driven motors, brushes have been eliminated, thus removing a source of dust that causes motor failure.

Because centrifuges generate heat, the temperature in the chamber in many centrifuge models may increase by as much as 5 °C after a single run. When the material to be centrifuged has a labile temperature, a refrigerated centrifuge should be used. In the simplest form, a refrigerator unit is mounted beside the centrifuge, and cold air is blown into the rotor chamber. This approach is usually inadequate to stabilize the low temperature. In more sophisticated centrifuges, refrigeration coils around the chamber make it possible to maintain a preset temperature within ±1 °C. The temperature of a refrigerated centrifuge should be measured monthly under reproducible conditions and should be within 2 °C of the expected temperature.

Measurement of Radioactivity

The rapid acceptance and extensive use of nonisotopic immunoassays by the clinical laboratory have resulted in decreased use of radioimmunoassays (RIAs) and ultimately a decreased requirement for their use in measuring radioactivity. Because of this deemphasis on the necessity of measuring radioactivity, only a brief discussion of the topic is presented here.

Basic Concepts

An *atom* is the smallest unit of an element having the properties of that element. An individual atom consists of a positively charged nucleus around which revolve negatively charged electrons. The *nucleus* is composed of positively charged protons and neutral neutrons. The *atomic number* (Z) of an element is the number of protons in its nucleus; the total number of nucleons and protons plus neutrons is its *mass number* (A). A *nuclide* is an atomic species with a given atomic number and a given mass number. *Isotopes* are nuclides with the same atomic number but different mass numbers. These represent various nuclear species of the same element. Radionuclides of clinical interest are listed in Table 9-12.

Radioactive Decay

Radioactive decay is a property of the atomic nucleus that provides evidence of nuclear instability. The rate of decay is unaffected by temperature, pressure, concentration, or any other chemical or physical condition, but is a characteristic of each individual radionuclide.

Alpha Decay. To achieve stable configurations, heavy elements, particularly those with atomic numbers above 70, may shed some of their nuclear mass by emitting a two-proton, two-neutron fragment identifiable after emission as a helium nucleus. Because nuclear radiations were observed before their identity was known, this fragment was called an *alpha* (α-) *particle,* and its emission is termed α*-decay.* Alpha particles are relatively large in mass and interact strongly with matter but are absorbed by as little as a sheet of paper. However, because they are so heavy, even with low velocity, their momentum is high. Consequently, they do not travel far, but when they collide with other molecules, they do a lot of damage; therefore α-emitters are considered to be very hazardous.

Beta Decay. For some heavy nuclides and for almost all those with atomic numbers below 60, stability is achieved by a rearrangement of the nucleus in which the total number of nucleons is unchanged. In terms of the neutron-proton model of the nucleus, this rearrangement is the conversion of a neutron to a proton or vice versa. During such conversions,

TABLE 9-12 Radiation Properties of Some Radionuclides Used in the Clinical Laboratory

Nuclides	Half-life	Decay Type*	Maximum Energy of Radiation (MeV)†	
			Beta	Gamma
^{3}H	12.3 y	β^-	0.186	None
^{14}C	5730 y	β^-	0.155	None
^{32}P	14.3 d	β^-	1.71	None
^{35}S	87 d	β^-	0.167	None
^{51}Cr	27.7 d	EC	None	0.320
^{57}Co	272 d	EC	None	0.122, 0.136, 0.014
^{58}Co	71 d	EC, β^-	0.474	0.811, annihilation photons only
^{59}Fe	45 d	β^-	0.475, 0.273	1.10, 1.29
^{99}Mo	66 h	β^-	1.21, 0.450	0.740, 0.181, 0.778
^{99m}Tc	6.0 h	IT	None	0.141
^{125}I	60 d	EC	None	0.035
^{131}I	8.04 d	β^-	0.607, 0.336	0.364, 0.637, 0.284

*β^-, β^+, EC, and IT refer to β-decay, positron decay, electron capture, and isomeric transition, respectively. Where nuclides are known to have more than one mode of decay, they are listed in the order of their prevalence.

†Energies are given only for the more prevalent β- and γ-radiations and are in approximate order of prevalence. Electron capture (EC) decay also yields the characteristic x-rays of the daughter; the energies of the x-rays are not included in this listing. As noted in the gamma column, positron decay (β^+) is accompanied by annihilation radiation, which consists principally of a pair of 0.511 MeV photons.

the nucleus emits either a negative electron or its positive equivalent, a *positron*. Emission of the negative electron, named the *beta* (β-) *particle,* is what is usually meant by the term β-*decay*.

Emission of a negative β-particle leaves the nucleus with one additional positive charge, a neutron is converted to a proton, and the nucleus assumes the next higher atomic number. Negative β-emission is characteristic of a nucleus that has more neutrons than required by its protons for stability. For example, tritium (^{3}H) is an unstable isotope of hydrogen, consisting of a proton, an electron, and two neutrons. When an atom of tritium decays, one of the neutrons is converted to a proton, one β-particle and one neutrino are released, and a helium isotope (^{3}He) remains. Tritium is called a "soft" β-emitter because its β-particles have relatively low velocities. A hard β-emitter, such as *phosphorus* 32 (^{32}P), is more hazardous because its β-particles carry more kinetic energy; however, it is easier to detect.

Other examples of nuclides that decay by negative β-emission are carbon-14 (^{14}C), iron-59 (^{59}Fe), and iodine-131 (^{131}I). Negatively charged β-particles are smaller in mass and interact less with matter than β-particles and easily penetrate paper and cardboard, but they are absorbed by metal sheets.

Electron Capture. An alternative decay process to the emission of positive β-particles is the capture of an electron. In this process, an orbital electron is "absorbed" by the nucleus. The end effect on nuclear structure is the same; a proton appears to have changed into a neutron, the atomic number decreases by one, and the atomic mass remains the same. For example, ^{125}I decays exclusively by electron capture to tellurium-125.

Gamma Radiation and Internal Conversion. Gamma radiation is high-energy electromagnetic radiation that resembles x-rays. An example of a γ-emitter is ^{131}I. Because γ-rays are high-energy photons, their penetrating power is very high and more difficult to shield.

Activity and Half-life

The rate of decay of a radioactive source is called its *activity* and is simply the rate at which radioactive parent atoms decay to more stable daughter atoms. In practice, it is often convenient to describe the rate of decay in terms of *half-life* ($t_{1/2}$), the time required for a nuclide's activity to decrease to half its initial value:

$$t_{1/2} = \frac{\ln 2}{\lambda} = \frac{0.693}{\lambda}$$

where λ is the decay constant characteristic of a given nuclide.

This equation is useful in planning experiments and in disposing of radioactive waste. For disposal, a rule of thumb is that a decay time of seven half-lives reduces the activity to less than 1% of its original value (2^{-7} = 1/128 = 0.78%), and after 10 half-lives, to less than 0.1%.

Units of Radioactivity

The *becquerel* (Bq) is the SI unit of radioactivity and is defined as one decay per second (dps). Because 1 Bq is a very small amount of activity, the activity of typical chemistry samples is often expressed in kilobecquerels (kBq). The *curie* (Ci) is the older, *conventional unit;* it is defined as 3.7×10^{10} dps. One curie equals 37 gigabecquerels (GBq). Because the becquerel is inconveniently small and the curie very large, they are typically used as their multiples or submultiples, for example,

megabecquerels (MBq) and millicuries (mCi). One mCi equals 37 MBq.

Specific Activity

The term *specific activity* has several meanings. It may refer to (1) radioactivity per unit mass of an element, (2) radioactivity per mass of labeled compound, or (3) radioactivity per unit volume of a solution. The denominator of reference must be specified. In terms of radioactivity per unit mass, the maximum specific activity attainable for each radionuclide is that for the pure radionuclide. For example, pure ^{14}C has a specific activity of 62 Ci/mol or 4400 Ci/kg. As usually available, ^{14}C is a tracer for compounds in which it represents only a small fraction of the total carbon, most of which is the naturally occurring mixture of stable ^{12}C and stable ^{13}C. If no stable element is present, the radionuclide is said to be *carrier free.*

Detection and Measurement of Radioactivity

Autoradiography, gas ionization, and fluorescent scintillation serve as the basis for techniques used to detect and measure radioactivity in the clinical laboratory.

Autoradiography

In *autoradiography,* a photographic emulsion is used to visualize molecules labeled with a radioactive element. For example, this technique is used to visualize nucleic acids and fragments that have been hybridized with nucleic acid probes labeled with ^{32}P (see Chapter 17). With such techniques, nucleic acid probes labeled with radioactive ^{32}P are incubated with target nucleic acid. After hybridization, hydrolysis, and separation of fragments by gel electrophoresis, a photographic film is applied to the covered gel and is allowed to incubate. Alternatively, the nucleic acid fragments are transferred to a nylon membrane, and the photographic film is applied to the membrane. With either approach, the film is developed with the resulting image reflecting the radioactivity of the target nucleic acid fragments.

Gas-Filled Detectors

Detectors filled with certain gases or gas mixtures are designed to capture and measure ions produced by radiation within the detector. Gas-filled detectors used to measure radioactivity include the (1) ionization chamber, (2) proportional counter, and (3) Geiger counter. In the clinical chemistry laboratory, the Geiger counter is used as a portable radiation monitor.

Scintillation Counting

In the scintillation process, absorption of radiation produces a flash of light. The principal types of scintillation detectors found in the clinical chemistry laboratory are the sodium iodide *crystal scintillation detector* and the *organic liquid scintillation detector.* Because of the crystal detector's relative ease of operation and economy of sample preparation, most clinical laboratory procedures have been developed to measure nuclides, such as ^{125}I, which is counted efficiently in a crystal detector. A liquid scintillation detector is used to measure pure β-emitters, such as tritium or ^{14}C.

Crystal Scintillation Detector. The *well detector* (often referred to as a γ-counter) is a common type of crystal scintillation detector and has a hole drilled in the end or side of the cylindrical crystal to accept a test tube. Because it is hygroscopic, the crystal is hermetically sealed in an aluminum can with a transparent quartz window at one end through which blue-violet (420 nm) scintillations are detected. The photons of gamma emitters, such as ^{51}Cr, ^{57}Co, ^{59}Fe, ^{125}I, and ^{131}I (see Table 9-8) in the sample, easily penetrate the specimen tube and the thin, low-density can, and enter the crystal where they are likely to be absorbed in the thick, high-density sodium iodide. A well counter is not suitable for measuring β-radiation because such radiation does not penetrate the sample container and the aluminum lining of the wall.

Liquid Scintillation Detector. This detector measures radioactivity by recording scintillations occurring within a transparent vial that contains the unknown sample and liquid scintillator. Because the radionuclide is intimately mixed with, or actually dissolved in, the liquid scintillator, the technique is ideal for the pure β-emitters, such as ^{3}H, ^{14}C, and ^{32}P. Typical efficiencies for liquid scintillation counting in the absence of significant quenching are 60% for tritium and 90% for ^{14}C.

The liquid scintillator is known as the *scintillation cocktail* and contains at least two components (the primary solvent and the primary scintillator). The *primary solvent* is usually one of the aromatic hydrocarbons such as toluene, xylene, or pseudocumene (1,2,4-trimethyl benzene). The *primary scintillator* absorbs energy from the primary solvent and converts it into light. The usual material is 2,5-diphenyloxazole (PPO) used in a concentration of 3 to 6 g/L. PPO emits ultraviolet light of 380 nm. In addition, other components added to the liquid scintillator include (1) a *secondary solvent* to improve the solubility of aqueous samples; (2) a surfactant to stabilize or emulsify the sample; (3) a *secondary scintillator,* sometimes referred to as a wavelength shifter, to absorb the ultraviolet photons of the primary scintillator and reemit the energy at a longer wavelength, which facilitates the response of some photomultiplier tubes; and (4) one or more *adjuvants,* such as suspension agents, solubilizers for biological tissue, and antifreezes, to prevent freezing and separation of water at low temperatures.

Description of other components of a scintillation counter and discussion of relevant topics are found in an earlier edition of this textbook.[23]

Gravimetry

Mass is an invariant property of matter. Gravimetry is the process used to measure the mass of a substance. Weight is a function of mass under the influence of gravity, a relationship expressed by the relationship

$$\text{Weight} = \text{Mass} \times \text{Gravity}$$

Two substances of equal weight and subject to the same gravitational force have equal mass. Mass is determined using

tahir99-VRG & vip.persianss.ir

a balance to compare the mass of an unknown with that of a known mass. This comparison is called *weighing,* and the absolute standards with which masses are compared are called *weights.* In practice, the terms *mass* and *weight* are used synonymously.

The classic form of a *balance* is a beam poised on an agate knife-edge fulcrum, with a pan hanging from each end of the beam and a rigid pointer hanging from the beam at the poised point. With the object to be weighed on one pan and weights of equal mass on the other pan, the pointer comes to rest at an equilibrium or balance point between the extremes of the path of excursion. The weight required to achieve the equilibrium is therefore equal to the weight of the substance being weighed.

Principles of Weighing

In practice, one of two modes of weighing is used: (1) analytical weights are added to equal the weight of the object being weighed, or (2) the material to be weighed is added to a balance pan to achieve equilibrium with a preset weight. This second mode is used more commonly in clinical laboratories, where the major necessity is to weigh a fixed quantity of chemical so that a calibrator or reagent solution of known concentration may be prepared. Before a sample of the chemical is weighed, the weight of the container must be determined to subsequently allow for deducting the weight of the container from the gross weight of the container plus sample to obtain the net weight of the sample. This is called "taring." When taring is impractical, the weight of the empty container must be subtracted from the combined weight of the container and the material to obtain the weight of the material alone.

Types of Balances

Double- and single-pan and electronic balances are frequently used in the clinical laboratory.

Double-Pan Balance

A double-pan balance conforms to the classic design, consisting of a single beam with arms of equal length. Standard weights are usually added by hand to the right-side pan to counterbalance the weight of the object on the other, but in some models, a dial or vernier with chain is used to make fine adjustments to the mass associated with the right-side pan. In *single-pan* balances, the arms are of unequal length. The object to be weighed is placed on the pan attached to the shorter arm. A restoring force is applied mechanically or electronically to the other arm to return the beam to its null position. Double- and triple-beam balances are forms of the unequal-arm balance.

Single-Pan Balance

The single-pan balance is a commonly used balance in the clinical laboratory. It is most often electronically operated and self-balancing. Such a balance may be coupled directly to a computer or recording device. In the electronic single-pan balance, a load on the pan causes the beam to tilt downward. A null detector senses the position of the beam and indicates when the beam has deviated from the equilibrium point.

Electronic Balance

In an electronic balance, an electromagnetic force is applied to return the balance beam to its null position. This force is proportional to the weight on the pan. Most electronic balances have a built-in provision for taring so that the mass of the container is subtracted easily from the total mass measured. In addition, in many modern balances, a built-in computer compensates for changes in temperature and provides both automatic zero tracking and calibration.

Analytical Weights

Analytical weights are used to counterbalance the weight of objects weighed on two-pan balances and to verify the performance of both single- and two-pan balances. The NIST recognizes five classes of analytical weights. Class S weights are used for calibrating balances. In the clinical laboratory, balances should be calibrated at least monthly and before very accurate analytical work is conducted. These weights are typically made from brass or stainless steel and are lacquered or plated for protection. The fractional weights of a set of class S standards are usually made of platinum or aluminum. Tolerances of the different weights have been defined by the NIST. For class S weights from 1 to 5 g, the tolerance is ±0.054 mg, from 100 to 500 mg it is ±0.025 mg, and from 1 to 50 mg it is ±0.014 mg.

Thermometry

In the clinical chemistry laboratory, measurements of temperature are made primarily to verify that devices measure within their prescribed temperature limits. Water baths and heated cells where reactions take place are examples of such devices, as are refrigerators, whose temperatures must be measured and recorded daily to meet laboratory regulatory requirements.

The two most popular types of thermometers in the chemistry laboratory are liquid-in-glass thermometers and thermistor probes.

All thermometers must be verified against a certified thermometer before they are placed into use. For example, the NIST SRM 934 is a mercury-in-glass thermometer with calibration points at 0 °C, 25 °C, 30 °C, and 37 °C. Some manufacturers supply liquid-in-glass thermometers that have ranges greater than the SRM thermometer and are verified to have been calibrated against the NIST thermometers. Details of verification of the calibration of a thermometer have been described.[9] The NIST also supplies several materials that melt at a known temperature, including gallium (SRM 1968), which melts at 29.7723 °C, and rubidium (SRM 1969), which melts at 39.3 °C.

Controlling Hydrogen Ion Concentration

In the laboratory, hydrogen ion concentration is controlled with buffers. *Buffers* are defined as substances that resist changes in the pH of a system. All weak acids or bases, in the

tahir99-VRG & vip.persianss.ir

presence of their salts, form buffer systems. The actions of buffers and their role in maintaining the pH of a solution are explained with the aid of the Henderson-Hasselbalch equation, which is derived as follows.

Chemically, the ionization of a weak acid, HA, and of a salt of that acid, BA, is represented as follows:

$$HA \rightleftharpoons H^+ + A^-$$

$$BA \rightleftharpoons B^+ + A^-$$

The dissociation constant for a weak acid (K_a) may be calculated from the following equation:

$$K_a = \frac{[H^+][A^-]}{[HA]}$$

Thus

$$[H^+] = K_a \times \frac{[HA]}{[A^-]}$$

or

$$\log[H^+] = \log K_a + \log\frac{[HA]}{[A^-]}$$

where brackets indicate the concentration of the compound contained within. Now multiplying throughout by −1, we obtain

$$-\log[H^+] = -\log K_a - \log\frac{[HA]}{[A^-]}$$

By definition, pH = –log[H] and pK_a = –log K_a, therefore

$$pH = pK_a + \log\frac{[A^-]}{[HA]}$$

This equation is known as the Henderson-Hasselbalch equation. Because A^- is derived principally from the salt, the equation is also written as

$$pH = pK_a + \log\frac{[salt]}{[undissociated\ acid]}$$

or simply as

$$pH = pK_a + \log\frac{[salt]}{[acid]}$$

where [salt] = [A^{-1}] = concentration of dissociated salt and [acid] = [HA] = concentration of undissociated acid.

This derivation demonstrates that the pH of the system is determined by the pK_a of the acid and the ratio of [A^{-1}] to [HA]. The buffer has its greatest buffer capacity at its pK_a [the pH at which the (A^{-1}) = (HA)].

The capacity of the buffer decreases as the ratio deviates from 1. In general, buffers should not be used at a pH greater than 1 unit from their pK_a. If the ratio is beyond 50/1 or 1/50, the system is considered to have lost its buffering capacity. This point is approximately 1.7 pH units to either side of the pK_a of the acid

$$pH = pK_a \pm 1.7$$

Procedures for Processing Solutions

Several procedures are used routinely to process solutions in the clinical laboratory, including those used for diluting, concentrating, and filtering solutions.

Dilution

Dilution is the process by which the concentration or activity of a given solution is decreased by the addition of solvent. In laboratory practice, most dilutions are made by transferring an exact volume of a concentrated solution into an appropriate flask and then adding water or other diluent to the required volume, with appropriate mixing to ensure homogeneity. A serial dilution is a sequential set of dilutions in mathematical sequence. A given dilution is expressed as the amount, either volume or weight, of a solute (analyte) in a specified volume. For example, a 1:5 volume-to-volume (vol/vol) dilution contains one volume in a total of five volumes (one volume plus four volumes).

To prevent errors that arise when two liquids of very different composition are mixed, the technique of diluting to volume is used. Instead of adding 90 mL of water to 10 mL of concentrated solution, the 10 mL of concentrated solution should be pipetted into a 100-mL volumetric flask. Water is added to bring the volume to the 100-mL mark on the neck of the flask.

When a dilution is performed, the following equation is used to determine the volume (V_2) necessary to dilute a given volume (V_1) of solution of a known concentration (C_1) to the desired lesser concentration (C_2):

$$C_1 \times V_1 = C_2 \times V_2$$

or

$$V_2 = \frac{C_1 \times V_1}{C_2}$$

Likewise, the equation is also used to calculate the concentration of the diluted solution when a given volume is added to the starting solution.

Evaporation

Evaporation is a process used to convert a liquid or a volatile solid into vapor. It is used in the clinical laboratory to remove liquid from a sample, thereby increasing the concentrations of analyte(s) left behind.

Lyophilization

Lyophilization (also known as "freeze drying") is used in laboratory medicine for the preparation of (1) calibrators, (2) control materials, (3) reagents, and (4) individual specimens for analysis. Lyophilization entails first freezing a material at −40 °C or less and then subjecting it to a high vacuum. Very low temperatures cause the ice to sublimate to a vapor state. The solid nonsublimable material remains behind in a dried state.

Filtration

Filtration is defined as the passage of a liquid through a filter and is accomplished by gravity, pressure, or vacuum. *Filtrate*

tahir99-VRG & vip.persianss.ir

is the liquid that has passed through the filter. The purpose of filtration is to remove particulate matter from the liquid. Many filtrations in the clinical laboratory are carried out with *filter paper* and with plastic *membranes* of controlled pore size.

Membrane filters are used (1) under vacuum, (2) with positive pressure, or (3) with gravity. Filters have been incorporated into certain disposable tips for use with semiautomatic pipettes. These filters minimize the exchange of aerosol droplets between the tips and the pipette. This is of particular importance for DNA amplification and microbiological procedures. Other membrane filters are designed for ultrafiltration and are available with a variety of pore sizes for selective filtration. *Ultrafiltration* is a technique for removing dissolved particles using an extremely fine filter. It is used to concentrate macromolecules, such as proteins, because smaller dissolved molecules pass through the filter.

SAFETY

In the United States, the Federal Occupational Safety and Health Act of 1970 marked the beginning of formal regulatory oversight of employee safety. Since 1970, the Occupational Safety and Health Administration (OSHA) and the Centers for Disease Control and Prevention (CDC) have published numerous safety standards that apply to clinical laboratories. Each year, as The Joint Commission (JC) and the College of American Pathologists (CAP) revise their guidelines, more attention is devoted to safety. Consideration for the health and responsibility for the safety of employees are now accepted as obligations of all employers and laboratory directors. In May of 1988, OSHA expanded the Hazard Communication Standard to apply to hospital workers. Part of this standard is frequently referred to as the "Lab Right to Know Standard."

There are many aspects to the safe operation of a clinical laboratory. Key elements for safety in the clinical laboratory include

1. A formal safety program.
2. Documented policies and effective use of mandated plans and/or programs in the areas of chemical hygiene, control of exposure to bloodborne pathogens, tuberculosis control, and ergonomics.
3. Identification of significant occupational hazards, such as biological, chemical, fire, and electrical hazards, and clear identification and documentation of policies for employees to deal with each type of hazard (e.g., packaging and shipping of diagnostic specimens and infectious substances).
4. Recognition that there are additional important and relevant safety areas of concern. These areas include effective waste management and bioterrorism and chemical terrorism response plans in the event of potential threats or casualties involving these types of agents.

Safety Program

Every clinical laboratory must have and implement a comprehensive formal safety program. Regardless of the size of the clinical laboratory, a specific individual should be designated as the "Safety Officer" or "Chair of the Safety Committee" and given the responsibility to implement and maintain a safety program. Safety is each employee's responsibility, but responsibility for the entire program begins with the laboratory leadership (directors, administrative directors, supervisors, managers, etc.) and is delegated through the leadership to the safety officer or safety committee. This individual or committee then has the duties of providing guidance to laboratory leadership on matters related to the provision of a safe workplace for all employees. Although a small institution may have one individual who deals with all safety-related matters for all departments, including the laboratory, OSHA mandates that the laboratory specifically have a chemical hygiene officer, who is designated on the basis of training or experience to provide technical guidance in the development of the *chemical hygiene plan (CHP)* discussed later.

An integral part of the laboratory safety program is the education and motivation of all laboratory employees in all matters related to safety. All new employees should be given a copy of the general laboratory safety manual as part of their orientation. The continuing education program of the laboratory should include periodic talks on safety. Safety information is available from a variety of sources to support the continuing education element of the safety program.[6,7,11]

Another important part of the laboratory safety program relates to ensuring that the laboratory environment meets accepted safety standards. This would include, but would not be limited to, attention to such items as (1) proper labeling of chemicals, (2) types and locations of fire extinguishers, (3) hoods that are in good working order, (4) proper grounding of electrical equipment, (5) ergonomic issues (which include equipment, such as pipetting devices, laboratory furniture, and prevention of musculoskeletal disorders),[19] and (6) providing means for the proper handling and disposal of biohazardous materials, including all patient specimens.[7]

Safety Equipment

OSHA requires that institutions provide employees with all necessary personal protective equipment (PPE). Key important safety items are (1) clothing (such as laboratory coats, gowns, and/or scrubs), (2) gloves, and (3) eye protection. These safety items should be used in areas where they are appropriate. Eye washers or face washers should be available in every chemistry laboratory. Many types are available, and some simply connect to existing plumbing. A handheld eye and/or face safety spray is a requisite safety device and is typically placed in a position next to each sink using only a few inches of space. Safety showers, strategically located in the laboratory, must be available and should be tested on a regular schedule.

Heat-resistant (nonasbestos) gloves should be available for handling hot glassware and dry ice. Safety goggles, glasses, and visors, including some that fit conveniently over regular eyeglasses, are available in many sizes and shapes. Personnel wearing contact lenses should be aware of the danger of irritants getting under a lens, making it difficult to irrigate the

tahir99-VRG & vip.persianss.ir

eye properly. Shatterproof safety shields should be used in front of systems posing a potential danger because of implosion (vacuum collapse) or pressure explosions. *Desiccator* guards should be used with vacuum desiccators. Hot beakers should be handled with tongs. Inexpensive polyethylene pumps are available to pump acids from large bottles. Spill kits for acids, caustic materials, or flammable solvents come in various sizes. Such kits and the other appropriate safety materials should be located in convenient and appropriate sites in the laboratory.

A chemical fume hood is a necessity for every clinical chemistry laboratory. In practice, it is used for (1) opening any container of a material that gives off harmful vapors, (2) preparing reagents that produce fumes, and (3) heating flammable solvents. In the event of an explosion or a fire in the hood, closing its window contains the fire.

Safety Inspections

It is good laboratory practice to organize a safety inspection team from the laboratory staff. This team is responsible for conducting periodic and scheduled safety inspections of the laboratory.[8]

In the United States, several regulatory, private accreditation, state, and federal organizations may conduct a safety inspection of the laboratory. Some of these safety inspections may occur unannounced. From an external perspective, OSHA inspectors have the authority to enter a clinical laboratory unannounced and, on presentation of credentials, inspect it. The inspection may be regular or may occur as the result of a complaint. In addition, the Commission on Inspection and Accreditation of the CAP inspects clinical laboratories and uses various safety checklists (available to the laboratory before inspection) when evaluating a laboratory for accreditation. Although the The Joint Commission (JC) will accept CAP accreditation of a laboratory, it still may conduct a safety inspection of the laboratory when it inspects the hospital. The CAP and JC conduct their accreditation inspections, which may include a full laboratory or laboratory safety component, unannounced.

Depending on the group designated as responsible for accrediting a particular laboratory, selected laboratories may be subject to inspections for the purposes of accreditation and/or safety only by state agencies or local Centers for Medicare and Medicaid Services (CMS) groups. Inspections may be made on a regular basis by state or local health departments or by local fire departments to determine conformance with their particular safety requirements. Currently a laboratory that meets federal or state OSHA requirements is likely to satisfy the standards of any other inspecting agency.

Plans for the Clinical Laboratory

In 1991, OSHA mandated that all clinical laboratories in the United States must have a CHP and an exposure control plan. OSHA has since updated their requirements for the exposure control plan to provide new examples of engineering controls and to place significantly greater responsibility on employers to minimize and manage employee occupational exposure to bloodborne pathogens.[21] The CAP and other groups require that an accredited laboratory must have a documented tuberculosis exposure control plan that conforms with biosafety guidelines published by the CDC.[3] Elements of the plan must include regularly defined intervals for employee exposure, as well as process controls, to minimize exposure to aerosolization of *Mycobacterium tuberculosis*.

In addition, it is now recognized that the workplace setting of a clinical laboratory exposes employees to the occupational risk of developing various musculoskeletal disorders. As a result, the focus of OSHA on laboratories that have an effective ergonomics program has led to federal, state, and private accreditation groups addressing this area of occupational safety. However, considerable controversy on this issue is ongoing, with a final ergonomics rule published and then withdrawn in 2001.[14]

Chemical Hygiene Plan

Major elements of a CHP include listing of responsibilities for employers, employees, and a chemical hygiene officer. Also, every laboratory must have a complete chemical inventory that is updated annually. A copy of the *Material Safety Data Sheet (MSDS),* which defines each chemical as toxic, carcinogenic, or dangerous, must be on file and readily accessible and available to all employees 24 hours a day, 7 days a week. The MSDS contains important information for the benefit of laboratory employees. The chemical manufacturer's information as supplied on the MSDS is used to ascertain whether a certain chemical is hazardous. Each MSDS must give the product's identity as it appears on the container label and the chemical and common names of its hazardous components. The MSDS also provides physical data on the product, such as boiling point, vapor pressure, and specific gravity. Easily recognized characteristics of the chemical are also listed on the line for "appearance and odor." Information about hazardous properties is given in detail on the MSDS; this includes fire and explosion hazard data and health-related data, including the threshold limit value (TLV), exposure limits, and toxicity values. The TLV is the exposure allowable for an employee during one 8-hour day. It also notes effects of overexposure and details first-aid procedures. Each MSDS also provides information on spill and disposal procedures and protective personal gear and equipment requirements.

Exposure Control Plan

OSHA regulations require that each laboratory develop, implement, adhere to, and maintain a plan that ensures the protection of laboratory workers against potential exposure to bloodborne pathogens,[6,8] and that ensures that medical wastes produced by the laboratory are managed and handled in a safe and effective manner.[7,8] OSHA regulations also place responsibility on employers to implement new developments in exposure control technology; to solicit the input of employees directly involved in patient care in the identification, evaluation, and selection of these work practice controls; and in certain instances to maintain a log for employee percutaneous injuries from sharp devices, such as syringe

tahir99-VRG & vip.persianss.ir

needles.[21] Organizationally, the plan should include sections on (1) purpose, (2) scope, (3) applicable references, (4) applicable definitions, (5) definition of responsibilities, and (6) detailed procedural steps.

When implementing the plan, each laboratory employee must be placed into one of the following three groups.

Group I: A job classification in which all employees have occupational exposure to blood or other potentially infectious materials.

Group II: A job classification in which some employees have occupational exposure to blood or other potentially infectious materials.

Group III: A job classification in which employees do not have any occupational exposure to blood or other potentially infectious materials.

Tuberculosis Control Plan

The purpose of the tuberculosis control plan is to prevent the transmission of tuberculosis (TB), which occurs when an individual inhales a droplet that contains *Mycobacterium tuberculosis*. *M. tuberculosis* is aerosolized when an infected individual sneezes, speaks, or coughs (http://www.cdc.gov/tb/publications/guidelines/control_elim.htm/accessed April 26, 2011). Transmission of TB and exposure to TB are greatly diminished with (1) early identification and isolation of patients at risk, (2) environmental controls, (3) appropriate use of respiratory protection equipment, (4) education of laboratory employees, and (5) early initiation of therapy.

An effective tuberculosis control plan will include determination of exposure at regular intervals for all employees who are at occupational risk. Engineering and work practice controls are particularly important in laboratory areas, such as surgical pathology and microbiology. But there is clearly a risk of exposure from specimens of patients with suspected or confirmed tuberculosis in every section of the laboratory, including chemistry.

Pandemic Plan

A *pandemic* is an epidemic of infectious disease that spreads through populations across a large region or even worldwide. An influenza pandemic is a worldwide outbreak or epidemic caused by an influenza virus. For example, the influenza pandemic of 1918-1919 killed between 20 and 40 million people with more than 500,000 deaths reported in the United States alone (http://1918.pandemicflu.gov; accessed March 16, 2011).

Influenza viruses capable of causing a pandemic (1) must cause human disease, (2) have novel surface antigens, and (3) must be able to be spread effectively from person to person. Beginning in 1997, an outbreak of avian influenza (strain H5N1) affected birds in several countries in Asia, Africa, and Europe. This strain has been shown to cause lethal disease among humans and created concern that it might evolve into a strain of virus capable of causing a pandemic. Subsequently, many states in the United States developed pandemic influenza control or response plans (http://www.pandemicflu.gov; accessed March 16, 2011).[24]

A novel influenza A (H1N1) of swine origin was first detected in April of 2009.[22] This virus was found to be highly infectious, easily spreading from person to person, and led to an outbreak of illness in the United States and internationally as well (http://www.cdc.gov/h1n1flu; accessed March 16, 2011). A global pandemic was declared by the World Health Organization in June of 2009.

Because of the potential for exposure of individuals working in healthcare settings, the CDC has published recommendations for establishing infection control.[4] These recommendations provide guidance for all individuals who may be processing or performing diagnostic testing on clinical specimens from patients with suspected novel influenza A (H1N1) virus infection, or performing viral isolation.

Ergonomics Program

Several areas of occupational risk for development of musculoskeletal disorders have been identified in the clinical laboratory. These include (1) routine laboratory activity, (2) functionality of the workspace (including laboratory floor matting, bright lighting, and noise generation), and (3) equipment design (computer keyboards and displays, workstations, and chairs). One particular laboratory function, pipetting and related pipette design, has received considerable attention. As depicted in Figure 9-2, pipettes are being designed with the goal of reducing an employee's risk of developing cumulative stress disorders caused by awkward posture, repetitive motion, and repeated use of force.

The CAP requires accredited laboratories to have a comprehensive and defined ergonomics program that is designed to prevent work-related musculoskeletal disorders through prevention and engineering controls. The documented ergonomics plan should include elements of employee training regarding the areas of risk, engineering controls to minimize or eliminate risks, and an assessment process to identify problematic issues for documentation and remediation.

Hazards in the Laboratory

Various types of hazards are encountered in the operation of a clinical laboratory. These hazards must be identified and labeled, and work practices developed for dealing with them. The major categories of hazards encountered include (1) biological, (2) chemical, (3) electrical, and (4) fire hazards.

Identification of Hazards

Clinical laboratories deal with each of the nine classes of hazardous materials. These are classified by the United Nations (UN) as (1) explosives, (2) compressed gases, (3) flammable liquids, (4) flammable solids, (5) oxidizer materials, (6) toxic materials, (7) radioactive materials, (8) corrosive materials, and (9) miscellaneous materials not elsewhere classified. Shipping and handling of class 6 toxic materials, specifically biological and potentially infectious materials, has received considerable attention. In 2002, the U.S. Department of Transportation (DOT) released a revised rule with standards for infectious substance hazardous material handling.[12] Warning labels aid in the identification of

tahir99-VRG & vip.persianss.ir

chemical hazards during shipment. Under regulations of the DOT, chemicals that are transported in the United States must carry labels based on the UN classification. DOT placards or labels are diamond shaped with a digit imprinted on the bottom corner that identifies the UN hazard class (1 to 9). The hazard is identified more specifically in printed words placed along the horizontal axis of the diamond. Color coding and a pictorial art description of the hazard supplement the identification of hazardous material on the label; the artwork appears in the top corner of the diamond (Figure 9-5, *A*).

The system is used by the DOT for shipping hazardous materials; however, when the hazardous material reaches its destination and is removed from the shipping container, this identification is lost. The laboratory must then label each individual container. Usually the information necessary to classify the contents of the container appropriately is contained on the shipping label and should be noted. Important first aid information is usually provided on this label.

Even though OSHA at present prescribes the use of labels or other appropriate warnings, no single uniform labeling system for hazardous chemicals exists for use by clinical laboratories. Appropriate hazard warnings include any words, pictures, symbols, or combinations that convey the health or physical hazards of the container's contents and must be specific as to the effect of the chemical and the specific target organs involved. The National Fire Protection Association (NFPA) has developed the 704-M Identification System, which classifies hazardous material from 0 to 4 (most hazardous) according to flammability and reactivity (instability). This system uses diamond-shaped labels (Figure 9-5, *B*), which are available from most companies that sell laboratory safety equipment. The labels are color coded and are divided into quadrants. Three of the quadrants have a characteristic color and represent a type of hazard. A number in the quadrant indicates the degree of hazard. The fourth (lower) quadrant contains information of special interest to firemen.

Biological Hazards

It is essential to minimize the exposure of laboratory workers to infectious agents, such as the hepatitis viruses, human immunodeficiency virus (HIV), and flu viruses. Exposure to infectious agents results from (1) accidental puncture with needles, (2) spraying of infectious materials by a syringe or spilling and splattering of these materials on bench tops or floors, (3) centrifuge accidents, and (4) cuts or scratches from contaminated vessels. Any unfixed tissue, including blood slides, must also be treated as potentially infectious material.

OSHA has mandated that all U.S. laboratories have an exposure control plan. In addition, the National Institute for Occupational Safety and Health (NIOSH), a functional unit of the CDC, has prepared and widely distributed a document entitled *Universal Precautions* that specifies how U.S. clinical laboratories should handle infectious agents.[18] In general, it mandates that clinical laboratories treat all human blood and other potentially infectious materials as if they were known to contain infectious agents, such as hepatitis B virus (HBV), HIV, and other bloodborne pathogens. These requirements apply to all specimens of (1) blood, (2) serum, (3) plasma, (4) blood products, (5) vaginal secretions, (6) semen, (7) cerebrospinal fluid, (8) synovial fluid, and (9) concentrated HBV or HIV viruses. In addition, any specimen of any type that contains visible traces of blood should be handled using these universal precautions.

Universal precautions also specify that barrier protection must be used by laboratory workers to prevent skin and mucous membrane contamination from specimens. These barriers, also known as PPE, include (1) gloves, (2) gowns, (3) laboratory coats, (4) face shields or mask and eye protection, (5) mouthpieces, (6) resuscitation bags, (7) pocket masks, and (8) other ventilator devices. For some individuals, latex allergy is a problem when latex gloves are used for

tahir99-VRG & vip.persianss.ir

barrier protection. For such individuals, medical grade nonlatex gloves made of materials such as vinyl, nitrile, neoprene, or thermoplastic elastomer are available. If latex gloves are to be used, they should be made of powder-free, low-allergen latex.

New products for increasing employee protection against needlesticks include an array of novel containers for sharps (e.g., needles, scalpels, glass) and biological safety disposal bags and needle sheaths that may be closed following venipuncture without physically touching the needle or the sheath. Although additional studies on their efficacy and effects on laboratory test results are required, microlaser devices are now available for piercing a patient's skin to collect a capillary blood specimen.

The CLSI has published a similar set of recommendations,[6,8] several of which are specified as requirements in the OSHA exposure control plan. They include the following:

"1. Never perform mouth pipetting and never blow out pipettes that contain potentially infectious material.
2. Do not mix potentially infectious material by bubbling air through the liquid.
3. Barrier protection, such as gloves, masks, and protective eye wear and gowns, must be available and used when drawing blood from a patient and when handling all patient specimens. This includes the removal of stoppers from tubes. Gloves must be disposable, nonsterile latex or of other material to provide adequate barrier protection. Phlebotomists must change gloves and adequately dispose of them between drawing blood from different patients.
4. Wash hands whenever gloves are changed.
5. Facial barrier protection should be used if there is a significant potential for the spattering of blood or body fluids.
6. Avoid using syringes whenever possible and dispose of needles in rigid containers (Figure 9-6, *A*) without handling them (Figure 9-6, *B*).
7. Dispose of all sharps appropriately.
8. Wear protective clothing, which serves as an effective barrier against potentially infective materials. When leaving the laboratory, the protective clothing should be removed.
9. Strive to prevent accidental injuries.
10. Encourage frequent hand washing in the laboratory; employees must wash their hands whenever they leave the laboratory.
11. Make a habit of keeping your hands away from your mouth, nose, eyes, and any other mucous membranes. This reduces the possibility of self-inoculation.
12. Minimize spills and spatters.
13. Decontaminate all surfaces and reusable devices after use with appropriate U.S. Environmental Protection Agency (EPA)-registered hospital disinfectants. Sterilization, disinfection, and decontamination are discussed in detail in CLSI publication M29-A3.[6]
14. No warning labels are to be used on patient specimens since all should be treated as potentially hazardous.
15. Biosafety level 2 procedures should be used whenever appropriate.

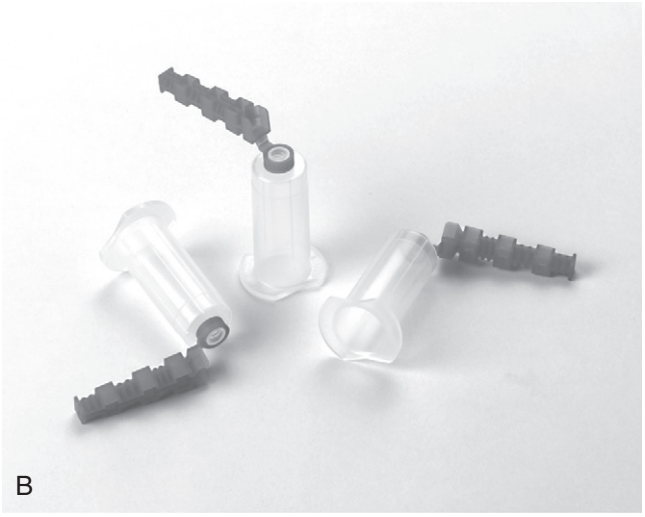

Figure 9-6 A, Convenient needle disposal system for sharps. B, Needle sheathing devices for prevention of body contact with needle. *(B, Courtesy MarketLab Inc.)*

16. Before centrifuging tubes, inspect them for cracks. Inspect the inside of the trunnion cup for signs of erosion or adhering matter. Be sure that rubber cushions are free from all bits of glass.
17. Use biohazard disposal techniques (e.g., 'Red Bag').
18. Never leave a discarded tube or infected material unattended or unlabeled.
19. Periodically, clean out freezer and dry-ice chests to remove broken ampoules and tubes of biological specimens. Use rubber gloves and respiratory protection during this cleaning.
20. OSHA requires that hepatitis B vaccine be offered to all employees at risk of potential exposure as a regular or

tahir99-VRG & vip.persianss.ir

occasional part of their duties. CDC's Advisory Committee on Immunization Practices (ACIP) recommends that medical technologists, phlebotomists, and pathologists be vaccinated with hepatitis B vaccine. It is a regulatory mandate that all of the above laboratory employees at a minimum [at least] be given the option to receive free hepatitis B vaccine."

Investigation of tragic air accidents in the late 1990s by the U.S. National Transportation Safety Board (NTSB) led to the development of revised and strict requirements for the shipping and handling of hazardous materials by DOT, in cooperation with the International Air Transport Association (IATA) and the International Civil Aviation Organization (ICAO).[12]

These regulations place particular emphasis on the hazardous material (HAZMAT) training that must be given to laboratory employees regarding shipping and handling of infectious substances. Elements include general awareness and familiarization, function-specific information, and safety training. Proper training, particularly in the areas of package labeling and documentation (including a shipper's declaration of contents for dangerous goods), is mandatory, and documented certification from employers that the relevant employees have had appropriate training programs is required. Although the adverse impact of improper training can be reflected most by potential human morbidity and mortality, identified violations of these regulations also carry large financial fines and penalties for both the infringing individual and the employer or institution.

Chemical Hazards

Proper storage and use of chemicals is necessary to prevent dangers, such as burns, explosions, fires, and toxic fumes. Thus knowledge of the properties of the chemicals in use and of proper handling procedures greatly reduces dangerous situations. Bottles of chemicals and solutions should be handled carefully, and a cart should be used to transport heavy or multiple numbers of containers from one area to another. Glass containers with chemicals should be transported in rubber or plastic containers that protect them from breakage and, in the event of breakage, contain the spill. Appropriate spill kits should be available in strategic locations.

Spattering from acids, caustic materials, and strong oxidizing agents is a hazard to clothing and eyes and is a potential source of chemical burns. A bottle should never be held by its neck but instead firmly around its body with one or both hands, depending on the size of the bottle. Acids must be diluted by slowly adding them to water while mixing; water should never be added to concentrated acid. When working with acid or alkali solutions, safety glasses should be worn. Acids, caustic materials, and strong oxidizing agents should be mixed in the sink. This provides water for cooling and for confinement of the reagent in the event that the flask or bottle breaks.

All bottles containing reagents must be properly labeled. It is good practice to label the container before adding the reagent, thus preventing the possibility of having an unlabeled reagent. The label should bear the (1) name and concentration of the reagent, (2) initials of the person who made up the reagent, and (3) date on which the reagent was prepared. When appropriate, the expiration date should also be included. The labels should be color coded or an additional label added to designate specific storage instructions, such as the requirement for refrigeration or special storage related to a potential hazard. All reagents found in unlabeled bottles should be disposed of using appropriate procedures and precautions.

Strong acids, caustic materials, and strong oxidizing agents should be dispensed by a commercially available automatic dispensing device. Under no circumstances is mouth pipetting permitted.

In some instances, all waste materials are not collected in the same container. With certain pieces of equipment, strong acids or other hazardous materials are pumped directly into the drain. This should always be accompanied by a steady flow of water from the faucet. Safety glasses should be used by instrument operators when acids are pumped under pressure.

Perchloric acid, because it is potentially explosive in contact with organic materials, requires careful handling. Perchloric acid should not be used on wooden bench tops, and bottles of this acid should be stored on a glass tray. Disposal may be accomplished by adding the acid dropwise (using a splatter shield) to at least 100 volumes of cold water and pouring the diluted acid down the drain with large amounts of additional cold water. Special perchloric acid hoods, with special wash-down facilities, should be installed if large amounts of this acid are used.

Special care is necessary when dealing with mercury. Even small drops of mercury on bench tops and floors may poison the atmosphere in a poorly ventilated room. The element's ability to amalgamate with a number of metals is well known. After an accidental spillage of mercury, the spill area should be cleaned carefully until no droplets are remaining. All containers of mercury should be kept well stoppered. Because it is highly hazardous, most recommend that no mercury be used in the laboratory.

The EPA controls the disposal of nonradioactive hazardous wastes. The Resource Conservation and Recovery Act of 1976 (RCRA) states that disposal of materials classifiable within any of the nine UN hazardous materials classes is enforced in such a way that health and safety professionals involved in the disposal of such materials are personally liable for each individual violation.

A CLSI publication[7] covers hazardous waste disposal; however, many municipalities and states have their own regulations. These agencies should be contacted by the laboratory for specifics.

Volatile chemicals and compressed gases pose specific hazards.

Hazards from Volatiles

The use of organic solvents in a clinical laboratory represents a potential fire hazard and hazards to health from inhalation

tahir99-VRG & vip.persianss.ir

of toxic vapors or skin contact. These solvents should be used in a fume hood. Storage of organic solvents is regulated by rules set down by OSHA. However, some local fire department rules are more stringent. Solvents should be stored in an OSHA-approved metal storage cabinet that is properly vented. The maximum working volume of flammable solvents allowed outside storage cabinets is 5 gallons per room. No more than 60 gallons of type I and II solvents may be stored in a single cabinet. No more than three cabinets may be located in each 5000 sq ft of laboratory space.

Vaporization is a major problem in the ignition and spread of fires. Vapors from flammable and combustible liquids and solids form a flammable mixture with air. They are characterized by their flash point, where the flash point is defined as the lowest temperature at which a solvent gives off flammable vapors in the close vicinity of its surface. The mixture at its flash point ignites when exposed to a source of ignition. At temperatures below the flash point, the vapor given off is considered too lean for ignition.

Disposal of flammable solvents in storm sewers or sanitary sewers generally is not allowed. Exceptions are small amounts of those materials that are miscible with water, but even disposal of these should be followed by large amounts of cold water. Other solvents should be collected in safety cans. Separate cans should be used for ether and for chlorinated solvents; all other solvents may be combined in a third can. The cans should be stored, in keeping with storage quantity rules, in a safety cabinet until pickup by a waste disposal firm. A more economical approach is to transfer the solvents to larger cans or drums in an outside storage facility, so that pickup can be less frequent. Some large institutions have their own in-house disposal facilities.

Hazards from Compressed Gases

DOT regulations cover the labeling of cylinders of compressed gases that are transported by interstate carriers. The diamond-shaped labels described previously are used on all large cylinders and on any boxes containing small cylinders. Some general rules for handling large cylinders of compressed gas are as follows:

1. Always transport cylinders using a hand truck to which the cylinder is secured.
2. Leave the valve cap on a cylinder until the cylinder is ready for use, at which time the cylinder should have been secured by a support around the upper one third of its body. Disconnect the hose or regulator, shut off the valve, and replace the cap before the cylinder is completely empty to prevent the possibility of development of a negative pressure. Place an "empty" sign or label on the cylinder.
3. Chain or secure cylinders at all times even when empty.
4. Always check cylinders for the composition of their contents before connection.
5. Never force threads; if a regulator does not thread readily, something is wrong.

The precautions cited for large, refillable gas cylinders also apply to small cylinders that are not refillable. Propane cylinders and cylinders of calibrating gases for blood gas equipment are examples of disposable cylinders. Cylinders in floor-standing base supports require the additional security of a chain or strap attached to a wall or fixed piece of furniture. Local fire department regulations (which vary considerably from place to place) govern the disposal of exhausted cylinders.

Electrical Hazards

Electrical wires or connections are potential shock or fire hazards. Worn wires on all electrical equipment should be replaced immediately, and all equipment should be grounded using three-prong plugs. OSHA regulations stipulate that the requirements for grounding of electrical equipment of the National Electrical Code (published by NFPA) be met. If grounded receptacles are not available, a licensed electrician should be consulted for proper alternative grounding techniques. Some local codes are more stringent than OSHA requirements and do not allow for two-pole mating receptacles with adapters for a three-pole plug.

Use of extension cords is prohibited. This standard is more stringent than any other existing regulation. In some instances, an extension cord may have to be used temporarily. In such cases, the cord should (1) be less than 12 feet in length, (2) include at least 16 American Wire Gauge (AWG) wire, (3) be approved by the Underwriters Laboratory (UL), and (4) have only one outlet at the end. If several outlets are necessary in a single area, a power strip with its own fuse or circuit breaker may be installed at least 3 inches above bench top level. Several manufacturers now sell devices to check for high resistance in neutral or ground wiring or excess voltage in neutral wiring.

Electrical equipment and connections should not be handled with wet hands, nor should electrical equipment be used after liquid has been spilled on it. The equipment must be turned off immediately and dried thoroughly. In case of a wet or malfunctioning electrical instrument that is used by several people, the plug should be pulled and a note cautioning coworkers against use should be left on the instrument.

Fire Hazards

NFPA and OSHA publish standards covering subjects from emergency exits (including means of egress) to safety and firefighting equipment. NFPA also publishes the National Fire Codes. Many state and local agencies have adopted these codes (some of which are more stringent than OSHA requirements), thus making them legally enforceable.

Every laboratory should have the necessary equipment to extinguish or confine a fire in the laboratory and to extinguish a fire on the clothing of an individual. Easy access to safety showers is essential. A safety shower should have a pull chain attached to the wall at a convenient height or hanging down from the shower head; the chain should have a large ring attached so that the shower may be easily activated, even with eyes closed. Fire blankets for smothering fire on clothing should be available in an easily accessible wall-mounted case. The blanket is unrolled from the case and is rolled around the

tahir99-VRG & vip.persianss.ir

TABLE 9-13 Classification of Fires and Fire Extinguisher Requirements

Type of Hazard	Class of Fire	Recommended Extinguisher Agents
Ordinary combustibles: wood, cloth, paper	A	Water, dry chemical foam, loaded steam
Flammable liquids and gases: solvents and greases, natural or manufactured gases	B	Dry chemical, carbon dioxide, loaded steam, Halon 1211 or 1301 foam
Electrical equipment: any energized electrical equipment. If electricity is turned off at source, this reverts to a class A or B.	C	Dry chemical, carbon dioxide, Halon 1211 or 1301 foam
Combinations of ordinary combustibles and flammable liquids and gases	A and B	Dry chemical, loaded steam, foam
Combinations of ordinary combustibles and electrical equipment	A and C	Dry chemical
Combinations of flammable liquids and gases and electrical equipment	B and C	Dry chemical, carbon dioxide, Halon 1211 or 1301 foam
Combinations of ordinary combustibles, flammable liquids and gases, and electrical equipment	A, B, and C	Triplex dry chemical

body by taking hold of the rope that is attached to the blanket and turning the body around. The location of this equipment and the locations of fire alarms and maps of evacuation routes are dictated by the local fire marshal.

Various types of fire extinguishers are available. The type to use depends on the type of fire. Because it is impractical to have several types of fire extinguishers present in every area, dry chemical fire extinguishers are among the best all-purpose extinguishers for laboratory areas. An extinguisher should be provided near every laboratory door and, in a large laboratory, at the end of the room opposite the door. Everyone in the laboratory should be instructed in the use of these extinguishers and any other available firefighting equipment. All fire extinguishers should be tested by qualified personnel at intervals specified by the manufacturer. The three classes of fires and the type of fire extinguisher to be used for each are listed in Table 9-13. Every fire extinguisher is labeled as to the type of fire it should be used to extinguish.

Two additional types of fires, designated "D" and "E," should be handled only by trained personnel. Type D fires include those involving powdered metal materials (e.g., magnesium). A special powder is used to fight this hazard. A type E fire is one that cannot be put out or is liable to result in a detonation (such as an arsenal fire). A type E fire is usually allowed to burn out while nearby materials are appropriately protected.

Many clinical laboratories now have a computer that is housed in a temperature- and humidity-controlled room. The most popular automatic fire control system used for these rooms is Halon 1301 (bromotrifluoromethane). Although this is the least toxic of the halons, NFPA regulations require a warning sign at the entrance to the room and availability of self-contained breathing equipment.

CHAPTER 10

Optical Techniques

*Larry J. Kricka, D.Phil., F.A.C.B., C.Chem., F.R.S.C., F.R.C.Path., and Jason Y. Park, M.D., Ph.D., F.C.A.P.**

Many determinations made in the clinical laboratory are based on measurements of radiant energy emitted, transmitted, absorbed, scattered, or reflected under controlled conditions. The principles involved in such measurements are considered in this chapter.

NATURE OF LIGHT

Electromagnetic radiation includes radiant energy that extends from cosmic rays with wavelengths as short as 10 nm up to radio waves longer than 1000 km. However, in this chapter, the term *light* is used to describe radiant energy from the ultraviolet and visible portions of the spectrum (180 to 800 nm).

The wavelength of light is defined as the distance between two peaks as the light travels in a wavelike manner. This distance is expressed in nanometers (nm) for wavelengths commonly used in photometry. Other units include

$$1\ \text{nm} = 1\ \text{millimicron (m}\mu\text{)} = 10\ \text{Angstroms (Å)} = 10^{-9}\ \text{m}$$

In addition to possessing wavelength characteristics, light has properties that indicate that it is composed of discrete energy packets called *photons.* The relationship between the energy of photons and their frequency is given by the equation

$$E = h\nu \qquad (1)$$

where E = energy in ergs, ν = frequency of light in cycles per second, and h = Planck's constant (6.62×10^{27} erg seconds). The frequency of light (ν) is related to the wavelength by an equation

$$\nu = \frac{c}{\lambda} \qquad (2)$$

where c = speed of light in a vacuum (3×10^{10} cm/s), and λ = wavelength in centimeters. Combining equations (1) and (2) results in

$$E = \frac{hc}{\lambda} \qquad (3)$$

This equation shows that the energy of light is inversely proportional to the wavelength. For example, ultraviolet (UV) radiation at 200 nm possesses greater energy than infrared (IR) radiation at 750 nm.

The human eye is able to detect radiant energy with wavelengths between about 380 and 750 nm, but modern instrumentation permits measurements at both shorter wavelength (UV) and longer wavelength (IR) portions of the spectrum. Sunlight, or light emitted from a tungsten filament, is a mixture of wavelengths or a spectrum of radiant energy of different wavelengths that the eye recognizes as "white." Table 10-1 shows approximate relationships between wavelengths and color characteristics for the UV, visible, and short IR portions of the spectrum. Thus a solution will appear green when viewed against white light if it transmits light maximally between 500 and 580 nm but absorbs light at other wavelengths. Similarly, a solid object appears green if it reflects light in this region (500 to 580 nm) but absorbs light at other portions of the spectrum. In general, if we compare the intensity of light transmitted by a colored solution versus that of a reference solution over the entire spectrum, we obtain a typical spectral transmittance curve characteristic for that spectrum. Such curves are shown in Figure 10-1 for solutions of nickel sulfate *(a)* and potassium permanganate *(b).* Inspection of the curves should lead us to predict that the color of solution *a* is green because light is transmitted maximally near the green portion of the spectrum. Curve *b,* on the other hand, illustrates the spectrum of a solution that transmits light maximally in the blue, violet, and red portions of the spectrum. The eye recognizes this mixture of colors as purple.

SPECTROPHOTOMETRY

Photometry is defined as the measurement of light; *spectrophotometry* is defined as the measurement of the intensity of light at selected wavelengths. Spectrophotometric analysis is a widely used method of quantitative and qualitative analysis in the chemical and biological sciences. The method depends on the light-absorbing properties of the substance or a

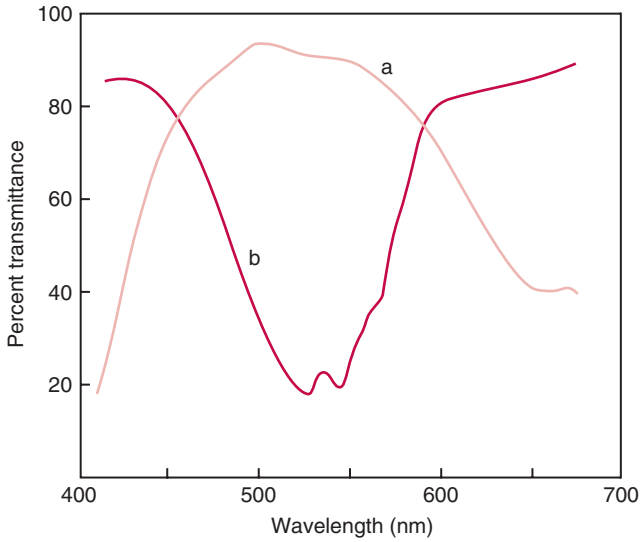

Figure 10-1 Spectral transmittance curves of nickel sulfate *(a)* and potassium permanganate *(b)*. Arbitrary concentrations read versus water as a blank (Beckman DB-G spectrophotometer).

TABLE 10-1 Ultraviolet, Visible, and Short Infrared Spectrum Characteristics

Wavelength, nm	Region Name	Color Observed*
<380	Ultraviolet†	Invisible
380-440	Visible	Violet
440-500	Visible	Blue
500-580	Visible	Green
580-600	Visible	Yellow
600-620	Visible	Orange
620-750	Visible	Red
800-2500	Near infrared	Not visible
2500-15,000	Mid infrared	Not visible
15,000-1,000,000	Far infrared	Not visible

*Owing to the subjective nature of color, the wavelength intervals shown are only approximations.
†The ultraviolet (UV) portion of the spectrum is sometimes further divided into "near" UV (200-380 nm) and "far" UV (<220 nm). This arbitrary distinction has a practical basis, because silica used to make cuvets transmits light effectively at wavelengths ≥220 nm.

derivative of the substance being analyzed. The intensity of transmitted light passing through a solution containing an absorbing substance (chromogen) is decreased by the absorbed fraction. This fraction is detected, measured, and used to relate the light transmitted or absorbed to the concentration of the analyte in question.

Basic Concepts

Consider an incident light beam with intensity I_0 passing through a square cell containing a solution of a compound that absorbs light of a certain wavelength, λ. Given that the intensity of the transmitted light beam is I_S, then transmittance *(T)* of light is defined as

$$T = \frac{I_S}{I_0} \quad (4)$$

A portion of the incident light, however, may be reflected by the surface of the cell or may be absorbed by the cell wall or solvent. To focus attention on the compound of interest, elimination of these factors is necessary. This is achieved using a reference cell identical to the sample cell, except that the compound of interest is omitted from the solvent in the reference cell. The transmittance *(T)* through this reference cell is I_R divided by I_O; the transmittance for the compound in solution then is defined as I divided by I_R. In practice, the light beam is blocked and the detector signal set to zero transmittance, then a reference cell is inserted and the detector signal adjusted to an arbitrary scale reading of 100 (corresponding to 100% transmittance), followed by the cell containing the sample to be measured, and the percent transmittance reading is made on the sample. As we increase the concentration of the compound in solution, we find that transmittance varies inversely and logarithmically with concentration (Figure 10-2). Consequently, it is more convenient to define a new term, absorbance *(A)*, which will be directly proportional to the concentration. Thus the amount of light absorbed *(A)* as the incident light passes through the sample is equivalent to

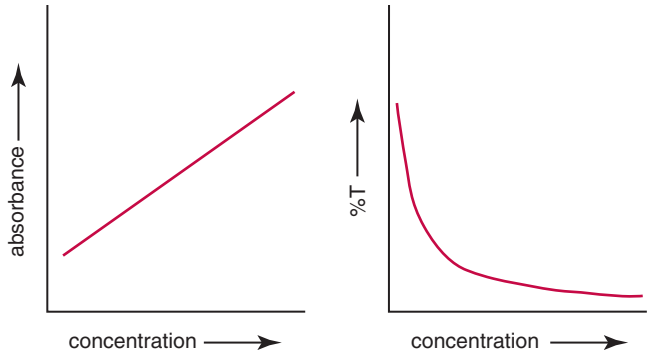

Figure 10-2 Absorbance and %*T* relationship.

$$A = -\log\frac{I_S}{I_R} = -\log T \quad (5)$$

Analytically, the amount of light absorbed or transmitted is related mathematically to the concentration of the analyte in question by Beer's law.

Beer's Law—Relationship Between Transmittance, Absorbance, and Concentration

Beer's law (also known as the Beer-Lambert law) states that the concentration of a substance is directly proportional to the amount of light absorbed or inversely proportional to the logarithm of the transmitted light (see Figure 10-2). Mathematically, Beer's law is expressed as

$$A = abc \quad (6)$$

tahir99-VRG & vip.persianss.ir

TABLE 10-2 Spectrophotometry Nomenclature

Name	Symbol	Definition
Absorbance	A	$\log T$ or $\log I_0/I$
Absorptivity	a	A/bc (c in g/L)
Molar absorptivity	ε	A/bc (c in mol/L)
Path length	b	Internal cell or sample length, in cm
Transmittance	T	I/I_0*
Wavelength unit	nm	10^{-9} m
Absorption maximum	λmax	Wavelength at which maximum absorption occurs

*I/I_0 is the ratio of the intensity of transmitted light to incident light.

where

A = Absorbance
a = Proportionality constant defined as absorptivity
b = Light path in centimeters
c = Concentration of the absorbing compound, usually expressed in moles per liter

This equation forms the basis of quantitative analysis by absorption photometry. When b is 1 cm and c is expressed in moles per liter, the constant a is called the molar absorptivity. The value for a is a constant for a given compound at a given wavelength under prescribed conditions of solvent, temperature, pH, and so forth. The nomenclature of spectrophotometry is summarized in Table 10-2. Values for a are useful for characterizing compounds, establishing their purity, and comparing the sensitivity of measurements obtained on derivatives. Pure bilirubin, for example, when dissolved in chloroform at 25 °C, has a molar absorptivity of 60,700 ± 1600 at 453 nm. The molecular weight of bilirubin is 584. Hence a solution containing 5 mg/L (0.005 g/L) should have an absorbance of

$$A = (60{,}700) \times \left(= -\frac{0.005}{584}\right) = 0.520 \qquad (7)$$

The molar absorptivity of the complex between ferrous iron and *s*-tripyridyltriazine is 22,600, whereas that with 1,10-phenanthroline is 11,000. Thus for a given concentration of iron, *s*-tripyridyltriazine produces a complex with an absorbance about twice that of the complex with 1,10-phenanthroline. Consequently, *s*-tripyridyltriazine is a more sensitive reagent to use in the measurement of iron.

Application of Beer's Law

In practice, a calibration relationship between absorbance and concentration is established experimentally for a given instrument under specified conditions using a series of reference solutions that contain increasing concentrations of analyte. Frequently, a linear relationship exists up to a certain concentration or absorbance. When this linear relationship exists, the solution is said to obey Beer's law up to this point. Within this limitation, a calibration constant *(K)* may be derived and used to calculate the concentration of an unknown solution by comparison with a calibrating solution.

Certain precautions must be observed with the use of such calibration constants. For example, under no circumstances should the calibration constants be used when the calibrator or unknown readings exceed the linear portion of the calibration relationship. In other words, calibration constants are used only when the curve obeys Beer's law. At least two and preferably more calibrators should be included in each series of determinations to permit direct comparison of unknown readings with calibrators or to calculate the calibration constant. These multiple calibrators are necessary because variations in reagents, working conditions, and cell diameters and deterioration or changes in instruments may result in day-to-day changes in the absorbance value for the calibrator. A nonlinear calibration curve may be used if a sufficient number of calibrators of varying concentrations are included to cover the entire range encountered for readings on unknowns.

In some cases, a pure reference material may not be readily available, and constants may be provided that were obtained on pure materials and reported in the literature. In general, published constants should be used only if the method is followed in detail and readings are made on a spectrophotometer capable of providing light of high spectral purity at a verified wavelength. Use of broader-band light sources usually leads to some decrease in absorbance. For example, the absorbance of nicotinamide adenine dinucleotide (NADH) at 340 nm is frequently used as a reference for determination of enzyme activity, based on a molar absorptivity of 6.22×10^3 (see Chapter 15). This value is acceptable only under the carefully controlled conditions previously described and should not be used unless these conditions are met. Published values for molar absorptivities and absorption coefficients should be used only as guidelines until they are verified by readings on pure reference materials for a given instrument. In addition, Beer's law is followed only if the following conditions are met:

- Incident radiation on the substance of interest is monochromatic.
- The solvent absorption is insignificant compared with the solute absorbance.
- The solute concentration is within given limits.
- An optical interferant is not present.
- A chemical reaction does not occur between the molecule of interest and another solute or solvent molecule.

Instrumentation

Modern instruments isolate a narrow wavelength range of the spectrum for measurements. Those that use filters for this purpose are referred to as *filter photometers;* those that use prisms or gratings are called *spectrophotometers*. Spectrophotometers are classified as single or double beam.

The major components of a *single-beam spectrophotometer* are shown schematically in Figure 10-3. In such an instrument, a beam of light is passed through a monochromator that isolates the desired region of the spectrum to be used

tahir99-VRG & vip.persianss.ir

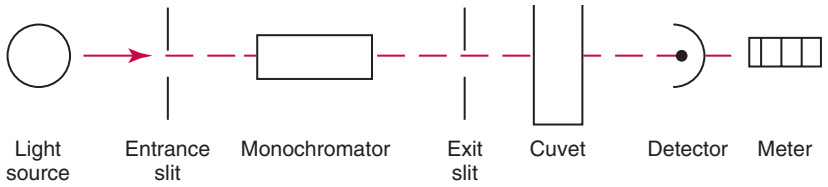

Figure 10-3 Major components of a single-beam spectrophotometer.

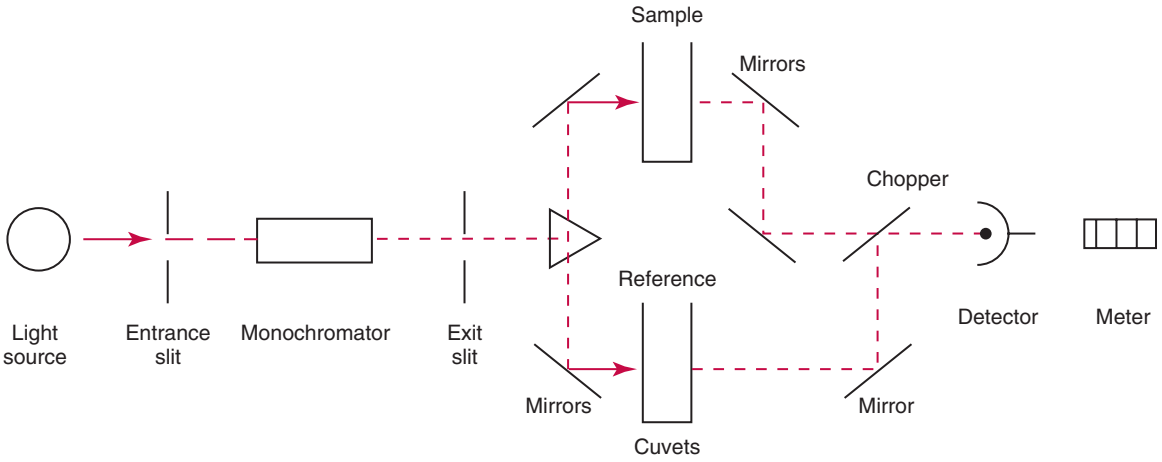

Figure 10-4 Double-beam spectrophotometer.

for measurements. The light next passes through an absorption cell (cuvet), where a portion of the radiant energy is absorbed, depending on the nature and concentration of the substance in the solution. Any light not absorbed is transmitted to a detector, which converts light energy to electrical energy that is registered on a meter or recorder or digitally displayed.

In operation, an opaque block is substituted for the cuvet, so that no light reaches the photocell, and the meter is adjusted to read 0% *T*. Next, a cuvet containing a reagent blank is inserted, and the meter is adjusted to read 100% *T* (zero absorbance). The composition of the reagent blank should be identical to that of calibrating or unknown solutions except for the substance to be measured. Calibrating solutions containing various known concentrations of the substance are inserted, and readings are recorded. Finally, a reading is made of the unknown solution, and its concentration is determined by comparison with readings obtained on the calibrators. In most spectrophotometers, digital hardware and software are integral components and perform these functions automatically.

Figure 10-4 illustrates schematically a typical double-beam instrument that uses a light-beam chopper (a rotating wheel with alternate silvered sections and cutout sections) inserted after the exit slit. A system of mirrors passes portions of the light reflected off the chopper alternately through the sample and a reference cuvet onto a common detector. The chopped-beam approach, using one detector, compensates for light source variation and for sensitivity changes in the detector.

Components

The basic components of a spectrophotometer include (1) a light source, (2) a device to isolate light of a desired wavelength, (3) a cuvet, (4) a photodetector, (5) a readout device, and (6) a data system.

Light Sources

Types of light sources used in spectrophotometers include incandescent lamps, xenon discharge lamps, light-emitting diodes, and lasers.

Incandescent, Arc, and Cathode Lamps. The light source for measurements in the visible portion of the spectrum is usually a tungsten light bulb. The lifetime of a tungsten filament is greatly increased by the presence of a low pressure of iodine or bromine vapor within the lamp. An example is the *quartz-halogen* lamp, which has a fused-silica envelope and which provides high-intensity light over a wide spectrum for extended operating periods (2000 to 5000 hours) before replacement is necessary.

However, a tungsten light source does not supply sufficient radiant energy for measurements in the UV region (below 320 nm). In the UV region of the spectrum, hydrogen and deuterium lamps, as well as high-pressure mercury and xenon arc lamps, provide sources of continuous spectra in the UV region with some sharp emission lines. These sources are more commonly used in UV absorption measurements. Low-pressure mercury vapor lamps also provide spectra in the UV region and are useful for calibration purposes, but they are not very practical for absorbance measurements, because of their limited wavelengths.

Mercury arc lamps emit an intense 254-nm resonance line and are widely used as detectors in high-performance liquid chromatography (HPLC) (see Chapter 13). Alternatively, some HPLCs employ a miniature hollow cathode lamp as a very-narrow-wavelength intense source. For example, a zinc hollow cathode lamp emits a line at 214 nm that is close to the maximum wavelength of peptide bond absorption (206 nm); this emission property permits the usage of such lamps to measure peptides and proteins. Details on the hollow cathode lamp are found in the section on "Atomic Absorption Spectrophotometry." The hollow cathode lamp also has a long, useful lifetime if a lower-current, nonpulsed power supply is used.

Laser Sources. A laser (light amplification by stimulated emission of radiation) is a device that controls the way that energized atoms release photons; lasers are used as light sources in spectrophotometers because they provide intense light of a narrow wavelength. Through selection of different materials, different wavelength(s) of light are emitted by different types of lasers (Table 10-3).

Three properties of laser sources distinguish them from "conventional" sources: (1) spatial coherence is a property of lasers that allows beam diameters in the range of several microns; (2) lasers produce monochromatic light; and (3) lasers have pulse widths that vary from microseconds (flash lamp–pulsed lasers) to nanoseconds (nitrogen lasers) to picoseconds or less (mode-locked lasers) in duration. Air-cooled argon ion lasers produce about 25 mW of energy output at 488 nm and have plasma tube lifetimes of 6000 hours or longer. Continuous-wave dye lasers typically use an argon ion laser with an output of 1 W or less as an energy pump and use different fluorescent dyes to achieve excitation wavelength ranges of 400 to 800 nm. Helium-neon and helium-cadmium lasers are useful because of their low cost and ease of operation, and because they emit a number of excitation wavelengths; however, the power output of helium-neon lasers has been limited to about 2 mW at 594 nm.

Infrared diode lasers are used in compact disc players and laser printers, and in bar code readers (see Chapter 19). They are solid-state devices, typically constructed of gallium arsenide, and energy is pumped into them at a low potential of −1.5 V. Depending on its construction, the wavelength output of the laser ranges from 550 to 1810 nm. Development of inexpensive near-IR lasers has led to interest in using reflective techniques in the near-IR region of the spectrum (0.8 to 2.5 μm wavelength). Reflectance spectrophotometry is now used clinically for the transcutaneous measurement of bilirubin in neonates.[14] Another application of reflectance spectrophotometry is measurement of blood oxygen saturation in near-IR and IR regions.

TABLE 10-3 Various Types of Lasers and the Wavelengths at Which They Operate

Laser	Wavelengths, nm
Argon fluoride	193
Argon fluoride	248
Helium-cadmium	325 or 442
Nitrogen	337
Argon (blue)	488
Argon (green)	514
Helium-neon (green)	543
Light-emitting diode—GaP	550 or 700
Rhodamine 6G dye (tunable)	570-650
Laser diode (AlGaInP, GaAlAs)	633-1660
Helium-neon (red)	633
Ruby ($CrAlO_3$) (red)	694
Light-emitting diode—GaAs	880
Light-emitting diode—Si	1100
Neodymium-YAG (yttrium aluminum garnet)	1064
Carbon dioxide	9300, 9600, 10,300, or 10,600

Spectral Isolation

Radiant energy of a desired wavelength can be isolated and that of other wavelengths excluded in various ways, including the use of (1) filters (interference or dichroic filters), (2) prisms, and (3) diffraction gratings. Combinations of lenses and slits may be inserted before or after the monochromatic device to render light rays parallel or to isolate narrow portions of the light beam. Variable slits may be used to permit adjustments in total radiant energy to reach the photocell.

Filters. The simplest type of filter is a thin layer of colored glass. Certain metal complexes or salts, dissolved or suspended in glass, produce colors corresponding to the predominant wavelengths transmitted. The spectral purity of a filter or other monochromator is usually described in terms of its *spectral bandwidth*. This is defined as the width, in nanometers, of the spectral transmittance curve at a point equal to one half the peak transmittance. Because glass filters have spectral bandwidths of approximately 50 nm, they are referred to as *wide-bandpass filters*.

Other glass filters include narrow-bandpass and sharp-cutoff types. Operationally, a cutoff filter typically shows a sharp rise in transmittance over a narrow portion of the spectrum and is used to eliminate light below a given wavelength. Historically, narrow-bandpass filters were constructed by combining two or more sharp-cutoff filters or regular filters. Currently, however, the availability of high-intensity light sources now favors the use of narrow-bandpass interference filters.

A narrow-bandpass interference or dichroic filter uses a dielectric material of controlled thickness sandwiched between two thinly silvered pieces of glass. The thickness of the layer determines the wavelength of energy transmitted after constructive and destructive wavelength interference caused by reflections between the glass surfaces separated by the dielectric spacing. These filters have narrow spectral bandwidths, usually from 5 to 15 nm. Because they also transmit harmonics, or multiples, of the desired wavelength, accessory glass filters are required to eliminate undesired

wavelengths. Thus an interference filter designed for 620 nm will also transmit some radiation at 310 and 1240 nm unless accessory cutoff filters are provided to absorb this undesired stray light.

Prisms and Gratings. Prisms and diffraction gratings are widely used as monochromators. A *prism* separates white light into a continuous spectrum because shorter wavelengths are bent, or refracted, more than longer wavelengths as they pass through the prism. A *diffraction grating* is prepared by depositing a thin layer of aluminum-copper alloy on the surface of a flat glass plate, then ruling many small parallel grooves into the metal coating. Better gratings contain 1000 to 2000 lines/mm and must be made with great care. These are then used as molds to prepare less expensive replicas for general use in instruments.

Modern holographic gratings are made using a laser in a "high-precision machining" mode. The focused beam of the laser is accurately scanned over a photosensitive material termed a *photoresist.* After multiple lines have been scribed on the photoresist, chemicals are used to dissolve and elute the exposed photoresist to create channels that become the lines of the grating. A layer of a highly reflective material is then sputtered onto the surface of the laser-etched channels, and the grating is ready for use. A flat photoresistive surface or a concave surface can be used to make this type of grating. These types of gratings are extremely accurate, have low light scatter, and are widely used in the spectrophotometers found in clinical chemistry instruments. For example, most UV-visible spectrophotometers and virtually all IR spectrophotometers use reflective gratings. In addition, HPLC detectors frequently use a concave holographic reflective grating in their optical system.

Each line ruled on the grating, when illuminated, reflects light and gives rise to a tiny spectrum. An array of parallel wave fronts are formed that reinforce those wavelengths in phase and cancel those not in phase. The net result is a uniform linear spectrum. Some instruments contain diffraction gratings that produce spectral bandwidths of 20 nm or more; higher-priced instruments may have a resolution of 0.5 nm or less.

The flat surface grating discussed previously is called a plane *transmission grating.* Lines are engraved on the surface of a mirror, which may be a polished metal slab or a glass plate on which a thin, metallic film has been deposited. A grating may also be ruled at a specified angle, so that a maximum fraction of the radiant energy is directed into wavelengths diffracted at a selected angle. This type of grating is called an *echelette* and is said to have been given a *blaze* at a particular angle or to have been blazed at a certain wavelength (e.g., 250 nm).

Selection of a Wavelength Isolation Device. The type of monochromator chosen depends on the analytical purpose for which it is to be used. For example, narrow spectral bandwidths are required in spectrophotometers for resolving and identifying sharp absorption peaks that are closely adjacent. Lack of agreement with Beer's law will occur when a part of the spectral energy transmitted by the monochromator is not absorbed by the substance being measured. This is more commonly observed with wide-bandpass instruments. In practice, an increase in absorbance and improved linearity with concentration are usually observed with instruments that operate at narrower bandwidths of light. This is especially true for substances that exhibit a sharp peak of absorption.

The *natural bandwidth* of an absorbing substance is defined as "the bandwidth of the spectral absorbance curve at a point equal to one half of the maximum absorbance." As a general rule, for peak absorbance readings to be within 99.5% of true values, the spectral bandwidth should not exceed 10% of the natural bandwidth. For example, many chemistry procedures used in the clinical laboratory produce an absorbing species for which the natural bandwidth ranges from 40 to over 200 nm. The natural bandwidth of NADH is 58 nm (λmax = 339 nm). Therefore, for accurate measurements of this compound, a spectral bandwidth of 6 nm or less should be used.

In practice, the wavelength selected is usually at the peak of maximum absorbance to attain the maximum measurement; however, it may be desirable to choose another wavelength to minimize interfering substances. For example, turbidity readings on a spectrophotometer are greater in the blue region than in the red region of the spectrum, but the latter region is chosen for turbidity measurements to avoid absorption of light by bilirubin (460 nm) or hemoglobin (417 and 575 nm). The absorbing species developed in the alkaline picrate procedure for creatinine produces a relatively flat peak in the visible region of the spectrum at approximately 480 nm, but the reagent blank itself absorbs light strongly below 500 nm. A compromise is made by selecting a wavelength at 520 nm to minimize the contribution of the blank. Blank readings should, of course, be kept to a minimum. A small difference between two large numbers is subject to greater uncertainty; hence minimizing absorbance of the blank improves precision and accuracy. The linear working range of a method can be expanded by not measuring at the peak absorbance. However, measurements should not be taken on the steep slope of an absorption curve, because a slight error in wavelength adjustment would introduce a significant error in absorbance readings.

Cuvets

A cuvet (also often termed a cuvette) is a small vessel used to hold a liquid sample to be analyzed in the light path of a spectrometer. Cuvets may be round, square, or rectangular and are constructed from glass, silica (quartz), or plastic. Square or rectangular cuvets have plane-parallel optical surfaces and a constant light path. The most popular have a 1.0-cm light path, held to close tolerances. Ordinary borosilicate glass or plastic cuvets are suitable for measurements in the visible portion of the spectrum. For readings below 340 nm, however, quartz cells are usually required. Some plastic cells have good clarity in both the visible and UV range but can present problems related to tolerances, cleaning,

etching by solvents, and temperature deformations. Many of the plastic cuvets are designed for disposable, single-use applications. However, in many clinical analyzers, cuvets are cleaned and reused many times before optical degradation requires them to be replaced.

Cuvets must be clean and optically clear, because etching or deposits on the surface affect absorbance values. Cuvets used in the visible range are cleaned by copious rinsing with tap water and distilled water. Alkaline solutions should not be left standing in cuvets for prolonged periods, because alkali slowly dissolves glass and produces etching. Cuvets may be cleaned in mild detergent or soaked in a mixture of concentrated HCl:water:ethanol (1:3:4). Cuvets should never be soaked in dichromate cleaning solution, because the solution is hazardous and tends to adsorb onto and discolor the glass.

Cuvets used for measurements in the UV region should be handled with special care. Invisible scratches, fingerprints, or residual traces of previously measured substances may be present and may absorb significantly. A good practice is to fill all such cuvets with distilled water and measure the absorbance for each against a reference blank over the wavelengths to be used. This value should be essentially zero.

Photodetectors

A *photodetector* is a device that converts light into an electric signal that is proportional to the number of photons striking its photosensitive surface. The photomultiplier tube is a commonly used photodetector for measuring light intensity in the UV and visible regions of the spectrum. Alternatively, photodiodes are solid-state devices that are also used in modern instruments. In older instruments, barrier layer cells (also known as *photovoltaic cells*) were used as photodetectors, because they were rugged and less expensive.

Photomultiplier Tubes. A photomultiplier tube (PMT) contains (1) a cathode, (2) a light-sensitive metal, and (3) a series of dynodes, all of which are enclosed in an evacuated glass enclosure. As many as 10 to 15 stages or dynodes are present in common photomultipliers. Photons that strike the photoemissive cathode emit electrons that are accelerated toward the dynodes. Additional electrons are generated at each dynode. Depending on the number of dynodes and the accelerating voltage, the cascading effect creates 10^5 to 10^7 electrons for each photon hitting the first cathode. This amplified signal is finally collected at the anode, where it can be measured.

When such a tube is operated, voltage is applied between the photocathode and each successive stage. The normal incremental increase in voltage at each photomultiplier stage is from 50 to 100 V larger than that of the previous stage (Figure 10-5). Typically, a conventional PMT tube has approximately 1500 V applied to it.

PMTs have (1) extremely rapid response times, (2) are very sensitive, and (3) are slow to fatigue. Because these tubes are very sensitive and have a rapid response, they must be carefully shielded from all stray light. A PMT with the voltage applied should never be exposed to room light because it will burn out. The rapid response times of PMTs are needed when a spectrophotometer is being used to determine an absorption spectrum of a compound. Also, PMTs are sensitive over a wide range of wavelengths.

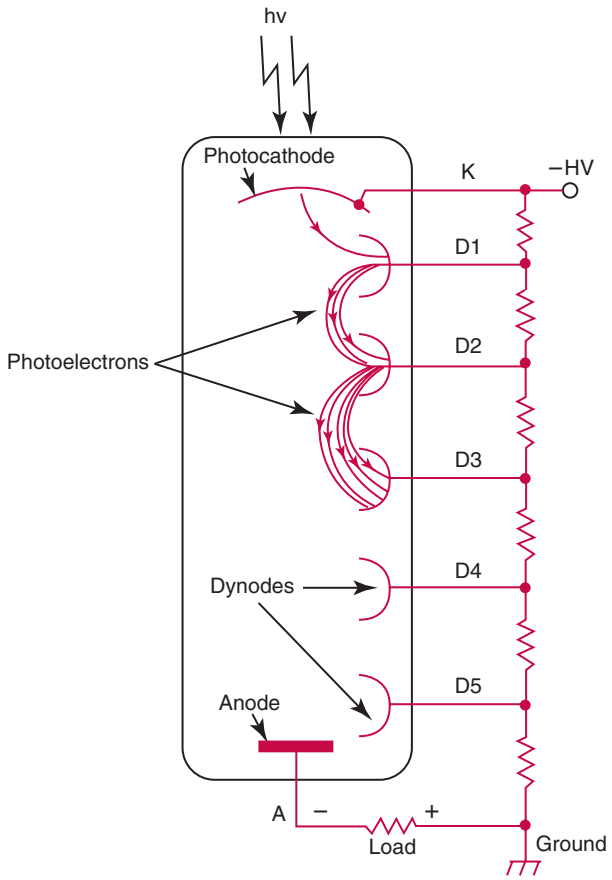

Figure 10-5 Schematic diagrams of a glass photomultiplier tube.

When voltage is applied to a PMT in the absence of any incident light, some current is usually produced. This current is called *dark current.* It is desirable to have the dark current of a PMT at its lowest level because this current appears as background noise.

Photodiodes. Photodiodes are solid-state photodetectors that are fabricated from photosensitive semiconductor materials such as (1) silicon, (2) gallium arsenide, (3) indium antimonide, (4) indium arsenide, (5) lead selenide, and (6) lead sulfide. These materials absorb light over a characteristic wavelength range (e.g., 250 nm to 1100 nm for silicon). Their development and use as detectors in spectrophotometers have resulted in instruments capable of measuring light at a multitude of wavelengths. When a photodetector consists of two-dimensional arrays of diodes, it is known as a photodiode array. Each photodetector within the array responds to a specific wavelength. For example, photodiode arrays have been designed to have a 2-nm resolution per diode from 200 to 340 nm, and a 1-nm resolution per diode from 340 to 800 nm.

In practice, all diodes are initially charged to 5 V, and they discharge when they are struck by light. Each diode then is sequentially scanned and recharged to 5 V. The amount of energy required for recharging is proportional to the quantity of light striking that diode. Because scan time for all diodes is in the millisecond range, many scans are typically taken. The resultant data is processed using a variety of algorithms, including signal averaging, background subtraction, and correction for scattered light. Consequently, an optical spectrum of an ongoing chemical reaction can be monitored as a function of time with a high degree of resolution and accuracy.

Readout Devices

Electrical energy from a detector is displayed on some type of meter or readout system. In the past, analog devices were widely used as readout devices in spectrophotometers. However, they have been replaced by digital readout devices that provide a visual numeric display of absorbance or converted values of concentrations. Spectrophotometers may be equipped with recorders in addition to or instead of a digital display. These are synchronized to provide line traces of transmittance or absorbance as a function of time or wavelength. When a continuous tracing of absorbance versus wavelength is recorded, the resultant display is called an *absorption spectrum*. If a substance absorbs light, distinct peaks of absorbance will be observed (see Figure 10-1). Measuring the absorption spectra of an unknown sample and comparing them with spectra from known compounds is very useful for qualitative purposes. For example, this type of procedure is especially useful for identification of drugs that absorb in the UV region.

Performance Parameters

In most spectrophotometric analytical procedures, the absorbance of an unknown is compared directly with that of a calibrator or a series of calibrators. Under these circumstances, minor errors in wavelength calibration, variation in spectral bandwidths, and the presence of stray light are compensated for and usually do not contribute serious errors. Use of a series of calibrators covering a wide range of concentrations also provides a measure of linearity (i.e., agreement with Beer's law for a given procedure and instrument). When calculations are based on published or previously determined values for molar absorptivities or absorption coefficients, however, the spectrophotometer must be checked more rigorously. Performance verification of spectrophotometers on a periodic basis also improves reliability of routine comparative analyses.

To verify that a spectrophotometer is performing satisfactorily, the device must be shown to be able to operate within the specifications provided for it. Parameters to be tested include (1) wavelength accuracy, (2) spectral bandwidth, (3) stray light, (4) linearity, and (5) photometric accuracy.

The National Institute of Standards and Technology (NIST) provides several standard reference materials (SRMs) for spectrophotometry that are useful in the calibration or verification of the performance of photometers or spectrophotometers (e.g., SRM 930e is for the verification and calibration of the transmittance and absorbance scales of visible absorption spectrometers) (http://www.nist.gov, accessed March 23, 2011).

The Institute for Reference Materials and Measurements (IRMM) belongs to the European Commission and provides reference materials for verification of the performance of photometers or spectrophotometers. These materials are listed in the IRMM ERM Reference Materials Catalogue (http://www.irmm.jrc.be, accessed March 23, 2011).

Wavelength Calibration

With narrow-spectral-bandwidth instruments, a *holmium oxide glass* may be scanned over the range of 280 to 650 nm. This material shows very sharp absorbance peaks at defined wavelengths, and the operator may compare the wavelength scale readings that produce maximum absorbance with established values. If compared values do not coincide, a calibration correction table can be constructed to relate scale readings to true wavelengths. A typical spectral transmittance curve for holmium oxide glass is shown in Figure 10-6. Selected absorption peaks for this filter, which are suitable for calibration purposes, occur at the following wavelengths: 279.3, 418.5, 287.6, 536.4, 333.8, 637.5, and 360.8 nm. Solutions of holmium oxide in dilute perchloric acid have also been recommended and may be used with any spectrophotometer.

With broader-bandpass instruments, a didymium filter may be used to verify wavelength settings. This filter should show a minimum percent transmittance at 530 nm against an air blank (Figure 10-7). Because didymium has several absorption peaks, the setting should be verified grossly by visual examination of transmitted light. This light should appear green at 530 nm.

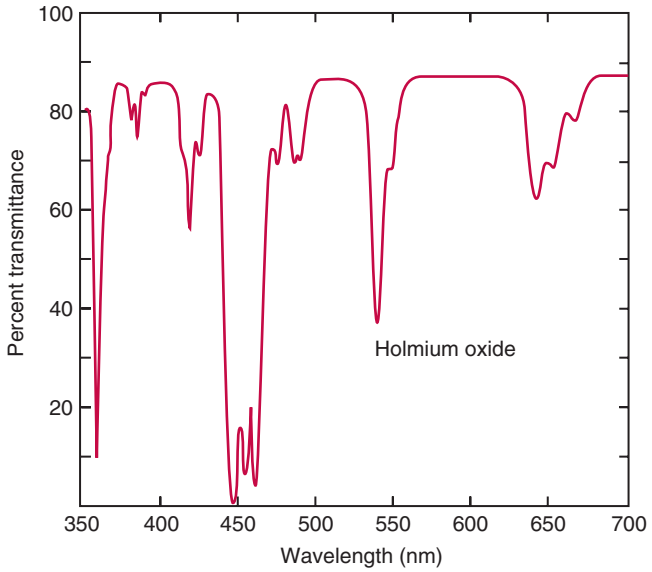

Figure 10-6 Spectral transmittance curve of holmium oxide filter.

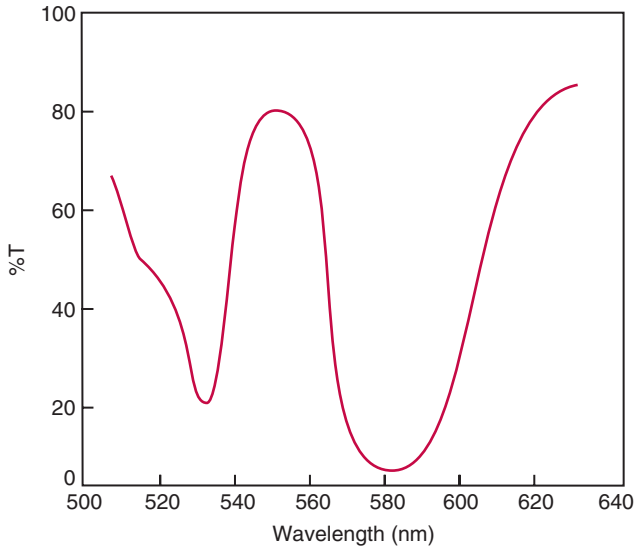

Figure 10-7 Spectral transmittance curve of a didymium filter (Perkin-Elmer Model 35 spectrophotometer, 8-nm nominal spectral bandwidth).

Spectral Bandwidth

The apparent width of an emission band at half-peak height is taken to be the spectral bandwidth of the instrument. The spectral bandwidth may also be calculated from the manufacturer's specifications. Interference filters with spectral bandwidths of 1 to 2 nm are available and may be used to check those instruments with a nominal spectral bandwidth of 8 nm or more.

Stray Light

Stray light, in general terms, is radiation of wavelengths outside the narrow band nominally transmitted by the monochromator that hits the detector. A perfect monochromator would transmit light only within its bandpass. In practice, scattering and diffraction inside the monochromator introduce light of other wavelengths into the exit beam. This light is further modified by other components of the spectrophotometer and by the sample itself. Stray light is usually defined as a ratio or percent to the total detected light.

Other sources of unwanted light include light leaks and fluorescence of the sample. Light leaks should be excluded by covering the cell compartments. Light arising from fluorescence can increase the signal to the detector and cause an apparent decrease in absorbance. These sources of light are not included in the usual definition of stray light.

The major effect of stray light on the performance of a spectrophotometer is an absorbance error, especially in the upper end of the absorbance range of the instrument. Most spectrophotometers are equipped with one or more stray-light filters. Thus a blue filter is used with a tungsten lamp for wavelength settings below about 400 nm. When the spectrophotometer is set to 350 nm, for example, most of the stray light is of wavelengths in the visible range. The blue filter absorbs most of the visible light but transmits well in this UV portion of the spectrum. By analogy, a red filter is used for wavelengths in the range of 650 to 800 nm.

Cutoff filters are satisfactory for the detection of stray light. These may be of glass, similar to the stray-light filters discussed previously, and produce a sharp cut in the spectrum with almost complete absorption on one side and high transmittance on the other. Liquid cutoff filters are satisfactory and convenient in the UV range, where stray light is usually more of a problem. A 50-g/L aqueous solution of sodium nitrite should show essentially 0% *T* when read against water over the range of 300 to 385 nm. Acetone, read against water, should show 0% *T* over the range of 250 to 320 nm.

TABLE 10-4 Absorbance Values for Acidic Potassium Dichromate Solutions on a Calibrated Spectrophotometer

	Absorbance	
Wavelength, nm	Solution A	Solution B
235 (min)	0.626 ± 0.009	1.251 ± 0.019
257 (max)	0.727 ± 0.007	1.454 ± 0.015
313 (min)	0.244 ± 0.004	0.488 ± 0.007
350 (max)	0.536 ± 0.005	1.071 ± 0.011

Photometric Accuracy

Neutral density filters (SRM 1930) available from the NIST are used to check an instrument's photometric accuracy. In addition, solutions of potassium dichromate ($K_2Cr_2O_7$) may be used for overall checks on photometric accuracy. In practice, analytical reagent grade $K_2Cr_2O_7$ is dried at 110 °C for 1 hour, and then the following solutions in 0.005 mol/L sulfuric acid are prepared:

Solution A: 0.0500 g/L for the absorbance range from 0.2 to 0.7

Solution B: 0.1000 g/L for the absorbance range from 0.4 to 1.4

Measurements should be made in 10-mm cells with the temperature controlled in the range of 15 to 25 °C, using 0.005 mol/L sulfuric acid as the reference. Table 10-4 gives the expected values for the two absorbance maxima and minima of the solutions based on literature values. Because the natural bandwidth of solution A at 350 nm is approximately 63 nm, the values shown apply strictly to spectrophotometers with a spectral bandwidth of 6 nm or less.

Multiple-Wavelength Readings

Background interference due to interfering chromogens can often be eliminated or minimized by inclusion of blanks or by reading absorbance at two or three wavelengths. In one approach, termed *bichromatic,* absorbance is measured at two wavelengths—one corresponding to peak absorbance and another at a point near the base of the peak to serve as a baseline. The difference in absorbance at the two wavelengths is related to concentration.

Before the correction is used, knowledge of the shape of the absorption curve for the substance of interest and of the interference is required. The linearity of the baseline shift should be verified by measuring the absorption spectrum of commonly encountered interferences. Care should be exercised in the use of the correction because if it is not properly used, it may introduce larger errors than would be observed without correction. For example, such a situation may occur if the background reading is not linear over the region measured.

REFLECTANCE PHOTOMETRY

In *reflectance photometry,* diffuse reflected light is measured. The reaction mixture in a carrier is illuminated with diffused light, and the intensity of the reflected light from the chromogen is compared with the intensity of light reflected from a reference surface. Because the intensity of reflected light is nonlinear in relation to the concentration of the analyte, the Kubelka-Munk equation or the Clapper-Williams transformation is commonly used to convert the data into a linear format (see Chapter 19). The electro-optical components used in reflectance photometry are essentially the same as those required for absorbance photometry, except that the geometry of the system is modified so that the light source and the detector are located next to each other on one side of the sample, as opposed to on opposite sides of the sample cuvet as in absorption photometry. Reflectance photometry is used as the measurement method with dry-film chemistry systems.

FLAME EMISSION AND INDUCTIVELY COUPLED PLASMA SPECTROPHOTOMETRY

Flame emission spectrophotometry is based on the characteristic emission of light by atoms of many metallic elements when given sufficient energy, such as that supplied by a hot flame. The wavelength to be used for the measurement of an element depends on the selection of a line of sufficient intensity to provide adequate sensitivity and freedom from other interfering lines at or near the selected wavelength. For example, lithium produces a red, sodium a yellow, potassium a violet, rubidium a red, and magnesium a blue color in a flame. These colors are characteristic of the metal atoms that are present as cations in solution. Under constant and controlled conditions, the light intensity of the characteristic wavelength produced by each of the atoms is directly proportional to the number of atoms that are emitting energy, which in turn is directly proportional to the concentration of the substance of interest in the sample. Although this technique once was used widely for analysis of sodium, potassium, and lithium in body fluids, it now has been replaced largely by electrochemical techniques.

Inductively coupled plasma (ICP) atomic emission spectroscopy is a technique for elemental analysis (e.g., trace metals) that uses an inductively coupled plasma to produce excited species that emit light at wavelengths characteristic of a particular element present in the sample. An ICP spectrometer consists of an optical spectrometer and an ICP torch. The torch produces an argon gas plasma (10,000°K) by means of radiofrequency induction coil and an electric spark. A nebulized sample is injected into the argon gas plasma, and elements in the sample become excited and the electrons emit energy at a characteristic wavelength as they return to ground state. The emitted light is then measured by optical spectrometry.

ATOMIC ABSORPTION SPECTROPHOTOMETRY

Atomic absorption (AA) spectrophotometry is used widely in clinical laboratories to measure elements such as aluminum, calcium, copper, lead, lithium, magnesium, zinc, and other metals.

Basic Concepts

Atomic absorption is an absorption spectrophotometric technique in which a metallic atom in the sample absorbs light of a specific wavelength. However, the element is not appreciably excited in the flame, but is merely dissociated from its chemical bonds (atomized) and placed in an unexcited or ground state (neutral atom). Thus, the ground state atom absorbs radiation at a very narrow bandwidth corresponding to its own line spectrum. A hollow cathode lamp with the cathode made of the material to be analyzed is used to produce a wavelength of light specific for the atom. Thus, if the cathode were made of sodium, sodium light at predominantly 589 nm would be emitted by the lamp. When the light from the hollow cathode lamp enters the flame, some of it is absorbed by the ground-state atoms in the flame, resulting in a net decrease in the intensity of the beam from the lamp. This process is referred to as *atomic absorption.*

A specific hollow cathode lamp serves as the light source, and the sample heated in the flame is the sample in the cuvet. The path length of the flame is the light path through the cuvet. Hence, most of the atoms are in the ground state and are able to absorb light emitted by the cathode lamp. In general, AA methods are approximately 100 times more sensitive than flame emission methods. In addition, owing to the unique specificity of the wavelength from the hollow cathode lamp, these methods are highly specific for the element being measured.

Instrumentation

Figure 10-8 shows the basic components of an AA spectrophotometer. The hollow cathode lamp is made of the metal of the substance to be analyzed and is different for each metal analysis. In some cases, an alloy is used to make the cathode, resulting in a multielement lamp. The hollow cathode lamp usually contains argon or neon gas at a pressure of a few millimeters of mercury. An argon-filled lamp produces a blue-to-purple glow during operation, and the neon produces a reddish-orange glow inside the hollow cathode lamp. Quartz, or special glass that allows transmission of the proper

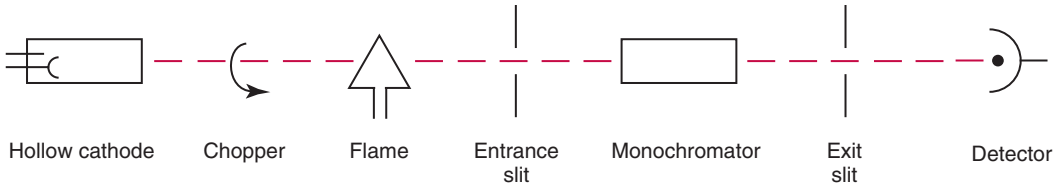

Figure 10-8 Basic components of an atomic absorption spectrophotometer.

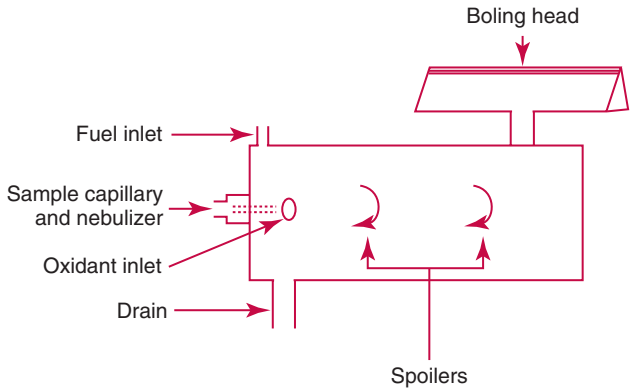

Figure 10-9 Laminar flow burner.

wavelength, is used as a window. A current is applied between the two electrodes inside the hollow cathode lamp, and metal is sputtered from the cathode into the gases inside the glass envelope. When the metal atoms collide with the neon or argon gases, they lose energy and emit their characteristic radiation. Calcium has a sharp, intense, analytical emission line at 422.7 nm, which is used most frequently for calcium analysis. In an ideal interference-free system, only calcium atoms absorb the calcium light from the hollow cathode as it passes through the flame.

A pulsed hollow cathode lamp and a tuned amplifier are incorporated into most AA instruments. Operationally, the power to the hollow cathode lamp is pulsed, so that light is emitted by the lamp at a certain number of pulses per second. On the other hand, all of the light originating from the flame is continuous. When light leaves the flame, it is composed of pulsed, unabsorbed light from the lamp and a small amount of nonpulsed flame spectrum and sample emission light. The detector senses all light, but the amplifier is electrically tuned to the pulsed signals and can subtract the background light measured when the lamp is off and the total light that includes both lamp and flame background light. In this way, the electronics, in conjunction with the monochromator, discriminates between the flame background emission and the sample atomic absorption.

Figure 10-9 shows a laminar flow premix burner and illustrates how the sample is aspirated, volatilized, and burned to form atoms of the metal in the gas phase. Note that the gases are mixed and the sample is atomized before it is burned. An advantage of this system is that the larger droplets go to waste while the fine mist enters the flame, thus producing a less noisy signal.

In *flameless AA* techniques (carbon rod or "graphite furnace"), the sample is placed in a depression on a carbon rod in an enclosed chamber. Strips of tantalum or platinum metal may also be used as sample cups. In successive steps, the temperature of the rod is raised to dry, char, and finally atomize the sample into the gas phase in the chamber. The atomized element then absorbs energy from the corresponding hollow cathode lamp. This approach is more sensitive than conventional flame methods and permits determination of trace metals in small samples of blood or tissue.

With flameless AA, a novel approach used to correct for background absorption is called the *Zeeman correction.*[16] In Zeeman background correction, the light source or the atomizer is placed in a strong magnetic field. In practice, because Zeeman correction requires special lamps, the analyte is placed in the magnetic field. The intense magnetic field splits the degenerate (i.e., of equal energy) atomic energy levels into two components that are polarized parallel and perpendicular to the magnetic field, respectively. The parallel component is at the resonance line of the source, whereas the two perpendicular components are shifted to different wavelengths. The two components interact differently with polarized light. A polarizer is placed between the source and the atomizer, and two absorption measurements are taken at different polarizer settings. One measures both analyte and background absorptions, A_t, the other only the background absorption, A_{bc}. The difference between the two absorption readings is the corrected absorbance.

The major advantage of the Zeeman correction method is that the same light source at the same wavelength is used to measure the total and the background absorption. The implementation is complex and expensive, and the strength of the magnetic field needs to be optimized for every element, but the method gives more accurate results at higher background levels than are attained with the other correction techniques.

Interferences in Atomic Absorption Spectrophotometry

Interferences in AA spectroscopy are divided into spectral and nonspectral interferences.

Spectral Interferences

Spectral interferences include absorption by other closely absorbing atomic species, absorption by molecular species, scattering by nonvolatile salt particles or oxides, and background emission (which can be electronically filtered). Absorption by other atomic species usually is not a problem

because of the extremely narrow bandwidth (0.01 nm) used in the absorption measurements. Absorption and scattering by molecular species are particularly problematic in lower atomizing temperatures.

Nonspectral Interferences

Nonspectral interferences may be nonspecific or specific. *Nonspecific interferences* affect nebulization by altering the viscosity, surface tension, or density of the analyte solution, and consequently the sample flow rate. Certain contaminants also decrease desolvation and atomization efficiency by lowering the atomizer temperature. *Specific interferences* are also called *chemical interferences* because they are more analyte dependent. *Solute volatilization interference* refers to the situation in which the contaminant forms nonvolatile species with the analyte. An example is phosphate interference in the determination of calcium that is caused by the formation of calcium–phosphate complexes. The phosphate interference is overcome by adding a cation, usually lanthanum or strontium; the cation competes with calcium for the phosphate. Enhancement effects are also observed, in which the addition of contaminants increases the volatilization efficiency. Such is the case with aluminum, which normally forms nonvolatile oxides but in the presence of hydrofluoric acid forms more volatile aluminum fluoride. *Dissociation interferences* affect the degree of dissociation of the analyte. Analytes that form oxides or hydroxides are especially susceptible to dissociation interferences. *Ionization interference* occurs when the presence of an easily ionized element, such as K, affects the degree of ionization of the analyte, which leads to changes in the analyte signal. Ionization interference is controlled by adding a relatively high concentration of an element that is easily ionized to maintain a more consistent concentration of ions in the flame and to suppress ionization of the analyte. In the case of *excitation interference,* the analyte atoms are excited in the atomizer, with subsequent emission at the absorption wavelength. This type of interference is more pronounced at higher temperatures.

FLUOROMETRY

Fluorescence refers to the condition when a molecule absorbs light at one wavelength and reemits light at a longer wavelength. An atom or molecule that fluoresces is termed a *fluorophore. Fluorometry* is defined as the measurement of emitted fluorescent light. Fluorometric analysis is a widely used method of quantitative analysis in the chemical and biological sciences; it is a very accurate and sensitive technique.

Basic Concepts

Figure 10-10 illustrates the relationship between absorption, fluorescence, and phosphorescence. As indicated, each molecule contains a series of closely spaced energy levels. Absorption of a quantum of light energy by a molecule causes the transition of an electron from the singlet ground state to one of a number of possible vibrational levels of its first singlet state. The actual number of molecules in the excited state

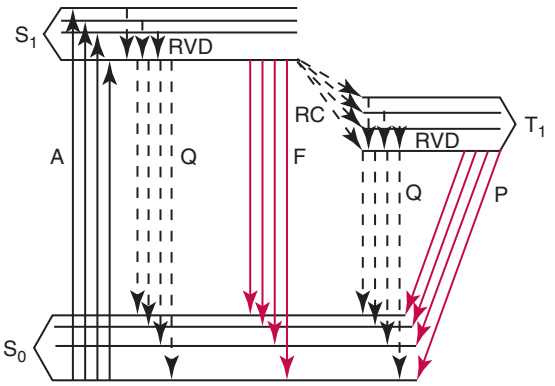

Figure 10-10 Luminescence energy-level diagram of typical organic molecule. S_0 is the ground-level singlet state; S_1 is the first excited singlet state; *A* is the absorption process; T_1 is the first excited triplet state; and *RVD* is the radiation-less vibrational deactivation. *Q* is quenching of the excited singlet or triplet state; *F* is the fluorescence process from the first excited singlet state; *P* is the phosphorescence process from the first excited triplet state; and *RC* is the radiation-less crossover from the first excited singlet state to the first excited triplet state.

under typical reaction conditions and excited with a typical 150-W light source is very small and is estimated to be about 10^{-13} mole per mole of fluorophore. Once the molecule is in an excited state, it returns to its original energy state in several ways. These include (1) radiation-less vibrational equilibration, (2) the fluorescence process from the excited singlet state, (3) quenching of the excited singlet state, (4) radiation-less crossover to a triplet state, (5) quenching of the first triplet state, and (6) the phosphorescence process of light emission from the triplet state.

As shown in Figure 10-10, vibrational equilibration before fluorescence results in some loss of the excitation energy. The emitted fluorescence light is therefore of less energy or has a longer wavelength than the excitation light. The difference between the maximum wavelength of the excitation light and the maximum wavelength of the emitted fluorescence light is a constant referred to as the *Stokes shift.* This constant is a measure of energy lost during the lifetime of the excited state (radiation-less vibrational deactivation) before returning to the ground singlet level (fluorescence emission).

Time Relationships of Fluorescence Emission

The time required for a molecule to absorb radiant energy and to be promoted to an excited state is approximately 10^{-15} s. The length of time for vibrational equilibration to occur to the lowest excited state is of the order of 10^{-14} to 10^{-12} s. The length of time required for fluorescence emission to occur is of the order of 10^{-8} to 10^{-7} s. Relatively speaking, there is a considerable time delay between the (1) absorption of light energy, (2) return to the lowest excited state, and (3) emission of fluorescence light. This time relationship is shown in Figure 10-11. In this figure, phase I represents the

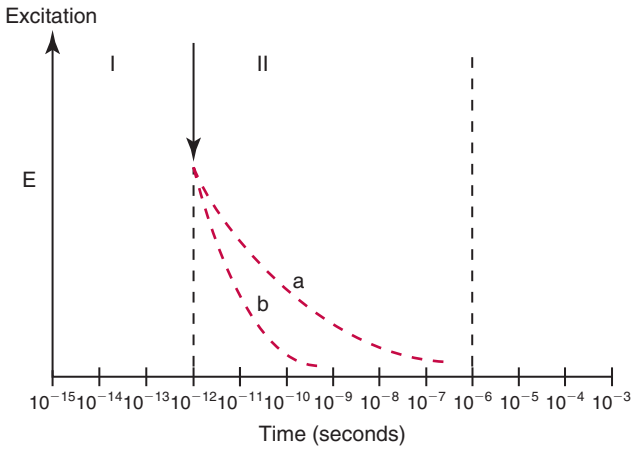

Figure 10-11 Fluorescence decay process. *E* is the absorption of energy; *I* is the vibrational deactivation time phase; *II* is the fluorescence emission time phase; *a* is long fluorescence decay time; and *b* is short fluorescence decay time.

time period between absorbance of light energy and radiationless loss of energy during vibrational rearrangement to the lowest excited energy state. This time period is represented by the up and down arrows in the diagram. Phase II shows the emission and decay of a short-lived *(b)* and a longer-lived *(a)* fluorophore. If the fluorescence emission is measured over time following a pulse of light from an excitation source, such as a xenon lamp or laser, the intensity of the emitted light decays as a first-order process similar to radioactive decay (i.e., phase II of Figure 10-11). The time required for the emitted light to reach 1/e of its initial intensity, where *e* is the Naperian base 2.718, is called the average lifetime of the excited state of the molecule, or the fluorescence decay time.

The time delay between absorption of quanta of energy and fluorescence is used in fluorescence instrumentation called *time-resolved fluorometers.*[8] Advantages of a time-resolved fluorometer include the elimination of background light scattering due to Rayleigh and Raman signals and a short-lived fluorescence background with a consequent dramatic increase in signal-to-noise and detection sensitivity.

Time-resolved fluorometry[3] falls into one of two categories, depending on how the fluorescence emission response is measured: (1) pulse fluorometry, in which the sample is illuminated with an intense brief pulse of light and the intensity of the resulting fluorescence emission is measured as a function of time with a fast detector system, or (2) phase fluorometry, in which a continuous-wave laser illuminates the sample, and the fluorescence emission response is monitored for impulse and frequency response.[8]

Relationship of Concentration and Fluorescence Intensity

The relationship of concentration to the intensity of fluorescence emission is derived from the Beer-Lambert law. By expansion through a Taylor series, rearrangement, logarithm base conversion, and basic assumptions about dilute solutions, the following equation is obtained:

$$F = \varnothing[I_o(2.3 - abc)] \quad \textbf{(8)}$$

where

F = relative fluorescence intensity
$\varnothing$ = fluorescence efficiency (i.e., the ratio between quanta of light emitted and quanta of light absorbed)
I_0 = initial excitation intensity
a = molar absorptivity
b = volume element defined by geometry of the excitation and emission slits
c = the concentration in mol/L

Equation (8) indicates that fluorescence intensity is directly proportional to the concentration of the fluorophore and the excitation intensity. This relationship holds only for dilute solutions, in which absorbance is less than 2% of the exciting radiation; the fluorescence intensity becomes nonlinear as the absorbance of the solution increases to above 2% of the exciting radiation. This phenomenon, called the *inner filter effect,* is discussed in more detail in a later section. Other factors influencing the measurement of fluorescence intensity include the sensitivity of the detector and the degree of background light scatter seen by the detector.

Fluorescence intensity measurements are more sensitive than absorbance measurements. The magnitude of absorbance of a chromophore in solution is determined by its concentration and the path length of the cuvet. The magnitude of fluorescence intensity of a fluorophore is determined by its concentration, the path length, and the intensity of the light source. The sensitivity of fluorescence measurements can be 100 to 1000 times greater than the sensitivity of absorbance measurements through the use of more intense light sources, digital signal filtering techniques, and sensitive emission photometers. All of these are incorporated into conventional spectrofluorometric instrumentation, described later in this chapter.

Frequently, fluorescence measurements are expressed in relative intensity units. The word *relative* is used because the intensity measured is not an absolute quantity. It is a small part of the total fluorescence emission, and its magnitude is defined by the instrument slit width, detector sensitivity, monochromator efficiency, and excitation intensity. Because these are instrument-related variables, establishing an absolute intensity unit for a given concentration of a fluorophore that is valid from instrument to instrument is difficult, if not impossible.

Fluorescence Polarization

Light is composed of electrical and magnetic waves at right angles to each other. Light waves produced by standard excitation sources have their electrical vectors oriented randomly. Light waves, passed through certain crystalline materials (polarizers), have their electrical vectors oriented in a single plane and are said to be plane-polarized. Fluorophores absorb light most efficiently in the plane of their electronic energy levels. If their rotational relaxation (Brownian movement) is slower than their fluorescence decay time, as is the case for large fluorescent-labeled molecules, the emitted fluorescence

light will be polarized. Because small molecules have rotational relaxation times that are much shorter than their fluorescence decay time, their emitted fluorescence light is depolarized. However, if the small fluorescent molecule is attached to a macromolecule, or if it is placed in a viscous solution, the small molecule will emit polarized light. Fluorescence polarization, *P,* is defined by the following equation:

$$P = \frac{(I_v - I_h)}{(I_v + I_h)} \quad (9)$$

where

I_v = intensity of the emitted fluorescence light in the vertical plane

I_h = intensity of the emitted fluorescence light in the horizontal plane

As indicated, *P* is the difference between the two observed intensities divided by their sum. Fluorescence polarization is measured by placing a mechanically or electrically driven polarizer between the sample cuvet and the detector. A diagram of a fluorescence polarization measurement system is shown in Figure 10-12. In the normal instrumentation mode, the sample is excited with polarized light to obtain maximum sensitivity. First, the polarization analyzer is positioned to measure the intensity of the emitted fluorescence light in the vertical plane *(I_v);* then the polarization analyzer is rotated 90° to measure the emitted fluorescence light intensity in the horizontal plane *(I_h). P* is then calculated manually or automatically by using equation (9).

Fluorescence polarization is used to quantitate analytes by using the change in fluorescence depolarization following immunologic reactions (see Chapter 16). Quantitation is accomplished by adding a known quantity of fluorescent-labeled analyte molecules to a reaction solution containing an antibody specific to the analyte. The labeled analyte binds to the antibody and causes a change in its rotational relaxation time, resulting in fluorescence polarization. The addition of a nonlabeled analyte, such as an unknown quantity of a therapeutic drug in a serum specimen, will result in competition for binding to the antibody with the fluorescent-labeled analyte. This change in binding of the fluorophore-labeled analyte causes a change in fluorescence polarization that is inversely proportional to the amount of analyte contained in a given sample. Because the change in fluorescence polarization is a direct response to the reaction mixture, the bound fluorophore need not be separated from free fluorophore. Thus fluorescence polarization is applicable to homogeneous assays of low molecular weight analytes, such as therapeutic drugs.[10]

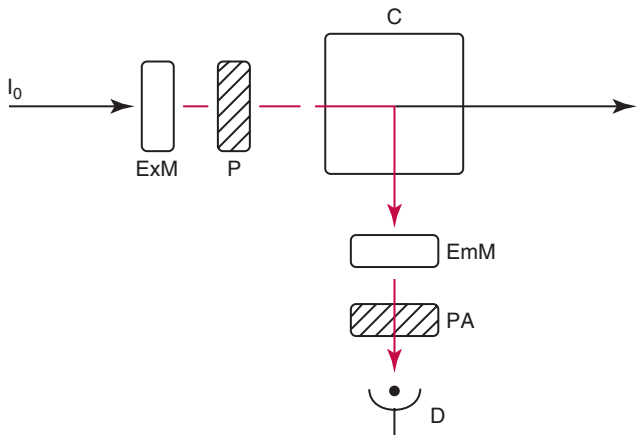

Figure 10-12 Schematic diagram of a fluorescence polarization analyzer. *P* is the polarizer used to provide polarized excitation light; *PA* is the polarizer analyzer, which is rotated to provide measurements of parallel and perpendicular polarized fluorescence emission intensity. *ExM* is the excitation monochromator; *EmM* is the emission monochromator; *D* is the detector; and *C* is the reaction cell or cuvet.

Instrumentation

Fluorometers and spectrofluorometers are used to measure fluorescence. Operationally, a fluorometer uses interference filters, glass filters, gratings, or prisms to produce monochromatic light for sample excitation and for isolation of fluorescence emission.

Components

Basic components of fluorometers and spectrofluorometers include (1) an excitation source, (2) an excitation monochromator, (3) a cuvet, (4) an emission monochromator, and (5) a detector.

Excitation Source

The absorption spectra of most fluorescent compounds of interest are in the spectral region of 300 to 700 nm. The fluorescence emission intensity is proportional to the initial excitation intensity and to concentration and size of the volume element being measured in the sample cell. Therefore, an intense lamp capable of emitting radiant energy over a large spectral region is desirable. Excitation sources used in fluorometers and spectrophotometers include xenon, quartz halogen, and mercury arc lamps and lasers. Some provide high-intensity spectra at one or more wavelengths; others provide a continuum over the spectral range of interest.

Xenon Lamp. The xenon lamp is a popular excitation source, as it provides a continuum of relatively high-intensity radiant energy over the spectral region of 250 to 800 nm. It is widely used for certain fluorescence applications because of its high energy output, stability of lamp flashes, and higher ultraviolet and visible spectral output. These flash lamps can be pulsed at rates up to 2500 pulses per second. Light output is typically in the 0.01- to 0.1-J interval, with a spectral distribution ranging from 250 to 800 nm. The life of flash lamps varies from 10^6 to 10^9 flashes, with spectral stability maintained throughout the life of the flash lamp. A limitation of xenon lamps for analytical use is arc wandering or flicker. However, the use of current-stabilized power supplies has minimized this problem and improved the performance of fluorescence instrumentation using xenon lamps.

Lasers. Laser sources (discussed earlier in the "Spectrophotometry" section) are widely used in fluorescence

applications in which highly intense, well-focused, and essentially monochromatic light is required. Examples of these applications include time-resolved fluorometry, flow cytometry, pulsed laser confocal microscopy, laser-induced fluorometry, and light scattering measurements for particle size and shape. Several different types of lasers are available as an excitation source for fluorescence measurements (see Table 10-3).

Excitation and Emission Monochromator

Monochromators used in fluorescence instrumentation include interference filters, colored glass filters, gratings, and prisms. Most modern analytical instruments using interference filters use the all-dielectric multicavity filter or a hybrid Fabry-Perot coupled-dielectric-layer filter (a filter with metal reflective layers). Either type of filter is combined with appropriate sharp cutoff glass filters to form a single filter package, which removes undesired transmission of higher orders and provides narrow bandwidth, higher peak wavelength transmission, and increased band slope. The increased slope of the spectral band makes the transition from peak transmission to nontransmission more abrupt, which is very important for the spectral separation of excitation and emission bands with a small Stokes shift.

Colored glass filters selectively absorb certain wavelengths of light. These filters have been used for both excitation and emission wavelength selection, but they are more susceptible to transmitting stray light and unwanted fluorescence.

Grating monochromators are devices that isolate regions of the spectrum. The spectral resolution of the light at the slit is a function of slit width and resolution of the grating. Spectrofluorometers generally use larger slit widths than absorbance spectrophotometers to obtain higher excitation intensities. An advantage of the grating monochromator is that it provides selectivity of the excitation and emission wavelengths required when working with new fluorophores with absorbance and emission maxima for which specially fabricated interference filters may not exist. The rotation of the grating is digitally controlled when spectral scans of fluorescence excitation and emission are automated. In the conventional operation of a spectrofluorometer, the excitation wavelength or the emission wavelength is held constant, and the other is scanned. With more automated instrumentation, both excitation and emission monochromators are synchronized and scanned together at programmed rates. This provides a change in emission intensity as a function of change in excitation and emission wavelength and gives an additional dimension of specificity to fluorescence measurements. Because of their high degree of monochromaticity, lasers are used as both the excitation light source and the monochromator. When a laser is used as a combination excitation source and monochromator, a narrow-band interference filter is usually placed before the detector to eliminate additional orders of emission.

Cuvet

As with spectrophotometers, cuvets are used in fluorometers and spectrofluorometers to hold the liquid sample to be analyzed. For fluorescence instruments, the cuvets used are typically square or rectangular and are constructed from a material that allows the excitation and the emitting light to pass (glass or plastic for visible light; quartz for ultraviolet light). However, some plastic cuvets contain ultraviolet absorbers that fluoresce, causing unwanted background signal and loss of sensitivity.

With fluorometers and spectrofluorometers, placement of the cuvet and excitation beam relative to the photodetector is critical in establishing the optical geometry for fluorescence measurements. Because fluorescence light is emitted in all directions from a molecule, several excitation/emission geometries are used to measure fluorescence (Figure 10-13). Although the end-on approach allows the adaptation of a fluorescence detector to existing 180° absorption instruments, it is not widely used, because its sensitivity is limited by the quality of the excitation and/or emission interference filter pair, the excitation and/or emission spectral band overlap, and the inner filter effect. In practice, most commercial spectrofluorometers and fluorometers use the right angle–detector approach, because it minimizes the background signal that limits analytical sensitivity. The front

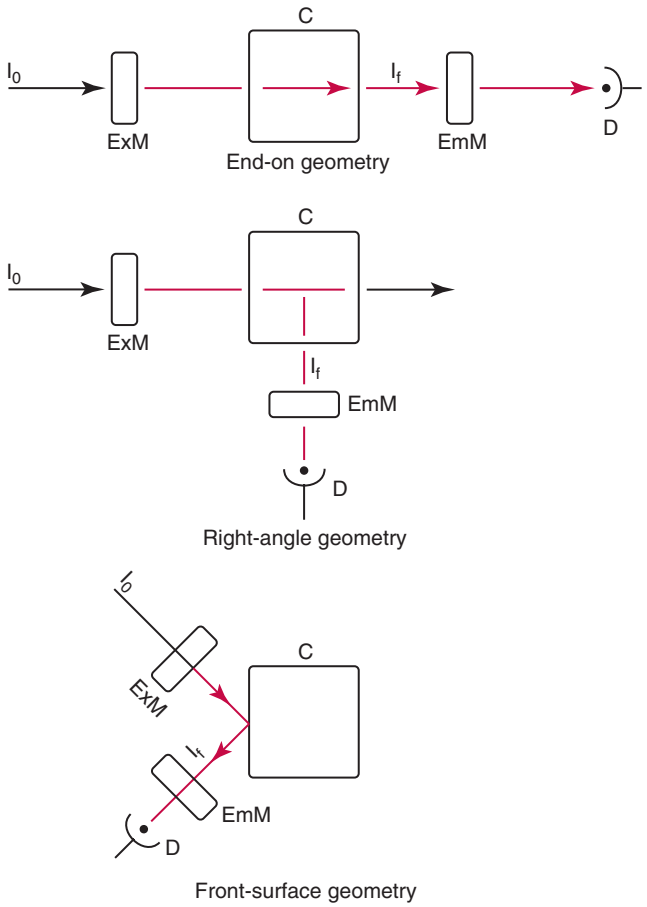

Figure 10-13 Fluorescence excitation/emission geometries: I_0 is the initial excitation energy; *ExM* is the excitation monochromator; *C* is the sample cuvet; I_f is the fluorescence intensity; *EmM* is the emission monochromator; and *D* is the detector.

surface approach provides the greatest linearity over a broad range of concentration because it minimizes the inner filter effect. The front surface approach shows similar sensitivity to the right-angle detectors but is more susceptible to background light scatter. Front surface fluorometry has been widely applied to heterogeneous solid phase fluorescence immunoassay systems.

To accommodate these different geometries, the sample cell is oriented at different angles in relation to the excitation source and the detector. Major concerns related to the geometry of the sample cell include light scattering, the inner filter effect, and the sample volume element seen by the detector. Figure 10-14, *A*, shows the sample cell and slit arrangement for a conventional fluorescence spectrophotometer with the excitation and emission slits oriented at a right angle. S_1 and S_2 designate the excitation and emission slits, respectively. The position of the emission slit and the width of the slit are important. If the emission slit is located near the front edge of the sample cell, as shown in Figure 10-14, *B*, the inner filter effect is minimized. If the emission slit width is increased, sensitivity will increase, but specificity may decrease.

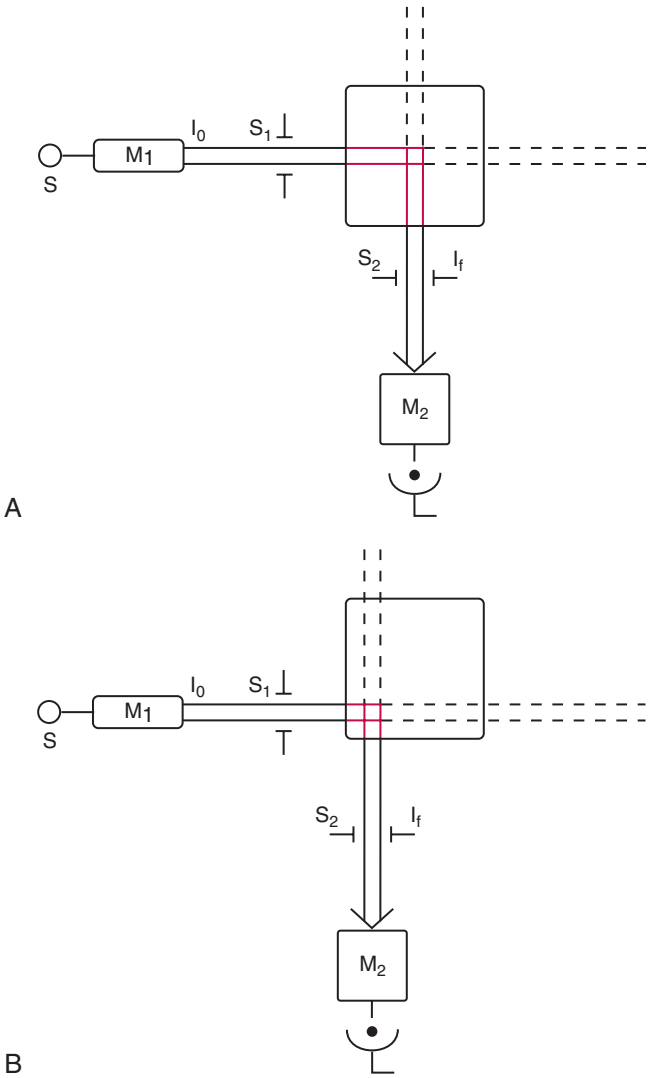

Figure 10-14 Two right-angle fluorescence sample cuvet positions. A shows the standard 90° configuration. B shows the offset positioning of the cuvet to minimize the inner filter effect.

Photodetectors

As with spectrophotometric instruments, a number of devices are used as photodetectors in fluorometric instruments, including the photomultiplier tube (PMT) and the charge-coupled detector (CCD). In addition, visual observation is used for some applications.

Visual Observation. Because the human eye is a very sensitive detector with a wide range of spectral recognition, qualitative fluorescent thin-layer chromatographic methods in the clinical laboratory use short- and long-wavelength ultraviolet lamp sources coupled with visual observation.

Photomultiplier Tube. For quantitative assays, the most commonly used detector in fluorometers and spectrofluorometers is the PMT. Important features of the PMT for fluorescence measurements consist of (1) a wide choice of spectral responses, (2) nanosecond photon response time, and (3) sensitivity. Sensitivity is due to the possible gain of 10^6 electrons at the anode of the PMT for each incident photon hitting the photo cathode.

Depending on the light level (photon flux) striking the PMT cathode and the desired sensitivity, measurement of electron flow at the PMT anode is accomplished in different ways. At high light intensities, analog techniques for measurement of PMT current are used. The analog signal is converted to a digital signal for computer use or for panel digital display. At low light levels, spikes or pulses generated at the cathode of the PMT are counted. The number of pulses that occur per unit of time is directly proportional to the intensity of emitted fluorescence light striking the PMT. This method is called *photon counting*. The use of photon counting increases the signal-to-noise ratio and decreases the lower limit of detection of the measurement of fluorophores at very low concentrations.

Charge-Coupled Detector. CCDs are multichannel devices with a dynamic range and a signal-to-noise ratio that are superior to those of PMTs.[4,21] These solid-state devices are composed of a large number of photo-detecting shift registers that are read horizontally and vertically. CCDs were first used for astronomy applications and in ground-based optical telescopes, in which sensitive low-light measurements are required. Because of their ability to detect very low levels of light, they have been used for molecular fluorescence measurement of very low concentrations of fluorescent molecules[21] and as quantitative electronic imagers for quantitative confocal microscopy.[11] A data-reading technique called *binning* has been developed that allows multielement devices to have functional elements linked together, much like rectangular slit widths.

Performance Verification

As with spectrophotometers, NIST provides a number of SRMs for use in calibration or verification of the performance

of fluorometers or fluorospectrophotometers. These include SRM 936a (quinine sulfate dihydrate) for calibrating such instruments and SRM 1932 (fluorescein) for establishing a reference scale for fluorescence measurements (http://www.nist.gov/accessed April 26, 2011).

Types of Fluorometers and Spectrofluorometers

Fluorometers and fluorescence spectrophotometers that offer a variety of features are available. These features include ratio referencing, microprocessor-controlled excitation and emission monochromators, pulsed xenon light sources, photon counting, rhodamine cells for corrected spectra, polarizers, flow cells, front-surface viewing adapters, multiple cell holders, and microprocessor-based data reduction systems.

In addition to the basic spectrofluorometer discussed earlier, other types of fluorometric instruments include a ratio-referencing spectrofluorometer, a time-resolved fluorometer, a flow cytometer, and a hematofluorometer.

Ratio-Referencing Spectrofluorometer

A typical ratio-referencing spectrofluorometer is illustrated in Figure 10-15. Basically, this is a simple right-angle instrument that uses two monochromators (M1 and M2), two photomultiplier tube detectors (D1 and D2, the reference and sample PMTs), and a xenon lamp source. The light from the exciter monochromator (M1) is split, and a small portion (10%) is directed to the reference PMT (D1) for ratio-referencing purposes. The remaining excitation light is focused into the sample cuvet (C). Emission optics are positioned at a right angle to the excitation optics. An emission monochromator (M2) is used to select or scan the desired portion of the emission spectra, which is directed to the sample PMT (D2) for measurement of emission intensity. Output signals from the reference and sample PMTs are amplified (A1 and A2), and the ratio of the sample to the reference signal is provided by a digital display or a chart recorder. The operational mode of a ratio fluorometer is similar to that of a spectrofluorometer; however, only discrete excitation and emission wavelengths are available, and use of this type of instrument is precluded from scanning fluorophores to obtain emission and excitation spectra. The ratio filter fluorometer is most useful for obtaining concentration measurements at defined excitation and emission wavelengths.

The ratio-referencing spectrofluorometer is operated at fixed excitation and emission wavelength settings for concentration measurements; alternatively, it is used to measure the excitation or emission spectrum of a given compound. Measurement of the concentration of a specimen is accomplished in a similar manner as with a single-beam fluorometer. A blank and a calibrating solution are measured first; then the unknown specimens are measured. The ratio-referencing spectrofluorometer in Figure 10-15 offers two advantages over single-beam spectrofluorometers. First, it eliminates short- and long-term xenon lamp energy fluctuations (i.e., arc flicker and lamp decay) and thus minimizes the need for frequent calibration of the instrument during analysis. Second, it provides "essentially" corrected excitation spectra by compensating for wavelength-dependent energy fluctuations.

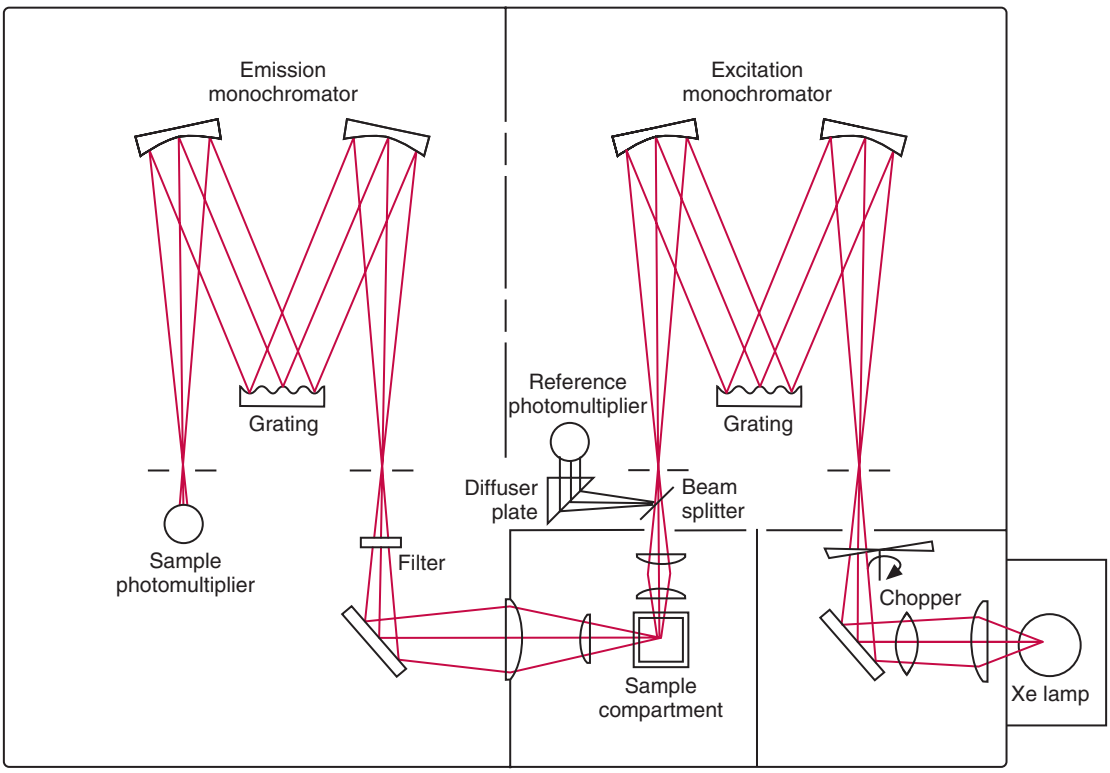

Figure 10-15 **Diagram of a typical ratio-referencing spectrofluorometer.**

Time-Resolved Fluorometer

The time-resolved fluorometer was introduced in the mid-1970s, when Weider developed a pulsed nitrogen laser fluorometer in conjunction with a lanthanide-based immunoassay system to measure the fluorescence decay of lanthanide chelates as a means of eliminating background interferences from light scatter and short decay time fluorescence compounds. The time-resolved fluorometer[3,17] is similar to the ratio-referencing fluorometer, with the exceptions that the light source is pulsed and the detector monitors, in a fast photon-counting mode, the exponential decay of the fluorescence signal after excitation. Time-resolved fluorometry requires the use of long-lived fluorophores, such as the lanthanide (rare earth) metal ions europium (Eu^{3+}) and samarium (Sm^{3+}). Whereas most fluorescence compounds have decay times of 5 to 100 ns, europium chelates decay in 0.6 to 100 s. Thus time-resolved fluorescence assays take advantage of the difference in lifetimes of fluorophore and background fluorescence by measuring the decaying fluorescence signal. This eliminates background interferences and at the same time averages the signal to improve the precision of measurement. Detection limits of approximately 10^{-13} mol/L can be achieved with time-resolved fluorometry; this is an improvement of about four orders of magnitude compared with conventional fluorometric measurements. For example, Eu^{3+}-labeled nanoparticles in combination with time-resolved fluorometry have been used to develop a highly sensitive immunoassay for free and total prostate-specific antigen having a functional sensitivity of 0.5 ng/L.[7,18,19]

Flow Cytometer

Cytometry refers to the measurement of physical and/or chemical characteristics of cells or, by extension, of other biological particles. Flow cytometry is a process in which such measurements are made while cells or particles pass, preferably in single file, through the measuring apparatus in a fluid stream. Flow sorting extends flow cytometry by using electrical or mechanical means to divert and collect cells with one or more measured characteristics that fall within a range or ranges of values set by the user.[13-16]

Operationally, flow cytometry combines laser-induced fluorometry with particle light scattering analysis that allows different populations of molecules, cells, or particles to be differentiated by size and shape using low-light and right-angle light scattering. The use of a laser is ideally suited for low-angle light scattering. These cells, molecules, or particles are labeled with specific fluorescent labels, such as β-phycoerythrin, fluorescein isothiocyanate, rhodamine-6G, and other dye-labeled antibodies. As they move in a fluid stream through the flow cell, simultaneous fluorescence and light scattering measurements are automatically performed by the flow cytometer. Most flow cytometers incorporate two or more fluorescence emission detection systems, so that multiple fluorescent labels can be used. In this manner, molecules, cells, or particles can be classified by size, shape, and type according to their light scattering and fluorescent properties. A schematic diagram of a flow cytometer is shown in Figure 10-16. An optical stop is placed in the 180° beam after the flow capillary to block the main laser beam and permit low-angle forward light scattering measurements. The 90° emission signal is split and directed to two PMTs to determine right-angle light scattering and detect at least two separate fluorescence emission signals. Two narrow-bandpass interference filters (530 nm and 596 nm) are placed in front of the two 90° fluorescence emission PMTs. A computer with substantial resident software is employed to reduce the

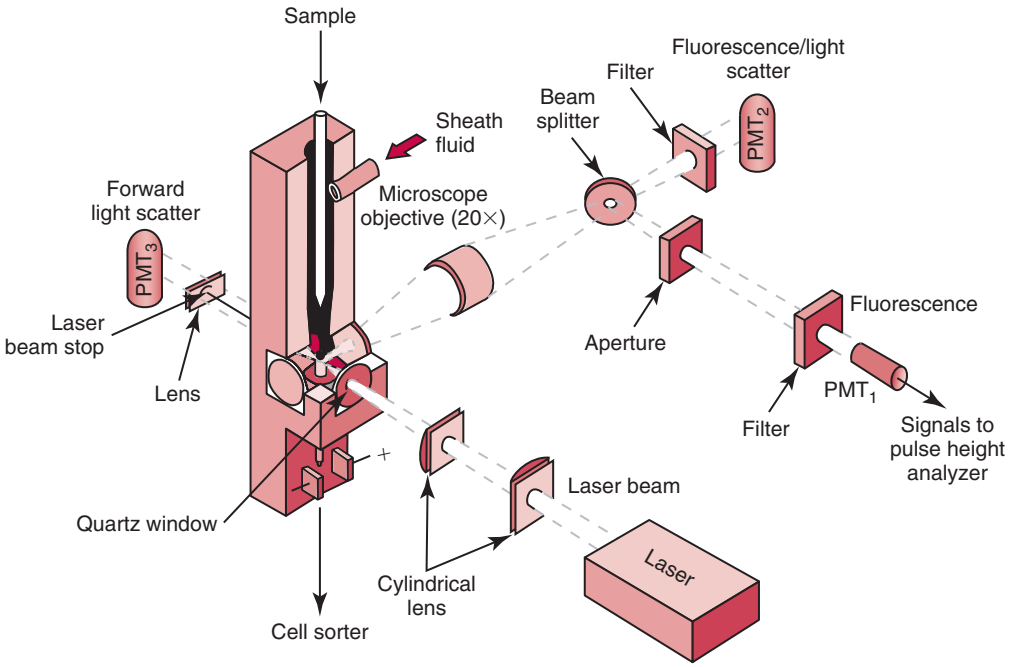

Figure 10-16 Schematic diagram of a flow cytometer.

acquired data to appropriate histograms for final result reporting. Cell-sorting electrodes are shown in the schematic drawing. Most commercial flow cytometers use one or more laser light sources. For example, the LSR II (BD Biosciences, Rockville, MD) can be equipped with seven lasers [355 nm (UV), 405 nm (violet), 488 nm (blue), 532 nm (green), 594 nm (yellow), 638 nm (red), and 785 nm (IR)], which are used to simultaneously measure 18 emission spectra.

Flow cytometers are able to measure multiple parameters, including (1) cell size (forward scatter), (2) granularity (90° scatter), (3) DNA content, (4) RNA content, (5) DNA (A + T)/(G + C) nucleotide ratios, (6) chromatin structure, (7) antigens, (8) total protein content, (9) cell receptors, (10) membrane potential, and (11) calcium ion concentration as a function of pH. These parameters are used in hematology, immunology (e.g., in T-cell subsets, tissue typing, lymphocyte stimulation, and antigen-antibody reactions), oncology (e.g., in diagnosis, prognosis, and treatment monitoring), microbiology (e.g., in bacterial identification and antibiotic sensitivity), virology, genetics (e.g., in karyotyping and carrier state detection), parasitology, and reproduction and fertility studies, and may have application in cervical cytology. Flow cytometry also has potential applications for the development of sensitive laser-induced fluoroimmunoassays. Phycoerythrin is a large phycobiliprotein molecule [molecular weight (MW) = 250,000 Da] with the fluorescence emission equivalent of 25 rhodamine-6G molecules, a quantum yield of 0.98, a broad emission spectrum of 530 to 630 nm, and low photodecomposition. It is an excellent label for cells and possibly for use in new fluoroimmunoassays.

Of particular note have been the development and use of particle-based flow cytometric assays. With this technology, a flow cytometer is combined with microspheres that are used as the solid support for conventional immunoassay, affinity assay, or DNA hybridization assay.[22] The resultant system is very flexible, and its use has led to the development of multiplexed assays that simultaneously measure many different analytes in a small sample volume.

Hematofluorometer

The *hematofluorometer* is a single-channel front-surface photofluorometer dedicated to the analysis of zinc protoporphyrin in whole blood (see Chapter 33). A typical hematofluorometer uses a quartz-tungsten lamp, a narrow-bandpass excitation filter (420 nm), front-surface optics, a narrow-bandpass filter (594 nm), and a PMT. A drop of whole blood is placed on a small rectangular glass slide that serves as a cuvet.

Limitations of Fluorescence Measurements

Factors that influence fluorescence measurements include concentration effects (e.g., inner filter effects, concentration quenching), background effects (due to Rayleigh and Raman scattering), solvent effects (e.g., interfering nonspecific fluorescence, quenching from the solvent), sample effects (e.g., light scattering, interfering fluorescence, sample adsorption), temperature effects, and photodecomposition (bleaching) of the sample.

Inner Filter Effects

The linear relationship between concentration and fluorescence emission [equation (8)] is valid when solutions that absorb less than 2% of the exciting light are used. As the absorbance of the solution increases above this amount, the relationship becomes nonlinear, a phenomenon known as the *inner filter effect*. It is caused by loss of excitation intensity across the cuvet path length as excitation light is absorbed by the fluorophore. Thus as the fluorophore becomes more concentrated, absorbance of the excitation intensity increases, and loss of the excitation light as it travels through the cuvet increases. This effect is most often encountered with a right-angle fluorescence instrument, in which the emission slits are set to monitor the center of the sample cell, where absorbance of excitation light is greater than at the front surface of the cuvet. Therefore it is less problematic if a front-surface fluorescence instrument is used. However, most fluorescence measurements are made on very dilute solutions, and the inner filter effect therefore is not a problem.

Concentration Quenching

Another related phenomenon that results in a lower quantum yield than expected is called *concentration quenching*. This can occur when a macromolecule, such as an antibody, is heavily labeled with a fluorophore, such as fluorescein isothiocyanate. When this compound is excited, the fluorescence labels are in such close proximity that radiation-less energy transfer occurs. Thus, the resulting fluorescence is much lower than expected for the concentration of the label. This is a common problem in flow cytometry and laser-induced fluorescence when attempts are made to enhance detection sensitivity by increasing the density of the fluorescing label.

Light Scattering

Light scattering—Rayleigh and Raman—limits the use of fluorescence measurements. Rayleigh scattering occurs with no change in wavelength. For fluorophores with small Stokes shifts, the excitation and emission spectra overlap and are particularly susceptible to loss of sensitivity because of background light scatter. Rayleigh-type light scatter is controlled by the use of well-defined emission and excitation interference filters, or by appropriate monochromator settings and the use of polarizers.

Raman scattering occurs with lengthening of a wavelength. This type of light scattering is independent of excitation wavelength and is a property of the solvent. Because Raman light scattering appears at longer wavelengths than the exciting radiation, it is a difficult interference to eliminate when working at very low fluorophore concentrations. As an example, the wavelength shift in water is ≈50 nm at an excitation wavelength of 365 nm, and ≈75 nm at an excitation wavelength of 436 nm. This shift would represent a problem if the excitation maximum of a fluorophore was 365 nm and the emission maximum was 415 nm. Raman light scattering is controlled by setting the excitation and emission wavelengths far enough apart to prevent the Raman scatter. It is also controlled by narrowing the slit width on the excitation

monochromator. However, both options tend to decrease sensitivity.

Cuvet Material and Solvent Effects

Certain quartz glass and plastic materials that contain ultraviolet absorbers will fluoresce. Some solvents, such as ethanol, are also known to cause appreciable fluorescence. It is therefore important when developing a fluorescence assay to assess the background fluorescence of all components of the reaction mixture. Solvents and cuvets with minimal fluorescence emission are commercially available; these reagents minimize background fluorescence problems.

Quenching by the solvent can be a problem and should be investigated when a new fluorometric method is established. Quenching is related to the interaction of the fluorophore with the solvent or with a solute dissolved in the solvent. Such interaction results in loss of fluorescence owing to energy transfer or other mechanisms, but no effect on the absorbance spectrum of the fluorophore is noted. An example of quenching is the loss of fluorescence when halides are added to quinine in dilute sulfuric acid. Quenching can be a useful tool for studying molecular structure, because fluorescence emission is sensitive to and specific for changes in atomic and molecular structure.

Sample Matrix Effects

A serum or urine sample contains many compounds that fluoresce. Thus the sample matrix is a potential source of unwanted background fluorescence and must be examined when new methods are developed. The most serious contributors to unwanted fluorescence are proteins and bilirubin. However, because protein excitation maxima are in the spectral region of 260 to 290 nm, their contribution to overall background fluorescence is minor when excitation above 300 nm occurs.

Light scattering of proteins and other macromolecules in the sample matrix has been known to cause unwanted background signal. Lipemic samples, for example, are noted for their intense light scattering, and the relative contributions of lipids to the background signal of a fluorescence measurement should be investigated when setting up a new method.

In addition to background interferences, dilute solutions of some fluorophores in the concentration range of 10^{-9} mol/L and below will adsorb to the walls of glass cuvets and other reaction vessels. Also, dilute solutions of fluorophores, when excited over long periods of time, are susceptible to photodecomposition by intense excitation light. Operationally, these problems are avoided by selecting proper reaction vessels, adding wetting agents, and minimizing the length of time a sample is exposed to the excitation light.

Temperature Effects

The fluorescence quantum efficiency of many compounds is sensitive to temperature fluctuations. Therefore, the temperature of the reaction must be regulated to within ±0.1 °C. In general, fluorescence intensity decreases with increasing temperature by approximately 1 to 5% per degree Celsius. Furthermore, collisional quenching decreases with increasing viscosity, thus reducing quenching of fluorescence. Operationally, fluorescence intensity is therefore enhanced by increasing reaction viscosity or lowering solvent temperature. Temperature effects are minimized by controlling reaction temperature and warming samples or reagents, or both, if they have been refrigerated.

Photodecomposition

In conventional fluorometry, excitation of weakly fluorescing or dilute solutions with intense light sources will cause photochemical decomposition of the analyte (photobleaching).

The following steps help to minimize photodecomposition effects:

1. Always use the longest feasible wavelength for excitation that does not introduce light scattering effects.
2. Decrease the duration of excitation of the sample by measuring the fluorescence intensity immediately after excitation.
3. Protect unstable solutions from ambient light by storing them in dark bottles.
4. Remove dissolved oxygen from the solution.

In addition, highly intense laser light sources with an energy output greater than 5 to 10 mW are used for flow cytometry, fluorescence microscopy, and laser-induced fluorescence measurements. These intense light sources rapidly photodecompose some fluorescence analytes. This decomposition introduces nonlinear response curves and loss of the majority of the sample fluorescence. Fluorescence-based assays for analytes at ultralow concentrations require optimization of laser intensity and use of a sensitive detector.

PHOSPHORESCENCE

Phosphorescence is the luminescence produced by certain substances (e.g., zinc sulfide) after radiant energy or other types of energy are absorbed. Phosphorescence is distinguished from fluorescence in that light emission results from the relaxation of molecules in an excited triplet electronic state, as opposed to an excited singlet electronic state in fluorescence emission. The decay time of emission of phosphorescence light is usually longer (10^{-4} to 10^{2} s) than the decay time of fluorescence emission because of the longer lifetime of molecules in an excited triplet state. Phosphorescence shows a larger shift in emitted light wavelength than is seen with fluorescence.

CHEMILUMINESCENCE, BIOLUMINESCENCE, AND ELECTROCHEMILUMINESCENCE

Chemiluminescence, bioluminescence, and *electrochemiluminescence* are types of luminescence in which the excitation event is caused by a (1) chemical,[14A] (2) biochemical, or (3) electrochemical reaction, and not by photoillumination.

Basic Concepts

The physical event of light emission in chemiluminescence, bioluminescence, and electrochemiluminescence is similar to

fluorescence in that it occurs from an excited singlet state, and light is emitted when the electron returns to the ground state.

Chemiluminescence and Bioluminescence

Chemiluminescence is the emission of light when an electron returns from an excited or higher energy level to a lower energy level. The excitation event is caused by a chemical reaction and involves the oxidation of an organic compound, such as luminol, isoluminol, acridinium esters, or luciferin, by an oxidant (e.g., hydrogen peroxide, hypochlorite, oxygen); light is emitted from the excited product formed in the oxidation reaction. These reactions occur in the presence of catalysts, such as enzymes (e.g., alkaline phosphatase, horseradish peroxidase, microperoxidase), metal ions, or metal complexes (e.g., Cu^{2+} and Fe^{3+} phthalocyanine complex), and hemin.[2,5,6,12,23]

Bioluminescence is a special form of chemiluminescence found in biological systems. In bioluminescence, an enzyme or a photoprotein increases the efficiency of the luminescence reaction. Luciferase and aequorin are two examples of these biological catalysts. The quantum yield (e.g., total photons emitted per total molecules reacting) is approximately 0.1 to 10% for chemiluminescence, and 10 to 30% for bioluminescence.

Chemiluminescence assays are ultrasensitive (attomole to zeptomole detection limits) and have wide dynamic ranges. They are now widely used in automated immunoassay and DNA probe assay systems [e.g., acridinium ester and acridinium sulfonamide labels, 1,2-dioxetane substrates for alkaline phosphatase labels, enhanced-luminol reaction for horseradish peroxidase labels (see Chapter 16)].

Electrochemiluminescence

Electrochemiluminescence differs from chemiluminescence in that the reactive species that produce the chemiluminescent reaction are electrochemically generated from stable precursors at the surface of an electrode.[1] A ruthenium (Ru^{2+}), tris(bipyridyl) chelate is the most commonly used electrochemiluminescence label, and electrochemiluminescence is generated at an electrode via an oxidation-reduction–type reaction with tripropylamine. This chelate is very stable and relatively small and has been used to label haptens or large molecules (e.g., proteins, oligonucleotides). The electrochemiluminescence process has been used in both immunoassays and nucleic acid assays. Advantages of this process include (1) improved reagent stability, (2) simple reagent preparation, and (3) enhanced sensitivity. With its use, detection limits of 200 fmol/L and a dynamic range extending over six orders of magnitude can be obtained.

Instrumentation

Luminometers are instruments used to measure chemiluminescence and electrochemiluminescence.[2] Basic components are (1) the sample cell housed in a light-tight chamber, (2) the injection system used to add reagents to the sample cell, and (3) the detector. The detector is usually a PMT. However, CCD, x-ray film, or photographic film has been used to image chemiluminescence reactions on a membrane or in the wells of a microplate. For electrochemiluminescence, the reaction vessel incorporates an electrode, at which electrochemiluminescence is generated.

Limitations of Chemiluminescence and Electrochemiluminescence Measurements

Light leaks, light piping, and high background luminescence from assay reagents and reaction vessels (e.g., plastic tubes exposed to light) are common factors that degrade analytical performance. The extreme sensitivity of chemiluminescence assays requires stringent controls on the purity of reagents and the solvents (e.g., water) used to prepare reagent solutions. Efficient capture of light emission from reactions that produce a flash of light requires an efficient injector that provides adequate mixing when the triggering reagent is added to the reaction vessel. Chemiluminescent and electrochemiluminescent assays have a wide linear range, usually several orders of magnitude, but very high-intensity light emission can lead to pulse pile-up in PMTs, and this can lead to a serious underestimation of true light emission intensity.

NEPHELOMETRY AND TURBIDIMETRY

Light scattering is a physical phenomenon that results from the interaction of light with particles in solution. Nephelometry and turbidimetry are analytical techniques used to measure scattered light. Light scattering measurements have been applied to immunoassays of specific proteins and haptens.

Basic Concepts

Light scattering occurs when radiant energy passing through a solution encounters a molecule in an elastic collision, which results in scattering of the light in all directions. Unlike fluorescence emission, the scattered light is of the same frequency as the incident light.

Factors that influence light scattering include effects of particle size, wavelength dependence, distance of observation, effects of polarization of incident light, concentration of the particles, and molecular weight of the particles.

Particle Size

The Rayleigh scattering equation (see next section) applies to the scattering of light from small particles with much smaller dimensions than the wavelength of incident light (e.g., particle size $<\lambda/10$). When the dimensions of the particles are much smaller than the wavelength of the incident light, each particle is subjected to the same electric field strength at the same time. Reradiated or scattered light waves from the small particle are in phase and reinforce each other. As the particles become larger than the incident light wave, radiated light waves are no longer all in phase. Reinforcement of radiation occurs in some directions, and destructive interference occurs in others. Scattering patterns from these large particles are characteristic of the size and shape of the particle.

Wavelength Dependence of Light Scattering

In 1871, Lord Rayleigh derived the following equation, which demonstrates the relationship of the intensity (I_S) of scattered light to the intensity (I_0) of incident light:

$$\frac{I_S}{I_0} = \frac{16\pi^2 a \sin^2 \varnothing}{\lambda^4 r^2} \qquad (10)$$

where

I_s = intensity of scattered light
I_0 = intensity of the excitation light
a = polarizability of the small particle
θ = angle of observation
λ = wavelength of incident light
r = distance from light scattering to the detector

As indicated, the intensity of light scattering is inversely proportional to the wavelength of the incident light. Another useful observation from equation (10) is the fact that scattered light intensity is also inversely proportional to the distance r from the light scattering particles to the detector. Thus, the detector should be located close to the analytical cell by the juxtaposition of the cell to the detector or by the use of good collection optics.

Concentration and Molecular Weight Factors in Light Scattering

The direct relationship of light scattering to the concentration of particles and to the molecular weight of particles is derived from equation (10), showing that

$$\frac{I_S}{I_0} = \frac{4\pi^2 \left(\frac{dn}{dc}\right)^2 Mc \sin^2 \varnothing}{N_a \lambda^4 r^2} \qquad (11)$$

where

I_s = intensity of scattered light from small particles excited by polarized light
I_0 = incident intensity
dn/dc = change in refractive index of the solvent with respect to change in solute concentration
M = molecular weight (g/mol)
c = concentration (g/mL) of the particles
θ = angle of observation
N_a = Avogadro's number
λ = wavelength of the incident light
r = distance from light scattering to the detector

The important observation to be made from equation (11) is the direct relationship of light scattering to the concentration and the molecular weight of particles.

Effects of Polarized Light on Light Scattering

Equations (10) and (11) are different forms of the Rayleigh expression for light scattering from small particles if excited by polarized light. Figure 10-17, *A*, shows the effects of polarized and nonpolarized light on light scattering intensity from small particles as a function of scattering angle. Curve 2 shows a spherically symmetric intensity diagram as predicted by equation (10). Curve 3 is the resultant intensity diagram when curves 1 and 2 are summed and is the scattering angular

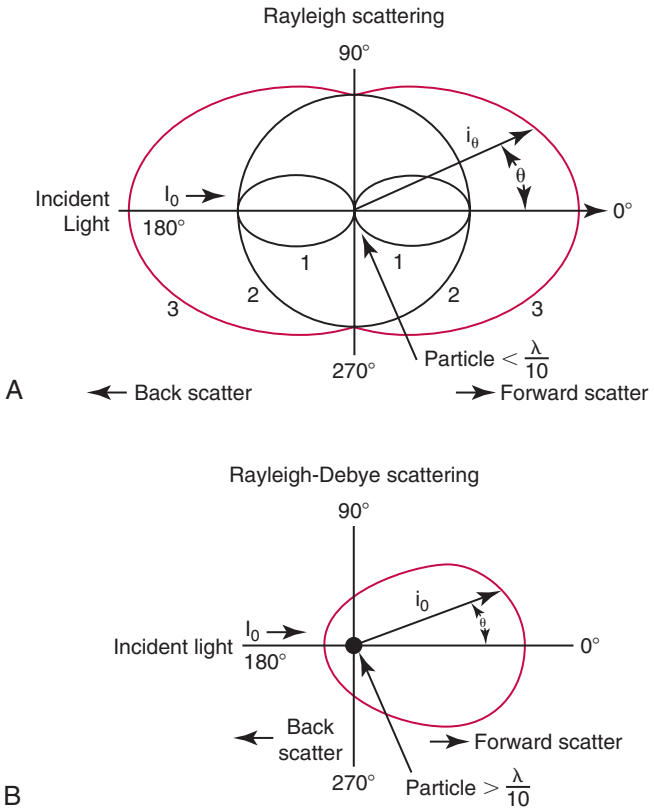

Figure 10-17 Intensity of scatter in different directions under different particle size conditions relative to the wavelength of light. Panel A shows the angular dependence of light scattering intensity with nonpolarized and polarized incident light for small particles (1, 2, and 3). Panel B shows the angular dependence of light scattering with nonpolarized light for larger particles.

intensity diagram obtained when light scatters from small particles excited with nonpolarized light. Curves 1 and 2 represent intensity diagrams from vertically and horizontally polarized light components that are considered to comprise nonpolarized light. The Rayleigh light scattering expression for small particles excited by nonpolarized light is given by equation (12):

$$\frac{I_S}{I_0} = \frac{2\pi^2 \left(\frac{dn}{dc}\right)^2 Mc\,(1+\cos\varnothing)}{N_a \lambda^4 r^2} \qquad (12)$$

Two important observations can be made from equation (12) and Figure 10-17, *A*. First, the total light scattered by small particles is less when excited by polarized light than by nonpolarized light, and reduction of background signal from light scattering in fluorescence measurements is achieved if an appropriately oriented polarizer is used in front of the emission detector. Second, light scattering intensity from small particles excited by nonpolarized light shows symmetric angular dependence of light scattering about the 90° axis (refer to Figure 10-17, *A*, curve 3).

Angular Dependence of Light Scattering

The angular dependence of light scattering from small particles (i.e., less than λ/10), as indicated in the previous section, is represented by Figure 10-17, *A*. Examination of Figure 10-17, *A* (curve 3), shows that light scatter intensity values for forward scatter and back scatter (I_0 at 0° and 180°) from small particles excited by nonpolarized light are equal. However, light scatter intensity at 90° is much less. As particles become larger (e.g., >λ/10), the angular dependence of light scatter takes on the dissymmetric relationship shown in Figure 10-17, *B*. In this situation, light-scattering intensities at forward and back angles are not equal; forward scatter intensity is much larger. Also, light scattering intensity at 90° is much less than intensity at the forward (0°) angle. As particles become even larger, this dissymmetry increases even further. This dissymmetry and the change in angular dependence of light scattering with change in the size of particles are very useful for characterization and differentiation of various classes of macromolecules and cells. As was previously mentioned, this property of light scattering is being used in the design of flow cytometers. These instruments measure near forward light scattering and right-angle light scattering from cellular particles flowing through an optical cell and excited by a high-intensity laser. The ratio of near forward light scattering intensity to right-angle light intensity is used in these instruments to distinguish among cell sizes.

Light Scattering and Plasma Proteins

The expression for light scattering given in equation (10) holds true in dilute solution for small particles if the largest dimension is less than one tenth the wavelength of the incident light. Thus the upper limit on the size of particles exhibiting Rayleigh scattering is about 40 nm when visible light is used at 400 nm. Many of the plasma proteins—such as immunoglobulins, β-lipoproteins, and albumin—are below this limit. For larger particles (≈40 to 400 nm), the angular dependence of the scattered light loses symmetry around the 90° axis, as seen in Figure 10-17, and shows an increase in forward scattering. Some plasma proteins of the immunoglobulin M class, chylomicrons, and aggregating immunoglobulin–antigen complexes fall into this size category. Scattering from particles in this size range is known as Rayleigh-Debye scattering, and the equation for this type of scattering becomes more complex. Particles such as red blood cells and bacteria are larger yet (i.e., 7000 to 40,000 nm). These particles show a complex angular dependence of light scattering, and this type of scattering from very large particles is called Mie scattering. These large particles produce a predominance of scattered light in a narrow angular region in the forward direction.

Measurement of Scattered Light

Turbidimetry and nephelometry are methods used to measure scattered light. Such measurement has proven useful for the quantitation of serum proteins (see Chapters 15 and 22).

Turbidimetry

Turbidity decreases the intensity of the incident beam of light as it passes through a solution of particles. Measurement of this decrease in intensity is called *turbidimetry*. Analogous to absorption spectroscopy, turbidity is defined as follows:

$$I = I_0 e^{-bt} \quad \textbf{(13)}$$

or

$$t = \frac{1}{b} \ln \frac{I_0}{I} \quad \textbf{(14)}$$

where

t = turbidity
b = path length of incident light through the solution of light scattering particles
I = intensity of transmitted light
I_0 = intensity of incident light

Turbidity is measured at 180° from the incident beam or, more simply, in the same manner as absorbance measurements are made in a spectrophotometer. Turbidity can be measured on most spectrophotometers and automated clinical chemistry analyzers. The stability and resolution of modern microprocessor-driven spectrophotometers and photometers have greatly improved their ability to measure turbidity with accuracy and precision.

Nephelometry

Nephelometry is defined as the detection of light energy scattered or reflected toward a detector that is not in the direct path of the transmitted light.[9] Common nephelometers measure scattered light at right angles to the incident light. The ideal nephelometric instrument would be free of stray light, and neither light scatter nor any other signal would be seen by the detector when the solution in front of the detector is free from particles. However, because of stray light-generating components in the optical system and in the sample cuvet or the sample itself, a truly dark field situation is difficult to obtain when making nephelometric measurements. Some nephelometers are designed to measure scattered light at an angle other than 90° to take advantage of the increased forward scatter intensity caused by light scattering from larger particles (e.g., immune complexes).

Selection of Method

The choice between turbidimetry and nephelometry depends on the application and the available instrumentation. Nephelometry, however, still offers some advantage in terms of sensitivity when low-level antigen-antibody reactions are measured.[10]

Instrumentation

Turbidimeters and nephelometers are used to measure the intensity of light scattering.

Turbidimeter

Turbidimetric measurements are easily performed on photometers or spectrophotometers and require little optimization.

The principal concern of turbidimetric measurements is signal-to-noise ratio. Photometric systems with electro-optical noise in the range of ±0.0002 absorbance unit or less are useful for turbidity measurements.

Nephelometer

Although light scattering can be measured with standard analytical fluorometers or photometers, the angular dependence of light scattering intensity has resulted in the design of special nephelometers. These devices place the PMT detector at appropriate angles to the excitation light beam. The design principle of a nephelometer is similar to the design principle applied in fluorescence measurement. The major operational difference between the fluorometer and the nephelometer is that the excitation and detection wavelengths will be set to the same value when operating a nephelometer. The principal concerns of light scatter instrumentation include excitation intensity, wavelength, distance of the detector from the sample cuvet, and minimization of external stray light. As shown in Figure 10-18, the basic components of a nephelometer include (1) a light source, (2) collimating optics, (3) a sample cell, and (4) collection optics, which include light scattering optics, a detector optical filter, and a detector. The schematic diagram also shows the different angles from the incident light beam where the detector, filter, and optics are placed to measure light scattering. Figure 10-18, *A*, shows the straight-through arrangement for turbidimetry, whereas Figure 10-18, *B* and *C*, shows arrangements frequently found in nephelometers. The detector arrangement shown in Figure 10-18, *B*, is used for measurement of forward scatter at 30°—the optical arrangement used with some commercial nephelometers.

Operationally, the optical components used in turbidimeters and nephelometers are similar to those used in fluorometers and photometers. For example, the light sources commonly used are quartz-halogen lamps, xenon lamps, and lasers. He-Ne lasers, which operate at 633 nm, typically have been used for light scattering applications, such as nephelometric immunoassays and particle size and shape determinations. The laser beam is used specifically in some nephelometers because of its high intensity; in addition, the coherent nature of laser light makes it ideally suited for nephelometric applications.

In addition, ratio-referencing fluorometers are well suited for nephelometric measurements.

Limitations of Light Scattering Measurements

Antigen excess and matrix effects are limitations encountered in the use of turbidimeters and nephelometers for measurement of analytes of clinical interest.

Antigen Excess

Antigen-antibody reactions are complex and appear to result in a mixture of aggregate sizes. As turbidity increases during addition of antigen to antibodies, the signal increases to a maximum value and then decreases. The point at which the decrease begins marks the beginning of the phase of antigen excess; this phenomenon is explained in Chapter 16. Consequently, light scattering methods for quantitation of antigen-antibody reactions must provide a method for detecting

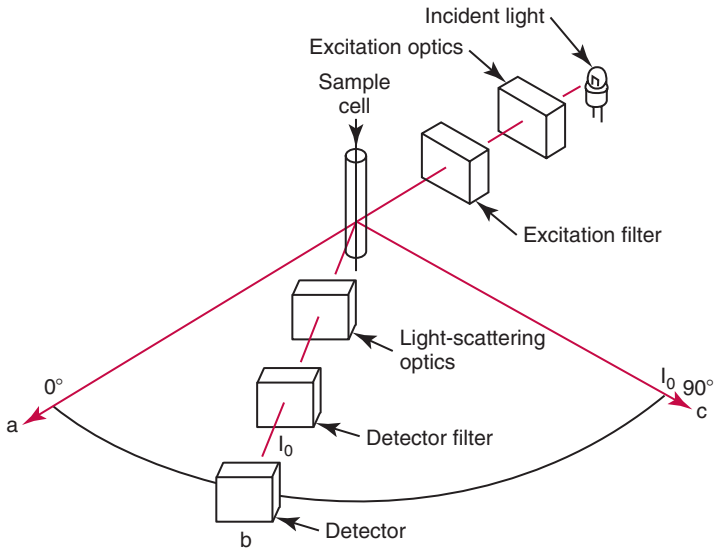

Figure 10-18 Schematic diagram of light scattering instrumentation showing (A) the optics position for a turbidimeter; (B) the optics position for a forward scattering nephelometer; and (C) the optics position for a right-angle nephelometer.

antigen excess. The kinetics of immune complex formation measured by nephelometry or turbidimetry is sufficiently different in each of the three phases—antibody excess, equivalence, and antigen excess—that computer algorithms have been developed to flag antigen excess automatically.[9,20]

Matrix Effects

Particles, solvent, and all serum macromolecules scatter light. Lipoproteins and chylomicrons in lipemic serum provide the highest background turbidity or nephelometric intensity. With appropriate dilutions, the relative intensity of light scattering from a lipemic sample is less than that of the antiserum blank. However, as the concentration of the antigen in serum decreases and correspondingly less dilute samples are used, background interference from lipemic samples becomes greater. An effective method for minimizing this background interference is the use of rate measurements, in which the initial sample blank is eliminated. Large particles, such as suspended dust, also cause significant background interference. This background interference is controlled by filtering all buffers and diluted antisera before analysis is attempted.

CHAPTER 11

Electrochemistry and Chemical Sensors

*Paul D'Orazio, Ph.D., and Mark E. Meyerhoff, Ph.D.**

Electrochemical and optical sensors (and associated biosensors) are firmly established in clinical analysis systems. Sensors for measurement of blood gases, electrolytes, and metabolites are particularly well suited for incorporation into automated, point-of-care, and critical-care analyzers (see Chapters 19, 20, and 28, respectively), because of their ease of use, low maintenance, and ability to measure clinically important analytes in undiluted blood.[62] When integrated into chromatographic systems (see Chapter 13), electrochemical detectors provide a highly sensitive and selective means of detecting a variety of other analytes, such as therapeutic drugs, neurotransmitters, glutathione, and homocysteine. Also, electrochemical detection has been applied successfully for monitoring coagulation reactions, detecting toxic lead in blood samples, and developing novel ultrasensitive immunoassays. When bioelements are integrated with electrodes, the resultant biosensors further expand the analytical capabilities of such devices. In addition, the development and application of *optodes,* based on some of the same selective chemistries used in electrochemical devices, have resulted in another analytical tool for measuring blood gases and electrolytes.

In this chapter, the fundamental electrochemical principles of (1) potentiometry, (2) voltammetry/ amperometry, (3) conductance, and (4) coulometry will be summarized and clinical applications presented. Next, optodes and biosensors will be discussed. The chapter concludes with a discussion of in vivo and minimally invasive sensors.

POTENTIOMETRY AND ION-SELECTIVE ELECTRODES

Potentiometry is widely used clinically for the measurement of pH, PCO_2, and electrolytes (Na^+, K^+, Cl^-, Ca^{2+}, Mg^{2+}, Li^+) in whole blood, serum, plasma, and urine, and as the basis for some biosensors for metabolites of clinical interest.

Basic Concepts

Potentiometry is the measurement of an electrical potential difference between two electrodes (half-cells) in an electrochemical cell (Figure 11-1) when the cell current is zero (galvanic cell). Such a cell consists of two electrodes (electron and metallic conductors) that are connected by an electrolyte solution (ion conductor). An *electrode,* or *half-cell,* consists of a single metallic conductor that is in contact with an electrolyte solution. Ion conductors have been composed of one or more phases that are either in direct contact with each other or separated by membranes permeable only to specific cations or anions (see Figure 11-1). One of the electrolyte solutions is the unknown or test solution; this solution may be replaced by an appropriate reference solution for calibration purposes. By convention, the cell notation is shown so that the left electrode (M_L) is the reference electrode, and the right electrode (M_R) is the *indicator (measuring) electrode* [see later equation (3)].[11]

The *electromotive force* (E or EMF) is defined as the maximum difference in potential between the two electrodes (right minus left) obtained when the cell current is zero. The cell potential is measured using a *potentiometer,* of which the common pH meter is a special type. The *direct-reading potentiometer* is a voltmeter that measures the potential across the cell (between the two electrodes); however, to obtain an accurate potential measurement, it is necessary that no current flow through the cell. This is accomplished by incorporating high resistance within the voltmeter (input impedance $>10^{12}$ Ω). Modern direct-reading potentiometers are accurate and can be modified to provide direct digital displays or printouts.

Within any one conductive phase, the potential is constant as long as the current flow is zero. However, a potential difference arises between two different phases in contact with each other. The overall potential of an electrochemical cell is the sum of all potential gradients that exist between different

**The authors gratefully acknowledge the original contributions of Drs. Richard A. Durst and Ole Siggard-Andersen on which portions of this chapter are based.*

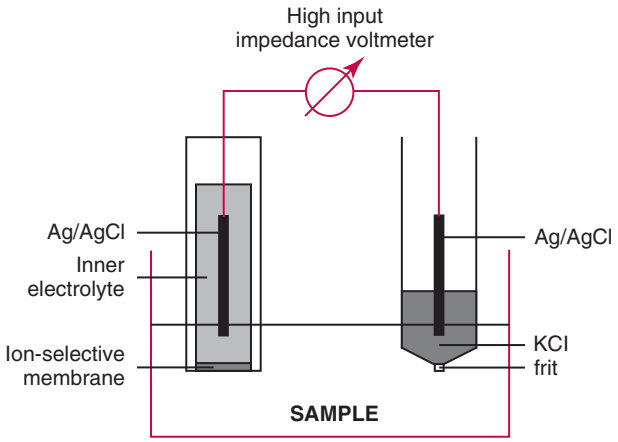

Figure 11-1 Schematic of ion-selective membrane electrode–based potentiometric cell.

phases of the cell. The potential of a single electrode with respect to the surrounding electrolyte and the absolute magnitude of the individual potential gradients between phases are unknown and cannot be measured. Only *potential differences* between two electrodes (half-cells) can be measured. Potential gradients can be classified as (1) redox potentials, (2) membrane potentials, or (3) diffusion potentials. Generally, it is possible to devise a cell in such a manner that all potential gradients except one are constant. This potential then can be related to the activity of a specific ion of interest (e.g., H^+, Na^+).

Types of Electrodes

Many different types of electrodes are used for potentiometric applications. They include redox, ion-selective membrane (glass and polymer), and PCO_2 electrodes.

Redox Electrodes

Redox potentials are the result of chemical equilibria involving electron transfer reactions:

$$\text{Oxidized form (Ox)} + ne^- \longleftrightarrow \text{Reduced form (Red)} \quad \textbf{(1)}$$

where n represents the number of electrons involved in the reaction. Any substance that accepts electrons is an *oxidant* (Ox), and any substance that donates electrons is a *reductant* (Red). The two forms, Ox and Red, represent a redox couple (conjugate redox pair). Usually, homogeneous redox processes take place only between two redox couples. In such cases, electrons are transferred from a reductant (Red_1) to an oxidant (Ox_2). In this process, Red_1 is oxidized to its conjugate Ox_1, whereas Ox_2 is reduced to Red_2:

$$Red_1 + Ox_2 \longleftrightarrow Ox_1 + Red_2 \quad \textbf{(2)}$$

In an electrochemical cell, electrons may be accepted from or donated to an inert metallic conductor (e.g., platinum). A reduction process tends to charge the electrode positively (remove electrons), and an oxidation process tends to charge the electrode negatively (add electrons). By convention, a heterogeneous redox equilibrium [equation (2)] is represented by the cell

$$M_L\,|Red_1 - Ox_1 :: Ox_2 - Red_2\,|M_R \quad \textbf{(3)}$$

A positive potential ($E > 0$) for this cell signifies that the cell reaction proceeds spontaneously from left to right; $E < 0$ signifies that the reaction proceeds from right to left; and $E = 0$ indicates that the two redox couples are at mutual equilibrium.

The *electrode potential* (reduction potential) for a redox couple is defined as the couple's potential measured with respect to the standard hydrogen electrode, which is set equal to zero (see later discussion of hydrogen electrode). This potential, by convention, is the electromotive force of a cell, where the standard hydrogen electrode is the reference electrode (left electrode) and the given half-cell is the indicator electrode (right electrode). The reduction potential for a given redox couple is shown by the Nernst equation:

$$E = E^0 - \frac{N}{n} \times \log \frac{aRed}{aOx} = E^0 - \frac{0.0592V}{n} \times \log \frac{aRed}{aOx} \quad \textbf{(4)}$$

where

E = electrode potential of the half-cell
E^0 = standard electrode potential when $a_{Red}/a_{Ox} = 1$
n = number of electrons involved in the reduction reaction
$N = (R \times T \times \ln 10)/F$ (the Nernst factor if $n = 1$)
$N = 0.0592$ V if $T = 298.15$ K (25 °C)
$N = 0.0615$ V if $T = 310.15$ K (37 °C)
R = gas constant (= 8.31431 Joules × K^{-1} × mol^{-1})
T = absolute temperature (unit: K, kelvin)
F = Faraday constant (= 96,487 Coulombs × mol^{-1})
ln 10 = natural logarithm of 10 = 2.303
a = activity
$aRed/aOx$ = product of mass action for the reduction reaction

Redox electrodes currently in use include (1) inert metal electrodes immersed in solutions containing redox couples and (2) metal electrodes whose metal functions as a member of the redox couple.

Inert Metal Electrodes

Platinum and *gold* are examples of inert metals used to record the redox potential of a redox couple dissolved in an electrolyte solution. The *hydrogen electrode* is a special redox electrode for pH measurement. It consists of a platinum or gold electrode that is electrolytically coated (platinized) with highly porous platinum (platinum black) to catalyze the electrode reaction:

$$H^+ + e^- \longleftrightarrow \frac{1}{2}H_2 \quad \textbf{(5)}$$

The electrode potential is given by

$$E = E^0 - N \times \log \frac{(fH_2)^{1/2}}{aH^+} \quad \textbf{(6)}$$

or

$$E = E^0 - N \times [\log(fH_2)^{1/2} - \log aH^+] \quad (7)$$

where

$E^0 = 0$ at all temperatures (by convention)

f_{H2} = fugacity of hydrogen gas

a_{H+} = activity of hydrogen ions

$-\log a_{H+}$ = negative log of H^+ activity (pa_{H+} or pH)

When the partial pressure of hydrogen (PH_2) in the solution (and hence f_{H2}) is maintained constant by bubbling hydrogen through the solution, the potential is a linear function of log a_{H+} (= −pH). In the *standard hydrogen electrode (SHE),* the electrolyte consists of an aqueous solution of hydrogen chloride with a_{HCl} equal to 1.000 (or c_{HCl} = 1.2 mol/L) in equilibrium with a gas phase, and with f_{H2} equal to 1.000 (or PH_2 = 101.3 kPa = 1 atm). The SHE is also used as a reference electrode.

Metal Electrodes Participating in Redox Reactions

The silver-silver chloride electrode is an example of a metal electrode that participates as a member of a redox couple. The silver-silver chloride electrode consists of a silver wire or rod coated with $AgCl_{(s)}$ that is immersed in a chloride solution of constant activity; this sets the half-cell potential. The Ag/AgCl electrode is itself considered a potentiometric electrode, as its phase boundary potential is governed by an oxidation-reduction electron transfer equilibrium reaction that occurs at the surface of the silver:

$$AgCl_{(solid)} + e^- \longleftrightarrow Ag^{\circ}_{(solid)} + Cl^- \quad (8)$$

The Nernst equation for the reference half-cell potential of an Ag/AgCl reference electrode is written as follows:

$$E_{Ag/AgCl} = E^0_{Ag/AgCl} + \frac{RT}{nF} \times \ln \frac{a_{AgCl}}{a_{Ag} a_{Cl-}} \quad (9)$$

Because AgCl and Ag are both solids, their activities are equal to unity ($a_{AgCl} = a^0_{Ag} = 1$). Therefore, from equation (9), the half-cell potential is controlled by the activity of chloride ion in solution (a_{Cl-}) contacting the electrode.

The Ag/AgCl electrode is used both as an internal reference element in potentiometric ion-selective electrodes (ISEs) and as an external reference electrode half-cell of constant potential, required to complete a potentiometric cell (see Figure 11-1). In both cases, the Ag/AgCl electrode must be in equilibrium with a solution of constant chloride ion activity.

The Ag/AgCl element of the external reference electrode half-cell is in contact with a high-concentration solution of a soluble chloride salt. Saturated potassium chloride is commonly used. A porous membrane or frit is frequently employed to separate the concentrated KCl from the sample solution. The frit serves both as a mechanical barrier to hold the concentrated electrolyte within the electrode and as a diffusional barrier to prevent proteins and other species in the sample from coming into contact with the internal Ag/AgCl element, which could poison and alter its potential. The interface between two dissimilar electrolytes (concentrated KCl/calibrator or sample) occurs within the frit and develops the liquid-liquid junction potential (E_j), a source of error in potentiometric measurements. The difference in liquid-liquid junction potential between calibrator and sample (residual liquid junction potential) is responsible for this error and can be minimized and usually neglected in practice if the compositions of the calibrating solutions are matched as closely as possible to the sample with respect to ionic content and ionic strength. An equitransferant electrolyte at high concentration as the reference electrolyte further helps to minimize the residual liquid junction potential. Potassium chloride at a concentration ≥2 mol/L is preferred. Differences of approximately −2% in the measurement of sodium by ISEs have been demonstrated when the KCl concentration in the reference electrolyte is lowered from 3 to 0.5 mol/L.[28] The magnitude of the residual liquid junction potential may also be estimated by the Henderson equation[106] with sufficient knowledge of ionic activities, ionic charges, and ionic mobilities for each electrolyte on both sides of the junction and the temperature. Using this estimate, a correction to the overall cell potential may be applied.

The presence of erythrocytes in the sample may affect the magnitude of the residual liquid junction potential in a less predictable manner. For example, erythrocytes in blood of normal hematocrit are estimated to produce approximately 1.8 mmol/L positive error in the measurement of sodium by ISEs when an open, unrestricted liquid-liquid junction is used.[13] This bias may be minimized if a restrictive membrane or frit is used to modify the liquid-liquid junction.

The *calomel electrode* consists of mercury covered by a layer of calomel (Hg_2Cl_2), which is in contact with an electrolyte solution containing Cl^-. Calomel electrodes are frequently used as reference electrodes for pH measurements using glass pH electrodes.

Ion-Selective Electrodes

Membrane potentials are caused by the permeability of certain types of membranes to selected anions or cations. Such membranes are used to fabricate ISEs that selectively interact with a single ionic species. The potential produced at the membrane-sample solution interface is proportional to the logarithm of the ionic activity or concentration of the ion in question. Measurements with ISEs are simple, often rapid, nondestructive, and applicable to a wide range of concentrations.

The ion-selective membrane is the "heart" of an ISE, as it controls the selectivity of the electrode. Ion-selective membranes are typically composed of glass, crystalline, or polymeric materials. The chemical composition of the membrane is designed to achieve an optimal permselectivity toward the ion of interest. In practice, other ions exhibit finite interaction with membrane sites and will display some degree of interference for determination of an analyte ion. In clinical practice, if the interference exceeds an acceptable quantity, a correction is required.

The Nicolsky-Eisenman equation describes the selectivity of an ISE for the ion of interest over interfering ions:

$$E = E^0 + \left[\frac{2.303\,RT}{z_i F}\right] \log\left(a_i + \sum K_{i/j} a_j^{z_i/x_j}\right) \quad (10)$$

where

a_i = activity of the ion of interest

a_j = activity of the interfering ion

$K_{i/j}$ = selectivity coefficient for the primary ion over the interfering ion. Low values indicate good selectivity for the analyte *i* over the interfering ion *j*

z_i = charge of primary ion

z_j = charge of interfering ion

All other terms are identical to those in the Nernst equation [equation (4)].

Various approaches may be used to determine the selectivity of an ISE for a primary ion over an interfering ion.[7,14] A straightforward approach is the *separate solution method,* whereby the potential of an ISE is determined in solutions of the primary and interfering ions separately, but at equal ionic activities. The selectivity coefficient is then calculated as follows:

$$\log K_{ij} = \frac{E_j - E_i}{\frac{2.303\,RT}{nF}} + \left(1 - \frac{z_i}{z_j}\right)\log a_i \qquad (11)$$

Most ISEs used in clinical practice have sufficient selectivity and do not require correction for interfering ions. Oesch and associates have published required ISE selectivity coefficients for ions commonly measured in clinical chemistry over other ions found in blood.[88] Table 11-1 shows required selectivity coefficients for the measurement of cations of interest in clinical chemistry over potentially interfering cations, assuming an acceptable maximum interference of 1% for the ion of interest.

Glass membrane and polymer membrane electrodes are two types of ISEs that are commonly used in clinical chemistry applications.

The Glass Electrode

Glass membrane electrodes are employed to measure pH and Na^+, and as an internal transducer for PCO_2 sensors. The H^+ response of thin glass membranes was first demonstrated in 1906 by Cremer.[26] In the 1930s, practical application of this phenomenon for measurement of acidity in lemon juice was made possible by the invention of the pH meter by Arnold Beckman.[11] Glass electrode membranes are formulated from melts of silicon and/or aluminum oxide mixed with oxides of alkaline earth or alkali metal cations. By varying the glass composition, electrodes with selectivity for H^+, Na^+, K^+, Li^+, Rb^+, Cs^+, Ag^+, Tl^+, and NH_4^+ have been demonstrated.[33] However, glass electrodes for H^+ and Na^+ are today the only types with sufficient selectivity over interfering ions to allow practical application in clinical chemistry. A typical formulation for H^+ selective glass is 72% SiO_2; 22% Na_2O; 6% CaO, which has a selectivity order of $H^+ >>> Na^+ > K^+$. This glass membrane has sufficient selectivity for H^+ over Na^+ to allow error-free measurements of pH in the range of 7.0 to 8.0 [$[H^+] = 10^{-7}$ to 10^{-8} mol/L] in the presence of >0.1 mol/L Na^+. Glass pH electrodes with selectivity coefficients ($K_{H/Na}$) over Na^+ of 10^{-7} and better have been realized. By altering slightly the formulation of the glass membrane to 71% SiO_2; 11% Na_2O; 18% Al_2O_3, its selectivity order becomes $H^+ > Na^+ > K^+$. Thus, the preference of the glass membrane for H^+ over Na^+ is greatly reduced, resulting in a practical sensor for Na^+ at pH values typically found in blood.[32]

TABLE 11-1 Required Selectivities for Cation-Selective Ion-Selective Electrodes for Whole Blood, Plasma, and Serum Measurements

Primary Ion (i)	Required Selectivity Coefficient ($\log K_{i/j}$) for Interfering Cation (j)					
	H^+	Li^+	Na^+	K^+	Mg^{2+}	Ca^{2+}
H^+	—	−6.5	−8.5	−7.0	−7.7	−7.7
Li^+*	2.1	—	−4.3	−2.8	−3.5	−3.6
Na^+	4.4	−0.1	—	−0.6	−1.2	−1.3
K^+	2.8	−1.7	−3.6	—	−2.8	−2.9
Mg^{2+}	8.9	0.1	−3.9	−0.9	—	−2.4
Ca^{2+}	9.3	0.4	−3.6	−0.6	−1.9	—

*Assumes a therapeutic range for Li^+ between 0.7 and 1.5 mmol/L.

Polymer Membrane Electrodes

Polymer membrane ISEs are employed for monitoring pH and for measuring electrolytes, including K^+, Na^+, Cl^-, Ca^{2+}, Li^+, Mg^{2+}, and CO_3^{2-} (for total CO_2 measurements). They are the predominant class of potentiometric electrodes used in modern clinical analysis instruments.

Mechanisms of response of these ISEs fall into three categories: (1) charged, dissociated ion exchanger; (2) charged associated carrier; and (3) neutral ion carrier (ionophore).[6,15] An early charged-associated ion-exchanger type ISE for Ca^{2+} was developed and commercialized for clinical application in the 1960s based on the Ca^{2+}-selective ion-exchange/complexation properties of 2-ethylhexyl phosphoric acid dissolved in dioctyl phenyl phosphonate.[37] A porous membrane was impregnated with this cocktail and mounted at the end of an electrode body. This type of sensor was referred to as the "liquid membrane" ISE. Later, a method was devised whereby these ingredients could be cast into a plasticized poly(vinyl chloride) (PVC) membrane that was more rugged and convenient to use. This same approach is still used today to formulate PVC-based ISEs for clinical use.[84]

A major breakthrough in the development and routine application of PVC-type ISEs was the discovery by Simon and coworkers that the neutral antibiotic valinomycin could be incorporated into organic liquid membranes (and later plasticized PVC membranes), resulting in a sensor with high selectivity for K^+ over Na^+ ($K_{K/Na} = 2.5 \times 10^{-4}$).[97] The K^+ ISE based on valinomycin was the first example of a neutral carrier ISE and is used extensively today for the routine measurement of K^+ in blood. Figure 11-2 shows the response of the valinomycin-based K^+ ISE in the presence of physiologic concentrations of Na^+, Ca^{2+}, and Mg^{2+}. The wide linear range of this ISE over three orders of magnitude makes it suitable for the measurement of K^+ in blood and urine. The K^+ range

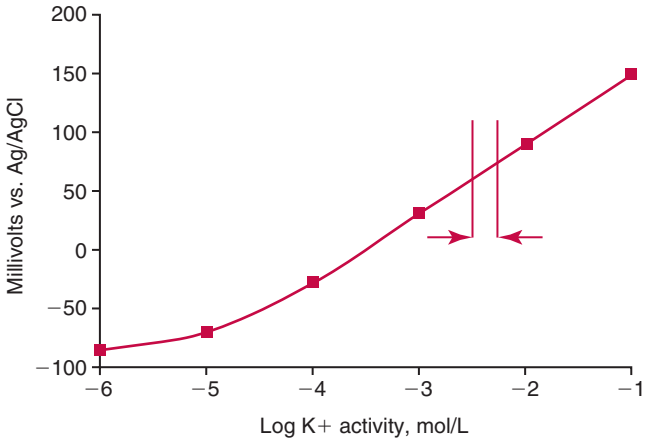

Figure 11-2 Typical electromotive force (EMF) response of potassium selective membrane electrode to changes in activity of potassium in the sample solution. Bracketed interval represents the normal reference interval of potassium concentration in blood. *(From D'Orazio P. In: Lewendrowski K, ed. Clinical chemistry: laboratory management and clinical correlations. Philadelphia: Lippincott, Williams and Wilkins, 2002:455.)*

in blood is only a small portion of the electrode linear range and is spanned by a total ΔEMF of about 9 mV. Interference from other cations, seen as deviation from linearity, is not apparent at K^+ activities $>10^{-4}$ mol/L. Other, less selective polymer-based ISEs (e.g., for the measurement of Mg^{2+} and Li^+) are subject to interference from Ca^{2+}/Na^+ and Na^+, respectively, requiring simultaneous determination and correction for the presence of significant concentrations of interfering ions.[81,99]

Studies regarding the relationship between molecular structure and ionic selectivity have resulted in the development of polymer-based ISEs using a number of naturally occurring and synthetic ionophores, with sufficient selectivity for application in clinical analysis. The chemical structures of several of these neutral ionophores are illustrated in Figure 11-3.

Dissociated anion exchanger-based electrodes employing lipophilic quaternary ammonium salts as active membrane components are still used commercially for the determination of Cl^- in whole blood, serum, and plasma despite some limitations.[68] Selectivity for this type of ISE is controlled by extraction of the ion into the organic membrane phase and is a function of the lipophilic character of the ion (because, unlike with the carriers described earlier, no direct binding interaction occurs between the exchanger site and the anion in the membrane phase). Thus, the selectivity order for Cl^- ISE based on an anion exchanger is fixed as $R^- > ClO_4^- > I^- > NO_3^- > Br^- > Cl^- > F^-$. Application of the Cl^- ion-exchange electrode therefore is limited to samples without significant concentrations of anions more lipophilic than Cl^-. Blood samples containing salicylate or thiocyanate, for example, will produce positive interference for the measurement of Cl^-. Repeated exposure of the electrode to the anticoagulant heparin will lead to loss of electrode sensitivity toward Cl^- because of extraction of negatively charged heparin into the membrane. Indeed, this extraction process has been used successfully to devise a method to detect heparin concentrations in blood by potentiometry,[75] as well as to develop a simple potentiometric technique to screen for the presence of toxic, high charge density polyanion contaminants (e.g., oversulfated chondroitin sulfate) in biomedical grade heparin preparations.[127]

High selectivity for carbonate anion can be achieved using a neutral carrier ionophore possessing trifluoroacetophenone groups doped within a polymeric membrane.[65,107] Such ionophores form negatively charged adducts with carbonate anions, and the resulting electrodes have proven useful in commercial instruments for determination of total carbon dioxide in serum/plasma, after dilution of the blood to a pH value in the range of 8.5 to 9.0, where a significant fraction of total carbon dioxide will exist as carbonate anions.

A typical formulation of a PVC membrane ISE used in clinical instrumentation consists of the following:

1 to 3 wt% ionophore
≈64 wt% plasticizer
≈30 wt% PVC
<1 wt% additives

The plasticizer is crucial in controlling the polarity of the membrane and thus, along with the ionophore, plays a pivotal role in determining the selectivity of the membrane toward the ion of interest. A large lipophilic anion (e.g., tetraphenylborate derivative) is often included as an additive for preparation of cation-selective ISE membranes. This anion serves as a counteranion for the cation of interest as it is extracted into the membrane phase, forming a positively charged complex with the neutral ionophore. However, it is the ratio of bound to unbound ionophore sites at the membrane surface that determines the magnitude of the phase boundary potential generated by the ISE membrane.[3] Thus, the selective response to the activity of the ion of interest is an interfacial property of the given ISE membrane.

Studies have demonstrated that the ultimate detection limits of polymer membrane–type ISEs are controlled in part by the leakage of analyte ions from the internal solution to the outer surface of the membrane, and into the sample phase in close contact with the membrane.[78] Hence, lower limits of detection can be achieved by decreasing the concentration of the primary analyte ion within the internal solution of the electrode. Further, this leakage of analyte ions, coupled with an ion-exchange process at the membrane sample interface when the selectivity of the membrane over other ions is assessed, can often yield a measured potentiometric selectivity coefficient that underestimates the true selectivity of the membrane. To determine "unbiased" selectivity coefficients by the separate solution method, the membrane should not be exposed to the analyte ion for extended periods of time, and the concentration of analyte ion in the internal solution should be low.[8] To avoid leakage of primary ions from the inner solution of conventional polymer membrane ISEs, new more stable designs for solid-state ion sensors have been suggested, in which the ionophore-doped polymer

ion-sensing membrane [based on more water repellent poly(methylmethacrylate)/poly(decylmethacrylate copolymer)] is coated onto a conductive poly(3-octylethiophene 2,5-diyl) (POT) polymer layer on the surface of an underlying gold electrode.[121]

An interesting application of sodium selective polymer (or glass) membrane electrodes is seen in the determination of whole blood hematrocrit.[58] Because intracellular sodium concentrations are much lower than those in the plasma phase, the change in sodium concentration (dilution) measured potentiometrically before and after erythrocyte lysis can be used to assess the hematocrit of the blood sample. This approach can be coupled with simultaneous measurement of changes in potassium ion concentration as determined with a valinomycin-based polymer membrane ISE to quantify the concentration of potassium ions within red blood cells.[96]

Electrodes for PCO_2

Electrodes have been developed to measure PCO_2 in body fluids. The first PCO_2 electrode, developed in the 1950s by Stow and Severinghaus, used a glass pH electrode as the internal element in a potentiometric cell for measurement of the partial pressure of carbon dioxide.[4] This important development paved the way for commercial availability of the three-channel blood analyzer (pH, PCO_2, PO_2) to give the complete picture of the oxygenation and acid-base status of blood.

Figure 11-4 shows a diagram of a typical Severinghaus-style electrode for PCO_2. A thin membrane (≈20 μm), permeable only to gases and water vapor, is in contact with the sample. Membranes of silicone rubber, Teflon, and other polymeric materials are suitable for this purpose. On the opposite side of the membrane is a thin electrolyte layer consisting of a weak bicarbonate salt (about 5 mmol/L) and a chloride salt. A pH electrode and an Ag/AgCl reference electrode are in contact with this solution. The PCO_2 electrode is a self-contained potentiometric cell. Carbon dioxide gas from the sample or calibration matrix diffuses through the membrane and dissolves in the internal electrolyte layer. Carbonic acid is formed and dissociates, shifting the pH of the bicarbonate solution in the internal layer as follows:

$$CO_2 + H_2O \rightleftarrows H_2CO_3 \leftrightarrow H^+ + HCO_3^- \qquad \textbf{(12)}$$

and

$$\Delta \log PCO_{2(\text{sample})} \approx \Delta pH_{(\text{internal layer})} \qquad \textbf{(13)}$$

The relationship between the sample PCO_2 and the signal generated by the internal pH electrode is logarithmic and is governed by the Nernst equation. The electrode may be calibrated using precision gas mixtures or using solutions with stable PCO_2 concentrations. Although Severinghaus-style electrodes for PCO_2 have gained widespread use in modern blood gas analyzers, the format in which such sensors may be

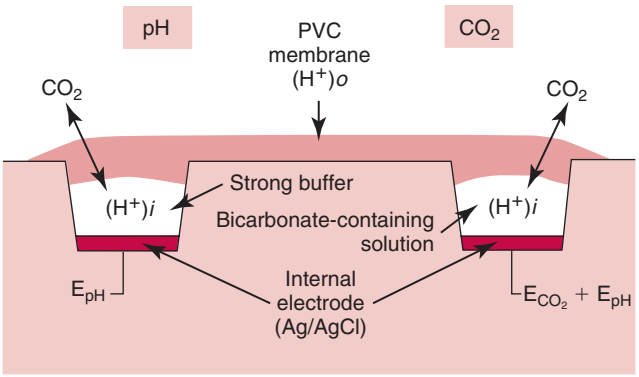

Figure 11-5 Differential planar PCO_2 potentiometric sensor design, based on two identical polymeric membrane pH electrodes, but with different internal reference electrolyte solutions. Both pH sensing membranes are prepared with H^+-selective ionophore.

constructed is limited by size, shape, and ability to fabricate the internal pH sensitive element.

A slightly different potentiometric cell for PCO_2 is shown in Figure 11-5. This cell arrangement uses two PVC-type pH-selective electrodes in a differential mode. The electrode membranes contain a lipophilic amine-type neutral ionophore that exhibits very high selectivity for H^+ (see Figure 11-3). One electrode has an internal layer that is buffered, and the other is unbuffered, consisting of a low concentration of bicarbonate salt. Carbon dioxide gas from the sample or calibration matrix diffuses across the outer H^+-selective PVC membranes of both sensors. On the unbuffered side, CO_2 diffusion produces a potential shift at the internal interface of the pH-responsive membrane proportional to sample PCO_2 concentration. The signal at the electrode with the buffered internal layer is unaffected by CO_2 that diffuses across the membrane. Consequently, one half of the sensor responds to pH alone, and the other half responds to both pH and PCO_2. The signal difference between the two electrodes cancels any contribution of sample pH to the overall measured cell potential. The differential signal is proportional only to PCO_2. Unlike the traditional Severinghaus-style electrode, this differential potentiometric cell PCO_2 sensor has been commercialized in a planar format and is more easily adaptable to mass production in sensor arrays.[16]

Direct Potentiometry by ISE—Units of Measure and Reporting for Clinical Applications

Older analytical methods such as flame photometry for the measurement of electrolytes provide the total *concentration (c)* of a given ion in the sample, usually expressed in units of millimoles of ion per liter of sample (mmol/L). *Molality (m)* is a measure of the moles of ion per mass of water (mmol/kg) in the sample. Using the sodium ion as an example, the relationship between concentration and molality is given by

$$c_{Na^+} = m_{Na^+} \times \rho H_2O \qquad (14)$$

where ρH_2O is the mass concentration of water in kg/L. For normal blood plasma, the mass concentration of water is approximately 0.93 kg/L, but in specimens with elevated lipids or protein, the value may be as low as 0.8 kg/L. In these specimens, the difference between concentration and molality may be as great as 20%. A significant advantage of direct potentiometry by ISE for the measurement of electrolytes is that the technique is sensitive to molality and therefore is not affected by variations in the concentration of protein or lipids in the sample. Techniques such as flame photometry, ISE methods requiring sample dilution (also called *indirect potentiometry*), and other photometric methods requiring sample dilution are affected by the presence of protein and lipids. In these methods, only the water phase of the sample is diluted, producing results lower than molality as a function of the concentration of protein and lipids in the sample. Thus there is a risk for errors, such as a falsely low Na^+ concentration (pseudohyponatremia), in cases of extremely elevated protein and lipid concentrations (see also Chapter 28).[2]

In addition to the difference between molality and concentration, measurement of ions by direct potentiometry provides yet another unit of measurement known as *activity (a)*, the concentration of free, unbound ion in solution. Unlike methods sensitive to ion concentration, ISEs do not sense the presence of complexed or electrostatically "hindered" ions in the sample. The relationship between activity and concentration using, again, sodium ion as an example, is expressed as

$$a_{Na^+} = \gamma_{Na^+} \times c_{Na^+} \qquad (15)$$

where γ is a dimensionless quantity known as the activity coefficient. The activity coefficient is primarily dependent on ionic strength of the sample as described by the Debye-Huckel equation:

$$\log\gamma = \frac{(A \times z^2 \times I^{0.5})}{1 + B \times a \times I^{0.5}} \qquad (16)$$

where A and B are temperature-dependent constants (A = 0.5213 and B = 3.305 in water at 37 °C), a is the ion size parameter for a specific ion, and I is the ionic strength ($I = 0.5\ \Sigma m \times z^2$, where z is the charge number of the ions). Equation (16) shows that a decrease in the activity coefficient occurs with an increase in ionic strength. This effect is more pronounced when the charge *(z)* of the ion is high. Activity coefficients for ions in biological fluids, such as blood and serum, are difficult to calculate with accuracy because of the uncertain contribution of macromolecular ions, such as proteins, to the overall ionic strength. However, assuming that the normal ionic strength of blood plasma is 0.160 mol/kg, estimates of activity coefficients at 37 °C are as follows: Na^+ = 0.75, K^+ = 0.74, and Ca^{2+} = 0.31. Referring to equation (15), activity and concentration will differ greatly in samples of physiologic ionic strength, especially for divalent ions.

Physiologically, ionic activity is assumed to be more relevant than concentration when chemical equilibria or biological processes are considered. Practically, however, *ionic concentration* is the more familiar term in clinical practice, forming the basis of reference intervals and medical decision

TABLE 11-2 Examples of Two-Value Calibrating Solutions for Measurement of pH and Electrolytes by Direct Potentiometry*

Analyte	Calibration Point, mmol/L	Slope Point, mmol/L	Expected Signal Δ, millivolts
Na^+	140	110	6.6
K^+	4.0	8.0	18

Cl^-	100	80	6
pH	7.38 (pH units)	6.84 (pH units)	32.4

*Ionic strength adjusted to 160 mmol/kg with buffer salts and inert electrolytes.

concentrations for electrolytes. Early in the evolution of ISEs as practical tools in clinical chemistry, it was decided that changing clinical reference intervals to a system based on activity instead of concentration was impractical and carried the risk for clinical misinterpretation. A pragmatic approach for using ISEs in modern analyzers without changing established concentration-based reference intervals is to formulate calibration solutions with ionic strengths and ionic compositions as close as possible to those of blood plasma. In this way, the activity coefficient of each ion in the calibrating solutions approximates that in the sample matrix, allowing calibration and measurement of electrolytes in units of concentration instead of activity.[90]

A typical set of solutions for multi-ISE calibration in an analyzer is shown in Table 11-2. Two points are used to calibrate each ISE. The difference in the cell potential generated by these two solutions (ΔE) is used to calculate the response slope of the cell (slope = ΔE/Δlog c), where *c* is the concentration of ion in each calibrating solution, substituted for activity. The standard electrode potential, E^0, is calculated as the *y*-intercept. Determination of ion concentration in an unknown sample is then a straightforward solution of the Nickolsky-Eisenman equation [equation (10)], after the cell potential generated by the sample is measured.

Calibration of the cell is done in units of concentration; however, as mentioned earlier, direct potentiometry is sensitive to the molality of the ion, which is related to concentration by the water content of the sample [equation (14)]. The water content of aqueous calibrating solutions shown in Table 11-2 is approximately 0.99 kg/L. The water content of normal blood plasma is ≈0.93 kg/L. Molality is 7% greater than concentration in this normal plasma specimen. The direct potentiometric cell will report results approximately 6% greater than the concentration in normal specimens because of this difference in water content between sample and calibrator (0.99/0.93 = 1.06). Direct potentiometry presents an advantage in that the technique is not affected by the presence of protein and lipids in the sample; however, the application of clinical reference intervals based on concentration again poses a risk for confusion and clinical misinterpretation. Most manufacturers of electrolyte measurement systems have overcome this problem in a practical way by following Clinical and Laboratory Standards Institute (CLSI) guidelines recommending the use of correlation factors to standardize ISE measurements to units of concentration. These factors may be obtained by standardizing the ISE measurement to certified reference materials based on human serum, with electrolyte values assigned in units of concentration.[21,22,49] Appropriate correlation factors are then applied to sample calculations using algorithms resident in the instrument software.

VOLTAMMETRY/AMPEROMETRY

Voltammetric and amperometric techniques are among the most sensitive and widely applicable of all electroanalytical methods.

Basic Concepts

In contrast to potentiometry, voltammetric and amperometric methods are based on electrolytic electrochemical cells in which an external voltage is applied to a polarizable working electrode (measured vs. a suitable reference electrode: $E_{appl} = E_{work} = E_{ref}$), and the resulting cathodic (for analytical reductions) or anodic (for analytical oxidations) current of the cell is monitored and is proportional to the concentration of analyte present in the test sample. Current flows only if E_{appl} is greater than a certain voltage (decomposition voltage), determined by the thermodynamics for a given redox reaction of interest [$Ox + ne^- \rightleftharpoons Red$; defined by the E^0 value for that reaction (standard reduction potential)] and the kinetics for heterogeneous electron transfer at the interface of the working electrode. Often, slow kinetics of electron transfer for the redox reaction on a given inert working electrode (Pt, carbon, gold, etc.) mandates use of a much more negative (for reductions) or positive (for oxidations) E_{appl} than predicted based merely on the E^0 for a given redox reaction. This is called an *overpotential* (η). Regardless of whether an overpotential for electron transfer exists, a specific oxidation or reduction reaction occurs at the surface of the working electrode in voltammetry/amperometry, and it is the charge transfer at this interface (current flow) that provides the analytical information.

For electrolytic cells that form the basis of voltammetric and amperometric methods.

$$E_{appl} = E_{cell} + \eta - iR_{cell} \quad (17)$$

where E_{cell} is the thermodynamic potential between the working and reference electrodes in the absence of an applied external voltage. When the external voltage is greater or less than this equilibrium potential, plus or minus any overpotential (η), then current will flow because of an oxidation or reduction reaction at the working electrode. A voltammogram is simply the plot of observed current, *i*, versus E_{appl} (Figure 11-6). In amperometry (see later), a fixed voltage is applied and the resulting current is monitored. The amount of current is inversely related to the resistance of the

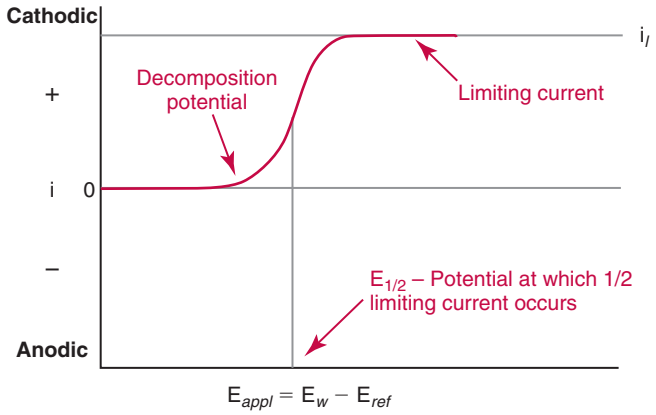

Figure 11-6 Illustration of the current versus voltage curve (voltammogram) obtained for oxidized species (Ox) reduced (Red) at the surface of the working electrode, as the E_{appl} is scanned more negatively and the solution is stirred to yield a steady-state response.

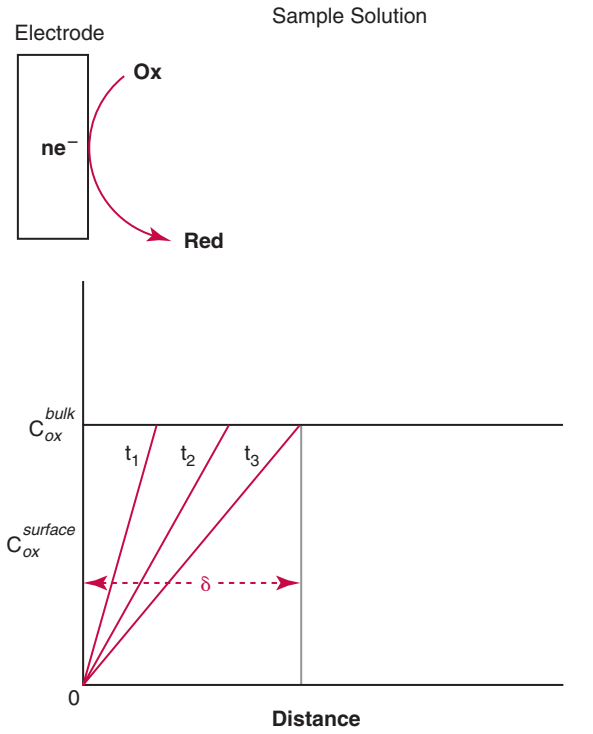

Figure 11-7 Concept of electrochemical reaction increasing diffusion layer thickness (concentration polarization) of analytes via reduction (or oxidation) at the surface of the working electrode. As time (t) increases, the diffusion layer thickness grows quickly to a value determined by degree of convection in the sample solution.

electrolyte solution and to any "apparent" resistance that develops because of mass transfer of the analyte species to the surface of the working electrode. Because electrochemical reactions are heterogeneous, occurring only at the surface of the working electrode, the amount of current observed is also highly dependent on the surface area (A) of the working electrode.

When a potential is applied to a working electrode that will oxidize or reduce a species in the solution phase contacting the electrode, the electrochemical reaction causes the concentration of electroactive species to decrease at the surface of the electrode (Figure 11-7), a process termed *concentration polarization.* This in turn causes a concentration gradient of analyte species between the bulk sample solution and the surface of the electrode.[35] When the bulk solution is stirred, the diffusion layer of analyte grows out from the surface of the electrode very quickly to a fixed distance controlled by how vigorously the solution is stirred. This diffusion layer is termed the *Nernst layer* and has a finite thickness (δ) after a relatively short time period (see Figure 11-7) when the solution is moving (convection). Voltammetry carried out in the presence of convection (by stirring the solution, rotating the electrode, flowing solution by electrode, etc.) is called *steady-state voltammetry.* When the solution is not moving, the diffusion layer grows further and further with time (i.e., not constant), creating larger and larger δ values over time. This is termed *non–steady-state voltammetry* and often results in peak currents in *i* versus E_{appl} plots for electrolytic cells.

In steady-state voltammetry, when the potential of the working electrode is scanned past a value that will cause an electrochemical reaction, the current will rise rapidly and then will plateau, even as E_{appl} changes further. Figure 11-6 illustrates such a wave for a hypothetical reduction of an oxidized species (Ox) via an *n* electron reduction to a reduced species (Red). When the applied potential is much more negative than required, the current reaches a limiting value (termed the limiting current, i_l). This limiting current is proportional to the concentration of the electroactive species (Ox in this case) as expressed by the following equation:

$$i_l = nFA\left(\frac{D}{\delta}\right)C_{ox} \qquad (18)$$

where *i* is the measured current in amperes, *n* equals the number of electrons in the electrochemical reaction (reduction in this case), *F* is Faraday's constant (96,487 coulombs/mol), *A* is the electrochemical surface area of the working electrode (in cm^2) (assuming a planar electrode geometry), *D* is the diffusion coefficient (in cm^2/sec) of the electroactive species (Ox in this case), δ is the diffusion layer thickness (in cm), and *C* is the concentration of the analyte species in mol/cm^3. The D/δ term is often denoted as m_o, the mass transfer coefficient of the Ox species to the surface of the working electrode. Note that equation (18) indicates a linear relationship for limiting current and concentration. The exact same equation applies for detecting reduced species by an oxidation reaction at the working electrode. In this case, by convention, the resulting anodic current is considered a negative current. As shown in Figure 11-6, the potential of the working electrode that corresponds to a current that is exactly one half the limiting current is termed the $E_{1/2}$ value. This value is not dependent on analyte concentration. The $E_{1/2}$ is determined by the thermodynamics (E^0) of the given redox reaction, the

solution conditions (e.g., if protons are involved in reaction, then the pH will influence the $E_{1/2}$ value), and any overpotential caused by slow electron transfer, etc., at a particular working electrode surface. The $E_{1/2}$ values are indicative of a given species undergoing an electrochemical reaction under specified conditions; hence, the $E_{1/2}$ values enable one to distinguish one electroactive species from another in the same sample. If the $E_{1/2}$ values for various species differ significantly (e.g., >120 mV), then measurements of several limiting currents in a given voltammogram can yield quantitative results for several different species simultaneously.

Electrochemical cells employed to carry out voltammetric or amperometric measurements can involve a two- or three-electrode configuration. In the two-electrode mode, external voltage is applied between the working electrode and a reference electrode, and the current monitored. Because the current must also pass through the reference electrode, such current flow can potentially alter the surface concentration of electroactive species that poises the actual half-cell potential of the reference electrode, changing its value by a concentration polarization process. For example, if an Ag/AgCl reference electrode were used in a cell in which a reduction reaction for the analyte occurs at the working electrode, then an oxidation reaction would take place at the surface of the reference electrode:

$$Ag^0 + Cl^- \rightarrow AgCl_{(s)} + 1\,e^- \qquad \textbf{(19)}$$

Hence, the activity/concentration of chloride ions near the surface of the electrode would decrease, which would make the potential of the reference electrode more positive than its true equilibrium value based on the actual activity of chloride ion in the reference half-cell, because the Nernst equation for this half-cell is

$$E_{Ag/AgCl} = E^0_{Ag/AgCl} - 0.059 \log(a^{surface}_{Cl^-}) \qquad \textbf{(20)}$$

Such concentration polarization of the reference electrode is prevented by keeping the current density (J; amperes/cm^2) very low at the reference electrode. This is achieved in practice by making sure that the area of the working electrode in the electrochemical cell is much smaller than the surface area of the reference electrode; hence the total current flow will be limited by this much smaller area, and J values for the reference will be very small, as desired, to prevent concentration polarization.

To completely eliminate changes in reference electrode half-cell potentials, a three-electrode potentiostat is often employed. In simple terms, the potentiostat applies a voltage to the working electrode, which is measured versus a reference electrode via a zero current potentiometric-type measurement, but the current flow is between the working electrode and a third electrode, called the *counter electrode*. Thus if reduction takes place at the working electrode, oxidation would occur at the counter electrode; but no net reaction would take place at the surface of the reference electrode, because no current flows through this electrode. A potentiostat circuit is relatively simple to construct using modern operational amplifiers.

In voltammetric methods, the E_{appl} is varying via some waveform to alter the working electrode potential as a function of time and the resulting current measured. The current change occurs at the decomposition potential range, which is best when specific for a given analyte. However, the location of the current response as a function of E_{appl} provides information on the nature of the species present (e.g., $E_{1/2}$), along with a concentration-dependent signal. This scan of E_{appl} can be linear (linear sweep voltammetry) or it can have more complex shapes that enable greatly enhanced sensitivity to be achieved for monitoring the concentration of a given electroactive species (e.g., normal pulsed voltammetry, differential pulse voltammetry, square wave voltammetry).[91] When a dropping mercury electrode (DME) is used, such voltammetric methods are considered polarographic methods of analysis.

Amperometric methods differ from voltammetry in that E_{appl} is fixed, generally at a potential value that occurs in the limiting current plateau region of the voltammogram and simply monitors the resulting current, which will be proportional to concentration. Amperometry can be more sensitive than common voltammetric methods because background charging currents, which arise from changing the E_{appl} as a function of time in voltammetry, do not exist. Hence, when selectivity can be assured at a given E_{appl} value, amperometry may be preferred to voltammetric methods for more sensitive quantitative measurements.

Applications

Molecular oxygen is capable of undergoing several reduction reactions, all with a significant overpotential at solid electrodes, such as Pt, Au, or Ag. For example, the following reaction,

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \qquad (E^0 = +0.179 \quad \text{vs} \quad Ag/AgCl;1\,M\,Cl^-) \qquad \textbf{(21)}$$

exhibits an $E_{1/2}$ at around −0.500 V on a Pt electrode (vs. a Ag/AgCl reference electrode), with a limiting current plateau beginning at approximately −0.600 V. This reaction is used to monitor the PO_2 in blood, which is the basis of the widely used Clark-style amperometric oxygen sensor (Figure 11-8). This device employs a small area planar platinum electrode as a working electrode (encased in insulating glass or other material) and an Ag/AgCl reference electrode, typically with a cylindrical design (see Figure 11-8). This two-electrode electrolytic cell is placed within a sensor housing, on which a gas-permeable membrane (e.g., polypropylene, silicone rubber, Teflon) is held at the distal end. The inner working platinum electrode is pressed tightly against the gas-permeable membrane to create a thin film of internal electrolyte solution (usually buffer with KCl added). Oxygen in the sample can permeate across the membrane and can be reduced in accordance with the above electrochemical reaction. An E_{appl} of −0.650 or −0.700 V versus Ag/AgCl (within the limiting current regime) to the Pt working electrode will result in an observed current that is proportional to the PO_2 present in

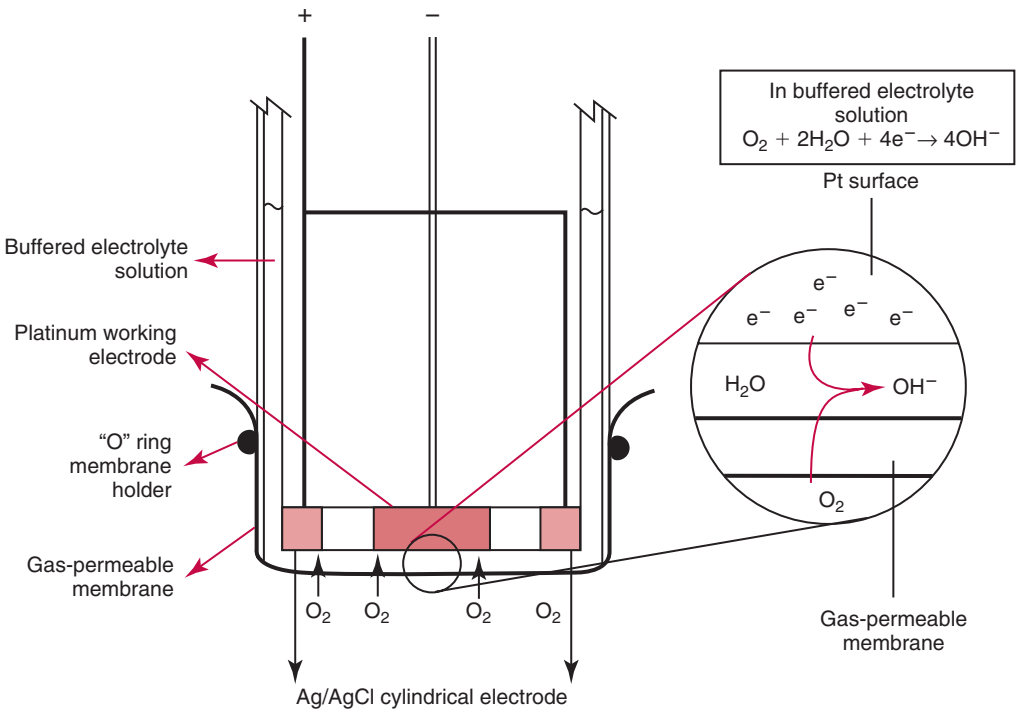

Figure 11-8 Design of Clark-style amperometric oxygen sensor used to monitor PO_2 in blood.

the sample (including whole blood). In the absence of any oxygen, the current at this applied voltage under amperometric conditions will be very near zero.

The outer gas-permeable membrane enables the Clark electrode to detect oxygen with very high selectivity over other easily reduced species that might be present in a given sample (e.g., metal ions, cystine). Indeed, only other gas species or highly lipophilic organic species can partition into and pass through such gas-permeable membranes. One type of interference in clinical samples can be caused by certain anesthesia gases, such as nitrous oxide, halothane, and isoflurane. These species can also diffuse through the outer membrane of the sensor, can be electrochemically reduced at the platinum electrode, and can yield a false-positive value for the measurement of PO_2.[30] However, optimized gas-permeable membrane materials and appropriate control of the applied potential to the cathode of the sensor have greatly reduced this problem in modern instruments. The outer gas-permeable membranes also help restrict the diffusion of analyte to the inner working electrode; hence the membrane can control the mass transport of analyte [D/δ term in equation (18)] such that in the presence or absence of sample convection, mass transport of oxygen to the surface of the platinum working electrode is essentially the same.

The basic design of the Clark amperometric PO_2 sensor can be used to detect other gas species by altering applied voltage to the working electrode. For example, it is possible to detect nitric oxide (NO) with high selectivity using a similar gas electrode design in which the platinum is polarized at +0.900 versus Ag/AgCl to oxidize diffusing NO to nitrate at the platinum anode.[12] Such NO sensors can be used for a variety of biomedically important studies to deduce the amount of NO locally at or near the surface of various NO-producing cells.

Beyond amperometric devices, one specialized method of detecting trace concentrations of toxic metal ions in clinical samples is anodic stripping voltammetry (ASV). In ASV, a carbon working electrode is used (sometimes further coated with an Hg film), and the E_{appl} is first fixed at a very negative E_{appl} voltage, so that all metal ions in the solution will be reduced to elemental metals (M^0) within the mercury film and/or on the surface of the carbon. Then the E_{appl} is scanned more positively, and reduced metals deposited in and/or on the surface of the working electrode are reoxidized, giving a large anodic current peak proportional to the concentration of metal ions in the original sample. The potential at which these peaks are observed indicates which metal is present, and the height of stripping peak current is directly proportional to the concentration of the metal ion in the original sample. Such ASV techniques can be used to detect the total concentration of Pb in whole blood samples, providing a rapid screening method for lead exposure and poisoning.[36]

Another biomedical example of modern voltammetry is a rapid scan cyclic voltammetric technique that has been used to quantify dopamine in brain tissue of freely moving animals.[101] In this application, oxidation of dopamine to a quinone species at an implanted microcarbon electrode (at approximately +0.600 V vs. Ag/AgCl) yields peak currents proportional to dopamine concentrations. The electrode can be used to measure this neurotransmitter in different regions of the brain or in a fixed location. Often, pharmacologic or electrical stimulation can be employed to measure the change

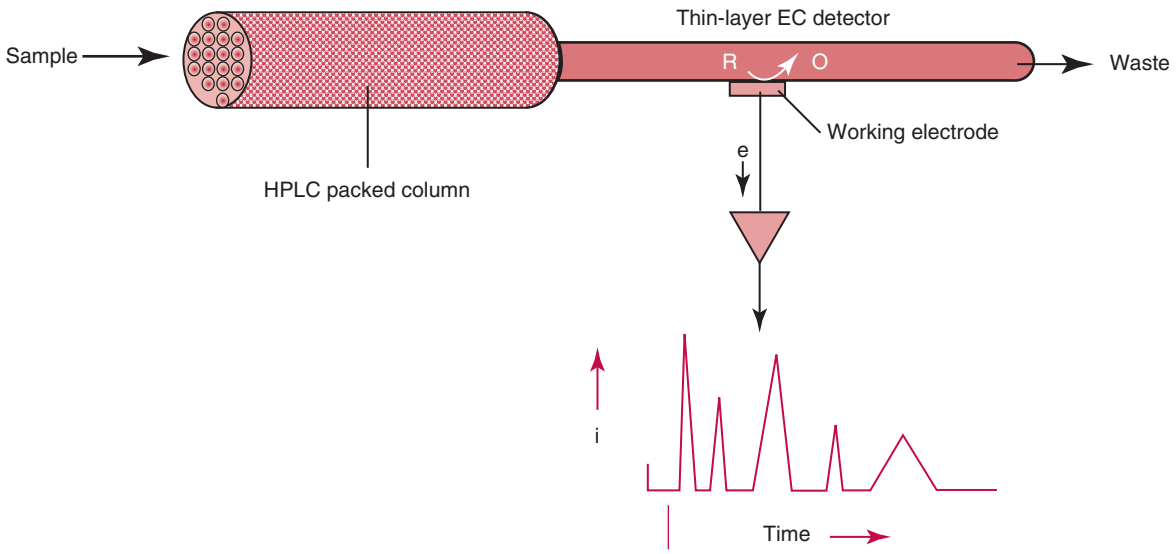

Figure 11-9 Schematic of liquid chromatography with electrochemical detection (LC-EC) system, with electrochemical detector monitoring elution of analytes from a high-performance liquid chromatography (HPLC) column by their oxidation or reduction (shown here as example) at a suitable thin-layer working electrode.

in local dopamine concentrations due to such stimulation techniques.

Although voltammetric/amperometric techniques can be applied to detect a wide range of species, the selectivity offered for measurements in complex clinical samples—where many species can be electroactive—is rather limited. For example, as stated in the previous discussion relevant to the Clark oxygen sensor, in the absence of the gas-permeable membrane, other species that can be reduced at or near the same E_{appl} as oxygen would cause significant interference.

To expand the range of analytes that can be detected with voltammetric/amperometric methods, electrochemical techniques can be used as highly sensitive detectors for modern high-performance liquid chromatography (HPLC) systems (see Chapter 13). In liquid chromatography with electrochemical detection (LC-EC), eluting solutes are detected by flow-through electrodes (usually carbon or mercury) designed to have extremely low dead volumes (Figure 11-9). The electrodes can be operated in amperometric or voltammetric modes (with high scan speeds), and several electrodes can be operated simultaneously in series or in parallel flow arrangements to gain additional selectivity.[57] For example, homocysteine can be measured with (1) the addition of reducing agents to a serum sample to generate free homocysteine, (2) precipitation of proteins in the sample (with trichloroacetic acid), and (3) separation of the serum components on a reversed-phase octadecylsilane HPLC column. The eluting homocysteine is detected and measured with online electrochemical detection via homocysteine oxidation to the corresponding mercuric dithiolate complex:

$$2\text{RSH} + \text{Hg} \rightarrow \text{Hg(RS)}_2 + 2\text{H}^+ + 2\text{e}^- \qquad (22)$$

using a thin-layer Hg/Au amalgam electrode poised at +0.150 V versus Ag/AgCl.[105] Integration of the eluting band for homocysteine provides quantitative results, with very high selectivity. Similarly, catechols and catecholamines can be readily detected in serum by a similar LC-EC method, with eluted catechols oxidized to quinones at a flow-through carbon working electrode poised at potentials typically >0.200 V versus Ag/AgCl. Further, a host of therapeutic drugs can also be quantitated in serum or urine via LC-EC methods.

CONDUCTOMETRY

Conductometry is an electrochemical technique used to determine the quantity of an analyte present in a mixture by measurement of its effects on the electrical conductivity of the mixture. It is the measure of the ability of ions in solution to carry current under the influence of a potential difference. In a conductometric cell, potential is applied between two inert metal electrodes. An alternating potential with a frequency between 100 and 3000 Hz is used to prevent polarization of the electrodes. A decrease in solution resistance results in an increase in conductance, and more current is passed between the electrodes. The resulting current flow is also alternating. The current is directly proportional to solution conductance. Conductance is considered the inverse of resistance and may be expressed in units of ohm^{-1} (siemens). In clinical analysis, conductometry is frequently used for measurement of the volume fraction of erythrocytes in whole blood (hematocrit) and as the transduction mechanism for some biosensors.

Erythrocytes act as electrical insulators because of their lipid-based membrane composition. This phenomenon was used first in the 1940s to measure the volume fraction of erythrocytes in whole blood (hematocrit) by conductivity[103] and is used today to measure hematocrit on multianalyte

instruments for clinical analysis. The conductivity of whole blood depends not only on the volume fraction and shape of the erythrocytes, but also on the conductivity of the surrounding plasma. An increase in the volume fraction of erythrocytes that are less conductive than the surrounding plasma leads to a decrease in conductivity shown by the following relationship[124]:

$$G_b = \frac{a}{1} + \frac{H}{100 - H} \times c \qquad (23)$$

where G_b is the conductivity of whole blood, a is the plasma conductivity, H is the percent of hematocrit, and c is a factor for erythrocyte orientation. In practice, plasma conductivity also contains correction factors for Na^+ and K^+ concentrations. These cations are usually measured in conjunction with hematocrit on systems designed for clinical analysis.

Conductivity-based hematocrit measurements have limitations.[112] Abnormal protein concentrations will change plasma conductivity and interfere with measurement. Low protein concentrations resulting from dilution of blood with protein-free electrolyte solutions during cardiopulmonary bypass surgery will result in erroneously low hematocrit values by conductivity. Preanalytical variables, such as insufficient mixing of the sample, will also lead to errors.[133] Hemoglobin is the preferred analyte to monitor blood loss and the need for transfusion during trauma and surgery. However, electrochemical measurement of hematocrit in conjunction with blood gases and electrolytes remains in use mainly because of simplicity and convenience, despite some limitations.

Another clinical application of conductance is for electronic counting of blood cells in suspension. Termed the *Coulter principle,* it relies on the fact that the conductivity of blood cells is lower than that of a salt solution used as a suspension medium.[25] The cell suspension is forced to flow through a tiny orifice. Two electrodes are placed on either side of the orifice, and a constant current is established between the electrodes. Each time a cell passes through the orifice, resistance increases; this causes a spike in the electrical potential difference between the electrodes. The pulses are then amplified and counted.

COULOMETRY

Coulometry measures the electrical charge passing between two electrodes in an electrochemical cell. The amount of charge passing between the electrodes is directly proportional to oxidation or reduction of an electroactive substance at one of the electrodes. The number of coulombs transferred in this process is related to the absolute amount of electroactive substance by Faraday's law:

$$Q = n \times N \times F \qquad (24)$$

where

Q = is the amount of charge passing through the cell (unit: C = coulomb = ampere × second)

n = the number of electrons transferred in the oxidation or reduction reaction

N = the amount of substance reduced or oxidized in moles

F = Faraday constant (96,487 coulombs/mol)

The measurement of current is related to charge as the amount of charge passed per unit time (ampere = coulomb per second). Coulometry is used in clinical applications for the determination of chloride in serum or plasma and as the mode of transduction in certain types of biosensors.

Commercial coulometric titrators have been developed for determination of chloride. A constant current is applied between a silver wire (anode) and a platinum wire (cathode). At the anode, Ag is oxidized to Ag^+. At the cathode, H^+ is reduced to hydrogen gas. At a constant applied current, the number of coulombs passed between the anode and the cathode is directly proportional to time (coulombs = amperes × seconds). Therefore, the absolute number of silver ions produced at the anode may be calculated from the amount of time current passes through it. In the presence of Cl^-, Ag^+ ions formed are precipitated as $AgCl_{(s)}$, and the amount of free Ag^+ in solution is low. When all Cl^- ions have been complexed, a sudden increase in the concentration of Ag^+ in solution is noted. Excess Ag^+ is sensed amperometrically at a second Ag electrode, polarized at negative potential. The excess Ag^+ is reduced to Ag, producing a current. When this current exceeds a certain value, the titration is stopped. The absolute number of Cl^- ions present in the sample is calculated from the time during which titration with Ag^+ was in progress. Given the volumetric amount of serum or plasma sample originally used, it is possible to calculate the concentration of Cl^- in the sample. Coulometric titration is one of the most accurate electrochemical techniques because the method measures the absolute quantity of electroactive substance in the sample. Coulometry is considered the gold standard for determination of chloride in serum or plasma. However, the method is subject to interference from anions in the sample with affinity for Ag^+ greater than chloride, such as bromide,[129] and is not commonly used in today's clinical laboratories.

OPTICAL CHEMICAL SENSORS

An *optode* is an optical sensor used in analytical instruments to measure blood gases and electrolytes. Optodes have certain advantages over electrodes, including (1) ease of miniaturization, (2) less noise (no transduction wires), (3) potential long-term stability using ratiometric-type measurements at multiple wavelengths,[108] and (4) do not require a separate reference electrode. These advantages initially promoted the development of optical sensor technology for design of intravascular blood gas sensors (see in vivo sensor section later). However, the same basic sensing principles can be used in clinical chemistry instrumentation designed for more classical in vitro measurements on discrete samples. In such systems, light can be brought to and from the sensing site by optical fibers or simply by appropriate positioning of light sources [light-emitting diodes (LEDs)], filters, and photodetectors to monitor absorbance (by reflectance), fluorescence, or phosphorescence (Figure 11-10).

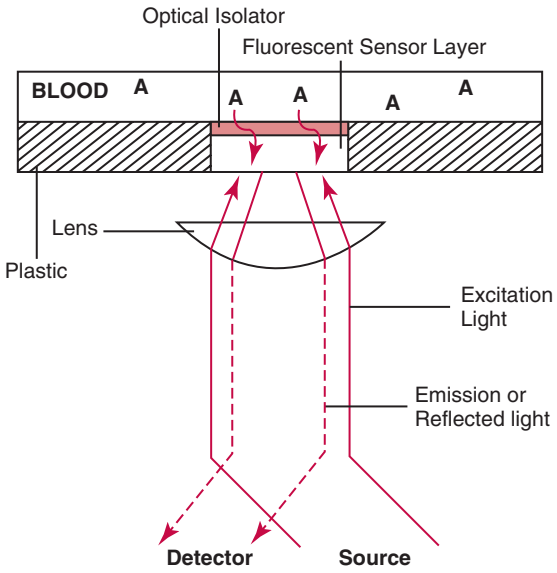

Figure 11-10 General design for in vitro optical sensor designed to detect given analyte in blood sample. Polymer film contains dye that changes spectral properties in proportion to the amount of analyte in the sample phase. Example shown is for sensing film that changes luminescence (fluorescence or phosphorescence).

Basic Concepts

Optical sensors devised for PO_2 measurements are typically based on immobilization of certain organic dyes (e.g., pyrene, diphenylphenanthrene, phenanthrene, fluoranthene) or metal ligand complexes [e.g., ruthenium(II) tris(dipyridine), Pt and Pd metalloporphyrins] within hydrophobic polymer films (e.g., silicone rubber) in which oxygen is very soluble.[29] The fluorescence or phosphorescence of such species at a given wavelength is often quenched in the presence of paramagnetic species, including molecular oxygen. In the case of embedded fluorescent dyes, the intensity of the emitted fluorescence of such films will decrease in proportion to the partial pressure of the oxygen (PO_2) in the sample in contact with the polymer film, in accordance with the Stern-Volmer equation for quenching:

$$\frac{I_0}{I_{PO_2}} = 1 + kPO_2 \qquad (25)$$

where

I_0 = fluorescence intensity in the absence of any oxygen

I_{PO_2} = fluorescence intensity at a given partial pressure of oxygen (PO_2)

k = quenching constant for the particular fluorophore used

Hence a linear relationship exists between the ratio I_0/I_{PO2} and the PO_2 in the sample phase. The larger the Stern-Volmer constant, the greater is the degree of quenching for the given fluorophore. However, it is important that the quenching constant is in a range that will yield linear Stern-Volmer behavior over the physiologically relevant range of PO_2 in blood. For example, if k is too large, then maximum quenching possible will occur over a range of PO_2 that is less than physiologic.

Phosphorescence intensity or phosphorescence lifetime measurements of immobilized metal ligand complexes can also be employed (i.e., binding of oxygen decreases excited state lifetimes). Sensors based on changes in luminescent lifetime have the inherent advantage of being insensitive to perturbations in the optical path length and the amount of active dye present in the sensing layer.

Optical pH sensors require immobilization of appropriate pH indicators [e.g., fluorescein, 8-hydroxy-1,2,6-pyrene trisulfonate (HPTS), phenol red] within thin layers of hydrophilic polymers (e.g., hydrogels), because equilibrium access of protons to the indicator is essential. The absorbance or fluorescence of the protonated or deprotonated form of the species can be used for sensing purposes.[108] One issue with respect to using immobilized indicators for accurate physiologic pH measurements is the effect of ionic strength on the pKa of the indicator. Because optical sensors measure the concentration of protonated or deprotonated dye as an indirect measure of hydrogen ion activity, variations in ionic strength of the physiologic sample can influence the accuracy of the pH measurement.

Applications

Optical sensors suitable for the determination of PCO_2 employ optical pH transducers (with immobilized indicators) as inner transducers in an arrangement similar to the classical Severinghaus-style electrochemical sensor design (see Figure 11-4). The addition of bicarbonate salt within the pH sensing hydrogel layer creates the required electrolyte film layer, which varies in pH depending on the partial pressure of carbon dioxide (PCO_2) in equilibrium with the film. The optical pH sensor is covered by an outer gas-permeable hydrophobic film (e.g., silicone rubber) to prevent proton access, yet it allows CO_2 equilibration with the pH sensing layer. As the partial pressure of the CO_2 in the sample increases, the pH of the bicarbonate layer decreases, and the corresponding decrease in the deprotonated form of the indicator (or increase in the protonated form) is sensed optically.

Two approaches have been used to sense electrolyte ions optically in physiologic samples. One method employs many of the same lipophilic ionophores developed for polymer membrane–type ISEs (see Figure 11-3).[6,15] These species are doped into very thin hydrophobic polymeric films along with a lipophilic pH indicator. In the case of cation ionophores (e.g., valinomycin for sensing potassium), when cations from the sample are extracted by the ionophore into the thin film, the pH indicator (RH) loses a proton to the sample phase to maintain charge neutrality within the organic film (yielding R^-). This results in a change in the optical absorption or fluorescence spectrum of the polymer layer. If the thickness of the films is kept at <10 μm, equilibrium response times on the order of <1 min have been achieved. The main limitation of this design is that the pH of the sample phase also influences the overall extraction equilibrium for ions into the film.

Thus simultaneous and independent measurement of sample pH is required, or buffered dilution and/or pH control of the sample phase is necessary to obtain accurate measurements of electrolytes.

A second technique used to sense electrolyte ions is immobilization of a cation and/or anion recognition agent within a hydrogel matrix, similar to the pH sensors described earlier. The recognition agent in this case is not usually lipophilic; therefore it must be covalently anchored to the hydrogel, so that it does not leach into the sample phase. The agent is designed so that selective cation or anion binding alters the absorbance or fluorescence spectrum of the species within the hydrogel. Typically, this is achieved by linking ion recognition and chromophoric properties within a single organic molecule. Such ion sensors have been used successfully in at least one commercial blood gas-electrolyte analyzer using an array of sensors of the generic design similar to that illustrated in Figure 11-10.

BIOSENSORS

A biosensor is a specific type of chemical sensor consisting of a biological recognition element and a physicochemical transducer, often an electrochemical[52,117] or an optical device. The biological element is capable of recognizing the presence and activity and/or concentration of a specific analyte in solution. The recognition may be a *biocatalytic reaction (enzyme-based biosensor)* or a *binding process (affinity-based biosensor)* when the recognition element is, for example, an antibody, DNA segment, or cell receptor. Interaction of the recognition element with a target analyte results in a measurable change in a solution property locally at the surface of the device, such as formation of a product or consumption of a reactant. The transducer converts the change in solution property into a quantifiable electrical signal. The mode of transduction may be one of several, including electrochemical or optical measurement and measurement of mass or heat. The present discussion will be limited to biosensors based on electrochemical and optical modes of transduction because they constitute the majority of biosensors used for clinical applications.

Enzyme-Based Biosensors With Amperometric Detection

Enzyme-based biosensors based on electrochemical transducers, specifically amperometric electrodes, are the most commonly used for clinical analyses and the most frequently cited in the literature.[51] Clark and Lyons developed the first amperometric biosensor; it was used to measure glucose in blood and was based on immobilizing glucose oxidase on the surface of an amperometric PO_2 sensor.[20] A solution of glucose oxidase was physically entrapped between the gas-permeable membrane of the PO_2 electrode and an outer semipermeable membrane (Figure 11-11, see general design). The outer membrane was of a low molecular weight cutoff to allow substrate (glucose) and oxygen from the sample to pass, but not proteins and other macromolecules. In this way, enzymes could be concentrated at the sensor's surface. Oxidation of glucose, catalyzed by glucose oxidase as follows,

$$\text{Glucose} + O_2 \xrightarrow{\text{glucose oxidase}} \text{gluconic acid} + H_2O_2 \quad \textbf{(26)}$$

consumes oxygen near the surface of the sensor. The rate of decrease in PO_2 is a function of the glucose concentration and is monitored by the PO_2 electrode. A steady-state reduced partial pressure of oxygen can be achieved at the surface in a short period of time, yielding a steady-state current value that

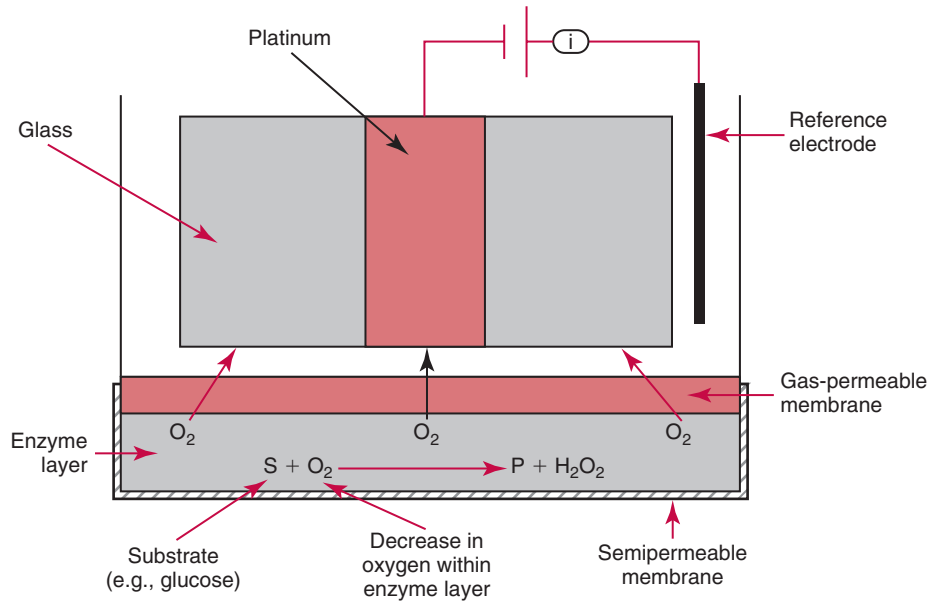

Figure 11-11 Illustration of enzyme electrode prepared using oxidase enzyme immobilized at the surface of amperometric PO_2 sensor. Increase in substrate concentration *S* reduces the amount of oxygen present at the surface of the sensor.

decreases as a function of glucose concentration in the sample.

If the polarizing voltage of the PO_2 electrode is reversed, making the platinum electrode positive (anode) relative to the Ag/AgCl reference electrode, and if the gas-permeable membrane is replaced with a hydrophilic membrane containing the immobilized enzyme, it is possible to oxidize the H_2O_2 produced by the glucose oxidase as follows:

$$H_2O_2 \rightarrow 2H^+ + O_2 + 2e^- \qquad (27)$$

The steady-state current produced is now directly proportional to the concentration of glucose in the sample.

In practice, a sufficiently high voltage (overpotential) must be applied to the platinum anode to drive the oxidation of the hydrogen peroxide. An applied voltage of +0.7 volts or greater (relative to Ag/AgCl) is typically used. Figure 11-12 illustrates this basic hydrogen peroxide detection design, which is suitable for use in devising clinically useful sensors for glucose, but also for a host of other substrates for which suitable oxidase enzymes generate hydrogen peroxide.

Immobilization of enzymes in the early biosensors was a simple entrapment method behind a membrane of low molecular weight cutoff; this approach is still used in some commercial applications. Many other schemes for enzyme immobilization for biosensor development have been suggested.[48] Most common are cross-linking of the enzyme with an inert protein, such as bovine serum albumin (BSA), using glutaraldehyde, simple adsorption of enzyme to electrode surfaces, and covalent binding of enzymes to insoluble carriers, such as nylon or glass. Another immobilization technique involves bulk modification of an electrode material, mixing enzymes with carbon paste, which serves as both the enzyme immobilization matrix and the electroactive surface.[45]

One of the first biosensor-based systems for the measurement of glucose in blood was commercialized by Yellow Springs Instruments, Inc. (YSI), Yellow Springs, Ohio, in 1975, and used the amperometric detection of H_2O_2 as the measurement principle (see Figure 11-12). Dependence of the measured glucose value on oxygen concentration in the sample was a problem because significantly less than the

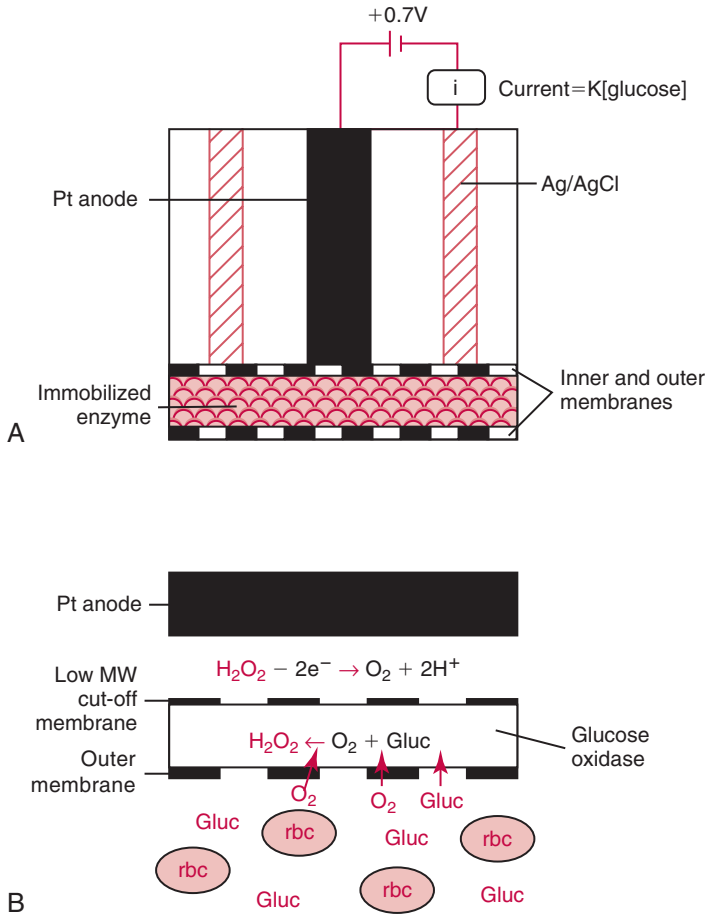

Figure 11-12 A, Design of amperometric enzyme electrode based on anodic detection of hydrogen peroxide generated from oxidase enzymatic reaction (e.g., glucose oxidase). B, Expanded view of the sensing surface shows the different membranes and electrochemical processes that yield the anodic current proportional to the substrate concentration in the sample. *(From Meyerhoff M. New in vitro analytical approaches for clinical chemistry measurements in critical care. Clin Chem 1990;36:1570.)*

stoichiometric amount of dissolved oxygen is present in blood to support the glucose oxidase reaction and produce a linear relationship of signal with glucose concentration. This is especially true at high concentrations of glucose found in samples from diabetic patients (>500 mg/dL). In the case of the YSI system, sample and calibration solutions are diluted at least 1 : 10 in buffer (depends on model), which is in equilibrium with atmospheric PO_2, fixing the oxygen concentration in the calibrator and sample at a constant value.

The problem of oxygen limitations of biosensors based on oxidase enzymes has been addressed by designing semipermeable membranes that restrict diffusion of the primary analyte (substrate) to the enzyme layer, avoiding saturation of the enzyme and keeping the ratio of oxygen to analyte always in excess of 1. This extends the linearity of response to analyte concentrations substantially higher than the K_m of the enzyme, and reduces the signal dependence on oxygen. Outer track-etched polycarbonate membranes are commonly used,[98] as are membranes of poly(vinyl chloride), polyurethanes, and silicone emulsions.[77] Another approach has been to use an oxygen-rich electrode material as a reservoir of oxygen to support the bioreaction. A fluorocarbon (Kel-F Oil) has been used to formulate a carbon paste electrode to act as a source of oxygen and as the working electrode.[126]

Electron acceptors other than oxygen can serve as mediators in the glucose oxidase reaction and completely eliminate any dependence of the amperometric response on oxygen concentration of the sample. The mediator, usually coimmobilized with the enzyme, transports electrons to the anode surface, where it is reoxidized, resulting in a cyclic reaction mechanism (Figure 11-13). Mediators with electron transfer kinetics (little or no overpotential) more favorable than that of oxygen allow operation of the sensor at lower applied potentials (+0.2 V vs. Ag/AgCl or lower) than are typically used for the oxidation of H_2O_2. This approach not only eliminates dependency of the reaction rate on oxygen, it also serves to reduce the contribution from oxidizable interfering substances (e.g., uric acid, ascorbic acid, acetaminophen) to the sensor response. Examples of mediators that have been used include quinones and conductive organic salts, such as tetrathiafulvalene-tetracyanoquinodimethane (TTF-TCNQ).[38,93] Ferricyanide and ferrocene derivatives have also been employed,[17] including commercial application in a first-generation device for home blood glucose monitoring. Dimethylferrocene is impregnated into a graphite electrode to which glucose oxidase has been immobilized. Reduced glucose oxidase from the enzymatic reaction is reoxidized by electrochemically generated ferricinium ion. Current produced during this cycling mechanism is proportional to the concentration of glucose in the blood sample.

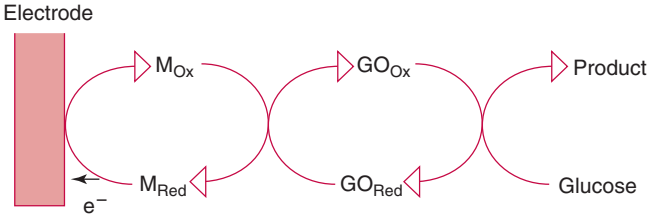

Figure 11-13 Scheme showing the use of electroactive mediator in the design of an amperometric enzyme electrode. The mediator accepts electrons directly from the enzyme and is oxidized at the surface of the working electrode, creating a more oxidized mediator to continue this process. *(From D'Orazio P. In: Lewendrowski K, ed. Clinical chemistry: laboratory management and clinical correlations. Philadelphia: Lippincott, Williams & Wilkins, 2002:464.)*

Another technique used to decrease interferences from easily oxidized species in a blood sample when traditional H_2O_2 electrochemical detection is used is to employ selectively permeable membranes in proximity to the electrode surface that allow transport of H_2O_2 to the electrode surface, but reject the interfering substances based on size exclusion (see Figure 11-12, *B*). An example is as simple as a low molecular weight cutoff membrane, such as cellulose acetate, used in many commercial amperometric biosensors.[61] Also used are electropolymerized films, such as poly(phenylenediamine) formed in situ, to reject interfering substances based on size.[34] Another approach employed in a commercial application involves using a second correcting electrode, identical to the working electrode, but without enzyme, sensitive only to the presence of oxidizable interfering substances. The resulting differential signal is proportional to the concentration of analyte.

A novel approach used for elimination of electroactive interfering substances in a commercially available glucose sensor is to directly "wire" the redox center of the enzyme glucose oxidase to a metallic, amperometric electrode using an osmium (III/IV)-based redox hydrogel.[89] Osmium sites effectively serve as mediators and can accept electrons directly from the entrapped enzyme, without the need for oxygen. This approach allows the operating potential of the electrode to be dramatically lowered to +0.2 V versus the saturated calomel reference electrode (SCE), where currents resulting from electro-oxidation of ascorbate, urate, acetaminophen, and L-cysteine are negligible.

Substitution of other oxoreductase enzymes for glucose oxidase allows amperometric biosensors for other substrates of clinical interest to be constructed. Practical sensors with commercial application in critical care analyzers for blood lactate have been realized.[1] By using the multiple enzyme cascade shown in the reactions discussed here, an amperometric biosensor for creatinine is also possible. Electrochemical oxidation of H_2O_2 is the detection mechanism.

$$\text{Creatinine} + H_2O \xrightarrow{\text{creatinine amidohydrolase}} \text{Creatine} \quad (28)$$

$$\text{Creatine} + H_2O \xrightarrow{\text{creatine amidinohyrdrolase}} \text{Sarcosine} + \text{Urea} \quad (29)$$

$$\text{Sarcosine} + H_2O + O_2 \xrightarrow{\text{sar cos ine oxidase}} \text{Glycine} + \text{formaldehyde} + H_2O_2 \quad (30)$$

This three-enzyme scheme suffers interference from endogenous creatine in the sample, requiring correction. Low concentrations of creatinine found in blood (≤100 μmol/L)

must be measured in the presence of oxidizable interfering substances, sometimes present at higher concentrations than the analyte.[56] Special electroactive layers within the biosensor have been proposed to remove redox-active interfering substances.[109] Because the useful life of the creatinine biosensor based on these reactions requires three enzymes to retain activity, reusable commercial biosensors for creatinine based on this measurement principle typically have suffered from a short (few days) useful life, but improvements in enzyme immobilization methods and/or use of stabilizers/activators within calibrating reagents may yield creatinine sensor devices with much longer lifetimes. The importance of developing creatinine sensors and progress to date in this field have recently been summarized in detail by Lad and colleagues.[64]

Enzyme-Based Biosensors With Potentiometric and Conductometric Detection

Ion-selective electrodes can be used as transducers in potentiometric biosensors. An example is a biosensor for urea [blood urea nitrogen (BUN)] based on a polymer membrane ISE (vinyl chloride) for ammonium ion (Figure 11-14).[63] The enzyme urease is immobilized at the surface of the ammonium-selective ISE based on the antibiotic nonactin (see structure of ionophore in Figure 11-3) and catalyzes the hydrolysis of urea to NH_3 and CO_2.

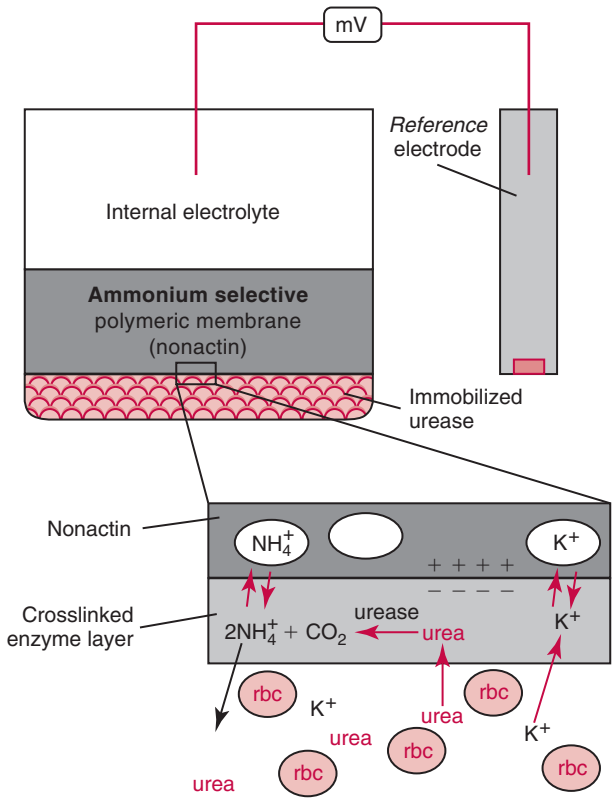

Figure 11-14 Potentiometric enzyme electrode for determination of blood urea, based on urease enzyme immobilized on the surface of an ammonium ion–selective polymeric membrane electrode.

$$\text{Urea} \xrightarrow{\text{urease}} 2NH_3 + CO_2 \qquad \textbf{(31)}$$

The ammonia produced forms NH_4^+, which is sensed by the ISE. The signal generated by the NH_4^+ produced is proportional to the logarithm of the concentration of urea in the sample. The response may be steady state or transient. Typically, correction for background potassium is required, because the nonactin ionophore has limited selectivity for ammonium over potassium ($K_{NH4/K} = 0.1$). Potassium is measured simultaneously with urea and is used to correct the output of the urea sensor using the Nicolsky-Eisenman equation [equation (10)].

The approach already described for measurement of urea using an enzyme-based potentiometric biosensor assumes that the turnover of urea to ammonium at steady state provides a constant ratio of ammonium ions to urea, independent of concentration. This is rarely the case, especially at higher substrate concentrations, resulting in a nonlinear sensor response. The linearity of the sensor is also limited by the fact that hydrolysis of urea produces a local alkaline pH in the vicinity of the ammonium-sensing membrane, partially converting NH_4^+ to NH_3 (pKa = 9.3). Ammonia (NH_3) is not sensed by the ISE. The degree of nonlinearity may be reduced by placement of a semipermeable membrane between enzyme and sample to restrict diffusion of urea to the immobilized enzyme layer.

A change in solution conductivity has also been used as a transduction mechanism in enzyme-based biosensors. Examples include the measurement of glucose, creatinine, and acetaminophen using interdigitated electrodes.[27] Practical applications of conductometric biosensors are few because of the variable ionic background of clinical samples and the requirement to measure small conductivity changes in media of high ionic strength. A commercial system for the measurement of urea in serum, plasma, and urine is a BUN analyzer (Beckman-Coulter, Brea, Calif) based on the enzyme urease.[31] Dissolution of products to NH_4^+ and HCO_3^- produces a change in sample conductivity. The initial rate of change in conductivity is measured to compensate for the background conductivity of the sample. This approach is limited to the measurement of analytes at relatively high concentrations because of small changes in conductivity produced by low concentrations of analyte.

Enzyme-Based Biosensors With Optical Detection

Optical sensors with immobilized enzymes and indicator dyes have been developed for the measurement of glucose and other substrates of clinical interest.[66] These biosensors are based on optical detection chemistries for pH and oxygen, described earlier in this chapter, and rely on absorbance/reflectance, fluorescence, and luminescence as modes of detection. Enzyme immobilization methods resemble those used to construct electrochemical biosensors, including physical entrapment or encapsulation in a gel matrix, physical adsorption onto substrates, and covalent binding or absorption on an insoluble support. Using an example based on an optode for PO_2, a sensitive indicator is co-immobilized with

an oxidase enzyme at the end of a fiber optic probe. The probe is used to monitor fluorescence of the indicator. Quenching of fluorescence of the indicator by O_2 is followed. A decrease in PO_2 resulting from a reaction catalyzed by the enzyme will result in less quenching of the indicator and a fluorescent signal directly proportional to the concentration of substrate. In an example of an optical biosensor probe for glucose, an oxygen-sensitive cationic dye, $Ru(phen)_3^{2+}$, is immobilized along with glucose oxidase on the surface of an optical fiber.[85] A decrease in PO_2 arising from the enzyme-catalyzed oxidation of glucose results in an increase in luminescence intensity of the ruthenium tris(phenanthrene).

Similar optical biosensors have been prepared for many other analytes. For example, a cholesterol optical biosensor has been devised based on fluorescence quenching of an oxygen-sensitive dye that is coupled to consumption of oxygen resulting from the enzyme-catalyzed oxidation of cholesterol by the enzyme cholesterol oxidase.[120] Serum bilirubin has been detected using bilirubin oxidase, co-immobilized with a ruthenium dye, on an optical fiber.[69] The bilirubin sensor was reported to exhibit a lower detection limit of 10 μmol/L, a linear range up to 30 mmol/L, and a typical reproducibility of 3% (CV), certainly adequate for clinical application.

The pH change resulting from enzyme-catalyzed reactions has also been measured optically. The indicator dye fluorescein is often used as a pH-sensitive indicator to construct such sensors. The protonated form of fluorescein does not fluoresce, but the conjugate base strongly fluoresces at 530 nm, when excited at 490 nm. Using glucose oxidase as the enzyme, a pH optode has been used to follow the formation of gluconic acid.[119] A disadvantage of optical sensors based on pH changes is that they are strongly dependent on the pH and buffer capacity of the sample. Moreover, the working range of the sensor is determined by the pKa of the indicator, 6.8 to 7.2 for fluorescein, depending on ionic strength of the sample matrix. A pH-sensitive indicator may also be used to follow enzymatic reactions that produce ammonia (e.g., urease action on urea).

Affinity Sensors

Affinity sensors are a special class of biosensors in which the immobilized biological recognition element is a binding protein, antibody (immunosensors), or oligonucleotide (e.g., DNA, aptamers) with high binding affinity and high specificity toward a clinically important analyte/partner. Such sensors are being developed as alternatives to conventional binding assays to enhance the speed and convenience of a wide range of assays that normally would be run on large, sophisticated instruments in a central laboratory. Affinity sensors may be more easily adapted than traditional assays to systems developed for point-of-care testing for infectious disease, cardiac markers, or other cases where speed and ease of use are required. Ideally, direct binding of the immobilized species with its target in a clinical sample should yield a sensor signal proportional to the concentration of the analyte. However, direct sensing (without use of exogenous labels/tracers) of the binding events at analyte concentrations that would cover the full range for clinical applications is very difficult to achieve. Further, high affinity of such binding reactions, required to achieve optimal sensitivity, also limits the reversibility of such devices (slow reverse rate constant). Indeed, unlike ISEs, oxygen sensors, and many of the enzyme-based biosensors described previously, affinity sensors based on electrochemical, optical, or other transduction modes are typically single-use devices. For repeated multiuse applications, some type of regeneration step (pH change, temperature change, etc.) to dissociate the tight binding between the recognition element and the target is required. A thermally reversible immunosensor, demonstrated to retain activity and specificity for up to 30 assays, has recently been described.[72] The sensor consists of an antibody conjugated to a polymer, which undergoes a reversible phase transition in response to temperature. Altering temperature produces a change in orientation of the conjugated polymer and affinity between the conjugate and a target antigen, resulting in a reversible antigen-antibody binding reaction.

Most affinity-type sensors that function well for real clinical measurements are based on labeled reagents such as enzymes, fluorophores, and electrochemical tags, and hence function more like traditional binding/immunoassays, except that one recognition element is immobilized on the surface of a suitable electrode or another type of transducer.[74,79,111] For example, electrochemical oxygen sensors have been used to carry out heterogeneous enzyme immunoassays (sandwich or competitive type), using catalase as a labeling enzyme (catalyzes $H_2O_2 \rightarrow 2H^+$ and O_2) and immobilizing capture antibodies on the outer surface of the gas-permeable membrane. After binding equilibration and washing steps, the amount of bound enzyme is detected by adding the substrate and following the increase in current generation caused by local production of oxygen near the surface of the sensor.

The basic advantage of immobilizing affinity reagents on the surfaces of electrodes and optical sensing devices is somewhat diminished when separate washing steps are required to remove unbound label species. Indeed, true biosensors should yield analytically useful responses in the presence of undiluted physiologic samples, without the need for discrete incubation and washing steps. One example of an electrochemical-based immunosensor method that partially achieves this goal is a technique termed *nonseparation electrochemical enzyme immunoassay (NEEIA)*.[82] The basic concept is illustrated in Figure 11-15. As indicated, no separation or washing steps are required. This method was used to detect prostate-specific antigen (PSA) and human chorionic gonadotropin (hCG) at ng/mL concentrations in undiluted plasma and whole blood.[82]

A host of "direct" sensing affinity sensors have been proposed, based on electrochemical (including capacitance and impedance changes), optical, thermal, mass, and acoustic detection methods.[54,74,79,111,125] Direct affinity sensors eliminate the need for labeled reagents because the binding reaction results in a change in a property that may be monitored directly. Of these, few have adequate specificity to be used in

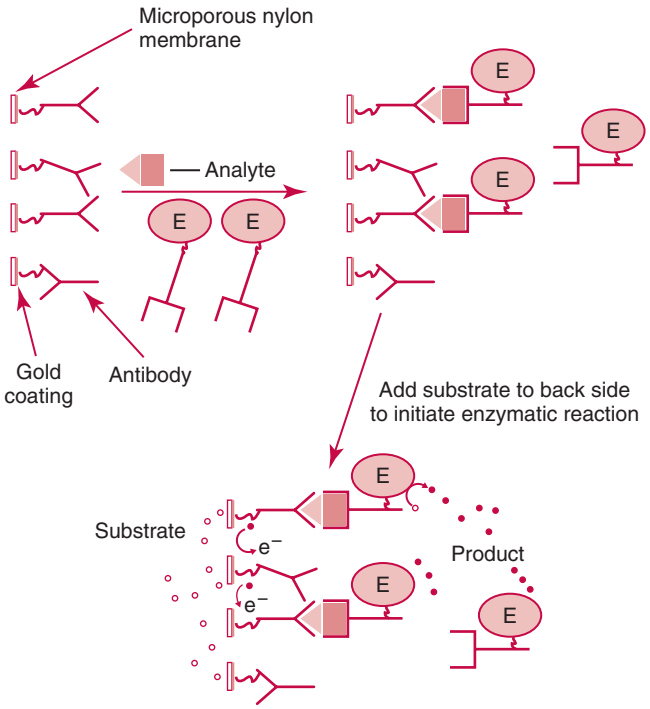

Figure 11-15 Principle of nonseparation electrochemical enzyme immunoassay (NEEIA) concept, configured in sandwich immunoassay mode to detect a given protein analyte. Enzyme label on reporter antibody generates an electroactive product that is detected at the surface of the porous gold electrode when substrate for enzyme is added to the back side of the membrane.

complex clinical samples, owing to significant signals arising from nonspecific binding. One report, however, suggests that alpha fetoprotein can be detected reliably in serum samples via a quartz crystal microbalance mass detector, possessing immobilized anti–alpha fetoprotein antibodies on the surface of the quartz crystal transducer.[19] Increasing concentrations of analyte in the sample yield increased binding to the surface, changing the mass loaded because of the immunologic reaction. Incubation times as low as 20 minutes are required to achieve results that compare favorably with those of a conventional radioimmunoassay method for serum samples. Direct immunosensors for sensitive assays of tumor markers have been reported. Examples include an electrochemical immunosensor for PSA with an enhanced lower limit of detection, based on an alternating current (AC)-impedance measurement,[10] and assay for carcinoma antigen 125 using a quartz crystal microbalance.[113] The former uses a control sensor with immobilized immunoglobulin (Ig)G antibody instead of anti-PSA to subtract out effects from nonspecific binding to achieve a limit of detection of 1 pg/mL toward PSA.

Some success for direct sensing affinity sensors has also been achieved in the area of DNA sensors.[54] Generally, with such devices, a segment of DNA complementary to the target strand is immobilized on a suitable transducer. DNA sensors show particular promise as the basis of point-of-care test devices, for example, for rapid detection of bacterial pathogens.[55,70] Methods for immobilizing DNA segments on electrode surfaces are similar to protein immobilization methods used for other biosensors. Electrically conducting polymers such as polypyrrole, polyaniline, and polythiophene are possible matrices for immobilization of a DNA segment using physical entrapment, covalent attachment, and affinity interactions as methods of immobilization.[95] The conducting polymer not only serves as an immobilization matrix but also plays an active role in the transduction mechanism, providing communication between the DNA binding event and an underlying metallic electrode. Electrochemical DNA sensors can operate in direct (based on electrochemical oxidation of guanine in target DNA) (see Figure 11-15, *A*) or indirect (with exogenous electrochemical markers/labels) (see later and Figure 11-16, *B*) transduction modes. For example, Ozkan and coworkers demonstrated a relatively simple label-free electrochemical *genosensor* to detect the presence of factor V Leiden mutations, using capture probes with inosine substituted for guanosine nucleic acids.[92] Probes were developed to bind wild-type and mutant DNA, based on known base sequences in regions of wild and mutant DNA species. These probes were immobilized on the surface of carbon paste working electrodes. After polymerase chain reaction (PCR) amplification of the sample DNA, a small volume of such samples (10 μL) is incubated for 6 minutes with the probe-modified electrode. Then, after a quick washing step, the presence of the target amplicon bound to the surface can be observed by differential pulse voltammetry using an anodic scan. The presence of a guanine oxidation peak, occurring at +1.00 V versus the Ag/AgCl reference, indicates the presence of the target DNA in the original sample. Another example of a direct DNA sensor uses a field effect transistor coated with an organic semiconducting polymer, poly(3-hexylthiophene).[131] Single-stranded DNA was immobilized at the source/drain electrodes. Single- and double-stranded DNA could be differentiated based on differences in the drain current caused by differences in resistance produced by the two types of DNA.

Weng and associates[128] have suggested an impedance-based detection scheme to monitor DNA hybridization using a boron-doped diamond electrode as the underlying transducer. Using single-stranded oligo sequences immobilized on the diamond electrode, a large decrease in AC impedance was detected when the surface was exposed to complementary single-stranded DNA sequences. Remarkable detection limits of 10^{-19} g/mL were reported using this approach.

DNA detection using electrochemical-labeled oligonucleotides or electrochemical probes that selectively intercalate into hybridized DNA duplexes represents a growing area of investigation, with several "gene" sensor arrays of this type poised to become commercial products (see Chapter 17). As illustrated in Figure 11-16, *B*, when the intrinsic electroactivity of guanine [that requires use of electrode-immobilized capture oligo probes with inosine replacing guanosine (see above)] is not used, detection of hybridization of a target DNA sequence is achieved in either of two ways. In one case, after the immobilized capture oligo anchored to the electrode

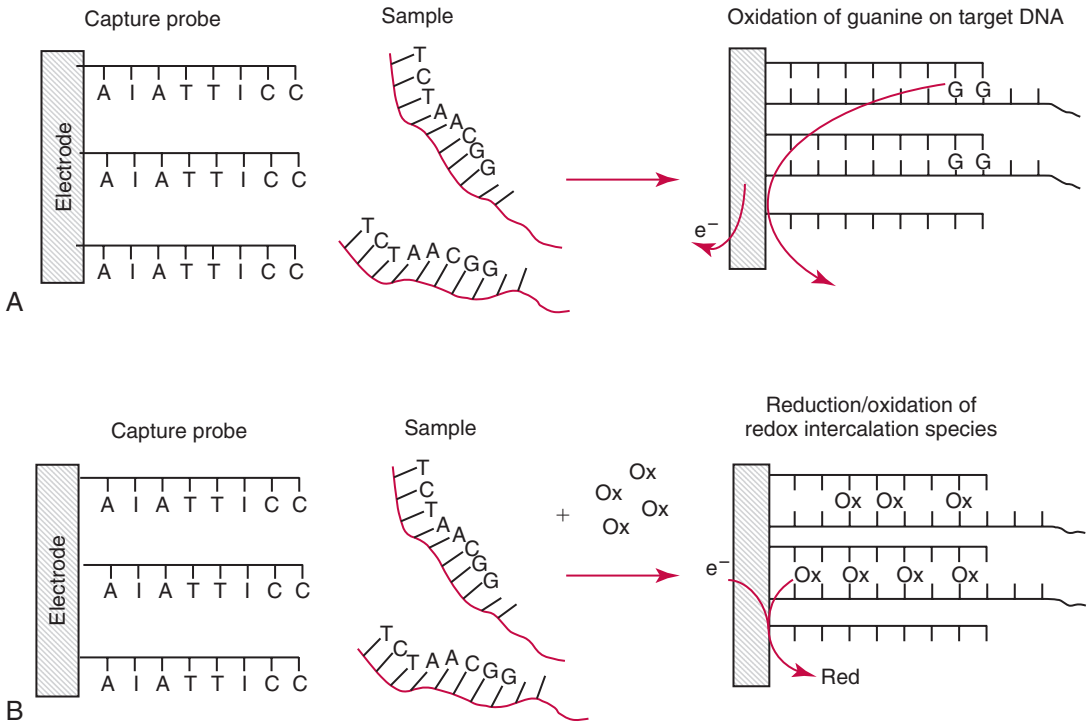

Figure 11-16 Examples of DNA biosensor configurations. A, Direct electro-oxidation detection of guanosine bases in target DNA after hybridization with immobilized capture probe on electrode surface. B, Electrochemical detection of hybridization using exogenous redox species that intercalates into hybridized complex between immobilized capture DNA probe and target DNA.

surface is allowed to bind the target sequence, hybridization is detected by exposing the surface of the electrode to an exogenous electroactive species [Co(III)tris-phenanthroline, ruthenium complexes, etc.] that can interact (intercalate) with the duplex but not single-stranded DNA. After unbound electroactive species are washed away, the presence of hybridization can be readily detected by voltammetry, scanning the potential of the underlying electrode to oxidize or reduce any intercalated electroactive species, with the current detected being proportional to the number of duplex DNA species on the surface of the electrode. Another route involves the detection of target DNA via a sandwich-type binding assay, using an electrochemical-labeled oligonucleotide [oligo labeled with ferrocene, osmium(III) trisbipyridine, etc.] to bind to another sequence of targeted DNA different from the capture oligo on the surface of the electrode. Sequential exposure of the electrode to the sample of DNA (usually after amplification via PCR), excessive labeled reporter oligo (a wash solution), and electrochemical detection of surface-bound label yields the analytical signal. Again, the amount of current monitored is proportional to the number of target DNA species present in the original sample.

A variant of the sandwich-type DNA assay scheme just discussed involves using proximity-dependent surface hybridization of a ferrocene-labeled reporter oligo nucleic acid sequence.[134] In this approach, a thiolated capture oligo probe is immobilized on a gold electrode. When the complementary target DNA was introduced, it was complementary to the region of the capture probe that is farther from the surface of the gold. The reporter oligo with the ferrocene label was prepared to be complementary to one end of the target and to the sequence of the surface immobilized capture probe closest to the gold electrode. Hence, in the presence of the target, the ferrocene tracer ends up being positioned extremely close to the surface of the gold, making it more easily observed electrochemically via a simple differential pulse voltammetric scan, allowing femtomolar detection of the target DNA.

Affinity sensors based on synthetic oligonucleotides, known as *aptamers,* have been explored as recognition elements for a variety of biosensing applications, including small molecules, proteins, and cells. In practice, aptamers are generated and selected in vitro to bind targets for which antibodies and other protein receptors are not easily obtained. Aptamers have been demonstrated to function in biosensors using various transduction methods, including optical sensing (using fluorescently labeled aptamers)[87] and acoustic, mass (cantilever-based), and electrochemical sensing, using, for example, aptamer probes labeled with a redox species such as ferrocene.[86,73] Practical applications for aptamer-based affinity sensors in clinical chemistry are still emerging. Model analytes such as adenosine triphosphate (ATP) and

thrombin have been used to demonstrate proof of concept for sensing schemes aimed at producing reversible sensors.[73] The method by which aptamers are selected against their targets makes them inherently suited to displacement assays because of greatly reduced affinity for the labeled form of the target. Thrombin-binding aptamer was shown to have an order of magnitude less affinity for thrombin labeled with horseradish peroxidase than native thrombin. A rapid (10 minute) displacement assay for thrombin was demonstrated with sensitive detection limits of 4.5 and <1 nanomolar using optical and electrochemical detection, respectively.[9]

CHEMICAL SENSORS BASED ON NANOTECHNOLOGY

Nanotechnology is defined as the study of the synthesis, properties, and application of structures and materials having at least one critical dimension on the scale of approximately 100 nm.[94] Structures such as nanowires, nanoparticles, and carbon nanotubes offer unique electrical, optical, and magnetic properties that can be exploited for chemical sensing. The large surface area available on nanostructures for immobilization of labels and biological recognition elements offers the potential for high signal amplification. Developments in the field of DNA nanodevices have resulted in complex molecular detection and amplification schemes, which may outperform PCR in terms of sensitivity and ease of use.[110]

The flexibility and the unique shape of carbon nanotubes and the presence of reactive groups on their surface has led to their being used as biocatalytic and affinity biosensors.[100,122] Direct electron transfer between immobilized glucose oxidase and carbon nanotubes allows construction of glucose biosensors without mediators. In addition, enhanced electron transfer between proteins and carbon nanotubes results in lower overpotentials and higher peak currents observed for the voltammetric response of several molecules at electrodes modified with carbon nanotubes.[100] For DNA sensors, using carbon nanotubes in a detector for the hybridization event provides an efficient way to amplify the label-free electrochemical detection of DNA hybridization and to enhance charge transfer between surface-anchored DNA sequences and carbon nanotubes.[114,125]

Nanomaterial labels, including gold, silver, and semiconductor nanoparticles, have been shown to result in large signal enhancements and to lower limits of detection in electrochemical immunosensors for disease-related protein biomarkers, and for detection of DNA hybridization events.[71] Gold nanoparticles have been used as both immobilization platforms and labels for electrochemical immunosensors.[80] Electrodes with layers of densely packed 5-nm gold nanoparticles were used as a matrix for immobilization of horseradish peroxidase in a sandwich immunoassay for PSA with a detection limit of 0.5 pg/mL.[104] In an optical assay, oligonucleotide targets labeled with gold nanoparticles instead of fluorophore probes have been shown to enhance sensitivity toward the oligonucleotide target by up to two orders of magnitude.[115] A commercial system using gold nanoparticle probes is the Verigene System (Nanosphere, Northbrook, Ill), which is capable of detecting single-nucleotide polymorphisms related to some common genetic disorders, such as thrombophilia, alterations of folate metabolism, cystic fibrosis, and hemochromatosis.

Other examples of nanotechnology applied to chemical sensing are emerging. For example, nanopores down to 1.4 nm in diameter have been created in lipid bilayers through the action of the protein α-hemolysin. A pore with nanometer-scale dimensions has a size comparable with that of a single large molecule (protein, single-stranded DNA). The molecule must be charged to be driven through the pore by an electric field. The contribution of the large molecule to the passage of electric (ionic) current through the pore is small compared with that of mobile small ions, allowing detection of the target analyte down to a single molecule.[67] Microfabricated cantilevers made of silicon or silicon nitride have been used as transducers in affinity biosensors for monitoring (1) DNA hybridization, (2) antigen-antibody interactions, or (3) absorption of bacteria. Mechanical bending of the cantilever on the order of nanometers, in response to affinity reactions, is monitored. Although the sensitivity of cantilever biosensors is limited by nonspecific binding, the technology is equivalent in sensitivity to that of other label-free methods, for example, in the picomolar range for detection of oligonucleotides, and in the ng/mL range for measurement of antigens.[39]

IN VIVO AND MINIMALLY INVASIVE SENSORS

Progress has been made in the development of miniaturized, implantable electrochemical/optical sensors that can be used for in vivo, real-time monitoring of clinically important species. Unfortunately, the biological response toward such sensors (e.g., clotting) can have a dramatic impact on the analytical accuracy of such indwelling probes[5,41,50,76,83] and has prevented their widespread use in clinical practice. However, progress is being made toward improving the reliability of in vivo measurements, and some commercial products for subcutaneous glucose monitoring are already on the market (see later).

Analytical sensors that can be implanted within human blood vessels or subcutaneously mandate that such sensing devices have an outside diameter of <0.6 mm. Both electrochemical and optical sensor technologies have been employed to create devices of the required size. These are basically miniaturized versions of the electrochemical and optical sensor devices described previously. However, in addition to their small size, such devices must exhibit very stable output signals, because reliable calibration of the probes with calibrating solutions is not possible once the probes are inserted. Although so-called in situ calibration is possible (periodically removing an in vitro blood sample to obtain current values of analytes and updating in vivo sensor output to this value), if the frequency of such in situ calibrations is high, the true advantage of having an in vivo probe is greatly diminished.

Continuous in vivo measurement of oxygen saturation (SaO_2) has been achieved by placing small optical fibers into the bloodstream via a catheter and then measuring the reflective absorbance of the blood at two or three appropriately selected wavelengths based on the absorbance spectra of oxy- and deoxy-Hb.[23] In addition, implantable analytical sensors that provide continuous readings of blood gases (pH/PCO_2/PO_2), when inserted within the radial artery, especially for critically ill patients already fitted with an arterial line, have been developed.[102] Such sensors are usually based on the classical Clark-style design, in which oxygen is reduced at a microplatinum, silver, or gold working electrode confined (along with Ag/AgCl reference) within a narrow-diameter gas-permeable catheter tube made of a given polymer (Figure 11-17, *A*), with the resulting current being proportional to the partial pressure of oxygen in the medium surrounding the catheter. Indwelling electrochemical pH and PCO_2 sensors are typically potentiometric devices, based on polymer membrane pH electrode technology or the use of solid-state metal oxide–based pH sensors. Incorporation of lipophilic proton ionophores (e.g., tridodecylamine; see Figure 11-3) within the walls of plastic tubing provides a convenient means of preparing a novel dual-lumen pH/PCO_2 sensing design that has been demonstrated in animal experiments to provide accurate in vivo results.[116]

Miniaturization of electrode designs that enable several sensors to be bundled into a single implantable device, however, remains a significant engineering challenge. Consequently, many efforts aimed at developing commercially viable intravascular blood gas sensors for simultaneously monitoring pH, PCO_2, and PO_2 have employed modern optical fiber–based technology alone or in combination with

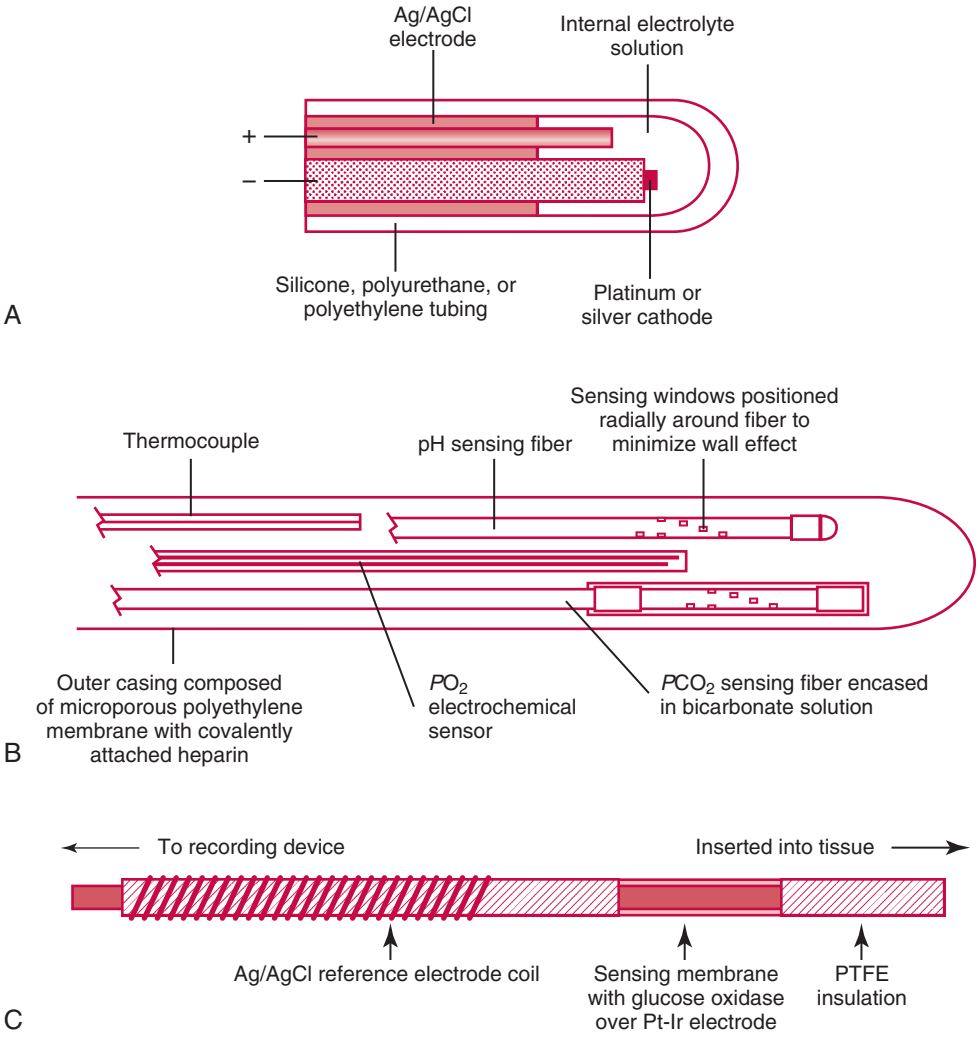

Figure 11-17 Schematics of various implantable electrochemical/optical sensors useful for continuous in vivo monitoring. A, Catheter-style amperometric oxygen sensor. B, Design of Paratrend intravascular combined PO_2, PCO_2, and pH sensor (hybrid electrochemical/optical design). C, Needle-type electrochemical glucose sensor useful for monitoring glucose subcutaneously to track blood glucose concentrations continuously.

a single electrochemical device. Because the outer diameter of available fibers continues to decrease, it is now possible to bundle three or more separate chemically sensitive fibers within a single catheter with an outer diameter <600 μm for implantation within human radial arteries, without dampening the pressure waveform detected by a microelectronic pressure transducer within the arterial line. Absorbance-, fluorescence-, and phosphorescence-based chemistries have been investigated in the design of sensors with suitable selectivity and calibration stability.[83] Appropriate indicators are usually immobilized on the distal ends of the fibers, although alternate configurations/locations have also been proposed. Most optical oxygen measurements are made with indicators whose luminescence is quenched in the presence of oxygen, whereas pH sensors are prepared by immobilizing pH indicators (e.g., phenol red) in hydrogel type films.[108] Optical sensors for PCO_2 can be easily prepared from the same pH sensors by incorporating bicarbonate salt in the hydrogel layer and then covering this layer with a gas-permeable polymeric film (usually silicone rubber material), as described previously in the section on optical sensors.

Despite significant efforts by a number of large biomedical companies in the 1980s/1990s, only the Paratrend probe was commercially available for a period of time for the intravascular measurement of blood gases. As shown in Figure 11-17, *B*, this indwelling sensor consisted of a novel hybrid design, in which oxygen is sensed electrochemically (catheter form of Clark sensor), while pH and PCO_2 are determined via fiber-based optical fluorescence sensors.[123] Although acceptable clinical performance of the Paratrend was reported, frequent in situ recalibrations have been suggested.[24] A later version of this product replaced the electrochemical oxygen sensor with an optical fiber design. However, continued problems with in vivo performance and concomitant costs of using the device have prevented widespread use, and the product is no longer available.

Another class of in vivo chemical sensor that is now available consists of glucose sensors designed to help manage diabetic patients, with the ultimate goal of attaining fully automated feedback control of subcutaneous insulin delivery via newly devised, highly portable insulin pumps. Because such sensors need to function within patients outside the hospital setting and for extended time periods (days, weeks), placement of such devices subcutaneously, rather than intravascularly, is desirable.[60] In addition, sensors are being developed that could be implanted within the vena cava for periods of 1 year. In the case of subcutaneous devices, several studies have shown that concentrations of glucose in interstitial fluid track blood concentrations closely, although some time delay has been noted in achieving identical values in the two sample environments.[42]

Implantable glucose (and lactate) sensors have been based, almost exclusively, on electrochemical transducers. For example, one such sensor is based on using dual oxygen sensors in a single catheter design for indwelling blood glucose and lactate measurements.[46] One oxygen sensor with immobilized glucose or lactate oxidase provides response to glucose concentrations (decreasing surface oxygen in response to increased glucose or lactate), while the second matched oxygen sensor, without enzyme, is able to correct for unknown and varying amounts of endogenous PO_2. Others have focused on the design of probes with amperometric detection of the hydrogen peroxide (via oxidation) at an underlying iridium/platinum anode similar in operation to those used in vitro in commercial instruments.[132] With such designs, the use of outer polymer films to restrict glucose (or lactate) diffusion relative to oxygen is critical to achieve a linear electrochemical response to glucose from normal (90 mg/dL) to elevated concentrations found in diabetic patients (>500 mg/dL). Figure 11-17, *C*, illustrates a design in which the needle-type probe is constructed by multiple membrane coatings and electrodeposition of the glucose oxidase layer.[18] Designs similar to this are among the currently Food and Drug Administration (FDA)-approved sensors available for subcutaneous monitoring of glucose.[44,47,59] In one instance, the sensor is actually fabricated on a very narrow planar substrate, rather than on a cylindrical wire–based system. Relatively frequent calibration of all such sensors is still required via periodic in vitro blood tests, especially in the early stages after subcutaneous implantation.[44]

Instead of implanting glucose sensors intravascularly or subcutaneously, an alternative approach employs electrochemical glucose sensors to monitor glucose concentrations in interstitial fluid brought to the surface of the sensors via an iontophoresis process.[44,118] Electrical current is passed through the skin to move fluid in a given direction toward the surface of the electrochemical glucose sensors that are based on peroxide detection (see Chapter 26 for additional discussion of this device).

Current research and development efforts have focused on the use of more biocompatible coatings to reduce the biological response of intravascular and subcutaneous devices. These efforts are based on the expectation that such developments will be critical to ultimate success in developing implanted sensors that yield continuous analytical results that match closely those attained by conventional in vitro test methods. One new approach in this direction employs novel NO release/generating polymers to coat the surface of intravascular sensors.[40,41,130] The potent antiplatelet activity of NO has been shown to greatly reduce the formation of thrombus on the surface of implantable electrochemical oxygen sensing catheters, and to yield much more accurate continuous PO_2 values in animal experiments. Further, NO has been shown to decrease the inflammatory response that occurs for glucose sensors implanted subcutaneously.[43,53]

CHAPTER 12

Electrophoresis

*Raymond E. Karcher, Ph.D., and James P. Landers, Ph.D.**

Developments in *deoxyribonucleic acid (DNA)* testing, improvements in ease of performance through automation, and advantages of speed and miniaturization afforded by the technique of *capillary electrophoresis (CE)* have led to a renaissance and growth of *electrophoresis* as an analytical tool that is widely used in clinical laboratories. These developments and improvements have enabled clinical laboratories to keep pace with higher volumes of testing and to introduce more sophisticated technology to meet the demands of modern clinical practice. This chapter will review the principles and practice of the technique and will separately discuss conventional, capillary, and microchip electrophoresis. Particular attention is given to newer methods and their promise in fields such as *genomics* and *proteomics.*

BASIC CONCEPTS AND DEFINITIONS

Electrophoresis is a comprehensive term that refers to the migration of charged solutes or particles of any size in a liquid medium under the influence of an electrical field. *Iontophoresis* and *isotachophoresis (ITP)* are similar terms but refer specifically to the migration of small ions. The first electrophoresis method used to study proteins was the free solution or moving boundary method devised by Tiselius in 1937. This technique was used in research to measure electrophoretic mobility and to study protein-protein interaction. It was able to resolve the serum proteins into only four component mixtures, with the α_1 fraction incompletely separated from albumin.

Zone electrophoresis refers to the migration of charged molecules of proteins, usually in a porous supporting medium like agarose gel film, such that each protein zone is sharply separated from neighboring zones by a protein-free area. Zones are visualized by staining with a protein-specific stain to produce an *electropherogram* that is then scanned and quantified using a densitometer. The support medium can also be handled after drying and kept as a permanent record. It is a most commonly applied technique in clinical chemistry and is used to separate proteins in serum, urine, cerebrospinal fluid (CSF), other physiologic fluids, erythrocytes and tissue, and nucleic acids in various tissue cells.

Although electrophoretic separation of biologically relevant macromolecules in gels (or paper) has been the workhorse of modern biomedical research, the advent of *capillary electrophoresis (CE)* has revolutionized separations. Intense interest in carrying out electrophoretic separation in capillaries with inner diameters ranging from 20 to 75 µm has resulted from its unprecedented resolving power, separation speed, and small sample analysis capabilities. However, the true significance of CE to the separations community is seen in its ability to apply these separation principles in a multimodal approach to a variety of analytes that obviously included proteins and polynucleic acids, but also peptides, small drug-like molecules, and even ions.

THEORY OF ELECTROPHORESIS

Depending on the charge they carry, ionized solutes move toward either the cathode (negative electrode) or the anode (positive electrode) in an electrophoresis system. For example, positive ions (cations) migrate to the cathode, and negative ions (anions) to the anode. An ampholyte (a molecule that is either positively or negatively charged, formerly called a *zwitterion*) becomes positively charged in a solution that is more acidic than its isoelectric point (pI)* and migrates toward the cathode. In a more alkaline solution, the ampholyte becomes negatively charged and migrates toward the anode. Because proteins contain many ionizable amino (—NH_2) and carboxyl (—COOH) groups, and because the bases in nucleic acids may also be positively or negatively charged, they both behave as ampholytes in solution.

The rate of migration of ions in an electrical field depends on the factors listed in Box 12-1. The equation expressing the driving force in such a system is given by

$$F = (X)(Q) = \frac{(EMF)\ (Q)}{d} \qquad \textbf{(1)}$$

where

F = the force exerted on an ion

*The isoelectric point of a molecule is the pH at which it has no net charge and will not move in an electrical field.

The authors gratefully acknowledge the original contributions of Drs. Emmanuel Epstein and Kern L. Nuttall, on which portions of this chapter are based.

tahir99-VRG & vip.persianss.ir

BOX 12-1 Factors Affecting the Motility of Ions in an Electrophoretic System

Net charge of the molecules
Size and shape of the molecules
Strength of the electrical field
Support medium properties
Ionic strength of the buffer
Temperature

X = the current field strength (V/cm) (i.e., voltage drop per unit length of medium)
Q = the net charge on the ion
EMF = the electromotive force [voltage (V) applied]
d = the length of the electrophoretic medium (cm)

Steady acceleration of the migrating ion is counteracted by a resisting force characteristic of the solution in which migration occurs. This force, expressed by Stokes' law, is

$$F' = 6\pi r\eta v \qquad (2)$$

where
F' = the counter force
$\pi = 3.1416$
r = the ionic radius of the solute
η = the viscosity of the buffer solution in which migration is occurring
v = the rate of migration of the solute = velocity, length (l) traveled per unit of time (cm/s)

The force F' counteracts the acceleration that would be produced by F if no counter force were present, and the result of the two forces is a constant velocity. Therefore, when

$$F = F' \qquad (3)$$

then

$$6\pi r\eta v = (X)(Q) \qquad (4)$$

or

$$\frac{v}{X} = \frac{1 \times d}{t \times E} = \frac{Q}{6\pi r\eta} = \mu \qquad (5)$$

where v/X is the rate of migration (cm/s) per unit field strength (E/cm), defined as the electrophoretic mobility. It is expressed by the symbol μ and has the units $cm^2/(V)(s)$.

Electrophoretic mobility is directly proportional to the net charge and inversely proportional to the size of the molecule and the viscosity of the electrophoresis medium. In practice, the equation $\mu = m^2/(V)(s)$ is used to calculate electrophoretic mobility. For example, if albumin travels 3 cm (l) on a 10-cm (d)-long agarose gel and does so in 75 minutes (or 75×60 s) at a voltage of 250 V, then

$$\mu = \frac{(3)(10)}{(75)(60)(250)} = 2.7 \times 10^{-5}\ cm^2/(V)(s)$$

Because 1 mobility unit is defined as 10^{-5} $cm^2/(V)(s)$, this result is converted to 2.7 mobility units. Mobility may be positive or negative, depending on whether a protein migrates in the same or the opposite direction as the electrophoretic field (defined as extending from the anode to the cathode). In the example just given, electrophoresis was performed at pH 8.6, where proteins have a negative charge; therefore migration occurred from the cathode to the anode, and the mobility would be −2.7 mobility units.

In addition to the factors listed in Box 12-1, other factors that affect electrophoretic mobility include electroendosmosis (endosmosis) and wick flow. Electroendosmosis affects mobility by causing uneven movement of water through the support medium. An electrophoretic support medium, such as a gel in contact with water, takes on a negative charge caused by adsorption of hydroxyl ions. These ions are fixed to the surface and are immobile. Positive ions in solution cluster about the fixed negative charge sites, forming an ionic cloud of mostly positive ions. The number of negative ions in the solution increases with increasing distance from the fixed negative charge sites until eventually positive and negative ions are present in equal concentrations (Figure 12-1).

When current is applied to such a system, charges attached to the immobile support remain fixed, but the cloud of ions in solution moves to the electrode of opposite polarity.

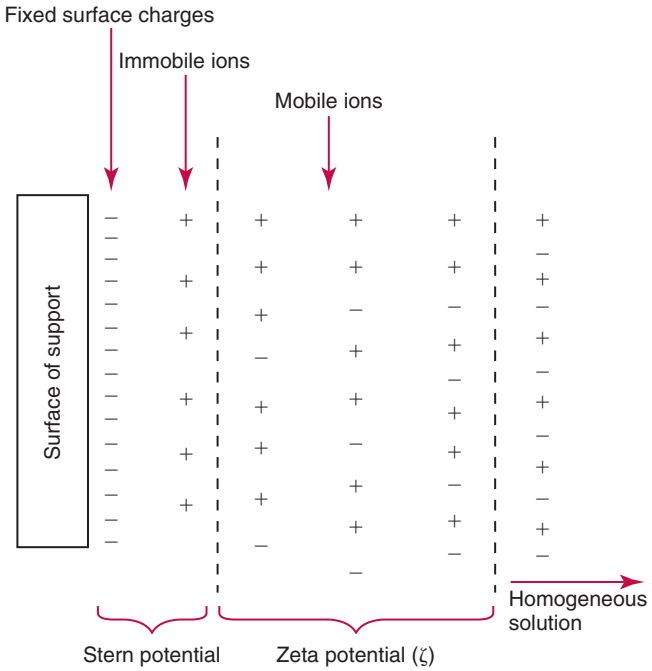

Figure 12-1 Distribution of + and − ions around the surface of an electrophoretic support. Fixed on the surface of the solid is a layer of − ions. (These may be + ions under suitable conditions.) A second layer of + ions is attracted to the surface. These two layers compose the Stern potential. The large, diffuse layer containing mostly + ions is the electrokinetic or zeta potential. Extending farther from the surface of the solid is homogeneous solution. The Stern potential plus the zeta potential equals the electrochemical potential, or epsilon potential.

tahir99-VRG & vip.persianss.ir

Because ions in solution are highly hydrated, this results in movement of the solvent as well. Movement of solvent and its solutes relative to the fixed support is referred to as *endosmosis* and causes preferential movement of water in one direction. Macromolecules in solution that move in the direction opposite this flow may remain immobile or may even be swept back toward the opposite pole if they are insufficiently charged. In media in which endosmosis is strong, such as conventional cellulose acetate and unpurified agarose gel, γ-globulins are swept back from the application point. Because the inner surface of a glass capillary contains many such charged groups, endosmosis is very strong and is actually the primary driving force for migration in CE systems. In practice, the endosmosis in CE is manipulated, however, to modify the magnitude of the endosmotic effect. In electrophoretic media in which surface charges are minimal (starch gel, purified agarose gel, or polyacrylamide gel), endosmosis is minimal.

Wick flow results from the movement of buffer into the support medium. During electrophoresis, heat evolved because of the passage of current through a resistive medium can cause evaporation of solvent from the electrophoretic support. This drying effect draws buffer into the support, and, if significant, the flow of buffer can affect protein migration and hence the calculated mobility.

CONVENTIONAL ELECTROPHORESIS

In this section, (1) instrumentation, (2) general electrophoretic operations, (3) technical and practical considerations, and (4) types of conventional electrophoresis are discussed.

Instrumentation

Although modern electrophoresis equipment and systems vary considerably in form and degree of automation, the essential components common to all systems (Figure 12-2) include two reservoirs *(1),* which contain the buffer used in the process, a means of delivering current from a power supply via platinum or carbon electrodes *(2),* which contact the buffer, and a support medium *(3)* in which separation takes place connecting the two reservoirs. In some systems, wicks *(4)* may connect the medium to the buffer solution or directly to the electrodes. The entire apparatus is enclosed *(5)* to minimize evaporation and protect both the system and the operator. The direct current power supply sets the polarity of the electrodes and delivers current to the medium.

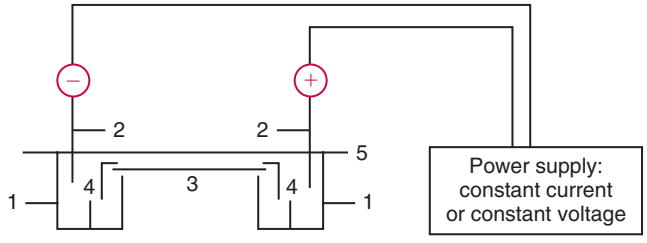

Figure 12-2 A schematic diagram of a typical electrophoresis apparatus showing two buffer boxes with baffle plates *(1),* electrodes *(2),* electrophoretic support *(3),* wicks *(4),* cover *(5),* and power supply.

Power Supplies

The power supply drives the movement of ionic species in the medium and allows adjustment and control of the current or the voltage. With more sophisticated units, the power may be controlled as well, and conditions may be programmed to change during electrophoresis. Capillary systems use power supplies capable of providing voltages in the kilovolt range.

Current flowing through a medium that has resistance produces heat:

$$Heat = (E)(I)(t) \quad \textbf{(6)}$$

where

E = EMF in volts (V)
I = current in amperes (A)
T = time in seconds (s)

This heat is released into the medium and increases the thermal agitation of all dissolved ions, and therefore the conductance of the system (decreases resistance). With constant-voltage power supplies, the resultant rise in current increases both protein migration and evaporation of water from the medium. Any water loss increases the ion concentration and further decreases the resistance *(R).* Under these circumstances, the current and therefore the migration rate will progressively increase. To minimize these effects, it is best to use a constant-current power supply. According to Ohm's law,

$$E = (I)(R) \quad \textbf{(7)}$$

Therefore if R decreases, the applied EMF also decreases, keeping the current constant. This in turn decreases the heat effect and stabilizes the migration rate.

For *isoelectric focusing (IEF)* (see later section), a power supply that provides constant power is advisable. During electrophoresis, current drops significantly because of lower conductivity as carrier ampholytes focus at their isoelectric points, and because of creation of zones of pure water. If a constant voltage supply is used, frequent voltage adjustments may be necessary. As a result, constant current power supplies are not customarily used in IEF. *Pulsed-power* or *pulsed-field* techniques (see later section) require a power supply that can periodically change the orientation of the applied field relative to the direction of migration.

Buffers

Buffer ions have a twofold purpose in electrophoresis: they carry the applied current, and they set the pH at which electrophoresis is carried out. Thus they determine (1) the type of electrical charge on the solute, (2) the extent of ionization of the solute, and therefore (3) the electrode toward which the solute will migrate. The buffer's ionic strength determines the thickness of the ionic cloud (buffer and nonbuffer ions) surrounding a charged molecule, the rate of its migration, and the sharpness of the electrophoretic zones. With increasing concentration of ions, the ionic cloud increases in size,

tahir99-VRG & vip.persianss.ir

and the molecule becomes more hindered in its movement. For the separation of serum proteins, the barbital or tris-boric acid ethylenediaminetetraacetic acid (EDTA) buffers remain the most popular.

According to Joule's law, power produced when current flows through a resistive medium is dissipated as heat. This heat increases in direct proportion to the resistance, but also in proportion to the square of the current. The reduction in resistance caused by a high ionic strength buffer therefore leads to increased current and excessive heat. These buffers yield sharper band separations, but the benefits of sharper resolution are diminished by the Joule (heat) effect that leads to denaturation of heat-labile proteins or degradation of other components.

Ionic strength (also denoted by the symbol μ) is computed according to the following:

$$\mu = 0.5 \sum c_i z_i^2 \quad \textbf{(8)}$$

where

c_i = ion concentration in mol/L

z_i = the charge on the ion

The ionic strength μ of an electrolyte (buffer) composed of monovalent ions is equal to its molarity (mol/L). The ionic strength of a 1-mol/L electrolyte solution with one monovalent and one divalent ion is 3 mol/L, and for a doubly divalent electrolyte, it is 4 mol/L.

A relatively high ionic strength buffer used in *high-resolution electrophoresis* improves the separation of serum proteins into as many as 13 bands, with two or more bands in the α_1, α_2, and β-globulin regions and one or more additional bands seen in various pathologic conditions. Because of higher conductivity and the associated heat produced, it is necessary to reduce the temperature of the system to 10 to 14 °C. "Submarine" techniques, in which gels are submersed in circulating buffer cooled by an external cooling device or are supported on an electrophoresis chamber cooled by circulating water or an integral Peltier plate,[41] provide exact temperature control. Effective cooling with less precise temperature control may also be achieved using chambers designed with a sealed compartment of cooled ethylene glycol, which is in contact with the gel during running.

Because buffers used in electrophoresis are good culture media for the growth of microorganisms, they should be refrigerated when not in use. Moreover, a cold buffer is preferred in an electrophoretic run, because it improves resolution and decreases evaporation from the electrophoretic support. Buffer used in a small-volume apparatus should be discarded after each run because of pH changes resulting from the electrolysis of water that accompany electrophoresis. If volumes used are larger than 100 mL, buffer from both reservoirs may be combined, mixed, and reused up to four times.

Support Media

The support medium provides the matrix in which protein separation takes place. Various types of support media have been used in electrophoresis and range from pure buffer solutions in a capillary to insoluble gels (e.g., sheets, slabs, or columns of starch, agarose, or polyacrylamide) or membranes of cellulose acetate. Gels are cast in a solution of the same buffer to be used in the procedure and may be used in a horizontal or vertical direction. In either case, maximum resolution is achieved if the sample is applied in a very fine starting zone. Separation is based on differences in charge-to-mass ratio of the proteins and, depending on the pore size of the medium, possibly molecular size.

Starch Gel

Starch gel was the first gel medium to be used for electrophoresis (SGE) and is only of historical interest. It separated proteins by both charge-to-mass ratio and molecular size, and because proteins compacted on the surface of the gel before migrating into it, they formed narrow bands with improved resolution.

Cellulose Acetate

Cellulose acetate, a thermoplastic resin made by treating cellulose with acetic anhydride to acetylate the hydroxyl groups, also is primarily of historical interest. When dry, the membranes contain about 80% air space within the interlocking cellulose acetate fibers and are opaque, brittle films. As the film is soaked in buffer, the air spaces fill with liquid, and it becomes pliable. Samples were applied with a twin-wire applicator or the edge of a glass slide. Because of their opacity, stained membranes needed to be made transparent (cleared) for densitometry by soaking in 95 : 5 methanol : glacial acetic acid. Cleared membranes were strong and could be stored as a permanent record, but because of the necessity for presoaking and clearing, cellulose acetate has largely been replaced by agarose gel in most clinical applications.

Agarose

Agarose is a linear polymer containing alternating D-galactose and 3,6-anhydro-L-galactose monomers. It is the purified, essentially neutral fraction of agar obtained by separating agarose from agaropectin, a more highly charged fraction containing acidic sulfate and carboxylic side groups. Because the pore size in agarose gel is large enough for all proteins to pass through unimpeded, separation is based only on the charge-to-mass ratio of the protein. Advantages of agarose gel include its lower affinity for proteins and its native clarity after drying, which permits excellent densitometry. It is essentially free of ionizable groups and so exhibits little endosmosis.

Most routine procedures for agarose electrophoresis (AGE) are now performed using commercially produced, prepackaged microzone gels, and the sample is applied by means of a comb or a thin plastic template, with small slots corresponding to sample application points. The template is placed on the agarose surface, and 5- to 7-μL samples are placed on each slot. The serum sample is allowed to diffuse into the agarose for 5 minutes, excess sample is removed by blotting, and the template is removed. AGE separation for most routine serum applications requires an electrophoresis time of 20 to 30 minutes.

Polyacrylamide Gel

Polyacrylamide is a polymeric matrix consisting of linear chains of acrylamide cross-linked with bis-acrylamide. It is thermostable, transparent, strong, and relatively chemically inert, and—depending on concentration—can be made in a wide range of pore sizes. Its average pore size in a typical 7.5% gel is about 5 nm (50 Å)—large enough to allow most serum proteins to migrate unimpeded. However, proteins with a molecular radius and/or length that exceeds critical limits will be impeded in their migration. Some of these proteins are (1) fibrinogen, (2) β-lipoprotein, (3) α_2-macroglobulin, and (4) γ-globulins. Thus separation is based on both charge-to-mass ratio and molecular size (a phenomenon referred to as *molecular sieving*), and serum proteins can be resolved into more individual fractions than with agarose gel. Furthermore, these gels are uncharged, thus eliminating electroendosmosis. Precast minigels are available in a variety of concentrations and acrylamide-to-bis-acrylamide ratios suitable for most protein or nucleic acid separations. Because of the potential carcinogenicity of acrylamide, however, appropriate caution must be exercised when handling this material if gels are prepared by hand.

Attempts to improve the hydrophilic nature of polyacrylamide have led to the development of mono- and di-substituted monomers, one of which is *N*-acryloyl-tris(hydroxymethyl) aminomethane, or poly NAT™.[5] This material is more hydrophilic than polyacrylamide, and its matrix has larger pores, thereby presenting less resistance to the passage of large molecules. It is ideally suited to the separation of DNA fragments up to 20 kilobases (kb) in size using a homogeneous (non-pulsed) electric field. Fragments that differ in size by as little as 2% can be resolved. Gels are submersed in buffer during use, allowing temperatures to be tightly controlled at values between 50 and 60 °C. Use of elevated temperatures results in shorter run times and more reproducible band migration.

Automated Systems

Because of increased volume of testing, primarily for serum proteins, many laboratories are converting to automated systems for electrophoresis. Such a system is the Helena SPIFE 4000 (Helena Laboratories, Beaumont, Tex), an automated electrophoresis system providing automated reagent application and a variety of gel sizes that permit analysis of 10 to 100 samples simultaneously. It also features (1) in-line sample application, (2) automated electrophoretic separation and staining of analytes, (3) multiple staining capability, and (4) positive sample identification. The Interlab Microgel system (Interlab Srl, Rome, Italy) also fully automates the process and integrates (1) sample application, (2) temperature-controlled electrophoresis, (3) staining, and (4) densitometry into a single unit with the capability of managing four gels simultaneously. Other systems that have partially automated the procedure or incorporated the ability to process sequentially multiple gels of different compositions include the (1) Phast System (Pharmacia LKB, Gaithersburg, Md), (2) HITE Fractoscan (Olympus, Invicon, München, Germany), (3) Hydragel-Hydrasys (Sebia Inc., Durham, NC), and (4) High-Performance Gel Electrophoresis (HPGE)-1000 system (LabIntelligence Inc., Belmont, Calif). Most CE systems (see "Capillary Electrophoresis" section) have autosampling capability for sequentially processing specimens, but the Sebia Capillarys permits simultaneous processing of seven samples by using multiple capillaries. Newer microchip-based analyzers like the Agilent 2100 Bioanalyzer (Agilent Technologies Inc., Santa Clara, Calif) significantly miniaturize and increase the speed of the process for separating proteins, nucleic acids, or even entire cells. These advances substantially reduce the labor component associated with this technique.

General Operations

General operations performed in conventional electrophoresis include (1) separation, (2) detection, (3) quantification, and (4) a number of "blotting" techniques.

Electrophoretic Separation

When electrophoresis is performed on precast microzone agarose gels, the following steps are typical: (1) excess buffer is removed from the support surface by blotting, taking care that bubbles are not present; (2) 5 to 7 μL of sample is applied using a comb or a plastic template and is allowed to diffuse into the gel; it is then blotted to remove the excess; (3) the gel is placed into the electrode chamber; (4) electrophoresis is performed at specified current, voltage, or power; (5) the gel is rinsed, fixed, and then dried; (6) the gel is stained and redried; and (7) the gel is scanned in a densitometer. If isoenzymes are to be determined, substrate dye solution is incubated on the gel to stain zones before fixing and drying. Alternative procedures would be required if the more sophisticated methods described later are used.

Detection and Quantification

Once separated, proteins may be detected by staining followed by quantification using a densitometer, or by direct measurement using an optical detection system set at 210 nm.

Staining

If staining is used to visualize separated proteins, the proteins usually are fixed first by precipitating them in the gel with a chemical agent such as acetic acid or methanol. This prevents diffusion of proteins out of the gel when submersed in the stain solution. The amount of dye taken up by the sample is affected by many factors, such as the type of protein and the degree of denaturation of the proteins by fixing agents.

Table 12-1 lists dyes commonly used in electrophoresis, along with suggested wavelengths for quantification by densitometry. Most commercial methods for serum protein electrophoresis use Amido Black B or members of the Coomassie Brilliant Blue series of dyes for staining. Isoenzymes are typically visualized by incubating the gel in contact with a solution of substrate, which is linked structurally or chemically to a dye before fixing. Silver nitrate and silver diammine stain proteins and polypeptides with sensitivity 10- to 100-fold greater than that of conventional dyes.[52] Selective fixing and

TABLE 12-1 Suggested Wavelengths for Quantitation of Protein Zones by Direct Densitometry After Staining

Separation Type	Stain	Nominal Wavelength, nm
Serum proteins in general	Amido Black (Naphthol Blue Black)	640
	Coomassie Brilliant Blue G–250 (Brilliant Blue G)	595
	Coomassie Brilliant Blue R–250 (Brilliant Blue R)	560
	Ponceau S	520
Isoenzymes	Nitrotetrazolium Blue	570
Lipoprotein zones	Fat Red 7B (Sudan Red 7B)	540
	Oil Red O	520
	Sudan Black B	600
DNA fragments	Ethidium bromide (fluorescent)	254 (Ex) 590 (Em)
CSF proteins	Silver nitrate	—

CSF, Cerebrospinal fluid.

staining of protein subclasses also can be achieved by combining a stain molecule with an antiglobulin, as is done in immunofixation.

Improvements in conducting sensitive measurements have been achieved by linking an enzyme such as alkaline phosphatase or peroxidase to a single or double antibody specific for particular proteins such as oligoclonal immunoglobulin (Ig)G,[53] or by spraying separated proteins with luminal and peroxide to develop chemiluminescence, which, in turn, exposes x-ray film to form a permanent image.[64] Chemiluminescence has been used in this way to quantify IgE (Lumi-Phos 530, Lumigen, Inc., Southfield, Mich),[67] and DNA fragments have been detected by linking with a fluorescent dye label.[35]

In practice, a typical stain solution may be used several times before it is replaced. A good rule of thumb is that a stain solution of 100 mL may be used for a combined total of 387 cm^2 (60 in^2) of agarose film. The stain solution may be considered faulty if leaching of stained protein zones occurs in the 5% acetic acid wash solution. Whenever protein zones appear too lightly stained, the stain or substrate reagent—in the case of isoenzymes—should always be suspected. Stain solution must be stored tightly covered to prevent evaporation.

Quantification

A *densitometer* is used to quantify stained zones. This instrument measures the absorbance of each fraction as the gel (or other medium) is moved past a photometric optical system and displays an *electropherogram* on a recorder chart or computer display. Microprocessor-containing units automatically integrate the area under each peak and report each as a percent of total or as absolute concentration or activity computed from the total protein or activity of enzyme in the sample.

Reliable densitometric quantitation requires (1) light of an appropriate wavelength, (2) linear response from the instrument, and (3) a transparent background in the medium being scanned. Linearity may be tested with a neutral density filter designed with separated or adjacent areas of linearly increasing density. The densities are permanent and have expected absorbance values. The very small sample sizes used and the transparency of agarose gels satisfy the requirement for a clear background. Nevertheless, problems occur with densitometry because of differences in the quantity of stain taken up by individual proteins and differences in protein zone sizes.

Essential features of a densitometer include (1) the ability to scan gels 25 to 100 mm in length; (2) electronic adjustment of the most intense peak to full scale; (3) automatic background zeroing (peaks are not lost or "cut off"); (4) variable wavelength control over the range of 400 to 700 nm; (5) variable slits to allow adjustment of the beam size; (6) an integrating device with both automatic and manual selection of cut points between peaks; and (7) automatic indexing, a feature that advances the electrophoresis strip from one sample channel to the next.

Desirable features of a densitometer include computerized integration and printout, built-in diagnostics for instrument troubleshooting, choice of one of several scanning speeds, and ability to measure in the reflectance mode. Models with a separate computer for data processing permit storage and reformatting of data, if desired, and reprinting or delayed transmission to a host computer.

DNA analysis requires the ability to scan larger gels, which may contain several dozen bands of DNA fragments of different length. Modern automated electrophoresis systems also use larger gels containing 30 or more samples, which are scanned on a new generation of densitometers referred to as *flat bed scanners* or *digital image analyzers.* These instruments are capable of scanning and storing digitized light intensity readings from large areas and use ultrasensitive charge-coupled device (CCD) detectors having a resolution of up to 1200 dots per inch (21 μm). Sophisticated data processing software permits manipulation of stored image information to produce conventional scans and computations or more complex outputs, such as overlaying and subtraction of patterns from two different samples.

Blotting Techniques

In 1975, Edward Southern developed a technique that is widely used to detect fragments of DNA. This technique, known as *Southern blotting*,[24] first requires electrophoretic

separation of DNA or DNA fragments by AGE. Next, a strip of nitrocellulose or a nylon membrane is laid over the agarose gel, and the DNA or DNA fragments are transferred or "blotted" onto it by capillary, electro-, or vacuum blotting. They are then detected and identified by hybridization with a labeled, complementary nucleic acid probe. This technique is widely used in (1) molecular biology for identifying a particular DNA sequence; (2) determining the presence, position, and number of copies of a gene in a genome; and (3) typing DNA (see Chapters 17, 38, and 39 for further details).

Northern and *Western* blotting techniques,[24] named by analogy to Southern blotting, were subsequently developed to separate and detect ribonucleic acids (RNAs) and proteins, respectively. Northern blotting is carried out identically to Southern blotting except that a labeled RNA probe is used for hybridization. Western blotting is used to separate, detect, and identify one or more proteins in a complex mixture. It involves first separating the individual proteins by polyacrylamide gel and then transferring or "blotting" onto an overlying strip of nitrocellulose or a nylon membrane by electro-blotting. The strip or membrane is then reacted with a reagent that contains an antibody raised against the protein of interest.

Technical and Practical Considerations

In performing electrophoretic separations, a number of technical and practical aspects need to be considered, as they affect the process.

Sampling

To achieve a proper balance between sensitive measurements and resolution, the amount of serum protein applied to an electrophoretic support must be optimum. Albumin is about 10 times more concentrated in serum than the smallest fraction, the α_1-globulins. Therefore, the amount of serum applied should prevent overloading with albumin, but should still be adequate to quantify α_1-globulin. For separation of serum proteins using polyacrylamide gel electrophoresis (PAGE), 3 µL of serum containing approximately 210 µg of total protein is applied. For alkaline phosphatase isoenzymes, up to 25 µL of a normal serum may be applied (less may be used if activity is greatly increased). Urine specimens require 50- to 100-fold concentration or extended application time for adequate sensitivity, and CSF may or may not require concentration, depending on the staining approach used.

Discontinuities in Sample Application

Discontinuities in sample application may be caused by (1) dirty applicators, (2) uneven absorption by sample combs, or (3) inclusion of an air bubble if sample is pipetted onto the gel. The pipette tip should be checked for air bubbles before sample is applied to the agarose gel template.

Unequal Migration Rates

Unequal migration of samples across the width of the gel may be caused by dirty electrodes, which may cause uneven application of the electric field, or by uneven wetting of the gel. If wicks are used to connect the gel to a power supply, uneven wetting of the wicks could cause unequal migration or bowing of sample lanes at the gel edges. Gels must be kept horizontal during storage to avoid sagging and uneven thickness. Finally, gels that may have been stored too close to heat sources (e.g., in a cabinet over a light fixture) could have partially and unevenly dried areas, contributing to similar problems.

Distorted, Unusual, or Atypical Bands

Distorted protein zones may be caused by bent applicators, incorporation of an air bubble during sample application, overapplication, or inadequate blotting of the sample. Distorted zones may also be caused by excessive drying of the electrophoretic support before or during electrophoresis. Irregularities (other than broken zones) in the sample application probably are due to excessively wet agarose gels. Portions of applied samples may look washed out.

In most cases, unusual bands are artifacts that may be easily recognized. Hemolyzed samples are frequent causes of increased β-globulin (where free hemoglobin migrates) or an unusual band between the α_2- and β-globulins, the result of a hemoglobin–haptoglobin complex. A band occurring at the starting point of an electropherogram may be fibrinogen. The sample should be verified as being serum before this band is reported as an abnormal protein. The α- and β-lipoproteins may migrate ahead of their normal positions in some samples. Occasionally, a split albumin zone is observed in the rare, benign, genetically related condition of bis-albuminemia. However, a grossly widened albumin zone could be due to albumin-bound medication and not to faulty practice of electrophoresis.

Atypical bands in an isoenzyme pattern may be the result of binding by an immunoglobulin (a macroenzyme), causing abnormal migration of one or more of the normal isoenzymes. Occasionally, an irregular but sharp protein zone is seen at the starting point. Unlike fibrinogen or other proteins that may be seen at about the same point, the artifact lacks the regular, somewhat diffuse appearance that proteins normally show; it is actually denatured protein resulting from deteriorated serum. When faced with an unusual band anywhere in a serum protein pattern, the possibility that it is a true paraprotein must always be considered. Finally, it is good laboratory practice to include a control serum with each electrophoretic run to evaluate its quality and that of the densitometer.

Types of Electrophoresis

With different media in different physical formats and a variety of instrumental configurations, several different types of electrophoretic techniques are used for the separation of a diverse range of analytes.

Slab Gel Electrophoresis

Traditional methods, using a rectangular gel regardless of thickness, are referred to collectively by the term *slab gel electrophoresis*. Its main advantage is its ability to simultaneously separate several samples in one run. Starch, agarose,

and polyacrylamide media have all been used in this format. It is the primary method used in clinical chemistry laboratories for separation of various classes of serum or CSF proteins and DNA and RNA fragments. Gels (usually agarose) may be cast on a sheet of plastic backing or completely encased within a plastic-walled cell, which allows horizontal or vertical electrophoresis and submersion for cooling, if necessary.

Slab gels may be cast with additives such as (1) ampholytes, which create a pH gradient (see "Isoelectric Focusing Electrophoresis"), or (2) sodium dodecyl sulfate (SDS), which denatures proteins [see "Two-Dimensional (2D) Electrophoresis"]. In some applications, a gradient of concentration or denaturant is created in the gel to improve separation.[14] Very thin gradient or nongradient gels have been used to improve the efficiency and speed of separation of DNA fragments.[63] In addition to conventional serum proteins, applications include separation of isoenzymes, lipoproteins, hemoglobins, and fragments of DNA and RNA. One-dimensional separations of the last two often involve the addition of a mixture of known fragment size markers, referred to as a *ladder,* in one lane to enable size identification of sample fragments.

Disc Electrophoresis

Protein electrophoresis using agarose gel yields only five zones, namely, (1) albumin, and (2) α_1-, (3) α_2-, (4) β-, and (5) γ-globulins, although some subfractionation of the α_2- and β-globulins is possible with high-resolution gels. *Disc electrophoresis* was developed by Davis and Ornstein to improve this situation and derived its name from *discontinuities* in the electrophoretic matrix caused by layers of polyacrylamide or starch gel that differ in composition and pore size. These gels may yield 20 or more fractions and were widely used to study individual proteins in serum, especially genetic variants and isoenzymes.

With this technique, samples are separated in a three-gel system prepared in situ. Such a system is constructed of a small-pore *separation gel,* followed by a thin segment of large-pore *spacer gel,* then another thin layer of large-pore monomer solution containing a small amount of serum—about 3 µL—was polymerized in open-ended glass tubes. When electrophoresis begins, all protein ions stack up on the separation gel in a very thin zone. This process improves resolution and concentrated protein components so that preconcentration of specimens with low protein content (e.g., CSF) may not be necessary. A schematic representation of serum protein electrophoresis is shown in Figure 12-3.

Isoelectric Focusing Electrophoresis

IEF separates amphoteric compounds, such as proteins, with increased resolution in a medium possessing a stable pH gradient. The protein becomes "focused" at a point on the gel as it migrates to a zone where the pH of the gel matches the protein's isoelectric point (pI). At this point, the charge of the protein becomes zero, and its migration ceases. Figure 12-4 illustrates the procedure and shows the electrophoretic conditions before and after current is applied. The protein zones are very sharp, because the region associated with a given pH

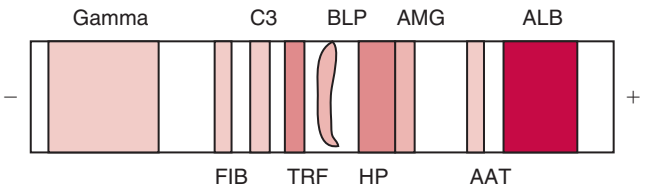

Figure 12-3 A simplified schematic drawing of a protein pattern from the serum of a subject with haptoglobin type 2-1 [separation by polyacrylamide gel electrophoresis (PAGE)]. Some zones contain more than the one protein shown, as demonstrated by immunologic techniques. *AAT,* α_1-Antitrypsin; *ALB,* albumin; *AMG,* α_2-macroglobulin; *BLP,* β-lipoprotein; *C3,* complement 3; *FIB,* fibrinogen; *gamma,* γ-globulin; *HP,* haptoglobin; *TRF,* transferrin.

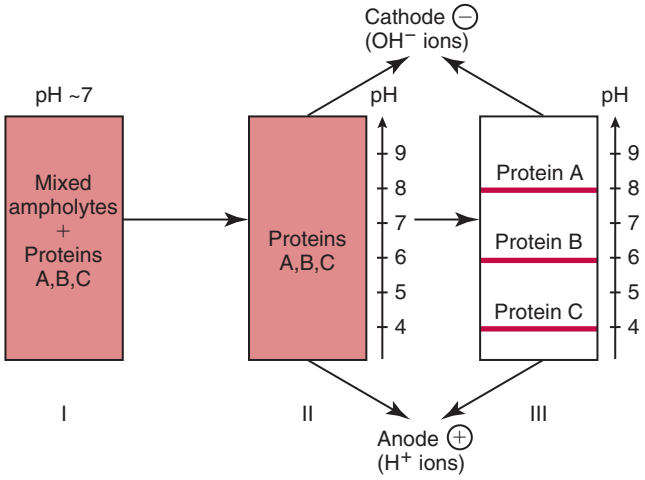

Figure 12-4 Schematic of an isoelectric focusing (IEF) procedure. *I,* A homogeneous mixture of carrier ampholytes, pH range 3 to 10, to which *proteins A, B,* and *C,* with isoelectric point (pI) of 8, 6, and 4, respectively, were added. *II,* Current is applied and carrier ampholytes rapidly migrate to pH zones where the net charge is zero (the pI value). *III, Proteins A, B,* and *C* migrate more slowly to their respective pI zones, where migration ceases. The high buffering capacity of the carrier ampholyte creates stable pH zones in which each protein may reach its pI.

is very narrow. Ordinary diffusion is also counteracted by the acquisition of a charge, as a protein varies from its pI position and subsequently migrates back because of electrophoretic forces (Figure 12-5). Proteins that differ in their pI values by only 0.02 pH unit have been separated by IEF.

The pH gradient is created with *carrier ampholytes,* a group of amphoteric polyaminocarboxylic acids that have slight differences in pKa value and molecular weights of 300 to 1000. Mixtures of 50 to 100 different compounds are added to the medium and create a "natural pH gradient" when individual ampholytes reach their pI values during electrophoresis. They establish narrow buffered zones, with stable but slightly different pHs, through which the slower-moving proteins migrate and stop at their individual pIs.

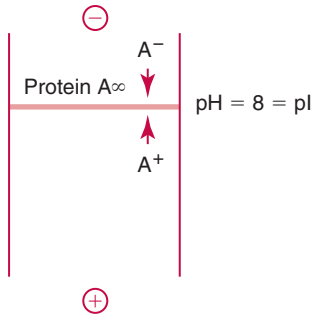

Figure 12-5 After the pH where protein A has a net charge of zero (Å) is attained, diffusion toward the cathode bestows a negative charge on A (A^-), and migration in the electric field forces A^- back to Å. Diffusion toward the anode causes A to take on the opposite charge A^+, and migration is toward the cathode and toward the point where Å exists. Isoelectric focusing processes of this type cause focus of proteins and formation of sharp zones.

As Figure 12-4 illustrates, the anode is surrounded by a dilute acid solution, and the cathode by a dilute alkaline solution. After focusing, the most negatively charged carrier ampholytes and proteins will be found at the anodal end, and the most positively charged near the cathodal end of the electrophoretic matrix. The other carrier ampholytes and proteins focus at intermediate points according to their isoelectric points. Because carrier ampholytes are generally used in relatively high concentrations, a high-voltage power source (up to 2000 V) is necessary (power is in the vicinity of 2 to 50 W, depending on experimental conditions). As a result, the electrophoretic matrix must be cooled. A modification of this technique (IPG-IEF), in which an immobilized pH gradient (IPG) is produced in the gel before the sample is applied, is reported to improve resolution and reproducibility.[13]

PAGE-IEF is widely used in analytical work, as it is essentially free of electroendosmosis. The polyacrylamide gel must have a large enough pore size, however, that protein migration will not be impeded by molecular sieving effects. In actual practice, impeded migration of some proteins, such as IgM, cannot be prevented. AGE-IEF has the advantages that operating conditions are simple, and that large pore sizes make it unlikely that any proteins will be excluded on the basis of molecular size. IEF has been applied to the separation of alkaline phosphatase isoenzymes and is widely used in neonatal screening programs to test for variant hemoglobins (see Chapter 32). Off-gel techniques carry out the separation in free solution with sample containing ampholytes loaded into each of a linear series of wells separated by semipermeable membranes and in contact with a pH gradient strip. Electrophoresis separates sample proteins into different wells depending on their pI values. Separated fractions are further resolved in a second similar focusing step or taken directly to further separation by 2D electrophoresis (see later section) or liquid chromatography-mass spectrometry (LC-MS/MS; see Chapter 14).[17,73] This technique has been useful in the study of the human proteome.

Isotachophoresis

ITP completely separates smaller ionic substances into adjacent zones that contact one another with no overlap, and all migrate at the same rate. In this technique, background electrolyte (buffer) is not mixed with the sample, so current flow is carried entirely by charged sample ions. An aliquot of a sample is typically placed in a capillary between a leading electrolyte solution that contains faster-migrating ions than any in the sample and a trailing solution containing slower-migrating ions than any in the sample. Once a faster-moving component separates completely from a slower-moving one, any further separation creates a region of depleted charge and increases the resistance and therefore the local voltage in that region. Increased voltage causes the slower component to migrate faster and close the gap, thereby concentrating it and increasing the conductivity of its zone until it matches that of the faster ion. Ultimately, all ions migrate at the rate of the fastest ion in zones that differ in size depending on their original concentrations. Zone size is determined by measuring ultraviolet (UV) absorbance, temperature difference, or conductivity as the sample passes a detector. Applications include the separation of small anions and cations, organic and amino acids, and peptides, nucleotides, nucleosides, and proteins.

Pulsed-Field Electrophoresis

In pulsed-field electrophoresis, power is alternately applied to different pairs of electrodes or electrode arrays, so the electrophoretic field is cycled between two directions. The directions can differ spatially by 105° to 180°, and molecules must reorient themselves to the new field direction during each cycle before migration can continue. Because reorientation time depends on molecular size, net migration becomes a function of the frequency of field alteration. This permits separation of very large molecules, such as DNA fragments greater than 50 kb, which cannot be resolved by the relatively small pores in agarose or polyacrylamide gels.[46] Fragments of 50 to 400 kb can be resolved using 10-s pulse times, whereas larger fragments up to 7 megabases in size or intact chromosomes require pulse times of several hours for complete resolution. This technique has been applied to typing various strains of bacterial DNA for research or epidemiologic studies.[10,19,54,56]

Two-Dimensional (2D) Electrophoresis

Two-dimensional (2D) electrophoresis is extensively used in the field of proteomics to study families of proteins and search for genetic- or disease-based differences, or to study the protein content of cells of various types.[37] It has also been applied to the study of human gene mutations[68] and the DNA of various bacteria and tumor cells as a means to earlier diagnosis.[14,51] By combining charge-dependent IEF in the first dimension with molecular weight–dependent electrophoresis in the second, the technique is able to resolve up to 1100 separate protein spots using autoradiographic detection, and up to 400 using Coomassie dyes. The first-dimension separation is carried out in a large-pore medium, such as agarose

gel or large-pore polyacrylamide gel. The second dimension is often polyacrylamide in a linear or gradient format.

Conventional 2D electrophoresis uses PAGE-IEF in 130 × 2.5-mm (internal diameter) tubes for the first dimension and covers a pH range of 3 to 10 units. After electrophoresis is complete, the gel is extruded from the tube and is placed in contact with a thin, polyacrylamide gradient gel slab that incorporates SDS. At the end of the process, the polypeptides are detected by one of several different methods. SDS is commonly used in the second dimension, because it denatures proteins to polypeptides by reducing disulfide bonds and depolymerizing proteins. When native proteins, such as enzymes, are desired for further study, nondenaturing sample preparation and electrophoresis conditions must be used.

Separated proteins are detected by the use of Coomassie dyes, silver staining, radiography (exposure of photographic film to emissions of isotopically labeled polypeptides or chemiluminescence), or fluorographic analysis (x-ray film exposed to tritium-labeled polypeptides in the presence of a scintillator). The latter two methods represent the most sensitive methods and are 100 to 1000 times more sensitive than staining with Coomassie dyes. Difference gel electrophoresis (DIGE) permits two samples to be compared on the same 2D gel by labeling each with a different fluorophor. Although each separated spot contains protein from both samples, selective excitation and scanning software allow differences in expression to be qualitatively identified.[47,59]

Newer developments in this area combine analytical techniques to achieve 2D separation by linking, for example, liquid IEF with nonporous silica reverse-phase high-performance liquid chromatography (HPLC; see Chapter 13) and detecting intact proteins by electrospray ionization, time of flight, and mass spectrometry[65,66,71] (see Chapter 14).

CAPILLARY ELECTROPHORESIS

With CE, the classic techniques of (1) zone electrophoresis, (2) ITP, (3) IEF, and (4) gel electrophoresis are carried out in a small-bore (10- to 100-µm internal diameter) fused silica capillary tube, 20 to 200 cm in length.[44]

Two distinct advantages of the capillary format include the (1) ability to apply much higher voltages than in traditional electrophoresis and (2) ease of automation. Applications are also more extensive and include separation of low molecular weight ions, in addition to proteins and other macromolecules. Even uncharged molecules can be separated using CE in the micellar electrokinetic chromatography (MEKC) mode discussed later in this section. CE has also proved useful for separation of (1) inorganic ions, (2) amino acids, (3) organic acids, (4) drugs, (5) vitamins, (6) porphyrins, (7) carbohydrates, (8) oligonucleotides, (9) proteins, and (10) DNA fragments.[9,26,62,74]

Instrumentation

A schematic diagram of a typical instrumental configuration for CE is shown in Figure 12-6. As indicated, the capillary serves as an electrophoretic chamber, analogous to a lane on a gel, that is connected to buffer reservoirs at either end, which, in turn, are connected to a high-voltage power supply. It is important to note that at some point along the length of the capillary (typically close to the end), a detector is interfaced for online detection. Improved heat dissipation from the capillary (as opposed to a slab gel) permits the application of voltages in the range of 10 to 30 kV, which enhances separation efficiency and reduces separation time, in some cases to less than 1 minute. Only a few microliters of the sample are required, with injected volumes in the nanoliter range. The small sample plug volume minimizes distortions in the applied field caused by the presence of analytes or other sample species.

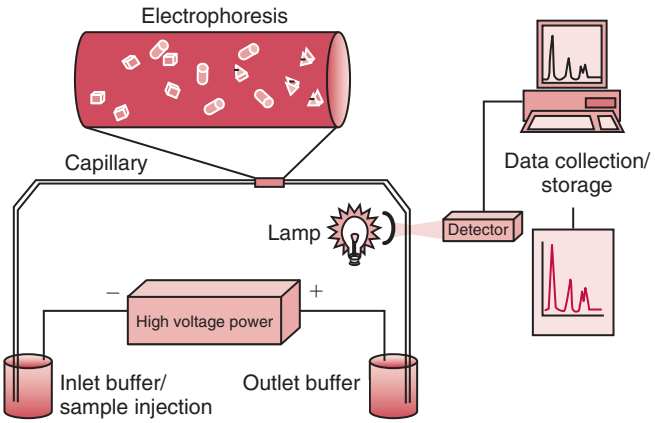

Figure 12-6 A schematic for capillary electrophoresis (CE) instrumentation.

In contrast to the cumbersome and time-consuming tasks of conventional electrophoresis, CE is easily automated. Analogous to HPLC technology, samples typically are stored in a temperature-controlled environment and are automatically injected into the capillary, with a variety of detector types available; the resulting electropherograms are analyzed and manipulated in much the same manner as chromatograms.

The Capillary Format

The capillaries used as separation columns in CE are most commonly made from fused silica (pure glass) coated with a thin exterior covering of polyimide to provide strength and flexibility. Although capillaries have been made from other materials, such as polyethylene or Teflon, such capillaries have seen limited use. The polyimide coating is usually removed from a small portion of the capillary close to the terminal end, creating a window for online optical detection. The outer diameter of the capillary tubing typically varies from 180 to 375 µm, the inner diameter from 20 to 180 µm, and the total length from 20 cm up to several meters. Noncylindrical capillary tubing suitable for CE is now available from some commercial providers. For example, rectangular capillaries (Polymicro Technologies, Phoenix, Ariz) provide a flat surface that is more amenable to optical detection than that of their curved counterparts.

Sample Injection

In CE, sample volumes of 1 to 50 nL are loaded into the capillary by (1) *hydrodynamic injection* or (2) *electrokinetic (EK) injection*. With hydrodynamic injection, an aliquot of a sample is introduced by applying positive pressure at the inlet vial or vacuum at the outlet vial. The volume of sample loaded is governed by a number of parameters, including (but not limited to) (1) the inner diameter of the capillary, (2) buffer viscosity, (3) applied pressure, (4) temperature, and (5) time. With some earlier commercial or homemade systems, gravity was used as the source of pressure by raising the inlet vial (or lowering the outlet vial), thus allowing "siphoning" to occur for a timed interval. With EK injection, an aliquot of a sample is introduced by applying a voltage for a timed interval. The magnitude of the voltage is dependent on the analyte and buffer system used but typically involves field strength three to five times lower than that used for separation. It is important to note that although hydrodynamic methods introduce a sample representative of the bulk specimen, EK injection favors the preferential movement of more electrokinetically mobile analytes into the capillary.

In practice, to maintain high separation efficiency, the sample plug length is usually less than 2% of the total capillary length.

Direct Detection

With CE, separated analytes are detected and measured as they migrate past a point on the capillary that is optically interrogated. Optical detection is based on classical methods, such as (1) photometric absorbance, (2) refractive index, and (3) fluorescence (see Chapter 10). As with HPLC, ultraviolet-visible photometers are widely used as detectors to monitor CE separations.[49] To interface such online detectors with the capillary, a *detection window* is created toward the outlet end of the capillary. This "window," which serves as an inline cuvet, typically is formed by burning off the polyimide with a small flame and cleaning the window with ethanol. This configuration allows high-efficiency separation, with the inner diameter of the capillary tube defining the optical path length (OPL) of the inline cuvet. Because absorbance is directly proportional to the length of the cuvet (OPL) used in an optical system, the 20- to 100-µm inner diameter of the capillary limits UV-visible absorbance detection limits to concentrations of 10^{-8} to 10^{-6} mol/L.

Improving Limits of Detection

Several approaches have been devised to improve the limit of detection of online CE detectors. These include (1) increasing the diameter of the OPL, (2) using more sensitive optical techniques, and (3) preconcentrating the sample.

Increased OPL. Capillary tubes modified at the detector window with a "bubble" cell (a glass-blown expansion of the internal diameter of the capillary tube) can increase the detection capability of the OPL by almost an order of magnitude, with concomitant lowering of the system's limit of detection. Alternatively, a "Z" geometry has been developed that increases the OPL via detection down the core of the capillary, with possible lengths up to 1 mm.

Sensitive Optical Detectors. Sensitive optical techniques that have been used with CE include (1) fluorescence, (2) refractive index, (3) chemiluminescence, (4) Raman spectrophotometry, and (5) circular dichroism.[62] The most sensitive optical detection method used in CE is laser-induced fluorescence (LIF), which is capable of detection limits in the 10^{-18} to 10^{-21} mol/L (or lower) range. This detection mode is easily accomplished with analytes that may be easily labeled with a fluorescent substrate (e.g., intercalators for double-stranded DNA) or may be naturally fluorescent (e.g., proteins or peptides containing tryptophan). CE systems have also been interfaced with mass spectrometers,[58] and electrochemical detection methods[15] have been developed, although such detectors must be isolated electrically from the electrophoretic voltages.

Online Sample Concentration. Another technique used in CE systems to enhance their limit of detection is preconcentration of the sample. One of the simplest methods for sample preconcentration is to induce a "stacking" effect with the sample components, which is accomplished by exploiting the ionic strength differences between the sample matrix and the separation buffer.[6] This results from the fact that sample ions have decreased electrophoretic mobility in a higher conductivity environment. When voltage is applied to the system, sample ions in the sample plug instantaneously accelerate toward the adjacent separation buffer zone. Upon crossing the boundary, the higher conductivity environment induces a decrease in electrophoretic velocity and subsequent "stacking" of the sample components into a smaller buffer zone than the original sample plug. Within a short time, the ionic strength gradient dissipates and the charged analyte molecules begin to move from the "stacked" sample zone toward the cathode. Stacking has been used with hydrostatic or EK injection and typically yields a tenfold enhancement in sample concentration, resulting in a lower limit of detection.

An alternative approach to stacking is "focusing" a technique that is based on pH differences between the sample plug and the separation buffer. This has been shown to be very useful for analysis of peptides, mainly because of their relative stability over a wide pH range.[1] By increasing the pH of the sample to above that of the net pI of the analytes of interest and flanking the sample plug with low pH separation buffer zones (i.e., an equivalent volume of low pH separation buffer following introduction of the sample plug), negatively charged peptides are electrophoretically driven toward the anode. Upon entering the lower pH separation buffer, a pH-induced change in their charge state causes a reversal in their electrophoretic mobility, resulting in "focusing" of the peptides at the interface of the sample (high pH) and low pH buffer plugs (similar to those in isoelectric focusing). After the pH gradient dissipates, the peptides, again positively charged, migrate toward the cathode as a sharp zone. This approach has been applied to a variety of analytes but is limited to those that are able to withstand inherent changes in pH without substantial denaturation, and may yield as

much as a fivefold enhancement of a system's limit of detection.[61]

Other types of sample concentration enhancement approaches applicable to CE include ITP[69] and those involving concentration of an online solid phase.[50] This latter method shows much promise for both small and large molecules and is discussed in detail in the review by Wettstein and Strausbauch.[70]

Indirect Detection

When strong chromophores are lacking in the analyte of interest, absorbance and fluorescence detection have been used in an indirect mode.[11,34,42] With the absorbance technique, a strongly absorbing ion is added to the running electrolyte and is monitored at a wavelength that gives a constant, high background absorbance. As solute ions move into their discrete zones during the electrophoretic process, they displace the indirect detection agent through mutual repulsion, and this produces a decrease in background absorbance as the zone passes through the detector. Reagents with appropriate fluorescence properties have been employed in a similar manner. Indirect detection of amino acids by CE has been demonstrated, with the potential for use in diagnosis of aminoacidurias.[38] Investigators have demonstrated the direct extrapolation of this technique to microchip detection when UV detection is difficult, if not impossible.

Technical Considerations

Temperature and surface effects influence the separation capabilities of CE. Artifacts also have been known to arise with CE.

Temperature Effects

In most slab or tube platforms for electrophoresis, moderate electric fields (up to 1000 volts) are used, because the Joule heating that accompanies the use of higher field strengths causes (1) nonuniform temperature gradients, (2) local changes in viscosity, and (3) subsequent zone broadening. CE is distinguished from other forms of electrophoresis by the fact that extraordinarily high fields (30,000 volts) are used to obtain rapid, high-efficiency separations. The problems encountered with noncapillary platforms are prevented by effective dissipation of Joule heat by forced air convection or liquid cooling of the capillary, both of which are possible because of the narrow bore of the capillary. The Joule heat produced is a function of (1) buffer type, (2) concentration, (3) voltage applied, (4) capillary inner diameter, and (5) length, and can be determined for any given system by generating an *Ohm's law plot,* which allows easy determination of the maximum voltage that can be used effectively.[40] Reducing the inner diameter of the capillary, the ionic strength of the running buffer, or the applied voltage will reduce the heat produced by the electrophoretic process. It should be noted that reducing the inner diameter will compromise the detection limit of UV measurements (smaller OPL); reducing the applied field is less desirable in that resolution is directly proportional to the applied field. Consequently, attempts should be made to alter other parameters before reducing inner diameter or the applied field.

Surface Effects

As in electrophoresis in general, the flow of fluid [electroosmotic or electroendosmotic flow (EOF)] in CE is a consequence of surface charge on the solid support. In CE, EOF is a significant factor in the separation process. The charge on the inner surface of a fused silica capillary is determined by the ionization state of the silanol groups (SiOH) that populate it. Interaction of positively charged buffer species with bound surface anions generates a layer of mobile cations that move toward the cathode when voltage is applied. This induces a very strong EOF that mobilizes all analytes in the same direction, regardless of their charge. Separation is consequently achieved because of differences in the electrophoretic migration rates of analytes superimposed on this EOF.

Because the driving force of the flow is distributed along the wall of the capillary, the flow profile is nearly flat or plug-like, contrasting with the laminar or parabolic flow generated by a pressure-driven system caused by shear forces at the wall. A flat flow profile is beneficial because it does not contribute to the dispersion of solute zones. The magnitude and direction of the EOF are influenced by several parameters, including (1) type of electrolyte used, (2) pH, (3) ionic strength, (4) use of additives (e.g., surfactants, organic solvents), and (5) polarity and magnitude of the applied electric field.

Although advantageous for dissipation of Joule heat, the large surface area-to-volume ratio of the inner capillary space increases the likelihood of analyte adsorption onto the surface of its inner wall. This causes phenomena such as peak tailing and even total and irreversible adsorption of the analyte. Adsorption is typically noted between cationic solutes and the negatively charged inner wall of the capillary, primarily through ionic interactions (with deprotonated silanols), but also involves hydrophobic interactions (with siloxanes). Because of the numerous charges and hydrophobic regions, significant adsorptive effects have been noted, especially for highly cationic proteins. In practice, adsorption of substances, whether from the sample or from the buffer, to the inner surface of the capillary will alter migration times and other separation characteristics; unaddressed, the capillary eventually may become "fouled." Buffer components and/or additives, such as surfactants, can often render permanent changes to the inner surface of the capillary (through adsorption) and may warrant dedication of specific capillaries for use with particular surfactants.

To minimize these inner wall effects, capillaries are conditioned by chemical treatment, most commonly with base, to remove adsorbates and rejuvenate the surface. A typical wash method includes flushing the chamber with 10 to 20 capillary volumes of 0.1 to 1.0 mol/L NaOH, followed by flushing with "run" buffer. To prevent exposing the capillary surface to drastic fluctuations in pH, conditioning procedures for separations at low pH may be better served by using strong acids (e.g., HNO_3), surfactants (e.g., SDS), or organic solvents, such as acetonitrile or methanol.

Modes of Operation

Modes in which CE systems are operated include (1) capillary zone electrophoresis (CZE), (2) MEKC, (3) capillary gel electrophoresis (CGE), (4) capillary IEF, and (5) capillary ITP.

Capillary Zone Electrophoresis

CZE, also called *open-tube* or *free-solution* CE, is the simplest form of CE. It includes *capillary ion electrophoresis,* which refers to the analysis of inorganic ions by CZE, often utilizing indirect detection. The power of the CZE mode is its ability to electrophoretically resolve charged species without a sieving matrix; this applies to a broad spectrum of analytes ranging from proteins, peptides, and amino acids to small molecules (e.g., drugs) and ions.

Serum Protein Analysis

Compared with AGE and CAE, CZE is more advantageous for serum protein analysis.[22,23,45] Figure 12-7 shows a comparison of the separation of serum proteins by (1) cellulose acetate (CAE), (2) agarose (AGE), and (3) CE. The presence of the classical zones with CE is apparent, albeit in reversed order, as is the identification of serum protein abnormalities in gamma regions. Retrospective studies have shown CE to be effective for detecting monoclonal proteins, which could then be immunotyped by conventional techniques.[45] Moreover, one study demonstrated the utility of CE in performing both serum protein electrophoresis and immunotyping for more than 1500 serum samples.[23] These and other studies put forth the same conclusion: that CE is more sensitive than AGE in identifying abnormalities. Other studies have shown the value of CZE in serum protein analysis. For example, in 2005, Luraschi and associates[31] described the use of CZE coupled with immunosubtraction to detect and characterize low concentrations of free γ-heavy chains in serum. In this study, they showed that a patient with γ-heavy chain disease could be detected by serum protein analysis in CZE in tandem with immunosubtraction. However, although studies have proven the clear utility of CZE for serum protein analysis, Bossuyt and coworkers[33] point to the fact that CZE is not flawless, describing a case where CZE failed to detect μ-heavy chain disease in a 90-year-old woman. This is countered by Maisnar and colleagues,[32] who submit that the laboratory diagnosis of patients with μ-heavy chain disease is typically challenging, and that detection of the monoclonal protein by standard electrophoretic approaches may fail in up to 75% of cases of μ-heavy chain disease. They describe a patient with multiple malignancies for whom CZE with immunotyping allowed the detection and characterization of monoclonal μ-heavy chains.

Finally, CZE for serum protein analysis is evolving in a high-throughput format that has leveraged the success of multiplexed CE systems developed for DNA analysis. Two commercial systems have evolved: the Beckman Paragon 2000 (Beckman Analytical, Milan, Italy) and Sebia CAPILLARYS (Sebia, Durham, NC). Although several studies have illustrated the potential of these systems for serum paraprotein characterization (essentially supplanting AGE and IFE),[2,12,20] studies have not yet settled the issue of paraprotein detection sensitivity and specificity for the clinical community.[3,28,29] For example, Yang and associates[75] compared the CAPILLARYS 2 system versus standard serum protein AGE for the detection and identification of monoclonal proteins in patient serum samples. After defining sensitivity for both, they concluded that AGE and CZE had the same specificity for detection of monoclonal proteins, but that CZE/immunosubtraction was slightly less sensitive than standard immunofixation in the detection of IgM and light chains.

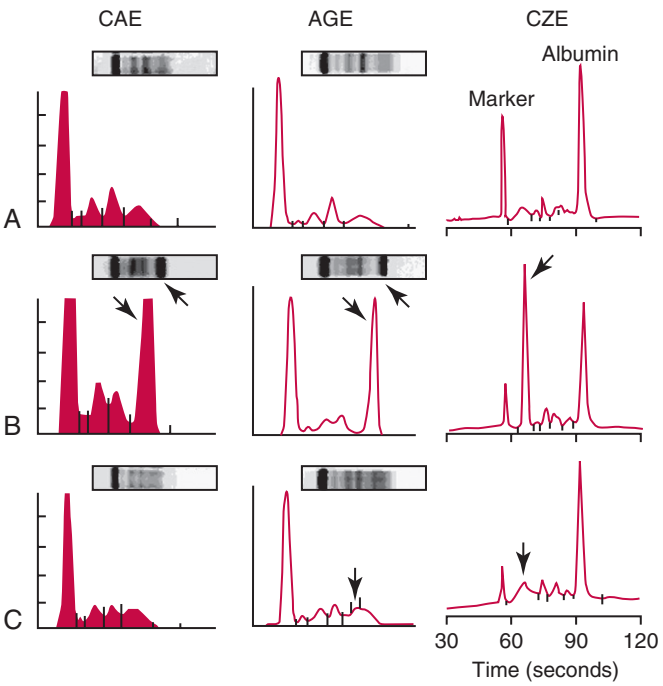

Figure 12-7 Rapid protein electrophoresis of serum protein; comparison with scanning densitometry profiles obtained from cellulose acetate (CAE) and agarose (AGE) electrophoresis. Panel A, Normal serum. Panel B, Patient serum containing a large M-protein. Panel C, Patient serum containing a small monoclonal protein. *Arrows* indicate the position of the monoclonal proteins.

Artifacts in Serum Protein Analysis

With CE utilizing online optical detection, artifacts can occur in the form of "system peaks." These often originate from the sample or from the interfaces between the sample and the separation buffer, because any species that absorbs at the detection wavelength will generate a response. This differs from protein slab gel electrophoresis, wherein detection specificity is governed by a protein-specific stain. It is not uncommon, for example, for buffer species present in the sample but not in the separation buffer to generate system peaks. However, clinical serum protein electrophoresis provides one example whereby artifacts are eliminated by CE.

One problem associated with conventional electrophoresis of serum proteins is its proclivity for point-of-application artifacts. These are bands that result from the fact that

electrophoretic mobility (e.g., with AGE) is bidirectional from the point of application. Consequently, the point of application remains part of the scanned area of interest. These bands must be immunotyped to distinguish real monoclonal proteins from artifacts—a process that is costly and time-consuming. CE prevents point-of-application artifacts in two ways. First, net mobility in CE results from the vectorial addition of both protein electrophoretic mobility and EOF. As a result of this unidirectional movement (toward the detector), the point of application is not scanned by detector. Second, unlike AGE, where precipitates cannot exit the loading well and enter the gel (thus appearing as a band in the scanned region of the gel), no gel matrix is present in CZE to impede electrophoretic migration, because analysis occurs in free solution. This was demonstrated by Clark and colleagues, who evaluated a small subset of serum samples containing monoclonal proteins that remained at the point of application on agarose gels (and cellulose acetate) but were handled by CZE with ease.[7] These precipitates may be euglobulin or cryoprecipitates and may or may not contain a monoclonal protein; only immunoelectrophoresis or immunofixation can identify the presence of monoclonal proteins.

Micellar Electrokinetic Chromatography (MEKC)

MEKC is a hybrid of electrophoresis and chromatography. MEKC, a mode that is separate and distinct from capillary electrokinetic chromatography (CEC), is an effective electrophoretic technique, because it can be used for the separation of neutral and charged solutes. The separation of neutral species is accomplished by exploiting micelles formed in the running buffer when the concentration of surfactant exceeds the critical micelle concentration (e.g., 8 to 9 mmol/L for SDS). During electrophoresis, neutral micelles can interact with analytes in a chromatographic manner through hydrophobic interactions in which analytes are micellized based on their degree of hydrophobicity. Under these conditions, partitioning into the micelle is the driving force for separation. With charged micelles (e.g., SDS), analytes can also interact through electrostatic interactions via the charge on the surface of the micelle.

Capillary Gel Electrophoresis

CGE is directly comparable with traditional slab or tube gel electrophoresis because the separation mechanisms are identical. Size separation is achieved with a suitable polymer, which acts as a molecular sieve or sizing mechanism. As charged analytes migrate through the polymer network, they become hindered to a degree that is governed by their size (larger molecules are hindered more than smaller ones). Macromolecules, such as DNA and SDS-saturated proteins, cannot be separated without a gel or some other separation mechanism, because they have a mass-to-charge ratio that is size independent. The term *gel* in CGE is a misnomer, primarily because cross-linked "gels," as we know them in slab format, are not routinely used in CE. A more suitable term is a *sieving matrix* or *soluble polymer network,* a linear polymeric structure that is soluble, has reasonably low viscosity, and is capable of self-entangling in a manner that forms pores through which sieving can occur. A variety of polymeric matrices have been defined for DNA (e.g., polyacrylamide, cellulosic materials) and protein analysis (e.g., dextran-base matrices), provided that pores can be formed inherently that have diameters in the range of tens to hundreds of nanometers. One of the requirements that often accompany this type of analysis is reduction of electro-osmotic flow. This is accomplished by covalently, adsorptively, or dynamically coating the surface. Cross-linked polyacrylamide was the main polymer of choice for this but recently has been supplanted by a host of polymeric matrices that not only provide effective molecular sieving but also adsorptively coat the capillary surface.[27,65] An example of CGE separation of DNA is provided in a later section.

Capillary Isoelectric Focusing Electrophoresis

Capillary isoelectric focusing electrophoresis (cIEF) is comparable with tube IEF and is governed by the same principles and procedures. It differs from conventional IEF in that it can be carried out using a free solution of ampholytes or a precast gel. As expected with a CE mode, and unlike conventional IEF, the focused zones migrate past the online detector during the focusing process or following it. Figure 12-8 shows an example of this, where separation by cIEF is completed in ≈15 minutes, circumventing conventional IEF protocols and/or the necessity for other electrophoretic methods (e.g., CAE), both of which are much less time efficient.[18]

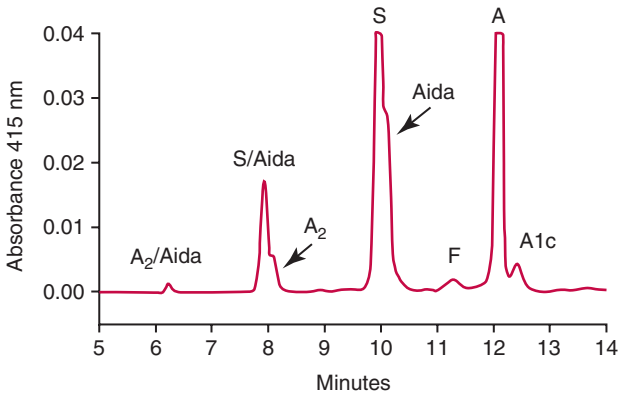

Figure 12-8 Capillary electrophoresis (CE)-based identification of uncommon hemoglobin (Hb) variants by capillary isoelectric focusing electrophoresis (cIEF).[18] Analysis of blood from a patient with Hb S/Aida trait detected the presence of seven different normal and abnormal structural Hb variants, some of which are not detectable by conventional electrophoresis because of lack of sensitivity or inadequate resolution. The four abnormal variants include Hb S, Aida, S/Aida hybrid, and A_2/Aida. Identifying ∀-variants of Hb A_2 by cIEF helps discriminate between α- and β-globin gene mutations in samples containing unknown Hb variants. Glycated Hb A (HbA_{1c}) is also apparent in the electropherogram.

Capillary Isotachophoresis

Capillary ITP has essentially the same features as ITP in other formats, except that conditions of pure ITP usually are not achieved but is not commonly used as a bonafide CE mode. Instead, it is more typically used for online sample preconcentration (as described earlier). Also, it functions as a preconcentrating step in a mixed mode with CZE, MEKC, or CGE. However, ITP may be undergoing a renaissance. Work done by groups such as the Santiago Group at Stanford is beginning to show that rigorous modeling of the process may begin to tease new capabilities and applications out of a technique that has been largely unheralded over the decades since Eaverarts first revealed it as a sample preparation technique for liquid chromatography.[57]

MICROCHIP ELECTROPHORESIS

Over the past decade, microchip electrophoresis has undergone substantial development, including (1) integrated microchip designs, (2) advanced detection systems, and (3) new applications.[8,16,30,36] In the arena of clinical diagnosis, the main analytes of interest for extrapolation to the microchip platform are proteins and DNA.[27,66A]

Among the attributes of microchip electrophoresis separation, the most notable is high speed—normally fourfold to tenfold faster than conventional CE, and at least an order of magnitude faster than the slab gel format. Other advantages of microchips include (1) simplicity, (2) capability for chip integration of multiple functions, and (3) certainly the potential for automation.

Instrumentation

Although similar in principle, instrumentally, the microchip system differs from its CE counterpart. For example, with the microchip approach, (1) separation channels, (2) sample injection channels, (3) reservoirs, and (4) sample preparation and/or (5) precolumn or postcolumn reactors are all fabricated onto the surface of a microchip, using photolithographic processes defined by the microelectronics industry (see Chapter 18 for additional details on the manufacturing of such devices). Thus creation of a truly multifunctional, "integrated" analytical device embedded in a single monolithic substrate is possible. The classic "cross-T" design of a single-channel microchip involves a short (injection) channel that intersects a longer (separation) channel and includes a reservoir at the end of each of these, as shown in Figure 12-9. The setup for LIF detection on a single-channel microchip is shown in Figure 12-10.

When solution volumes required to fill the architecture are compared, it is seen that the volume of the separation channel on a microchip is roughly an order of magnitude smaller (low nanoliters) than conventional capillary systems. With their decreased volume requirements (nanoliter and even picoliter range), pressure injection is more challenging (but not impossible), and the electrokinetic sample injection mode is used primarily. In practice, an injection voltage of several hundred volts is applied across the sample and sample waste reservoirs

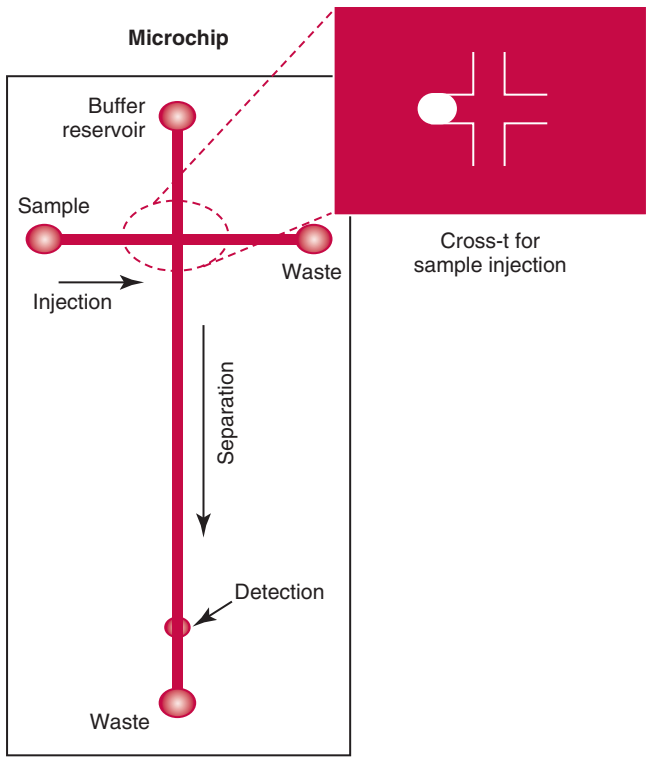

Figure 12-9 Simple cross-T microstructure design on chips used for electrophoretic separation.

to migrate the sample to the injection cross, which typically represents an injection volume of 50 to 100 pL. A separation voltage (1 to 4 kV) is then applied to the separation channel; this induces separation of the analyte zones before they reach the detection window downstream. It is important to note that, although the sample volume injected is ≈100 to 500 pL, the actual sample volume necessary (for handling) is still ≈2 to 4 μL, depending on the reservoir size.

Detection with a microchip occurs primarily through LIF, because this is easily implemented with the planar configuration of the microchip (see Figure 12-10). Limits of detection for fluorescein-like fluors have been easily demonstrated at 10^{-11} mole and even as low as 10^{-13} moles—a mass detection limit of a few hundred molecules.[43] This allows for detection, for example, of polymerase chain reaction (PCR)-amplified DNA fragments at a quantity that competes with ^{32}P-autoradiography from Southern blots.[48] Typical microchip separation times are around 50 to 200 seconds.

Fabrication of Microchips

Standard cross-T configuration microchips are commercially available from several small vendors, but chips of more complex architecture tend to be fabricated in the laboratories that use them. They are constructed from substrates such as (1) glass (Pyrex-like or soda lime), (2) silicon (as per microelectronic chips), or (3) a variety of polymeric materials (plastics), or (4) they may be cast from silicone-like materials (polydimethylsiloxane).[25] The first two of these

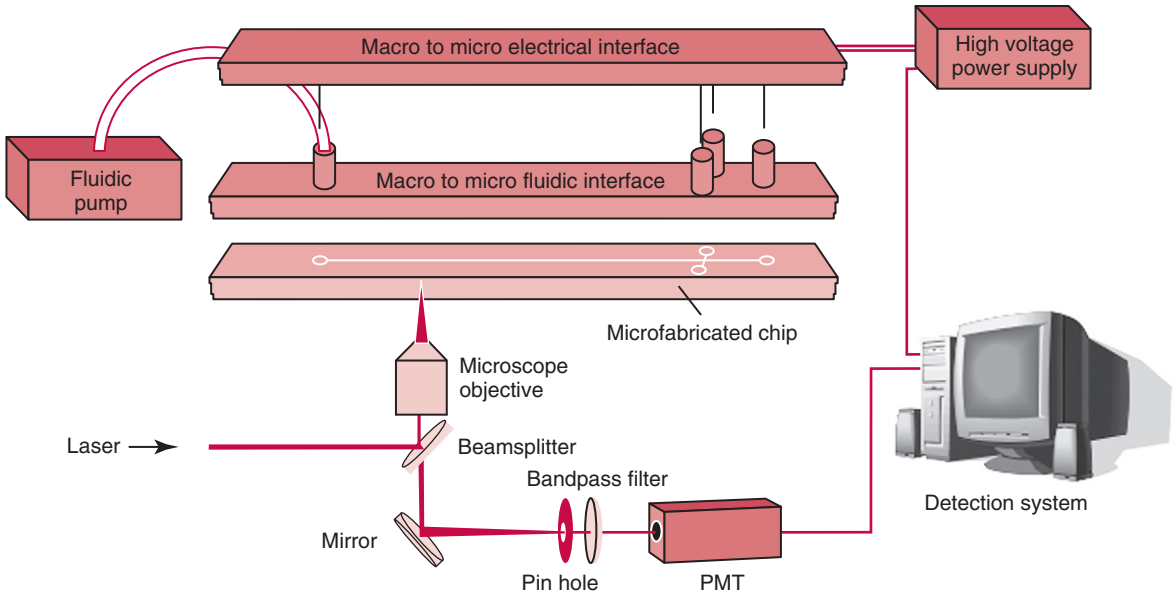

Figure 12-10 Detection system for laser-induced fluorescence (LIF) detection on microchips. Fluidic and electrical interfaces are indirectly fundamental to the detection system. The fluidic interface drives the preparation and flushing of the chip before separation and after separation, and the electrical interface drives the electrophoretic separation and controls the flow of fluid through the chip architecture via electrokinetic valving.

types constitute the vast majority of electrophoretic devices described in the literature.

A buffered solution of hydrofluoric acid is used to etch the desired structures into a glass wafer, thereby producing a series of U-shaped troughs [typically 70 μm (w) × 20 μm (d)] that interconnect appropriately. Smooth walls are typically achieved, but channels are U-shaped because of downward and lateral etching by the etch solution. Consequently, features are often designed to be smaller than they have to be to allow for this type of spreading. Following successful etching, the etched wafer is bonded to a second piece of glass, into which reservoirs have been drilled, to enclose chambers and channels of the device.

Molecular Diagnostics Using Microchips

As a result of the ease with which double-stranded (ds)DNA will fluoresce via high-affinity dsDNA fluorescent intercalators, and the excellent detection sensitivity that results from LIF, DNA separations on microchips have developed more rapidly than protein separations. Consequently, capillary and microchip types of electrophoresis have emerged as alternatives to traditional slab gel electrophoresis for DNA analysis; this is signified by sequencing of the human genome by Celera using primarily CE-based separation. A variety of polymers have been defined as *sieving matrices,* effective for molecular sieving and size-based microchip DNA separations, many of which had been used previously in CE.

As described in the CE section, the chemical nature of the microchannel surface is equally important in DNA separation, where electro-osmotic flow has to be minimized or eliminated. For microchip-based electrophoretic DNA analysis, the chip surface must be passivated to reduce EOF. This is accomplished through covalent modification with polymers such as polyacrylamide (PA)[21]; however, PCR samples must be desalted to achieve optimal resolution and acceptable longevity.[4,60] More attractive alternatives developed for CE involve polymers that have dual functionality, in that they both coat the microchannel surface and act as effective sieving polymers. Polydimethylacrylamide (PDMA) and the cellulosic polymers, hydroxyethyl cellulose and hydroxypropyl cellulose, have been shown to be very effective in this respect.[55]

In practice, microchip electrophoresis has been extensively utilized for the molecular diagnosis of disease based on PCR amplification of DNA (see Chapter 18).[27] For example, rudimentary microchip designs have been used to demonstrate the application of this platform in the most simplistic form, that is, detecting the presence of a PCR product of diagnostic significance. This has been demonstrated with a number of applications, including detection of (1) herpes simplex viral DNA in CSF for diagnosis of encephalitis, (2) gene rearrangements correlative with lymphoproliferative disorders, (3) polymorphisms in the methylenetetrahydrofolate reductase (MTHFR) gene, (4) tetranucleotide repeats associated with hypercholesterolemia, and the (5) diagnosis of fragile X syndrome and (6) muscular dystrophy. More complicated DNA assays have been accomplished on electrophoretic microchips, including single-stranded conformation polymorphism (SSCP) and heteroduplex analysis for the detection of common mutations in the breast cancer susceptibility genes, *BRCA1* and *BRCA2*.[27]

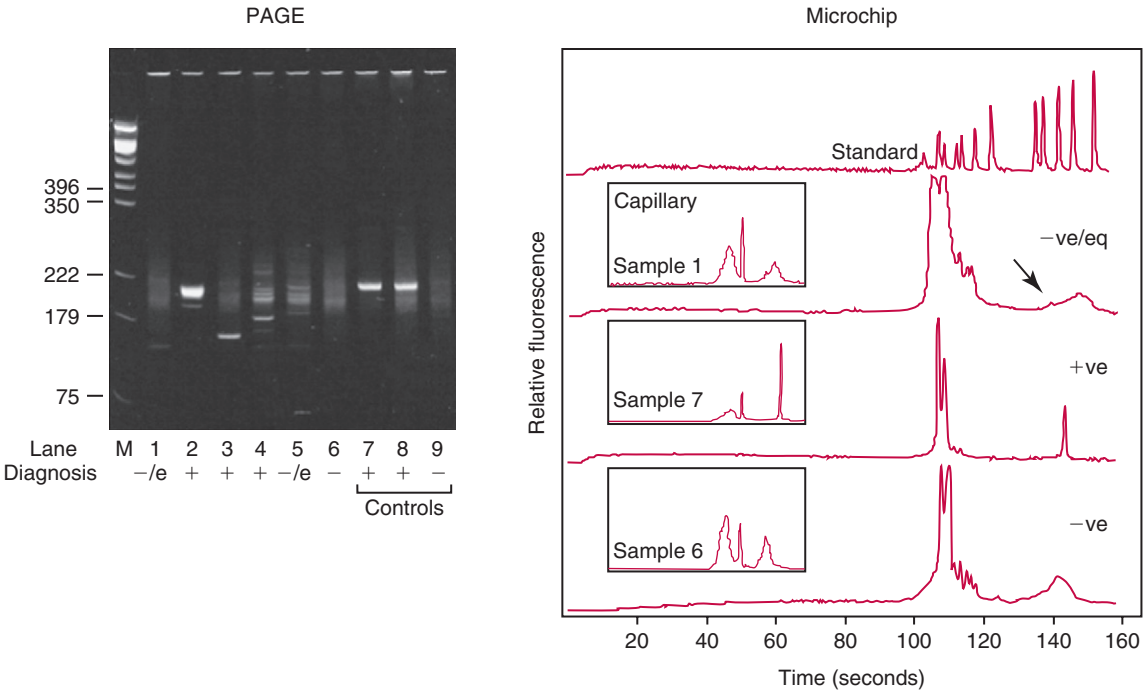

Figure 12-11 Electrophoretic detection of T-cell receptor γ-gene rearrangement products. Left, Slab gel electrophoresis of amplified products resulting from polymerase chain reaction (PCR) of nine patient samples. Right, Capillary *(inset)* and microchip separations of select samples analyzed by gel electrophoresis on the left. The top profile results from separation of a DNA sizing standard. Sample 6 was consistent with a negative diagnosis for gene rearrangement; sample 7 was positive, as indicated by the dominant peak signifying clonality (peak at 142 seconds); sample 1 was deemed negative and/or equivocal based on the suspicious peak indicated by the *arrow*. Separation in both systems used hydroxyethylcellulose (HEC) as a polymeric sieving matrix and applied fields of 300 volts/cm and 275 volts/cm, respectively, for the capillary and microchip systems.[39]

An example of microchip DNA separation applied to the diagnosis of lymphoproliferative disorders is shown in Figure 12-11.[39] The high-resolution (8%) acrylamide slab gel used for conventional analysis is given on the left for comparison. Because of the short separation length of the electrophoretic chamber (≈4 cm) and the use of applied electrical fields comparable with those used in CE, separation on the microchip is complete in 160 seconds (in comparison with 8 hours for the slab gel). Other examples are seen in chip-based methods for DNA extraction from sample, PCR amplification of purified DNA, and a method to inject this material with a DNA ladder for electrophoretic interrogation, with all processes interfaced on a single chip. Using whole blood from a mouse infected with *Bacillus anthracis,* analysis of less than 1 μL of blood allowed the detection of an *anthracis*-specific PCR product in less than 30 minutes, demonstrating the power of integrated microchip-based analysis.

More complicated microchip systems have been developed to address the high-throughput requirements of molecular diagnostics laboratories (see Chapters 17 and 39). For example, high-throughput genetic typing has been performed on a 96-channel radial capillary array electrophoresis microplate with an unprecedented sample throughput of ≈0.6 samples/s.[36,60] This has been extrapolated to a variety of other applications, including genotyping of the marker gene for diagnosis of hereditary hemochromatosis.[72]

CHAPTER 13

Chromatography and Extraction

Glen L. Hortin, M.D., Ph.D., and
*Bruce A. Goldberger, Ph.D.**

Biological fluids are complex mixtures, and clinical tests for specific components contained in these fluids often entail one or more sequential separation steps to isolate or enrich the component of interest. Common methods for achieving separation include (1) chromatography, (2) extraction, (3) differential precipitation, and (4) electrophoresis (see Chapter 12). This chapter describes basic concepts and principles of chromatographic and extraction techniques that are used as analytical techniques or as methods to prepare specimens for analysis.

CHOMATOGRAPHY

Chromatography is a process in which components of a mixture are separated by differential distribution between a mobile phase and a stationary phase.[12,48,66] Components with greater distribution into the stationary phase are retained and move through the system more slowly. The initial description of this technique by Mikhail Tswett in 1903 entailed the separation of plant pigments into separate colored bands on a column of calcium carbonate.[13] He originated the term *chromatography,* derived from chroma and graphein (Greek for "color" and "to write"), and this term has continued to be used even though most separations do not involve colored components.

Planar and column are the two basic forms of chromatography (Figure 13-1). In planar chromatography, the stationary phase is coated on a sheet of paper (paper chromatography) or is bound to a solid surface [thin-layer chromatography (TLC)]. For paper chromatography, the stationary phase is a layer of water or a polar solvent coated onto paper fibers. In TLC, a thin layer of particles of a material such as silica gel is spread uniformly on a glass plate or a plastic or aluminum sheet. When the thin layer consists of particles with small diameters (4.5 μm), the technique is known as *high-performance, thin-layer chromatography* (HPTLC).

In column chromatography, the stationary phase may be a pure silica or polymer, or it may be coated onto, or chemically bonded to, support particles.[6] The stationary phase may be "packed" into a tube, or it may be coated onto the inner surface of the tube. Column chromatography includes both gas chromatography (GC)[47] and liquid chromatography (LC)[62]; with classification dependent on whether the mobile phase is a gas or a liquid. Operationally, the instrument used to perform a GC or LC separation is known as a *gas* or *liquid chromatograph.* When the stationary phase in LC consists of small-diameter particles, the technique is known as high-performance liquid chromatography (HPLC). When a gas or liquid chromatograph is connected to a mass spectrometer, the combined or "hyphenated" techniques are gas chromatography–mass spectrometry (GC-MS) and liquid chromatography–mass spectrometry (LC-MS).[23]

In analytical GC and LC, the mobile phase, or eluent, exits from the column and passes through a detector that produces an electronic signal that is plotted as a function of (1) time, (2) distance, or (3) volume. The resulting graphical display is a chromatogram (Figure 13-2).

Retention time or volume is the interval or volume required for a solute to pass from the injector, through the column, and to the detector. Data represented by the chromatogram are used to help identify and quantify the solute(s). Because eluting solutes are displayed graphically as a series of peaks, they are frequently referred to as chromatographic peaks. These peaks are described in terms of peak (1) width, (2) height, and (3) area. In planar chromatography, the separated zones are detected by their natural colors or are visualized through chemical modification that produces colored "spots" or "bands," which are used to qualitatively identify various analytes, or to quantify them.

Separation Mechanisms

Chromatographic separations are classified by the chemical or physical mechanisms used to separate the solutes (Figure

The authors gratefully acknowledge the contributions of Drs. M. David Ullman, Carl A. Burtis, and Larry D. Bowers to this chapter in previous editions.

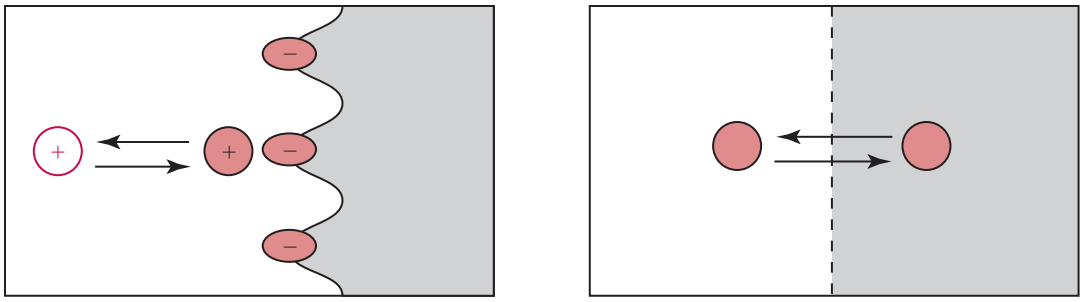
13-3). These include (1) ion-exchange, (2) adsorption, (3) partition, (4) affinity, and (5) size-exclusion mechanisms. Predominantly, clinical applications use chromatographic separations based on ion-exchange and partition mechanisms.

Ion-Exchange

Ion-exchange chromatography relies on the exchange of ions between charged groups bound to a stationary phase and ions of opposite charge in the mobile phase (see Figure 13-3). Depending on the charge of the stationary phase, components binding to the column may be cations (positively charged) or anions (negatively charged). Cation-exchange solid phases contain covalently bound, negatively charged functional groups. Examples include strongly acidic groups, such as sulfonate ions, or weakly acidic groups, such as carboxyl or carboxymethyl. Anion-exchange solid phases have strongly basic quaternary amines, such as triethylaminoethyl groups, or weakly basic groups, such as aminoethyl (AE) and diethylaminoethyl (DEAE) groups. Separations are performed under conditions where analytes are charged and bind to the ion-exchange stationary phase. Solutes are eluted with a solution containing competing counterions, such as sodium for cation exchange and chloride for anion exchange, and, in some cases, by adjustment of pH to decrease the charge of bound ions or the ion-exchange surface. Important factors in performance of ion-exchange chromatography include (1) type of stationary phase ionic group, (2) charge density, (3) stationary phase matrix, (4) type and concentration of ions in the mobile phase, and (5) mobile phase pH. Many stationary phases exhibit mixed mode retention by a combination of ion exchange and adsorptive binding. As an example, ion-exchange resins used for amino acid analysis are able to separate amino acids with virtually the same charge because of variable adsorptive interactions of different amino acids with the stationary phase. Some solid-phase extraction media are designed to have mixed hydrophobic–ion-exchange retention, offering improved selectivity versus extraction

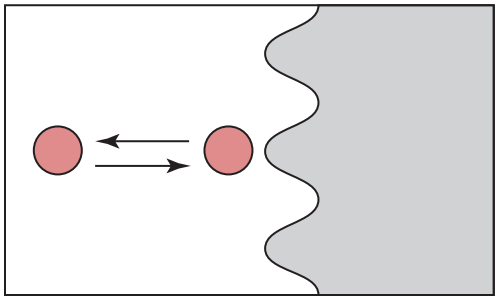


Ion-exchange chromatography

Separation is based on exchange of ions between surface and eluents.

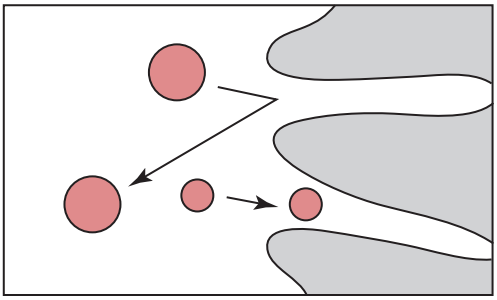
Partition chromatography

Separation is based on solute partitioning between two liquid phases.



Adsorption chromatography

Separation is due to a series of adsorption/desorption steps.



Size-exclusion chromatography

Separation is based on molecular size.

Figure 13-3 Examples of separation mechanisms used in chromatography. *(Courtesy James K. Hardy, Akron, Ohio [http://ull.chemistry.uakron.edu].)*

media designed predominantly for hydrophobic or ion-exchange extractions.

Ion-exchange chromatography has a number of clinical applications, including analyses of amino acids and hemoglobins. It is also used to analyze small inorganic and organic ions with conductivity detection, a technique termed *ion chromatography.* Water purification is an important preparative application of ion-exchange chromatography consists of using mixed-bed resins with both cation and anion exchangers. Ions are removed by exchange of hydrogen ions for other cations and hydroxyl ions for other anions. The hydrogen ions and hydroxyl ions displaced by salt ions form water.

Adsorption

The basis of separation by adsorption chromatography is the difference between adsorption and desorption of solutes at the surface of a solid particle (see Figure 13-3). Electrostatic, hydrogen-bonding, and dispersive (van der Waals) interactions are the physical forces that control this type of chromatography.[17,28] As solvent molecules compete for binding to the stationary phase, the strength of binding to the stationary phase depends on the properties of the stationary phase and of the mobile phase. In general, for a polar stationary phase, elution tracks the polarity of the components in a mixture: less polar ones elute first, followed by those of increasing polarity.[7]

In GC, this mode is used to separate low molecular weight compounds such as methyl, ethyl, isopropyl alcohols from compounds that are normally gases at room temperature. It uses particles of support, such as "molecular sieves," alumina, and styrene-divinylbenzene copolymers. In LC, three types of adsorbents are generally used: (1) nonpolar, (2) acid polar, and (3) basic polar. Nonpolar adsorbents include charcoal and polystyrene-divinylbenzene. The main acidic polar adsorbent is silica gel, the surface silanol (SiOH) groups of which adsorb basic substances. Alumina is the main basic adsorbent for retaining acidic substances. Florisil has also been used as a basic adsorbent when catalytic decomposition of the analyte is observed with alumina.

Hydrophilic interaction liquid chromatography (HILIC) is a type of adsorption chromatography that is used to separate highly polar compounds that form hydrogen bonds with a stationary phase having a relatively polar surface.[8,26,41] Examples of stationary phases used for HILIC include (1) unmodified silica, (2) silica with bonded zwitterionic groups, (3) hydroxyl-rich compounds, and (4) amide-rich compounds. Initial binding of solutes to the stationary phase is performed in relatively hydrophobic solvent, and elution is

attained with solvents of increasing polarity. A limitation of HILIC for clinical laboratory use is that biological fluids are highly polar and include a substantial quantity of salts that also interact with polar stationary phases. Therefore, the specimen may need to be extracted or modified by the addition of a less polar solvent such as acetonitrile to promote binding to the stationary phase. Interest is growing in the application of HILIC as a separation technique linked to mass spectrometry, but most separations in clinical laboratories have relied on reversed-phase or ion-exchange separations.

Partition Chromatography

The differential distribution of solutes between two immiscible liquids is the basis for separation by partition chromatography (see Figure 13-3).[46,55,56] Operationally, one of the immiscible liquids serves as the stationary phase. To prepare this phase, a thin film of liquid is adsorbed or chemically bonded onto the surface of support particles or onto the inner wall of a capillary column.

In reversed-phase, partition chromatography, the (1) stationary phase is nonpolar, (2) mobile phase is relatively polar, and (3) hydrophobic molecules are preferentially retained. It is the most widely used technique for solid-phase extraction and liquid chromatography in the clinical laboratory. An example of separation of several antidepressant drugs by reversed-phase chromatography is shown in Figure 13-2. Examples of stationary phases for reversed-phase adsorption include silica with bonded hydrophobic groups such as octadecyl (C18), octyl (C8), phenyl, or butyl (C4) and polystyrene-divinylbenzene. For solid-phase extractions, similar materials are used including copolymers of styrene with more hydrophilic monomers that form stationary phases with balanced hydrophobic-hydrophilic character or with charged groups that offer mixed-mode extraction with both hydrophobic and ion-exchange retention.[6,20,55] The retention characteristics of silica-based stationary phases depend on (1) the nature of bonded phases, (2) the amount of bonded phase (often expressed as % carbon load), (3) the surface area of the particles, (4) the pore size of the particles, and (5) the quantity of accessible silanol groups on silica particles that depend on surface treatments such as "end-capping," where such groups are replaced by trimethylsilyl groups. For reversed-phase separations, solutions are applied in relatively polar solvent such as water or water with a low concentration of organic solvent such as methanol or acetonitrile. Reversed-phase separations are often used with aqueous specimens such as blood and urine, because most of the solvent (water) and inorganic salts pass through the column with minimal retention. The partitioning of solutes in reversed-phase separations usually is favored by adjustment of pH to minimize the charge of solutes, such as decreasing the pH so that organic acids are in uncharged forms, or adding ion-pairing agents that yield less polar ion pairs. Prior to the introduction of a sample, hydrophobic stationary phases may require conditioning or "wetting" with a solvent such as methanol before equilibrating with a more polar solvent. Some stationary phases, such as C18-silica, may undergo "phase collapse" of the bonded phase if run in completely aqueous solvent, which probably represents the aliphatic bonded phase folding down onto the surface and having decreased access to solvent. During a solid-phase extraction, drawing air into the column can similarly require reapplication of organic solvent to wet surfaces. Use of balanced hydrophobic-hydrophilic phases for extractions reduces the need for wetting of the stationary phase and avoids problems of phase collapse with loading of aqueous solutions.[19,55] Polymeric stationary phases usually have higher capacity than bonded silica stationary phases, because the entire particle serves as the stationary phase.

Elution of compounds in reversed-phase separations relies on competition of molecules in the mobile phase with molecules bound to the stationary phase. Elution is hastened by changing the solvent strength with a linear or stepwise gradient, or by changing the pH to increase the polarity of solutes. The strength of solvents, sometimes referred to as the *eluotropic series,* for reversed-phase separations generally follows this order:

Pentane > Cyclohexane > Toluene > Dichloromethane >

Ethylacetate > Acetonitrile > Ethanol > Methanol > Water

More hydrophobic solvents generally are stronger eluents for reversed-phase separations. For normal-phase chromatography (polar stationary phase, nonpolar mobile phase), the eluotropic series is reversed. In practice, it is also possible to change the solvent strength by using mixtures of solvents and gradients of changing proportions of solvents during an analysis (Figure 13-4).[9] It is also possible to modify the

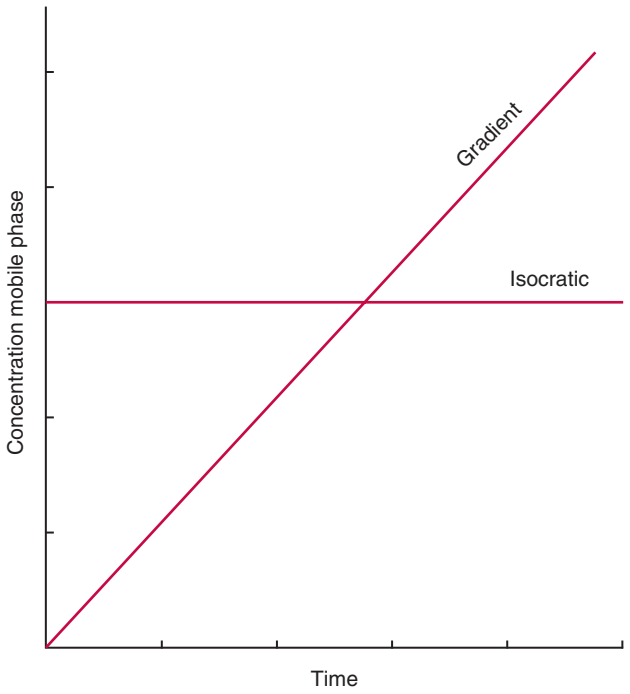


Figure 13-4 Examples of isocratic (constant composition) and gradient elution (varying composition) in LC. *LC,* Liquid chromatography.

polarity of aqueous solutions by changing the salt concentration. This characteristic is employed in a variation of reversed-phase chromatography termed *hydrophobic interaction chromatography,* which has been applied mainly for separation of proteins. Binding to a weakly hydrophobic stationary phase containing interaction groups such as phenyl or butyl groups is promoted by loading specimens in a high-salt concentration, and elution is achieved by lowering the salt concentration rather than by adding an organic solvent.

A wide range of solid phases for reversed-phase separations have slightly different specificities, and some have mixed modes of separation.[6,16,39] Some solid phases such as porous graphite or fluorinated hydrocarbons or hydrophobic stationary phases with embedded polar groups offer different selectivities than traditional C18-silica. Stationary phases bonded on silica have weak cation-exchange and normal-phase properties, depending on the quantity of accessible hydroxyl groups on the silica. Basic compounds may exhibit peak tailing caused by ion exchange with the silica. Ion-exchange properties of silica are minimized by chemically modifying the surface to block hydroxyls and by operating at low pH. Silica tends to dissolve slowly at pH > 7, so that silica particles usually require separations below pH 8, unless the silica is stabilized by surface treatment.[5] Other types of stationary phases such as polystyrene or porous graphite are stable at high pH and allow separations over a broader pH range.

Because of its wide diversity of stationary phases with differing selectivities and varying ability to change solvent conditions and ion-pairing agents, reversed-phase chromatography is a very versatile technique, and separations often achieve high efficiency and , sharp peaks. Compounds representing the greatest challenge for reversed-phase separations are small ions and highly polar compounds such as sugars or amino acids, which tend to be weakly retained by reversed-phase media, and basic compounds, which may exhibit peak tailing as the result of interactions with silica. Derivatization of some compounds such as amino acids has been employed to improve reversed-phase retention and to add chromophores or fluorophores to improve detection.[48] Separation of large peptides or proteins requires stationary phases with larger pore sizes than are routinely used for separation of small molecules.[3,32,63]

Chiral Separations

Many biological molecules occur as specific stereoisomeric forms, such as L-amino acids, and in some cases, only a particular stereoisomer of a therapeutic drug may be active. In general, the two mirror-image forms of a compound or enantiomers have very similar physical properties and do not separate in most chromatographic analyses. Separation of enantiomers generally requires use of a stationary phase that has an enantiomeric component that will interact with molecules in a stereospecific manner. For example, chiral stationary phases (CSPs) that contain groups such as derivatized L-amino acids or stereospecific carbohydrates have been used to separate enantiomers.[52,62A,72]

Size Exclusion Chromatography

Size exclusion chromatography, also known as (1) gel filtration, (2) gel permeation, (3) steric exclusion, (4) molecular exclusion, or (5) molecular sieve chromatography, is a technique that separates molecules or other particles based on size (Figure 13-5). In this technique, the stationary phase consists of porous particles with an inert surface designed to have minimal adsorption of components. Materials used for stationary phases include cross-linked dextran, polyacrylamide, agarose, polystyrene, and porous glass with an inert surface coating. Beads of these materials are porous and have pore sizes that allow small molecules to enter. Molecules too large to enter the pores remain entirely in the mobile phase and are rapidly eluted from the column. Molecules that are intermediate in size have access to various fractions of the pore volume and elute between large and small molecules according to the following relation:

$$V_r = V_0 + KV_i$$

where V_r is the retention volume, V_0 is the void volume between particles, K is the fraction of the pore volume accessible to the molecule, and V_i is the volume within the support particles.

By calibrating a size-exclusion column with molecules of known size, it is possible to estimate the molecular size of proteins or other molecules.[64] However, this is a relatively low-resolution technique, and separation of components requires substantial proportional differences in molecular weight. The diameter of globular proteins changes only in proportion to the cube root of molecular weight, so that an eightfold difference in molecular weight is required to yield a twofold change

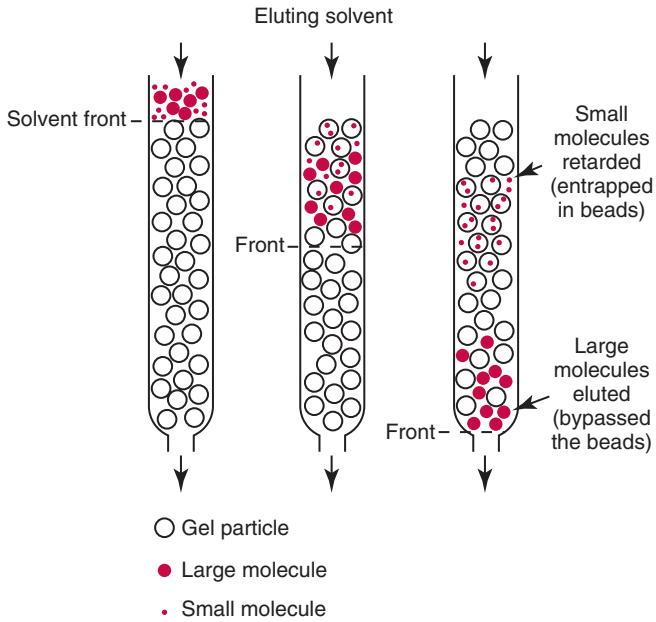

Figure 13-5 Schematic representation of gel filtration column chromatography. *(Modified from Bennett TP. Graphic biochemistry, vol 1: chemistry of biological molecules. New York: Macmillan, 1968.)*

in diameter.[64] Linear polymers, such as DNA, and proteins denatured with sodium dodecylsulfate or guanidine hydrochloride have a much larger diameter for the same molecular weight, and diameter changes approximately in proportion to the square root of molecular weight, allowing better resolution of linear molecules relative to molecular weight than of globular molecules. Therefore, analysis of molecules under denaturing conditions provides the ability to resolve molecules with smaller differences in molecular weight.

Size exclusion chromatography allows the separation of molecules under physiologic salt conditions; this is useful for identifying intact complexes of molecules such as lipoproteins, antibody-antigen complexes, and other binding proteins and their ligands under mild nondenaturing conditions. Also, it is used as a rapid preparative technique for salt exchange or to remove small molecules from large molecules using small centrifuge or gravity flow columns.

Other Size Exclusion Separations

Separations by size exclusion also are performed with ultrafiltration membranes or particles with defined pore sizes. Ultrafiltration is employed in the clinical laboratory as a preparative technique to separate small molecules such as amino acids or drugs, which pass through the membrane in the ultrafiltrate, from proteins, which remain in the retentate fraction. Ultrafiltration and equilibrium dialysis serve as means of separating free from protein-bound components, such as for measurement of free phenytoin or thyroxine concentrations. Ultrafiltration also is used as a technique for concentrating proteins in dilute solutions, such as urine, for analysis by electrophoresis or other techniques. Ultrafiltration is useful mainly for separating molecules or particles that have large differences in size, typically more than a 10-fold difference in molecular weight.

Affinity Chromatography

Specific molecular interactions are used as the basis for affinity chromatography (Figure 13-6).[25,57] Examples include (1) interactions of antibody with antigen, (2) enzyme with substrate, (3) aptamer with ligand, (4) receptor with ligand, and (5) lectin with sugar. The stationary phase for affinity chromatography is prepared by immobilizing one component of an interaction pair and using it to capture the other component of the interaction pair. Orientation of the capture molecule and its accessibility are important elements in the function of capture molecules. Using a spacer to provide distance from the surface of the stationary phase may improve access and function of the capture molecule. An alternative approach to developing affinity matrices without immobilized ligands is to form molecularly imprinted surfaces on the capture phase.[38] The shape and structure of pores formed by molecular imprinting yield selective binding of molecules that have a complementary structure.

To perform affinity chromatography, a solution is applied to the stationary phase under conditions that allow specific binding to the capture molecule, and nonbound components are removed by extensive washing of the stationary phase.

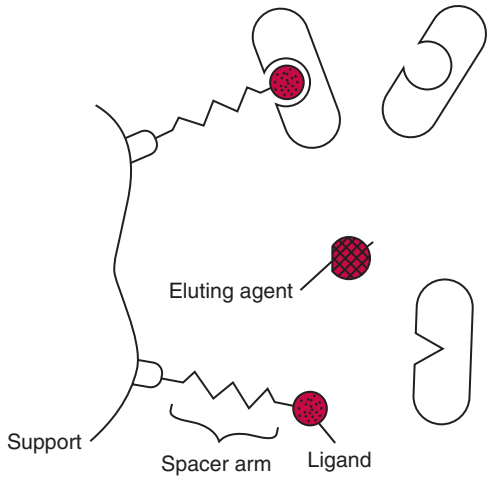

Figure 13-6 Principle of affinity chromatography. The analyte (enzyme, antibody, antigen, tissue receptor, etc.) binds to the support-bound ligand. Subsequently, it is eluted with a general eluent (such as a chaotropic agent), a pH change, or a biospecific eluent (such as an inhibitor or substrate).

Specifically bound components are eluted by adding competing ligand or changing conditions such as pH or ionic strength, so as to eliminate binding to the stationary phase. Affinity separations may be performed batchwise with sedimentation of the stationary phase, or by column chromatography. Chromatographic elution often is seen with stepwise change of solvent to allow elution of desired components in a single fraction.

The power of affinity chromatography lies in its selectivity. Affinity chromatography is widely applied to purifying antibodies and other proteins used in clinical assays. Lectin affinity chromatography offers a means of assessing changes in the oligosaccharide structures bound to glycoproteins. Immobilized phenylboronic acid has been used to separate glycated hemoglobin from unmodified hemoglobin. Most heterogenous assays in the clinical laboratory are based on the selective extraction or capture of a specific target molecule onto a solid phase with elution of all other molecules (see Chapter 16). Immunodepletion or immunopartitioning of high-abundance proteins has been used as a means of preparing biological specimens for proteomic analysis to assist in the detection of lower-abundance components.[53]

Resolution

Resolution *(R_s)* is a measure of the separation between two components (Figure 13-7). Improved resolution may result from sharper peaks (higher chromatographic efficiency) or from a greater separation between peaks (higher selectivity), as described in Figure 13-8. It is expressed mathematically as follows:

$$R_s = \frac{t_r(B) - t_r(A)}{\left[\frac{w(A) - w(B)}{2}\right]}$$

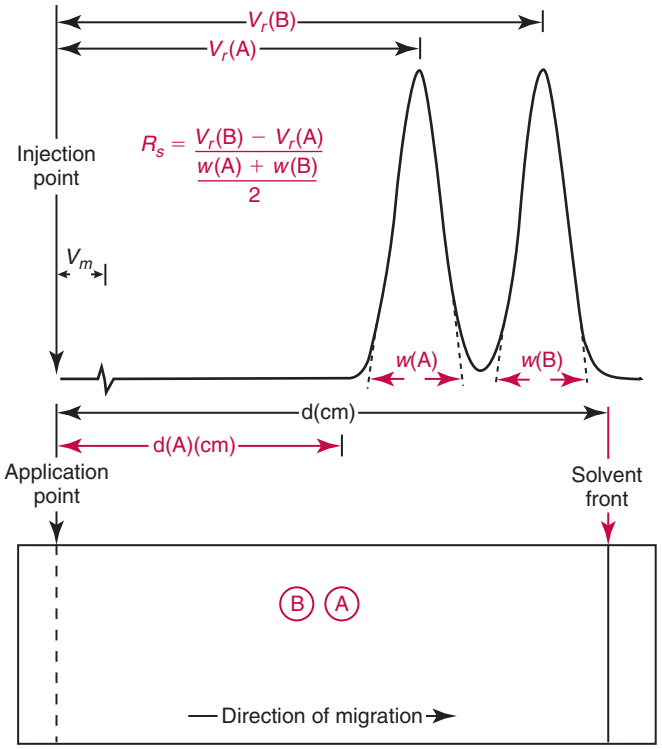

Figure 13-7 Schematic diagram of chromatograms obtained from a column and a planar chromatograph. In planar chromatography *(bottom)*, strongly retained compound *B* migrates less than weakly retained compound *A*. In column chromatography *(top)*, compound *B* is eluted later than compound *A*. *d(A)* and *d(B)*, Distance traveled by solutes *A* and *B*; R_s, resolution; V_m, volume between injector and detector; $V_r(A)$ and $V_r(B)$, retention volumes for solutes *A* and *B*; *w(A)* and *w(B)*, peak widths at base for solutes *A* and *B*.

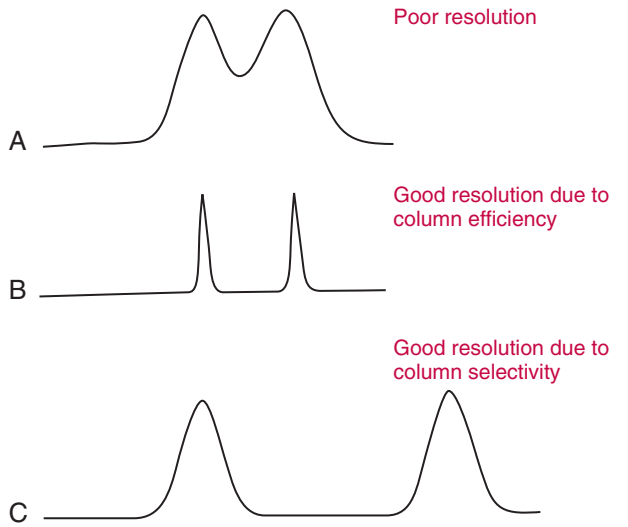

Figure 13-8 Effects of selectivity and efficiency on chromatographic resolution. A, Poor resolution. B, Good resolution because of high column efficiency. C, Good resolution because of column selectivity. *(From Johnson EL, Stevenson R. Basic liquid chromatography. Palo Alto, Calif: Varian Associates, 1978.)*

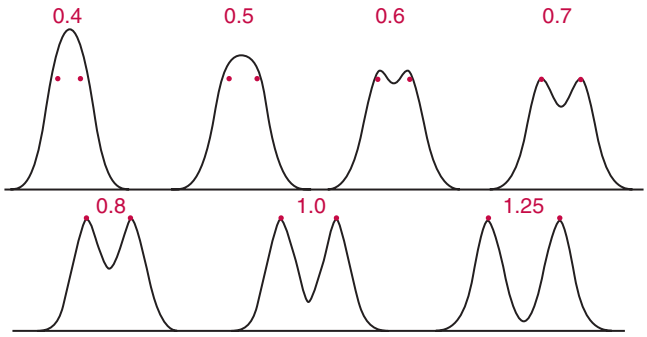

Figure 13-9 Separation of chromatographic peaks present in a 1:1 ratio as a function of resolution (R_s). *(From Snyder LR. A rapid approach to selecting the best experimental conditions for high-speed liquid column chromatography. Part I. Estimating initial sample resolution required by a given problem. J Chrom Sci 1972;10:202.)*

where

$t_r(A)$ = retention time for solute A
$t_r(B)$ = retention time for solute B
$w(A)$ = peak width (units of time) measured at base for solute A
$w(B)$ = peak width (units of time) measured at base for solute B

Retention may be expressed in units of time (previous equation) or volume (see Figure 13-7). A resolution of 1.25 or greater reflects baseline separation of peaks; lower resolution represents increasing degrees of overlap between peaks, as described in Figure 13-9. Resolution is improved by enhancing efficiency (achieving narrower peaks) or by improving selectivity to increase the separation between the two components. Two ways to increase resolution are by using a longer column and by selecting a column with higher efficiency. Either of these measures increases N, the number of theoretical plates. Resolution increases proportionally with the square root of N, so that doubling of column length (doubling of N) will increase resolution by a factor of 1.41.

Retention Factor

The retention factor k′ is a measure of the time a solute resides in the stationary phase relative to the time it resides in the mobile phase. Mathematically, it is the ratio of the adjusted retention volume(v_r) or retention time (t_r) to the void volume (v_0) or hold-up time (t_0) (the time for unretained components to elute from the column).

$$k' = \frac{v_r - v_0}{v_0} = \frac{t_r - t_0}{t_0}$$

A k′ of 0 indicates no binding between a solute and the stationary phase. Greater partitioning into the stationary phase results in longer retention times and increased k′. In practice, it is desirable to have a k′ between 1 and 10 for optimal separations that do not take an excessive length of time.

In planar chromatography, such as paper and thin-layer chromatography, all separation of solutes must occur within

the distance traveled by the mobile phase. Thus, a solute's migration is expressed by its R_f value, which is calculated as follows:

$$R_f = \frac{\text{distance from application point to solute center}}{\text{distance from application point to solvent front}}$$

Therefore, the greater the solute affinity for the stationary phase, the smaller the R_f value.

Efficiency (N)

Ideally, a component moving through a chromatographic column migrates as a very narrow band. However, nonuniformity of flow, diffusion, and mass transfer effects between particles and the mobile phase produce band broadening. Chromatographic efficiency is considered to be highest when band broadening is minimized. Column efficiency is commonly expressed as N, the number of theoretical plates. For a peak forming a Gaussian curve, $N = \left(\frac{t_r}{\sigma}\right)^2$, where t_r is retention time and σ is the standard deviation of the curve measured as time. A practical way to calculate N is based on the measurement of peak width ($w_{1/2}$) at half the maximal peak height; $w_{1/2}$ represents 2.354 σ. Therefore,

$$N = 5.55\left[\frac{t_r}{w_{1/2}}\right]^2 = \left[\frac{t_r}{\sigma}\right]^2$$

An increase in N represents improved chromatographic efficiency and sharper peaks. Efficiency is often expressed as the number of theoretical plates per column length (N/L). The efficiency and the number of theoretical plates for a column are directly related to the column length, but usually a tradeoff of longer analysis times for longer columns occurs. Column efficiency also is expressed as the height equivalent of a theoretical plate (HETP):

$$\text{HETP} = \frac{L}{N}$$

In theory, a theoretical plate is equivalent to the length of a column necessary to allow one equilibration of the solute to occur between stationary and mobile phases. To increase the efficiency of a column, the number of theoretical plates is increased. In practice, this typically is accomplished by increasing the length of the column.

The flow rate has a major effect on chromatographic efficiency as described by the van Deemter equation:

$$\text{HETP} = A + \frac{B}{v} + Cv$$

where

A = a constant related to *eddy-diffusion*
B = a constant related to longitudinal diffusion
C = a constant related to kinetics of mass transfer between mobile and stationary phases
v = the mobile phase velocity

Decreasing values for HETP represent improved efficiency, in that the number of theoretical plates for a particular column length is increased. The van Deemter equation predicts that optimization of flow rates involves a balance between peak broadening at low flow rates from diffusion and at high flow rates from increased mass transfer effects between mobile and stationary phases. It also predicts that, for a particular chromatographic system, an optimal flow rate yields the best efficiency. Empirically, the effects of flow rate on efficiency are tested by measuring peak widths at different flow rates. In practice, there usually is no interest in defining the complete van Deemter curve, but rather in identifying the highest flow rate that does not result in excessive peak broadening. The usual goal is to identify conditions for the most rapid analysis time that still yields adequate separations.

BOX 13-1 Factors That Affect Chromatographic Efficiency

Column length
Flow rate
Initial injection volume
Mobile-phase viscosity
Particle size of stationary phase
Temperature
Uniformity of the stationary phase
Volume of connecting tubing

Factors that affect chromatographic efficiency are listed in Box 13-1. In practice, efficiency is improved by using (1) smaller particles, (2) nonporous particles, or (3) a coated capillary surface as the stationary phase to minimize mass transfer effects (the C constant in the van Deemter equation). This allows the use of higher mobile phase flow rates without peak broadening, resulting in faster separations. The limiting factor in reducing particle size is the increased resistance to flow and the need to operate at higher pressures.

Selectivity

Selectivity of a separation of two components reflects variable partitioning of different components between the two phases of an extraction or between the stationary and mobile phases of a chromatographic system. The *selectivity factor* (α) for two components A and B is the ratio of retention factors for two components:

$$\alpha = \frac{k'(B)}{k'(A)} = \frac{[t_r(B) - t_0]}{[t_r(A) - t_0]}$$

with the later eluting component B in the numerator. If two components have the same retention times, then $\alpha = 1$. Separations of components generally seek to identify conditions in which there are moderate differences in retention times of components. This is achieved through appropriate selection of mobile phase, stationary phase, and analytical conditions. A large selectivity coefficient is desirable in extractions where analysts seek to selectively extract one component. However, a large selectivity component in chromatography may result in the need to change the mobile phase or temperature during an analysis to achieve elution of both components within a practical length of time. An α of 1.1 or greater for two components usually represents adequate chromatographic separation.

Peak Capacity

Peak capacity is the theoretical maximum of the number of components that are able to be separated in a single chromatographic analysis[20,51,54]; it assumes a continuous distribution of peaks separated by four standard deviations. In practice, the number of components that are resolved will be lower than expected, because retention times of components are not evenly distributed. The peak capacity, therefore, serves as an upper limit for the number of components that are able to be resolved and as a performance measure for a chromatographic method. The peak capacity of high-performance liquid chromatographic (HPLC) separation usually is limited to several hundred peaks. Some gains in peak capacity are achieved by (1) increasing column length, (2) elution with solvent gradients, (3) extended run times, or (4) increasing chromatographic efficiency. However, the greatest gain in peak capacity is achieved by using two-dimensional or multidimensional chromatography, where the different dimensions usually are performed sequentially (with the second dimension representing analyses of fractions collected from the first dimension).[20,58] Peak capacities of greater than 10,000 have been achieved for two-dimensional HPLC separations, but this requires prolonged analysis time for each sample to perform multiple runs in the second dimension. Linking of chromatographic methods to other analytical methods or detectors, such as mass spectrometers, with the capacity to resolve or detect multiple components serves as an alternative approach to overcome the fundamental limitation of chromatographic peak capacity without extending analysis time. This enables the practical analysis of up to thousands of components in a single specimen, such as for metabolomic[22] or proteomic analysis.[42]

Planar Chromatography

Paper chromatography and thin-layer chromatography (TLC) are classified as planar techniques.[59] TLC uses a thin layer of sorbent, such as silica gel, microparticulate cellulose, or alumina, spread uniformly on a glass plate, plastic sheet, or aluminum foil. The sample is added as a small spot or band on the plate, which is placed in a closed container with the lower edge within, and the sample band just above, the mobile phase (Figure 13-10). After the mobile phase travels a desired distance by capillary action, the plate is removed from the tank and dried. Separated components are located and identified by procedures such as (1) ultraviolet (UV) illumination (fluorescence); (2) spraying with specific, color-generating reagents; or (3) autoradiography. Paper chromatography and TLC tend to be used primarily for qualitative analysis. They allow two-dimensional separations using a different solvent in a second direction or the parallel analysis of multiple specimens. Applications of these techniques include analysis of amniotic fluid for lecithin-to-sphingomyelin ratios and screening of urine samples for drugs or metabolites such as amino acids that accumulate in hereditary disorders. These techniques (1) are relatively simple, (2) do not require much equipment, and (3) allow parallel analysis of multiple specimens for one-dimensional separations. However, application in clinical laboratories has been decreasing because of lack of automation and limited ability to perform precise quantification.

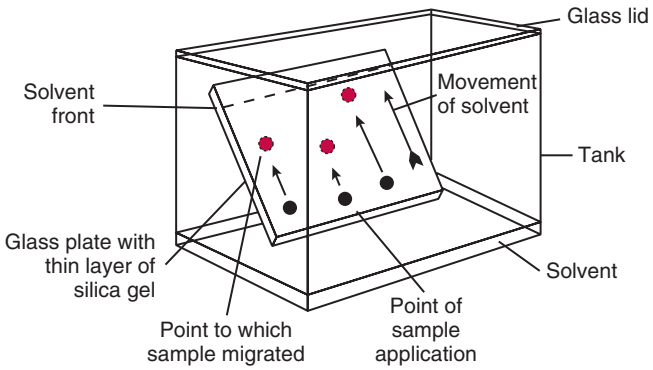

Figure 13-10 Illustration of thin-layer chromatography (TLC). The solvent moves up the thin layer of adsorbent by capillary action. *(Modified from Bennett TP. Graphic biochemistry, vol 1: chemistry of biological molecules. New York: Macmillan, 1968.)*

Liquid Chromatography

Separation by LC is based on the distribution of the solutes between a liquid mobile phase and a stationary phase.[62] In HPLC, particles of small diameter are used as the stationary-phase support. Because pressure drop is related to the square of the particle diameter, relatively high pressures are required to pump liquids through efficient HPLC columns. Consequently, the technique has also been referred to as *high-pressure liquid chromatography.* In the clinical laboratory, HPLC is the most widely used form of LC. It is an extremely versatile technique because of the wide variety of separation mechanisms, stationary phases, solvents, and detectors that have been employed.

Instrumentation

The components of a liquid chromatograph are illustrated in Figure 13-11.[36]

Solvent Reservoir

Solvents used as the mobile phase are contained in solvent reservoirs. In their simplest forms, the reservoirs are glass bottles or flasks into which "feed lines" to the pump are inserted. To remove particles from solvents, inline filters are placed on the inlets of the feed lines. Most also have a means of sparging solutions with a gas such as helium to remove dissolved oxygen that will interfere with the response of some detectors. Removal of gas bubbles and oxygen or "degassing" has also been achieved by applying a vacuum to the reservoir or to gas exchange devices placed in the flow path from reservoirs.

Solvent Delivery System

The solvent delivery system includes (1) valves, (2) a gradient mixing chamber, (3) pressure sensors, (4) pulse dampers, and

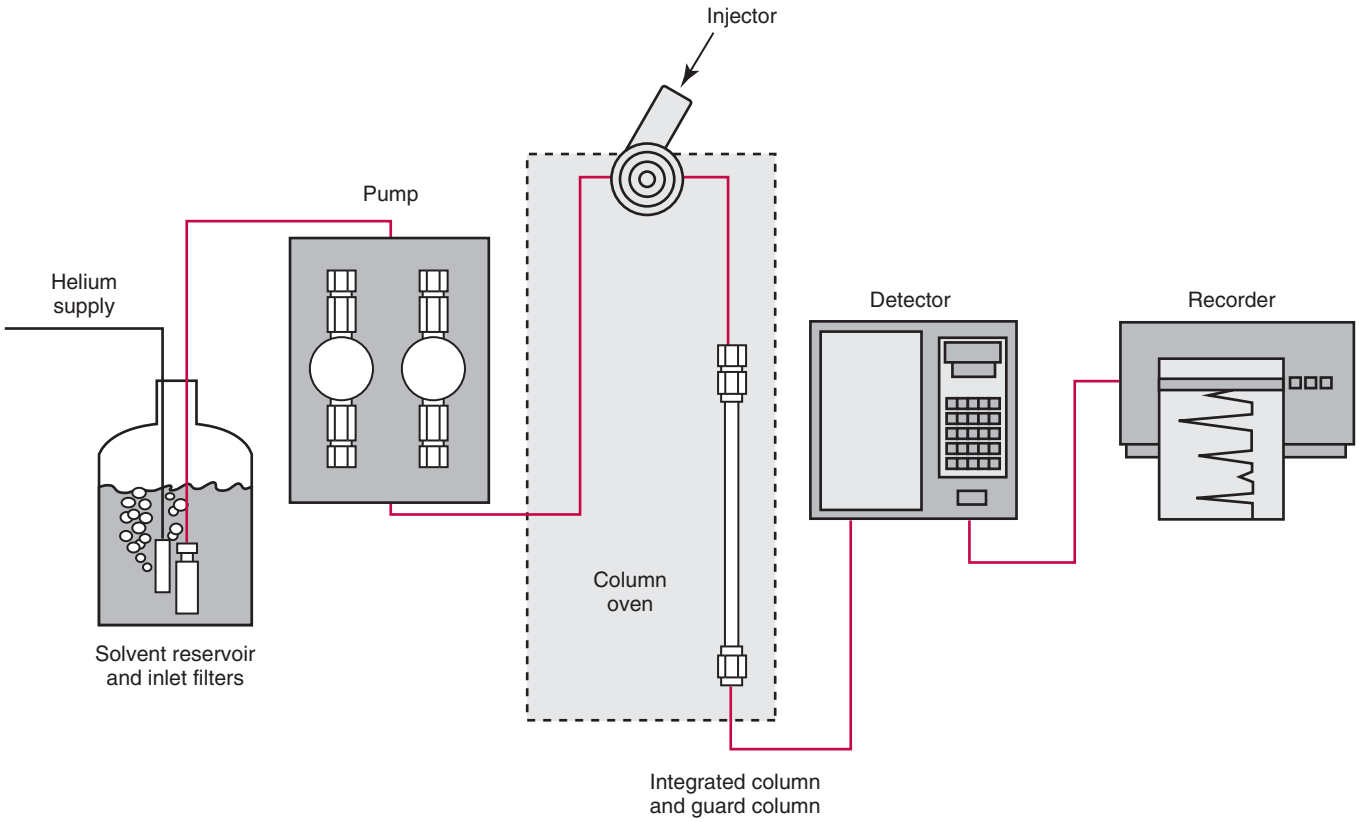

Figure 13-11 Diagram of a liquid chromatograph. HPLC components and types of columns. *(Courtesy Restek Corporation, Bellefonte, Pa.)*

(5) pumps to provide controlled flow and delivery of the correct solvent mixture. Several types of pumps have been used in liquid chromatography. For example, peristaltic and diaphragm-type pumps have been used, but they are suitable only for low-pressure chromatography. Piston-type or syringe-type pumps are used to achieve higher pressures. Reciprocating piston pumps are commonly used for HPLC, and the reciprocating action of the pump generates pulsation that is minimized by electronic pump control and pulse dampers in the flow path. Pulsation in flow is undesirable because of increases in baseline noise of many detectors.

Until recently, the upper pressure limit of most HPLC applications was about 400 bar (6000 psi), but some newer systems are designed for operation up to as high as 1000 bar (15,000 psi).[15,21,32A,67A,73] Such systems are termed UHPLC (for ultra-high performance or ultra-high pressure liquid chromatography). Operation at higher pressure limits not only requires appropriately designed pumps but also places some constraints on tubing, connections, and columns.

Systems for HPLC have pressure sensors to detect any obstruction to flow and usually shut down the system above defined pressure limits to prevent damage to components. At very high pressures, some solvents become slightly compressible and some compensation for solvent compression needs to be made to achieve constant flow rates.[21] Another extreme of operation is seen at very low flow rates for very small-bore microfluidic and capillary columns. Adaptation to low flow rates (<≅10 μL/min) may require specially designed pumping systems or flow splitting of the output from a standard pumping system. Use of flow rates in the nL/min range has been referred to as nanoflow chromatography and has been coupled to mass spectrometry by nanospray interfaces, which offer very high ionization efficiency.

A variety of techniques have been used to vary solvent composition, including the use of switching valves that change to different solvents at prescribed times, or the mixing of two or more solvents to form a solvent gradient. Gradients may be generated by a proportioning valve linked to two or more solvent reservoirs before the inlet to a single pump, or by two or more pumps linked to different solvents. The output of two pumps passes into a mixing chamber to thoroughly mix the solvents, and the composition is adjusted by varying the flow rates of the two pumps. Static mixers rely on flow-generated turbulence, whereas dynamic mixers use magnetic stirrers. Solvent miscibility and viscosity affect mixing characteristics; inadequate mixing may result in poorer chromatographic performance.

Sample Injector

The first step of an LC separation is the introduction of an aliquot of sample into the column via an injector. The most widely used type of injector is the fixed-loop injector that is switched into or out of the flow path by manual or automated injection. In the inject mode, the loop is switched into the

flow path, and the sample is carried downstream and into the column. The loop continues as part of the flow path until it is switched back to the fill position. Important characteristics of injection systems are their (1) reproducibility, (2) amount of carryover, and (3) range of injected volumes. Some automated injectors have the capability of injecting multiple aliquots or of mixing a sample and a reagent for derivatization reactions prior to injection. Refrigeration of specimens may be an important characteristic needed for analysis of specimens with limited stability, particularly when large batches of specimens will be analyzed.

Column Heaters/Chillers

Control of column temperature is a factor in the reproducibility and efficiency of LC separations. However, unlike GC separations, where temperature gradients are employed, in LC separations, a constant column temperature is maintained. It is achieved using a variety of techniques such as (1) column chambers, (2) water jackets, (3) temperature-controlled blankets, or (4) heating/cooling blocks. In addition, operation at high flow rates might require a heater/exchanger, usually a coil of tubing with good heat exchange properties, placed before the column inlet.

In operation, a stable column temperature is required to generate reproducible retention times. In addition, an increased column temperature (1) lowers solvent viscosity, (2) increases the rate of mass transfer between mobile and stationary phases, and (3) allows the use of higher flow rates and hence shortened analysis time. The thermal stability of the sample, however, imposes an upper limit on temperature. Also, in some instances, sample stability may require separations to be performed at reduced temperatures. Preparative work for proteins sometimes is performed in cold rooms or refrigerated cabinets to decrease the rates of denaturation and proteolytic degradation. Some systems for temperature control have the ability to operate at temperatures below room temperature through the action of Peltier coolers or other refrigeration systems. Important characteristics of column heater/chillers include temperature range, constancy of temperature, and number and length of columns that they accommodate.

Columns

The wide selection of columns available for liquid chromatography is based on combinations of packing materials and tubing of different diameters and lengths. Columns often include an inlet filter to remove particulate matter; a short guard column with the same packing material may be used to protect the more expensive separation column. The relatively inexpensive guard columns are replaced periodically and extend the usable life of the column.

The size of the column used depends on its application. The size of open or low-pressure columns, used for applications such as desalting or for affinity or ion-exchange purification, usually is related to the capacity needed for the separation. Gel-filtration columns, such as small centrifuge columns used for desalting, can accommodate specimens up to about 10% of column volume. The size of affinity columns depends on the amount of compound that needs to be separated and the capacity of the packing material.

TABLE 13-1 Size of Columns Commonly Used in Analytical HPLC

Column Terminology	Column ID, mm	Optimum Flow Rate
Standard	4.6	1.25 mL/min
	4.0	1.0 mL/min
Narrow bore	3.0	0.6 mL/min
	2.0	200 µL/min
Microbore/capillary	1.0	50 µL/min
	0.5	12 µL/min
	0.3	4 µL/min

HPLC, High-performance liquid chromatography; *ID,* internal diameter.

Column Dimensions. Modern column technology has produced columns in different dimensions with the tendency toward smaller internal volumes prevailing for analytical, especially hyphenated, techniques (see Chapter 14). For use in the clinical laboratory, most analytical HPLC columns are fabricated from tubes made of 316 stainless steel that have internal diameters (IDs) ranging from 0.3 mm to 5 mm and lengths from 50 mm to 250 mm (Table 13-1). Column end fittings, which have zero dead volume and frits to retain the support particles, are used to connect the column to the injector on the inlet end and the detector on the outlet end. Generally, lower detection limits are achieved with columns having smaller IDs. These smaller ID columns are manufactured from narrow-bore (approximately 2.1 mm ID) and microbore (approximately 1.0 mm ID) tubes.[2,34] In addition to providing improved efficiency, columns with smaller IDs use decreased volumes of mobile phase. For example, a 2-mm-ID column requires much less solvent than a 4.6-mm-ID column (see Table 13-1).

Capillary columns used in LC are constructed by coating the inner wall of a fused silica tube with a thin film of liquid phase. These columns vary from 0.1 to 0.5 mm in ID and from 10 to 50 cm in length.

Column Stationary Phase. The type of stationary phase in the column is the major determinant of selectivity and resolution of separations. The typical physical form of the stationary phase usually is a packed bed of small particles or a monolithic porous rod.[6,33,67,68]

Particulate Column Packings. Great variety is seen in the particles used to form packed beds, with particle diameters varying from 1.8 to 10 µm. As mentioned previously, the backpressure generated by packed beds varies approximately inversely with the square of the particle diameter. Thus, a twofold reduction in particle size results in about a fourfold increase in backpressure. Low-pressure separations, with packing materials such as cross-linked dextrans and agarose, commonly use particles of 50 to 200 µm in diameter.

Historically, separations by HPLC in clinical laboratories commonly used particles of about 5 µm in diameter, but there is a trend toward the use of progressively smaller particles extending to diameters <2 µm.[73] Smaller particles offer higher separation efficiency with the tradeoff of higher resistance to solvent flow and the need to operate at higher pressures. The use of columns with small-diameter particles has led to a new generation of HPLC systems with pressure limits of up to about 1000 bar (15,000 psi), which is about twofold to threefold higher than most previous HPLC systems.[73] High pressures may introduce some other changes related to compressibility of solvent, compression heating, and altered retention times.[15,21]

Types of particulate packings include (1) bonded, (2) polymeric, (3) chiral, and (4) restricted access materials.[5,6,16,39,67,68]

Bonded Phase Packings. In this type of packing, the stationary phase is bonded chemically to the surface of silica particles through a silica ester or silicone polymeric linkage. Bonded phase packings (1) are mechanically and chemically stable, (2) have long lifetimes, and (3) provide excellent chromatographic performance. They are available for ion-exchange and both normal-phase and reversed-phase chromatography. In normal-phase HPLC, the functional groups of the stationary phase are polar relative to those of the mobile phase, which usually consists of nonpolar solvents, such as hexane. Examples of polar functional groups for normal-phase HPLC packings are silanol, amino, and nitrile groups. Reversed-phase HPLC requires a nonpolar stationary phase. The most popular reversed-phase packing is the C18 type, in which octadecylsilane molecules are bonded to silica particles. A column with octadecyl packing is often called an *ODS column* [octadecyl silica (ODS)]. Reversed-phase column retention and selectivity characteristics are altered via attachment of other groups, such as octyl, phenyl, or cyanopropyl, to the silica.

Polymeric Packings. Graphitized carbon or mixed copolymers are used as polymeric packing (e.g., polystyrene-divinylbenzene) or are further derivatized with ion-exchange or C4, C8, or C18 functional groups. The performance of columns filled with these packings is comparable with that of silica-based columns and is stable from pH 2 to 13.

Chiral Packings. Chiral packings are used to separate enantiomers, which are mirror-image forms of the same compound. In the clinical laboratory, this type of packing is used to separate and quantify drug enantiomers.

Restricted Access Packings. With this type of packing, the outer surfaces of the support particles are protected by a hydrophilic network. Smaller solutes, such as drugs, pass through the network into the pores, which are coated with hydrophobic stationary phase. Large protein molecules are denied access to the inner core and pass through the column. Columns filled with restricted access packing allow the direct injection of biological samples with high protein concentrations; this bypasses sample preparation and improves analytical accuracy.

Monolithic Columns. As opposed to columns packed with discrete particles, monolithic columns are cylinders of silica- or polymer-based monolithic rods. Such columns have bimodal pore structures with large pores (approximately 2-µm diameter) that create high pore density, and smaller ones (approximately 13-nm diameter) that create a large internal surface area. They have been found to be capable of efficient fast separations, as they allow higher flow rates than particulate columns at reasonable backpressures. In addition, they are capable of fast mass transfer and have high binding capacity. The lower back pressure provides highly reproducible column characteristics because many of the factors that degrade particulate columns are eliminated (e.g., packing down and channeling). The monolithic rods are encased in inert polytetrafluoroethylene (PTFE) tubing and housed in stainless steel tubes. The inert tubing eliminates void volumes at the stainless steel tube/monolithic rod interface, thus improving resolution. Two additional advantages of these columns are that they can be used with mobile phase flow gradients (e.g., increasing flow rate at the end of a separation), and several columns can be coupled in a series to improve resolution with little increase in flow backpressure. Capillary monolithic columns also are available.

Of clinical interest, monolithic columns are being used to perform reversed-phase separations of peptides and proteins.[3,32,63,74]

Detectors

Many different types of detectors have been used as monitors in liquid chromatographs (Table 13-2). A key and integral component of such detectors is the flow cell through which the eluate from the chromatographic column passes. Dissolved analytes are detected and an electronic signal generated.

Operationally, detectors are used individually or are linked in series. In addition, postcolumn reactors have been interposed between the column and the detector to perform a chemical reaction such as the reaction of ninhydrin with amino acids to generate products with a stronger and more specific signal.

Photometers and Spectrophotometers. UV and visible photometers measure the radiant energy absorbed by compounds as they elute from the chromatographic column (see Chapter 10). These detectors operate in the radiant energy regions of 190 to 400 nm and 400 to 700 nm, respectively. The devices are versatile and detect many solutes because most aromatic compounds are detected in the ultraviolet region from 250 to 300 nm, and many other compounds are detectable in the ultraviolet region from 190 to 220 nm, where amide, carboxylic acids, and many other groups have substantial absorbance.

Photometers may operate as fixed-wavelength or variable-wavelength detectors. Most fixed-wavelength UV photometers use the intense 254-nm resonance line produced by a mercury arc lamp. This type of detector is extremely sensitive and is capable of operation at 0.005 absorbance unit full scale (AUFS). To provide fixed-wavelength detectors with greater flexibility, other less intense resonance lines of the mercury lamp are used. Alternatively, a phosphor is placed between

TABLE 13-2 Examples of Detectors Used in High-Performance Liquid Chromatography

Type of Detector	Principle of Operation	Range of Application	Detection Limit	Comments
Spectrophotometer	Measures absorbance of light at a single wavelength	Diverse	<1 ng	Analyte must absorb UV or visible light or must be derivatized
Spectrophotometer (diode array)	Measures absorbance of light at many wavelengths	Diverse	<1 ng	Detector provides complete spectra qualitative and quantitative information
Fluorometer	Measures fluorescence	Very selective	pg to ng	Analyte must fluoresce or be derivatized
Electrochemical	Electrochemically measures oxidized/reduced analyte	Selective	pg to ng	Detector is useful for catecholamines
Mass spectrometer	Detects ions after separation by mass-to-charge ratio	Diverse	fg to ng	Analytes must be converted to ionized form
Conductivity	Measures conductivity by ions	Selective	1 ng	Detection of ions used in ion chromatography
Refractometer	Measures change in refractive index	Universal	1 μg	Detection of most compounds but relatively low sensitivity
Evaporative light scattering	Light scattering by solutes after solvent evaporation	Nonvolatile compounds	1 ng	Detection of all nonvolatile compounds
Charged aerosol detector	Charged particle detection compounds	Nonvolatile	<1 ng	Detection of all nonvolatile compounds

the lamp and the flow cell, and the emitted fluorescence resulting from the 254-nm excitation is used as the light source. This latter approach is used in the dual-wavelength photometers that operate at two fixed wavelengths (e.g., 254 nm and 280 nm). The intense 214-nm or 229-nm resonance lines of a zinc or cadmium arc lamp, respectively, may be used for detection at lower wavelengths, where more compounds have strong absorbance.

The second type of photometer is the variable-wavelength detector. It operates at a wavelength selected from a given wavelength range. Thus the detector is "tuned" to operate at the absorbance maximum for a given analyte or set of analytes; this greatly enhances the applicability and selectivity of the detector. Another advantage of this detector is its ability to operate at lower wavelengths (e.g., 190 nm). Because more compounds (e.g., cholesterol) absorb at lower wavelengths, this capability enhances the versatility of the detector. At lower wavelengths, however, many solvents absorb UV light and cannot be used as mobile phases. Fortunately, acetonitrile and methanol, two widely used solvents in reversed-phase chromatography, have low UV absorptions at 200 nm.

Diode arrays also are used as HPLC detectors because they rapidly yield spectral data over the entire wavelength range of 190 to 600 nm in about 10 ms.[37] During operation, the diode array detector passes polychromatic light through the detector flow cell. The transmitted light is dispersed by a diffraction grating and then is directed to a photodiode array, where the intensity of light at multiple wavelengths in the spectrum is measured. Such detectors have been helpful in the identification of drugs in urine and serum.

In practice, it is necessary to use solvents, ion pairing agents, and buffers with low absorbance at wavelengths of interest to maintain a low background signal. Water, acetonitrile, methanol, isopropanol, and hexane are solvents that allow ultraviolet detection down to wavelengths of 200 nm, as are phosphate buffers. Many other solvents and buffers have substantial absorbance in the ultraviolet region that may limit ultraviolet detection. Also, flow cells of low volume are used in HPLC to avoid band broadening.

A problem with the operation of photometric detectors is the outgassing that occurs in the solvent as it exits from the high pressure of the column and into the low-pressure flow cell of the detector. Because these detectors are very sensitive, they detect these bubbles as noise that degrades the signal-to-noise ratio of the detector. Effective degassing of solvents and maintenance of some backpressure across the detector helps to minimize bubble formation.

Fluorometers. As discussed in Chapter 10, fluorescence occurs when a molecule absorbs light at one wavelength and reemits light at a longer wavelength. Online fluorometers are used in liquid chromatographs to detect fluorescing compounds as they elute from the column. Fluorescence detectors are generally more sensitive than photometric ones. In addition, precolumn or postcolumn reactors have been used to chemically tag a compound with a fluorescent label for subsequent detection. For example, amino acids and other primary amines often are labeled with a dansyl or fluorescamine tag, followed by HPLC separation and fluorometric detection. Most fluorometers used with liquid chromatographs are relatively simple in design and are extremely

selective and sensitive for compounds fluorescing within the detector's operating wavelength range. Deuterium or xenon arc lamps or lasers have been used as light sources in such detectors.

Electrochemical Detectors. In amperometric electrochemical detectors (see Chapters 11 and 30), an electroactive analyte enters the flow cell, where it may be oxidized or reduced at an electrode surface under a constant potential.[70] Use of multiple electrodes and cyclic changes in voltage allow detection of multiple components at different potentials and cyclic cleaning of the electrode. Electroactive compounds of clinical interest conveniently analyzed by HPLC with electrochemical detection include the urinary catecholamines (see Chapter 30), thiol-containing compounds such as homocysteine, and ascorbic acid. In addition, electrochemically active tags (e.g., bromine) are added to compounds such as unsaturated fatty acids or prostaglandins.

Coulometric detectors are also used. When placed in a series, such detectors are used to detect and quantify coeluting compounds that differ in their half-wave potentials (the potential at half-signal maximum) by at least 60 mV. These detectors are extremely selective and sensitive, with reasonably wide linear response ranges. They are used in the clinical laboratory for analysis of metanephrines, vanillylmandelic acid, homovanillic acid, and 5-hydroxyindole acetic acid in human urine without extensive sample preparation.

Low-sensitivity conductivity detectors also have been used to monitor gradients of varying salt composition in ion-exchange chromatography. The other application of conductivity detectors is their use in ion chromatography.[24] Elution of ions separated by anion- or cation-exchange chromatography can be detected with high sensitivity. Conductivity from a specific ion is related to its concentration, charge, and mobility. This technique is best suited for analysis of small inorganic and organic ions that have high mobility. It has been applied to measure components such as sulfate in biological fluids, but primary applications of this technique have been nonclinical.

Refractive Index Detectors. These detectors sense a change in the refraction of light as solutes pass through its flow cell. They offer a means of detecting substances, such as alcohols, polyethylene glycol, salts, and sugars that have low absorbance at wavelengths commonly used for spectrophotometric detection.[35,60]

Mass Spectrometry. As mentioned earlier, when a gas or liquid chromatograph is connected to a mass spectrometer (see Chapter 14), the combined or "hyphenated" techniques are referred to as gas chromatography–mass spectrometry (GC-MS) and liquid chromatography–mass spectrometry (LC-MS).[23,59A,69,69A] These very sensitive and specific techniques have increasing application in clinical and research laboratories and in the emerging field of proteomics.[4,18,27,43-45] For many applications, the high specificity of tandem mass spectrometers allows very short HPLC runs to be used, because most compounds do not need to be completely separated.

A critical element in linking a GC or an HPLC to a mass spectrometer is the interface between them. For example, the interface between the liquid chromatograph and the mass spectrometer has the challenging task of removing solvent molecules and transferring components from a liquid solution into a charged form in vacuum for analysis by the mass spectrometer. Therefore, all buffers used for chromatography need to be volatile to avoid overloading and contaminating the interface. For the same reason, a switching valve often is used to divert salts and other unretained components eluting early in the HPLC separation to waste. The switching valve then directs later parts of the HPLC run to the mass spectrometer. Several different ionization techniques, including electrospray, chemical ionization, and photoionization, are discussed in greater detail in Chapter 14.

Other Detectors. A number of other types of detectors have been used with liquid chromatographs, but primarily for research applications. Dynamic light scattering detectors measure light scattering related to molecular size and have been found useful in characterizing the size of large molecules and complexes.[49] Nuclear magnetic resonance has been performed on specimens passing through flow cells and may be useful for applications such as lipoprotein analysis, metabolomics, and characterization of metabolites of drugs. There has been an interest in detectors that are more sensitive than refractive index detectors for compounds with low spectrophotometric absorbance.

New types of detectors also have been developed that provide nearly universal detection of compounds that are nonvolatile.[35,60] For example, with the evaporative light scattering detector, solvent is evaporated by nebulizing the chromatographic effluent with a stream of gas. Nonvolatile solutes remain as particles in the gas stream, and particles are detected by measuring light scattering at an angle from incident light. Light scattering is proportional to the mass of nonvolatile substances. Detection limits of about 1 ng for compounds such as glucose have been achieved. Potential applications include analysis of lipids, sugars, and other compounds difficult to detect photometrically. A second type of evaporative detector, the charged aerosol detector, ionizes solutes with a corona discharge and measures ion currents rather than light scattering. This approach is very sensitive for most compounds. A disadvantage of such evaporative detectors is that they destroy the specimen so that components cannot be collected for further analysis or coupled for subsequent analysis by another detector.

System Controller and Data System

By using the simplest form of instrumentation for a liquid chromatograph, it is possible to perform injections and pump adjustments manually and to record results on a strip chart recorder. This may be suitable for infrequent preparative separations, but for high-volume applications in the clinical laboratory, there usually is an interest in automating the injections and chromatographic runs with hardware and software for system control. The system controller manages (1) sample injections; (2) solvent delivery; (3) temperature control; (4) and detectors; and (5) it provides an auditable record of analyst, method, calibration, controls, and specimens. Data

systems take the thousands of data points from an individual run and identify a set of peaks with parameters such as retention times, peak areas, peak heights, and peak widths. Comparison of these parameters with those generated from reference materials yields identification of peaks and quantitative values. Software for data analysis becomes more critical as data streams become larger, such as from diode array and mass spectrometric detection, and multiple components are analyzed in a single run; libraries of spectra or other databases are searched for identification of compounds, peptides, or nucleic acid sequences.

Safety

Normal laboratory precautions must be exercised during HPLC operation. Most organic solvents are flammable. The column effluent should be collected in a suitable container and stored appropriately before disposal. The explosive release of pressure in an HPLC system is not a major hazard; liquids compress only slightly and therefore accumulate little energy.

Supercritical Fluid Chromatography (SFC)

Under pressure, carbon dioxide occurs as a liquid that has some favorable properties as a solvent for chromatography.[1,40] It has low viscosity and high diffusion coefficients and dissolves many hydrophobic compounds. Consequently, SFC has performance characteristics somewhat intermediate between liquid and gas chromatography.[65] A variety of organic modifiers have been mixed with carbon dioxide to serve as the solvent. Columns are packed with a variety of stationary phases similar to those used for liquid chromatography. This technique has been used for analysis of lipids and other hydrophobic components that are soluble in liquid carbon dioxide. SFC has been applied to pharmaceutical research and analysis of natural products but, because of the need for specialized equipment, it has found limited use in clinical laboratories.

Gas Chromatography

GC was first developed by James and Martin in 1952 to separate fatty acids.[30] With this technique, a gaseous mobile phase is used to pass a mixture of volatile solutes through a column containing the stationary phase.[47] The mobile phase is typically an inert gas, such as nitrogen, helium, hydrogen, or argon, referred to as the *carrier gas*. Solute separation is based on relative differences in the solutes' vapor pressures and interaction with the stationary phase. Thus a more volatile solute elutes from the column before a less volatile one. In addition, a solute that selectively interacts with the stationary phase elutes from the column after one with a lesser degree of interaction. The column effluent carries the separated solutes to the detector in the order of their elution. Solutes are identified qualitatively by their similar retention times.[14] Furthermore, peak size (area or height) is proportional to the amount of solute detected and is used to quantify it.

Gas-solid chromatography (GSC) and gas-liquid partition chromatography (GLC) are variations of GC. In GSC, separations occur primarily through differences in absorption at the solid phase surface. In GLC, a nonvolatile liquid is coated or chemically bonded onto particles of column packing or directly onto the wall of a capillary column. Separation occurs primarily through differences in solute partitioning between the gaseous mobile phase and the liquid stationary phase.

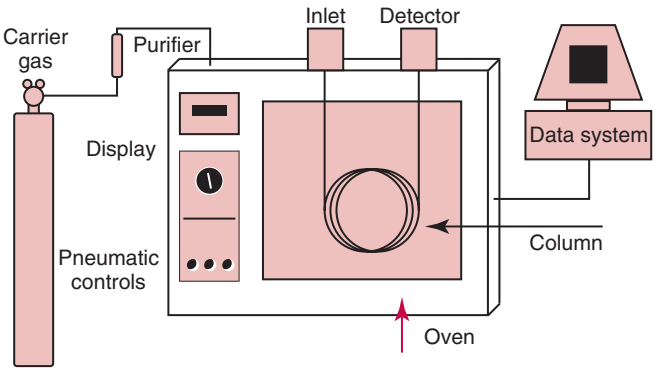

Figure 13-12 Diagram of a gas chromatograph. *(Courtesy Restek Corporation, Bellefonte, Pa.)*

Instrumentation

The components of a gas chromatograph are illustrated in Figure 13-12.

Columns

Both packed and capillary columns are used in gas chromatographs. Packed columns are filled with support particles that are used uncoated (GSC) or have been coated or chemically bonded with the stationary phase (GLC). Such columns vary from 1 to 4 mm in ID and from 1 m or more in length, and are fabricated from tubes of glass or stainless steel. Although narrow columns are more efficient, wider columns have increased sample capacities. For example, fast GC is a type of GC in which high-speed separations are achieved with short lengths of narrow-bore capillary columns in conjunction with rapid oven temperature ramp rates and increased linear velocity of the carrier gas.

Types of capillary columns include (1) porous layer open tubular (PCOT), (2) support coated open tubular (SCOT), and (3) wall-coated open tubular (WCOT) columns. In PCOT columns there is a porous layer on the inner wall. Porosity is achieved by either chemical means (e.g., etching) or by the deposition of porous particles on the wall from a suspension. The porous layer serves as a support for a liquid stationary phase or as the stationary phase itself (http://goldbook.iupac.org/P04763.html/accessed April 6, 2011). PLOT columns primarily are utilized for gas analysis and the separation of low molecular weight hydrocarbons.

The SCOT columns have their inner wall lined with a thin layer of support material onto which the stationary phase is adsorbed. Wall-coated open tubular columns consist of a capillary tube whose inner wall is coated with a liquid stationary phase. They are the most popular of the three types of capillary columns and are fabricated by coating the inner wall of a fused silica tube whose ID and length varies from 0.1 to

TABLE 13-3 Stationary Phases Commonly Used in Gas Chromatography for Clinical Separations

Composition	Polarity	Similar Phases	Applications
100% dimethyl-polysiloxane	Nonpolar	OV-1, SE-30	Drugs, amino acid derivatives
5% diphenyl–95% dimethyl-polysiloxane	Nonpolar	OV-101, SP-2100	Drugs
50% diphenyl–50% dimethyl-polysiloxane	Intermediate	OV-17	Drugs, steroids, glycols
50% cyanopropylmethyl–50% phenylmethyl-polysiloxane	Intermediate	OV-225	Fatty acid methyl esters, carbohydrate derivatives
Polyethylene glycol	Polar	Carbowax 20M	Acids, alcohols, glycols, ketones

0.5 mm and from 10 to 150 m, respectively. The ultrapure fused silica capillary tubing used in their manufacture is very fragile and to physically strengthen the tubing, a thin outside coating of polyimide or aluminum is added, which improves column durability. These modified capillary columns have the structural strength and flexibility necessary to withstand coiling and placement in ovens.

In addition to the packed and capillary columns, progress has been made in the development of micro GC columns on silicon chips.[1A] These microdevices have great potential for high-speed GC, a miniature GC, and eventually even a pocket GC.[10]

A variety of compounds have been used as the stationary phase in GLC. These include (1) methyl silicone polymers, (2) substituted silicone polymers, and (3) silicone polyesters (Table 13-3). These materials are coated or are chemically bonded onto the surface of the support particles or onto the walls of the column. Although they are more expensive, bonded materials are preferred because of their stability.

Carrier Gas Supply and Flow Control

The function of the carrier gas supply and flow control is to provide carrier gas to the chromatographic column and to regulate its flow through the system. Operationally, a constant flow of carrier gas is required for column efficiency and reproducible elution times. Systems that provide constant flow rates vary from simple mechanical devices to sophisticated electronic ones. More demanding temperature-programmed operation (discussed later) requires a more sophisticated differential flow controller, such as an electronic pressure control system programmed to regulate the carrier gas flow rate and pressure during a chromatographic run. Such a controller may be operated in a constant-flow or a constant-pressure mode. In the constant-flow mode, the pressure required to maintain a constant flow independent of carrier gas viscosity is calculated. A pressure transducer then measures and maintains the inlet pressure required for the constant flow.

The magnitude of the carrier gas flow rate depends on the type of column. For example, packed columns require a flow rate from 10 to 60 mL/min. Flow rates for capillary columns are much lower (1 to 2 mL/min), and maintenance of a constant flow rate is even more critical for the efficient operation of these columns. Microprocessor controls with specialized valves are currently used to control flow rates.

A number of gases are used as carrier gases, depending on the column and the detector. Hydrogen and helium are the carrier gases of choice with capillary columns. Only high-purity hydrogen and helium should be used because carrier gas impurities (1) harm the column, (2) negatively influence the performance of some detectors, and (3) adversely affect quantification in trace analysis. For packed columns, the most frequently used carrier gas is nitrogen, which is used with flame ionization (FID), electron capture (ECD), or thermal conductivity (TCD) detectors. Helium is used with FIDs and TCDs, and nitrogen-argon-methane gas mixtures are used with the ECD. Carrier gases must be dry, and the tubing used to connect the gas source to the GC must be uncontaminated. Molecular sieve beds and specialized inline traps are commonly used to remove the moisture, hydrocarbon, and/or oxygen content of the carrier gas.[11]

Injector

The injection of an aliquot of the sample to be analyzed into the column begins the chromatographic process and has to be done with minimal disruption of the gas flow into the column. In most clinical GC methods, samples are dissolved in nonaqueous liquids introduced into the column via an automated, highly precise, and rapid inline injector. With packed columns, a glass microsyringe is used to inject a 1- to 10-μL aliquot of the dissolved sample through a septum, which serves as the interface between the injector and the chromatographic system. In practice, the syringe needle is inserted through the injector septum and into a heating region. The volatile analytes and the solvent are then "flash-vaporized" and swept into the column by the carrier gas. To ensure rapid and complete solute volatilization, the temperature of the injector is typically maintained at least 30 to 50 °C higher than the column temperature.

Common problems with GC analysis include septum leaks and adsorption of components from the sample onto the septum during injection. In addition, because the septum is heated, decomposition products often form and "bleed" into the column. This results in spurious peaks, termed *ghost* peaks, which appear in the chromatogram. Septum bleed is greater at higher injection port temperatures. To minimize this problem, a Teflon-coated, low-bleed septum is used. The inner surface of the septum is purged continuously with the carrier gas that is vented before it passes into the column. This approach is especially effective, and most commercial

injectors are equipped with continuous-purge capabilities. The septum is a consumable component of the gas chromatograph and should be replaced at least once every 100 injections.

Because of the low sample capacities and carrier gas flow rates used with capillary columns, split and splitless injection techniques are used to introduce samples into the columns. In the split mode, only a small portion of the vaporized sample enters the column, whereas in the splitless mode, most of the sample enters the column.[66] Operationally, the split flow mode is used for samples that contain relatively high concentrations of the target analyte(s); the splitless mode is used for samples that contain relatively low concentrations of the target analyte(s).

Temperature-programmable injection ports are available and may be used in the split or splitless mode. The sample is injected at a temperature slightly higher than the boiling point of the solvent. Most of the sample components condense on glass or fused silica wool in the injector insert, while the solvent is removed. The injector is then rapidly heated at rates of up to 100 °C/min. The rapid heating vaporizes the analytes, which then move into the column. Very rapid heating is advantageous in that thermally labile compounds are exposed to high temperatures for only a short time. Separation of solvent removal and analyte vaporization allows injection of sample volumes up to hundreds of microliters. This obviously improves analyte detection when the sample matrix is not the limiting factor.

Temperature Control

Operationally, both packed and capillary GC columns require careful control of the column, injector, and detector temperatures. Control of the column temperature is achieved when the column is placed in an oven, or when the column is heated directly by resistive heating.[31] Injector and detector temperatures usually are controlled by electrical resistance heating. Depending on the application, the column temperature is maintained at a constant preset value (isothermal operation) during the chromatographic run or is varied as a function of time (temperature-programmed or temperature-gradient operation).

In practice, temperature-programmed column heating is used for most clinical applications. With temperature programming, the solutes having the lower boiling points elute first, followed by those having higher boiling points. Consequently, a complex mixture of solutes with a wide range of boiling points is separated into sharp, distinct chromatographic peaks in less time than with isothermal operation. The temperature is programmed and controlled by a computer and its resident software.

In capillary gas chromatographs, accurate and precise control of column and injector temperatures is required to obtain optimal performance and reliable results. Temperature control of the column is especially important, particularly in qualitative applications in which the retention times or volumes of eluting peaks are compared with those of authentic standards for compound identification. A change of only 1 °C causes a 5% change in retention time. In addition, instability of the column temperature adversely affects retention time or volume comparability among instruments or among values in the literature. Temperature gradients in the oven and rapid temperature programming rates also causes variable analyte retention.

The thermal stability of the stationary phase is also important. Because each stationary phase has a range of thermal stability, it is important to control column temperature within the specified operating range. For the nonpolar phases, the temperature limit is determined by the stability of the polyimide coating. The introduction of aluminum clad columns notably broadens the usable temperature range. Oxidation at higher temperatures limits the operating temperature of intermediate to polar phases.

Before any column is used, it must be "thermally conditioned" by heating the column at various temperatures for different lengths of time. This removes volatile contaminants, including residual monomers, in the polymeric stationary phase. In addition, thermal conditioning of used columns removes accumulated nonvolatile contaminants that cause unstable baselines. To condition a column thermally, it is disconnected from the detector and purged for at least 5 minutes with pure carrier gas. It is then heated to above 50 °C. The column temperature is cycled through a normal temperature program three or four times. Alternatively, the column can be maintained at the maximum operating temperature for 12 to 24 hours. Thermal conditioning of columns at lower temperatures prolongs the life of the column, but longer conditioning times are required to achieve baseline stability. Preconditioned capillary columns are also available.

Detectors

A variety of sensitive detectors are used with gas chromatographs (Table 13-4). These include universal units that detect most analytes and extremely selective devices that detect only specific ones. Examples include (1) FID, (2) thermionic selective (TSD), (3) ECD, (4) photoionization (PID), (5) TCD, and (6) mass spetrometers. Many other devices have been used as GC detectors, and it has become common practice to place two or more detectors in a series to enhance analytical specificity and sensitivity. Different types of mass spectrometers are also used as detectors for gas chromatographs (see Chapter 14).

Flame Ionization Detector. The FID is a commonly used detector in clinical laboratories. A common application is the analysis of ethanol and other volatiles in blood and other aqueous specimens. Chromatograms of volatiles analyzed by headspace gas chromatography with FID detection is shown in Figure 13-13. Its advantages include simplicity, reliability, versatility, and ease of operation. During operation, the column effluent is mixed with hydrogen and air, and the eluting compounds are burned by a flame. About one molecule in 10,000 produces an organic cation and releases an electron, which is detected by a collector electrode positioned above the flame. The magnitude of the generated current is related to the mass of carbon material delivered to the

TABLE 13-4 Examples of Detectors Used in Gas Chromatographs

Type of Detector	Principle of Operation	Selectivity	Limit of Detection	Comments
Thermal conductance (TCD)	Measures thermal conductivity change in carrier gas on elution of compounds	Universal	<400 pg propane/mL He	
Flame ionization (FID)	CHNO + heat → $CHNO^+$ + e^-; electrons collected for detection	Hydrocarbon	10-100 pg CHO	
Thermionic selective (TSD; NPD)	Alkali bead selectively ionizes N- or P-containing compounds	N, P	0.4-10 pg N 0.1-1.0 pg P	
Electron capture (ECD)	$e^- + R + N_2 \rightarrow Re^- + N_2 + e^-$; excess electrons collected; concentration inversely related	Electronegative groups	0.05-1.0 pg Cl^--containing compounds	
Mass spectrometer (MS)	e^- + ABC → A^+ BC; monitor mass-to-charge ratio by scanning or single-ion monitoring (SIM)	Universal (tunable)	1 ng scan 10 pg SIM	Provides structural confirmation; ion ratios constant in SIM
Photoionization (PID)	CHNO + photon → $CHNO^+$ + e^-; detect electron	Hydrocarbon	1-10 pg CHO	May be improvement on FID
Electrolytic conductivity (Hall)	Postcolumn reaction detector for selective detection of halogen-, S-, or N-containing compounds	Halogen-, S-, and N-containing compounds	0.1-1.0 pg Cl 2.0 pg S 4.0 pg N	
Flame photometric (FPD)	P- and S-containing hydrocarbons emit light when burned in FID-type flame; emitted light detected	P- and S-containing compounds	0.9 pg CHP 20 pg CHS	
Fourier transform infrared (FTIR)	Infrared wavelength light absorbed by the compound of interest	Universal (tunable)	1 ng strong infrared absorber	Scanned for structural information or absorbance—measured for quantitation

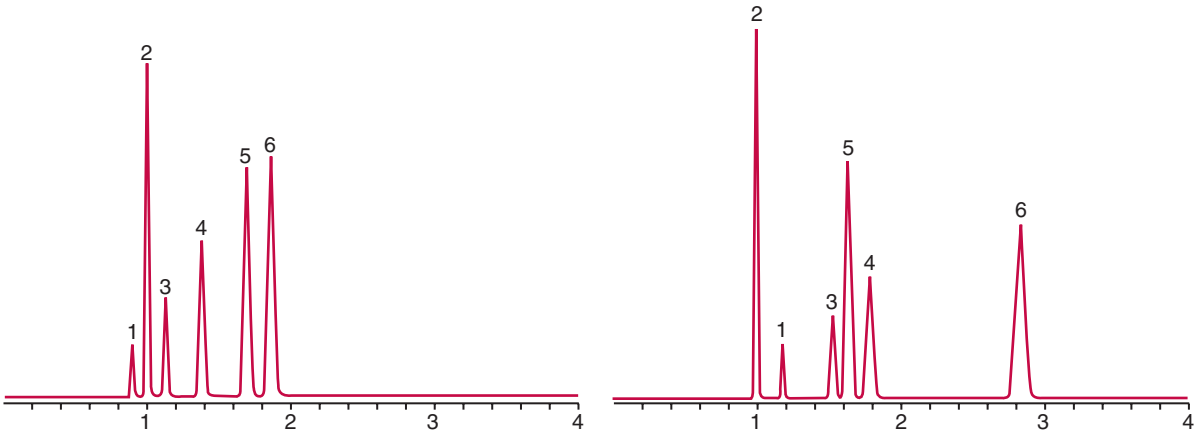
detector; after measurement, it is used for detection and quantification of the eluting solutes.

Thermionic Selective Detector. The TSD, also known as the *nitrogen-phosphorus detector (NPD),* is a modification of the FID in which an alkali bead is heated electrically in the area directly above the jet. In the presence of alkali atoms in the flame, nitrogen-containing compounds produce a 15 times greater, and phosphorus-containing compounds a 300 times greater, response. The TSD is frequently used in analytical laboratories for the detection of organic bases and acids.

Electron Capture Detector. The operating principle of the ECD is based on the reaction between electronegative compounds and thermal electrons. Electrons are normally provided from a radioactive source, such as ^{63}Ni or ^{3}H housed in the detector. A collector electrode is pulsed to collect "excess" electrons. This is called the *standing current.* If electronegative species are not present in the detector cell, the nitrogen or argon/methane (95/5) sweep gas removes most of the electrons from the cell. When a compound capable of capturing an electron passes through the cell, some electrons are removed and a decrease in the standing current is observed. The use of nitrogen or argon/methane is important, because these gases reduce the energy of the electrons via collisions and thus improve the ability of the compounds to "capture" them. It is also important that the gases are very pure and dry, because oxygen and water can foul the detector. In some detector designs, the collection pulse rate is varied to maintain a constant amount of current. Then the pulses are counted, and this number is used to determine the concentration of electronegative species passing through the cell. The



1. Methanol	Inj.:	1.0 mL headspace sample of a blood alcohol mix
2. Acetaldehyde	Sample conc.:	0.1% per compound
3. Ethanol	Oven temp.:	40 °C
4. Isopropanol	Inj./det. temp.:	200 °C
5. Acetone	Carrier gas:	helium
6. *n*-propanol	Linear velocity:	80 cm/sec. set @ 40 °C
	FID sensitivity:	1.28×10^{-10} AFS

Figure 13-13 Chromatograms of volatiles analyzed by headspace gas chromatography. *(Courtesy Restek Corporation, Bellefonte, Pa.)*

ECD is a concentration-dependent detector. The presence of electronegative constituents, such as fluorine, chlorine, bromine, and iodine, enhances the response of the ECD. Because not all compounds contain these functional groups, derivatization with reagents containing polychlorinated or polyfluorinated groups to increase detector response is a common practice.

Photoionization Detector. The PID is a variant of the FID. With the PID, however, energy for ionization is provided by an intense UV lamp rather than by a flame.

Thermal Conductivity Detector. The TCD is based on the principle that addition of a compound to a gas alters the thermal conductance of the gas.

Mass Spectrometry. Mass spectrometers are also used as detectors for gas chromatographs (see HPLC section earlier or Chapter 14).

Computer/Controller

As with most modern analytical instruments, an automated GC is computer controlled with the computer functioning as both a process controller and a data processor. For example, as a process controller, the computer regulates various parameters, such as (1) carrier gas composition and flow rate; (2) column backpressure; (3) column and detector temperatures; (4) sample injection, detector selection and operation; and (5) the various timing steps that command the operation of the system. For data processing, the computer monitors signals generated by the system's detectors and commands the acquisition and storage of data at specified time intervals. The area, or height, of each chromatographic peak is determined from the stored data, and this information is used to compute the analyte concentration represented by each peak. Available algorithms for this computation include those based on calibration curves or conversion factors from internal or external calibration. If desired, a complete report can be prepared and printed for each chromatographic run. Alternatively, data are stored to be recalled and reprocessed, with different integration parameters.

Qualitative and Quantitative Analyses

Chromatography is used to qualitatively identify and quantify the analyte(s) of interest.

Analyte Identification

The retention time or volume at which an unknown solute elutes from a column, or the distance traveled on a plate, is often compared and matched with that of a reference compound. The appearance of a solute peak, band, or spot at the same time, volume, or distance as that of a reference compound is consistent with the two compounds being the same. This simultaneous appearance does not prove identity, however, because other compounds can have the same retention time or volume or can travel the same distance as the reference compound.

In planar chromatography, reference compounds are chromatographed with the unknown sample. Tentative identification is made by comparison of migration distances and detection characteristics of the reference compounds with those of the unknown analytes. If the R_f of the unknown analyte and the R_f of the reference compound do not match, the compounds are judged to be different. If they match, the compounds are presumed to be identical. However, because

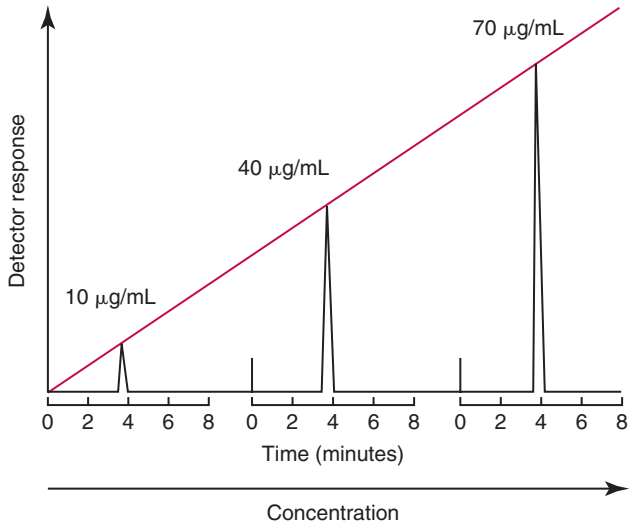


Figure 13-14 The use of external calibrators in the production of a calibration plot. *(From Krull I, Swartz M. Quantitation in method validation. LC-GC 1998;16:1084-90.)*

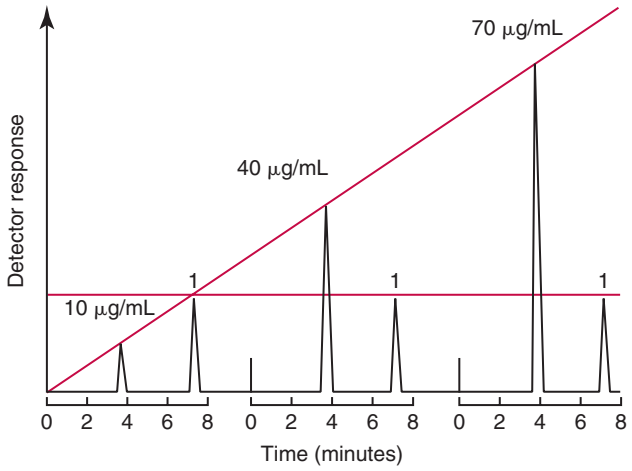

Figure 13-15 The use of internal calibrators in the production of a calibration plot (peak 1 being the internal standard). *(From Krull I, Swartz M. Quantitation in method validation. LC-GC 1998;16:1084-90.)*

more than one compound can have the same R_f in a particular chromatographic system, the presumptive identification should be confirmed by the use of specific spray reagents, antibody complexation, or isolation of the compound followed by chemical and/or instrumental analysis. Software is now available for compound identification by library searching of UV spectra based on corrected R_f values.

With capillary GC and LC columns, it is possible to simultaneously introduce the components of a single injection into two columns made of dissimilar stationary phases. These columns are connected to separate detectors of the same or a different type. Matching the retention properties of a single analyte with a reference compound on two columns of dissimilar phases enhances the chance for correct identification of the analyte. The most reliable analyte identification, however, is provided by a detector that features structural information, such as a mass spectrometer (see Chapter 14).

Analyte Quantification

Electronic signals from the detector(s) are also used to produce quantitative information. Both external and internal calibrating techniques have been used. With external calibration, reference solutions containing known quantities of analytes are processed in a manner identical to samples containing the analyte (Figure 13-14). A calibration curve of (1) peak height, (2) peak area, or (3) spot density versus calibrator concentration is constructed and used to calculate the concentration of the analyte in the samples. With internal calibration, also called *internal standardization,* reference solutions of known analyte concentrations are prepared, and a constant amount of a different compound, the internal standard, is added to each reference solution and each sample (Figure 13-15). By plotting the ratio of the peak height (or area) or spot density of the analyte to the peak height (or area) or spot density of the internal standard versus the concentration of the analyte, a calibration curve that corrects for systematic losses is constructed. This curve is then used to compute the analyte concentration in the samples by interpolation.

EXTRACTION AND DIFFERENTIAL PRECIPITATION

Extraction and differential precipitation refer to the separation of components into discrete fractions, often two separate liquid fractions or a liquid and a solid fraction that may be separated by centrifugation or filtration. A simple example of extraction is the separation of components into two immiscible solvents in a separatory funnel. Different components are partitioned differentially into two phases, which then are physically separated. Extraction or differential precipitation is often used to simplify specimens and to remove components such as proteins that may interfere with subsequent chromatographic or analytical methods. Extraction may also be used as a method to concentrate specimens; extraction by volatile organic solvents is often followed by evaporation, yielding an extract with a higher concentration than the original specimen. Differential precipitation uses conditions whereby some components are soluble, while others are precipitated. Precipitation of proteins in biological fluids with acid or organic solvent is often used to separate them differentially from drugs or other small molecules that remain in solution. Other examples include differential precipitation of albumin and globulins with salt solutions and lipoprotein fractions by selective precipitating agents.

Use of solid-phase extraction has been increasing for many applications,[61] and solid phases are packed in a variety of formats, including small open columns, cartridges, 96-well plates, and pipet tips.[19,55] The use of particles with pore sizes smaller than 10 nm (100 Å) results in exclusion of most proteins from pores, leading to removal of proteins from the

retentate. Solid-phase extraction can be performed on many specimens in parallel on a vacuum manifold or on extraction plates in 96-well formats. Solid-phase extraction generally yields more selective extraction than does liquid-liquid extraction, because it is possible to perform washing steps before elution of the desired components with solvents of defined composition. Solid-phase extraction may be amenable to automation with robots in a separate process from later chromatography steps, or the use of online extraction as an initial separation step in a chromatographic process.[50,71] Use of online extraction linked to liquid chromatographic separations improves the automation and reproducibility of sample handling, [29]

CHAPTER 14

Mass Spectrometry

*Alan L. Rockwood, Ph.D., D.A.B.C.C., Thomas M. Annesley, Ph.D., and Nicholas E. Sherman, Ph.D.**

Mass spectrometry (MS) is a powerful qualitative and quantitative analytical technique that is used to measure a wide range of clinically relevant analytes. When MS is coupled with gas or liquid chromatographs, the resultant analyzers have expanded analytical capabilities with widespread clinical applications. In addition, because of its ability to identify and quantify proteins, MS is a key analytical tool that is used in the emerging field of proteomics.

We begin this chapter with a discussion of the basic concepts and definitions of MS followed by discussions of MS instrumentation and clinical applications, and we end the chapter with a discussion of logistic/operational/quality issues. In this chapter, it is impossible to cover all concepts in a field as vast as mass spectrometry, even if one limits one's focus to clinical mass spectrometry. The Clinical and Laboratory Standards Institute (CLSI) has published recommendations on clinical mass spectrometry that can serve as a good next step for study of this topic and another gateway into the extensive literature on this topic.[27]

BASIC CONCEPTS AND DEFINITIONS

MS is the branch of science that deals with all aspects of mass spectrometers and the results obtained with them. *Molecular mass* (sometimes referred to as *molecular weight*) is measured in units of *unified atomic mass unit* (u), also known as the *dalton* (Da). The mass of a carbon atom in its lowest energy state is defined as 12 Da. Although the term *atomic mass unit (amu)* has been regarded as equivalent to the Da, it is only approximately equal to the Da and now is considered an obsolete unit; its use to refer to the Da is strongly discouraged. A *mass spectrometer* is an analytical instrument that first ionizes a target molecule and then separates and measures the mass of a molecule or its fragments. *Mass analysis* is the process by which one or more ionic species are identified according to the *mass-to-charge ratio (m/z)*.[117] The analysis is qualitative, quantitative, and extremely useful for determining the elemental composition and structure of both inorganic and organic compounds.

All MS techniques require an *ionization* step in which an ion is produced from a neutral atom or molecule. In fact, the development of versatile ionization techniques caused MS to become the excellent analytical tool it is today. In 2002, John Fenn and Koichi Tanaka shared the Nobel Prize for their development of electrospray[43,44] and laser desorption[72,92,115] ionization, respectively.

Ions may undergo *fragmentation* in a mass spectrometer. An unfragmented ion of the original molecule is called the *molecular ion*. If the ionization source is *soft,* meaning that it produces little fragmentation, the most abundant peak in the mass spectrum (the *base* peak) may be the molecular ion. Ions that are formed by fragmentation of a molecular ion in the ion source are known as *fragment ions*. If the ion source is *hard,* meaning that it produces extensive fragmentation, the base peak may be one of the fragment ions. By convention, the base peak in a mass spectrum is assigned a relative abundance value of 100%.

Fragment ions that are formed in a separate dissociation cell in a *tandem mass spectrometer* are known as *product ions*. A tandem mass spectrometer consists of two mass spectrometers operated in sequence, or a single mass spectrometer capable of sequential measurement of ions. Generally, ions are dissociated into product ions between the two stages of *m/z* analysis.

A *mass spectrum* is represented by the relative abundance of each ion plotted as a function of its *m/z* ratio (Figure 14-1). Usually, each ion has a single charge (z = 1); thus the *m/z* ratio is equal to the mass. However, in some cases, the charge may be represented by some other integer number, in which case the *m/z* ratio is not equal to the mass, but rather is some fraction of the mass.

Monitoring ions with higher mass usually results in lower limits of detection because fewer background ions are present. A peak in a mass spectrum can be characterized by its *resolution,* $[(m/z)/(\Delta m/z)]$, where $\Delta m/z$ is the width of the mass

*The authors gratefully acknowledge the original contributions by Larry D. Bowers on which portions of this chapter are based. We also wish to acknowledge technical assistance by Jacquelyn McCowen-Rose and helpful suggestions from N. Leigh Anderson, Julianne C. Botelho, Pierre Chaurand, David K. Crockett, Ulrich Eigner, Steven A. Hofstadler, Andrew N. Hoofnagle, Gary H. Kruppa, Mark M. Kushnir, Donald Mason, Michael Morris, Maria M. Ospina, and Hubert W. Vesper.

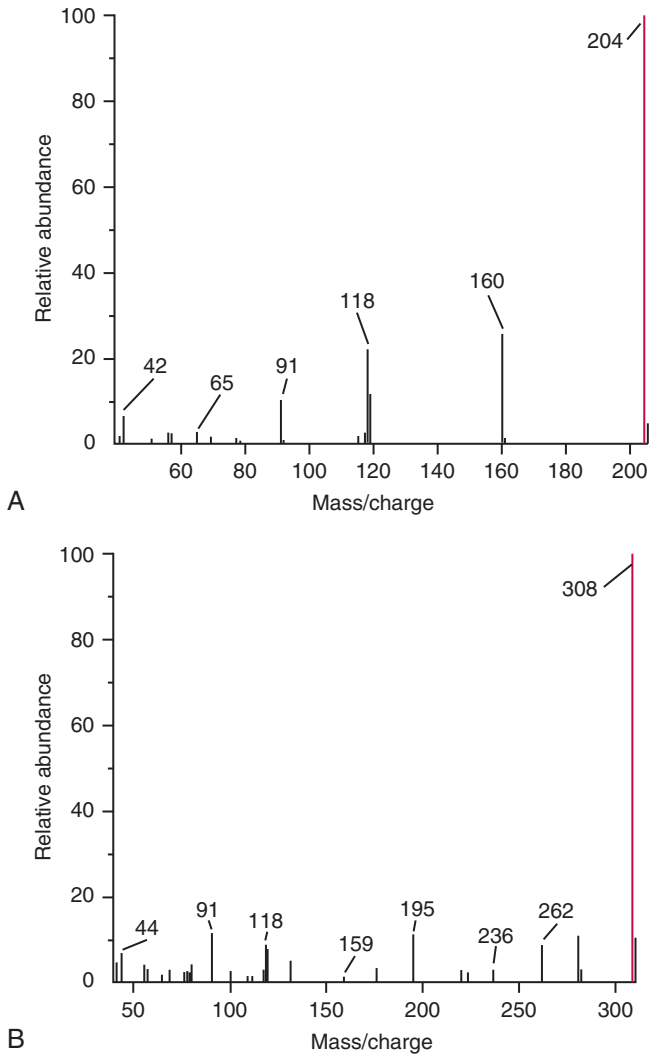

Figure 14-1 Mass spectrum of the pentafluoropropionyl (A) and carbethoxyhexafluorobutyryl (B) derivatives of D-methamphetamine.

spectral peak. This parameter characterizes the ability of a mass spectrometer to separate nearby masses from each other.

By setting the relative abundance of the base peak to 100% and therefore using the relative, rather than absolute, abundance of each ion fragment, instrument-dependent variability is minimized, and the mass spectrum can be compared with spectra obtained on other instruments. Because fragmentation at specific bonds depends on their chemical nature, the mass spectrum can be interpreted in terms of the molecular structure of the analyte. In some cases, the chemical structure of the analyte can be deduced, or at least reconciled with features found in the mass spectrum. Computer-based libraries of spectra are also available to assist in identification of the analyte(s). In some applications, the mass spectrum of an analyte may be matched against mass spectra in a database, thereby identifying the analyte by its mass spectral *fingerprint*.

When interfaced to a liquid or gas chromatograph, the mass spectrometer functions as a powerful detector, providing structural information in real time on individual analytes as they elute from a chromatographic column. Depending on the operating characteristics of the mass spectrometer and the chromatographic peak width, several mass spectral scans can be acquired across the peak. The sum of all ions produced is displayed as a function of time to yield a *total ion chromatogram.*

The mass spectrometer is considered to be a "universal detector" because all compounds have mass. The data system can also be programmed to display chromatograms of only preselected ions acquired during data acquisition. The resultant display is called an *extracted ion chromatogram,* sometimes referred to as an *extracted ion profile.* Both of these displays have the appearance of a chromatogram with signal intensity plotted as a function of time. Retention times can be measured and peak heights or peak areas can be integrated for use in quantitative analysis.

Sample preparation is critical to successful mass spectrometry, particularly when one is dealing with complex matrices, such as are commonly encountered in clinical chemistry. This typically involves one or more of the following steps: (1) protein precipitation, (2) solid-phase extraction, (3) liquid-liquid extraction, or (4) *derivatization*. Derivatization is the process of chemically modifying the target compound(s) to be more favorably analyzed by mass spectrometry. Derivatization usually involves the addition of some well-defined functional group. The goals of derivatization vary, depending on the application, but typically include one or more of the following: (1) increased volatility, (2) greater thermal stability, (3) modified chromatographic properties, (4) greater ionization efficiency, or (5) favorable fragmentation properties.

When only a few analytes are of interest for quantitative analysis and their mass spectrum is known, the mass spectrometer is programmed to monitor only those ions of interest. This selective detection technique is known as *selected ion monitoring* (SIM). Because SIM focuses on a limited number of ions, more ion signal is collected for each selected *m/z*. This increases the signal-to-noise ratio of the analyte and improves the lower limit of detection. In general, an unknown is considered identified if the relative abundances of three or four ions agree within ±20% of those from a reference compound.

A chemical element may be composed of a single *isotope* or multiple isotopes. Each isotope of an element has the same number of protons in its nucleus but different numbers of neutrons. For example, naturally occurring carbon is composed primarily of two isotopes: ^{12}C, whose nuclei contain six protons and six neutrons, and ^{13}C, whose nuclei contain six protons and seven neutrons. Some elements, such as arsenic, have only a single isotope in the naturally occurring state.

A distinct advantage of the mass spectrometer is that it can simultaneously differentiate and quantify a compound with a normal abundance of isotope from an analog enriched with a stable isotope [e.g., (1) ^{2}H relative to ^{1}H, (2) ^{13}C relative to ^{12}C, (3) ^{15}N relative to ^{14}N, (4) ^{18}O relative to ^{16}O]. A compound labeled with a stable isotope is used as an *internal*

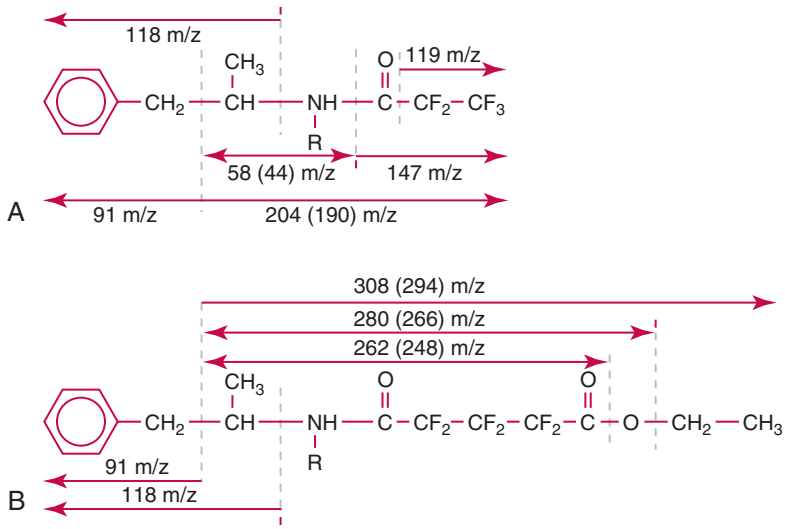

Figure 14-2 Fragmentation patterns for the pentafluoropropionyl (A) and carbethoxyhexafluorobutyryl (B) derivatives of methamphetamine (R = CH_3) and amphetamine (R = H; *masses in parentheses*). Compare the predicted masses with the spectrum shown in Figure 14-1. Note that for the pentafluoropropionyl derivative, only one ion (204, 190 *m/z*) is characteristic of the aliphatic portion of the molecule.

standard because it behaves nearly identically to the native compound during sample preparation and chromatographic analysis. The internal standard must have a sufficient amount of heavy isotope so that no naturally occurring isotope (such as ^{2}H or ^{13}C) contributes significantly to the ion current. For the methamphetamine derivatives shown in Figure 14-2, an internal standard with at least three ^{2}H or ^{13}C atoms is preferred, because at this point the natural abundance of these isotopes is ≈0.1% at 3 mass units above the molecular ion [$(M+3)^{+}$]. Placement of the stable isotope atoms in the structure is also important. For example, the *m/z* 204 ion for methamphetamine represents the aliphatic portion of the molecule (loss of the aromatic ring). If five deuterium atoms were present on the aromatic ring of methamphetamine, the pentafluoropropionyl derivatives of both native and isotope-labeled drug would yield the *m/z* 204 ion. Similarly, the stable isotope must be located so that it will not exchange with solvent molecules. The ability to quantify a compound relative to an isotopic species of known or fixed concentration is known as *isotope dilution analysis,* and the specific mass spectrometric technique is known as isotope dilution mass spectrometry (IDMS). The IDMS technique has been used to develop definitive methods for a number of clinically relevant analytes including drugs of abuse.

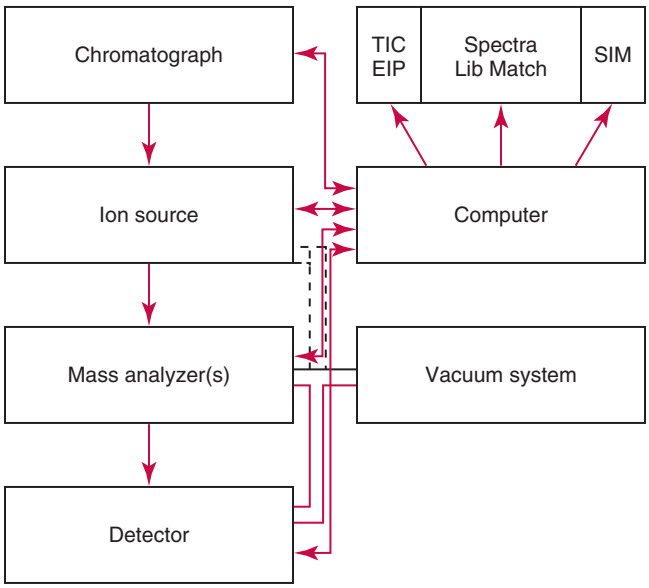

Figure 14-3 Block diagram of the components of a chromatograph–mass spectrometer system. The mass analyzer and the detector are always under vacuum. The ion source may be under vacuum or under near-atmospheric pressure conditions, depending on the ionization mode. The computer system is an integral part of data acquisition and output.

INSTRUMENTATION

A mass spectrometer consists of (1) an ion source, (2) a vacuum system, (3) a mass analyzer, (4) a detector, and (5) a computer (Figure 14-3).

Ion Source

Many approaches have been used to form ions in both high-vacuum and near-atmospheric pressure conditions. *Electron ionization* (EI) and *chemical ionization* (CI) are ionization techniques used when gas-phase molecules are introduced directly into the analyzer from a gas chromatograph. In other analyses, such as high-performance liquid chromatography-mass spectrometry (HPLC-MS), *electrospray ionization* (ESI), *atmospheric pressure chemical ionization* (APCI), and *atmospheric pressure photoionization* (APPI) interfaces are used as

ionization sources.[19,41,50,60] Other ionization techniques include (1) *inductively coupled plasma* (ICP), (2) *matrix-assisted laser desorption ionization* (MALDI), (3) *atmospheric pressure matrix-assisted laser desorption* (AP-MALDI), and (4) a number of other less well-known sources. This chapter will limit its discussion to ion sources of interest to clinical chemical analysis. The CLSI document C-50A contains recommendations for matching the capabilities of different ion source technologies to various application classes.[27]

Electron Ionization

In EI, gas-phase molecules are bombarded by electrons emitted from a heated filament and attracted to a collector electrode (Figure 14-4). This process must occur in a vacuum to prevent filament oxidation. A potential difference of 70 eV generates electrons with sufficient energy that a near collision with most organic molecules produces a *radical* cation that is both an ion and a radical.[117] The radical ion then often undergoes unimolecular rearrangement and dissociation to produce a cation and a radical:

$$AB^{+\bullet} \longrightarrow A^{+} + B^{\bullet}$$

Positive ions are repelled or drawn out of the ionization chamber by an electrical field. The cations are then electrostatically focused and introduced into the mass analyzer. EI is primarily used as an ion source in gas chromatography–mass spectrometry (GC-MS). As determined by their chemical stability, the relative proportions of molecular ions and fragment ions produced in an EI source are reasonably reproducible. The fragmentation pattern is often used as a fingerprint to identify compounds by comparison with mass spectral libraries.

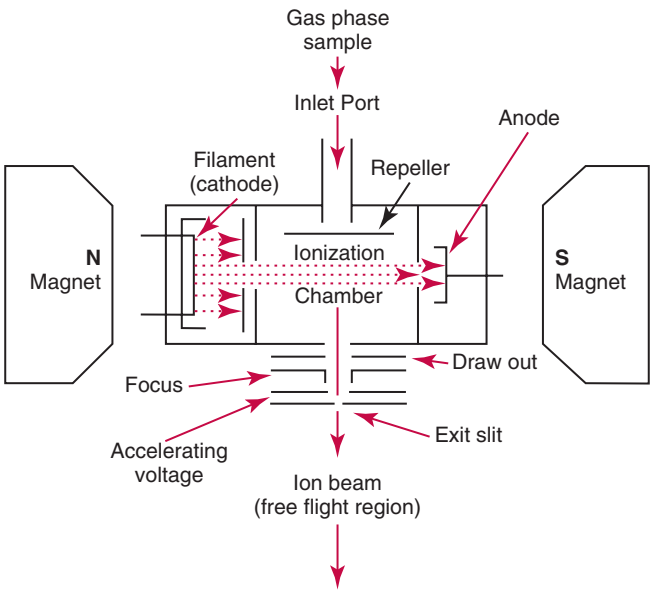

Figure 14-4 Electron impact ion source. The small magnets are used to collimate a dense electron beam, which is drawn from a heated filament placed at a negative potential. The electron beam is positioned in front of a repeller, which is at a slightly positive potential compared with the ion source. The repeller sends any positively charged fragment ions toward the opening at the front of the ion source. The accelerating plates strongly attract the positively charged fragment ions.

Chemical Ionization

CI is a "soft" ionization technique in which a proton is transferred to, or abstracted from, a gas-phase analyte by a reagent gas molecule such as methane, ammonia, isobutane, or water. The reagent gas is bled into a special CI source so the source pressure is increased to about 0.1 torr. (Note: For virtually all practical purposes "torr" is equivalent to "mm Hg" and is the more customary term used in the field of mass spectrometry.) An electron beam produces reactive species (such as CH_5^+ for methane). Through a series of ion-molecule reactions, analyte ions become charged, usually via attachment of a proton. In most cases, relatively little fragmentation occurs. Negative ion electron capture CI is also possible and has become popular for quantification of drugs such as benzodiazepines. Negative ion formation occurs when thermalized electrons are captured by an electronegative substituent, such as chlorine or fluorine on the analyte. When applicable, negative ion CI has very low limits of detection. CI also is used as an ion source in GC-MS.

Electrospray Ionization

ESI is a soft ionization technique in which a sample is ionized at atmospheric pressure before introduction into the mass analyzer.[121,126] The sample, typically an HPLC effluent, is passed through a narrow metal or fused silica capillary to which a 3- to 5-kV voltage has been applied (Figure 14-5, *A*). The partial charge separation between the liquid and the capillary results in instability in the liquid that in turn results in expulsion of a series of charged droplets from a Taylor cone, which forms at the tip of the capillary. A coaxial nebulizing gas, which is used in several types of ESI sources, helps direct the charged droplets toward a counter-electrode. The droplets evaporate as they migrate through the atmospheric pressure region, expelling smaller droplets as the charge-to-volume ratio exceeds the Raleigh instability limit. The proton- or ammonium-adduct of the molecule, which may be associated with solvent molecules, is "desolvated" to form "bare" ions and is typically formed in the ionization process. However, other ionization products are sometimes observed, such as metal ion adducts with analyte molecules, or ions formed by redox processes. Ions then pass through a sampling cone and one or more extraction cones (skimmers) before entering the high-vacuum region of the mass analyzer.

One unusual feature of ESI is the production of multiple charged ions, particularly from peptides and proteins. It is common to observe approximately one charge for every 10 amino acid residues in a protein. For example, because a molecule of mass 20,000 can yield 20 charges, it can be detected at m/z 1000 (20,000/20) on a lower resolution and with a less expensive analyzer. This greatly extends the accessible mass range of such an instrument. In these cases, one

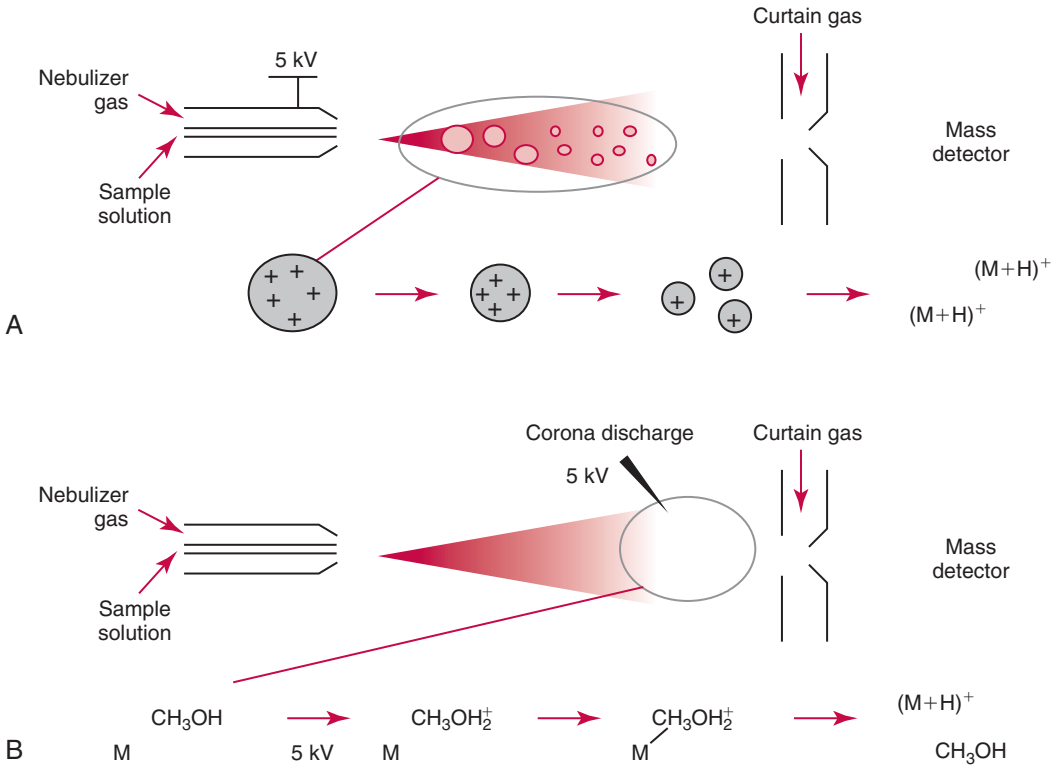

Figure 14-5 Schematics of (A) electrospray and (B) atmospheric pressure chemical ionization sources. Note the different points where ionization occurs, as described in the text.

usually observes a series of peaks, with each peak corresponding to a different number of charges. Nucleic acid polymers can also produce a series of multiply charged ions, particularly when ESI mass spectra are acquired in negative ion mode.

It should be noted that Figure 14-5 is a simplified illustration of the probe being directed toward the sampling cone of the mass detector. To enhance performance and minimize contamination of the mass detector, many modern hardware configurations have offset the probe and/or the mass detector relative to the sampling cone.

ESI tends to be an efficient ion source for polar compounds or for compounds that are ionized in solution, which include a high percentage of medically interesting compounds. ESI, along with APCI, allows an effective interface between a liquid chromatograph and a mass spectrometer. These have become the most widely used ion sources in clinical mass spectrometry.

Atmospheric Pressure Chemical Ionization

APCI is similar to ESI in the sense that ionization takes place at atmospheric pressure, involves nebulization and desolvation, and uses the same sample and extraction cones as ESI. The major difference lies in the mode of ionization. In APCI, no voltage is applied to the inlet capillary. Instead, a separate corona discharge needle[17] is used to generate a corona discharge. Somewhat analogously to the processes occurring in a CI source, ions generated by the corona discharge undergo ion-molecule reactions such as the following:

$$CH_3OH + H^+ \longrightarrow CH_3OH_2^+$$
$$A(\text{analyte}) + CH_3OH_2^+ \longrightarrow AH^+ + CH_3OH$$

or

$$H_2O + H^+ \longrightarrow H_3O^+$$
$$A(\text{analyte}) + H_3O^+ \longrightarrow AH^+ + H_2O$$

Because eluent solvent molecules (e.g., water, methanol) are present in excess relative to analytes in the sample, they are predominantly ionized early in the ion molecule cascade and then act as a reagent gas that reacts secondarily to ionize analyte molecules (Figure 14-5, *B*). Because the products of these secondary reactions may contain clusters of solvent and analyte molecules, a heated transfer tube or a countercurrent flow of a curtain gas, such as nitrogen, is used to decluster the ions. As with ESI, APCI is a soft ionization technique that produces relatively little fragmentation. Thus, compared with EI, the mass spectrum produced by APCI and other soft ionization techniques is less useful for analyte identification by mass spectral fingerprinting. However, because the ion current is concentrated into a single mass spectral peak (or relatively few mass spectral peaks if isotope peaks are considered), APCI and other soft ion sources are well matched to the requirements of tandem mass spectrometry (discussed later) and the combination of the two used for quantitative

analysis. APCI and ESI are generally useful for a similar range of compounds. However, APCI is often a more efficient ion source than ESI for relatively nonpolar compounds.

Atmospheric Pressure Photoionization

APPI is a relatively new and less frequently used ion source in clinical chemistry that provides a complementary approach to ESI or APCI. The physical configuration of an APPI source is similar to that for APCI, but an ultraviolet photon flux is used instead of a corona discharge needle to generate ions in the gas phase.[100,111,112] In APPI, an ionizable dopant, such as toluene or acetone, is often infused coaxially to the nebulizer to provide a source of ions that provide charge or proton transfer to analytes, thus increasing the efficiency of analyte ionization. APPI has a similar range of application to APCI but is often more useful than APCI for compounds of very low polarity, such as many steroids.

Inductively Coupled Plasma

As with ESI, APCI, and APPI, ICP is an atmospheric pressure ionization method. However, unlike most atmospheric pressure ionization methods, which are "soft" (i.e., producing little fragmentation), ICP is the ultimate in "hard" ionization, typically leading to complete atomization of the sample during ionization. Consequently, its primary use is for elemental analysis. In the clinical laboratory, it is particularly useful for trace metal and heavy metal analysis in tissue or body fluids. ICP is extremely sensitive (e.g., parts per trillion) and is capable of extremely high dynamic ranges.

Following sample preparation, which generally includes the addition of an internal standard such as yttrium and sometimes includes an acid digestion step, the sample is introduced into the ion source via a nebulizer fed by a peristaltic pump. The nebulized sample is transmitted into hot plasma generated at atmospheric pressure by inductively coupling power into the plasma using a high-powered, radiofrequency (RF) generator. A small orifice samples the plasma, and ions are transmitted to the mass analyzer through a series of differential pumping stages. The atmospheric sampling apparatus is conceptually similar to that of other atmospheric pressure ion sources, such as electrospray, except that the device must withstand the extremely high temperatures generated by the plasma.

ICP-MS is comparatively free from most interference. However, some interfering species can be extremely troublesome. Most interfering species are small polyatomic ions formed in the torch via ion-molecule reactions. For example, ArO^+ interferes with iron at *m/z* 56. One solution to this problem is to use a reaction cell, which consists of a moderate-pressure gas placed before the *m/z* analyzer.[12] A reactant gas, such as NH_3, is bled into the reaction cell. The reactant gas reacts with polyatomic interferences and removes them before introduction into the *m/z* analyzer. Another approach to removing interferences of the same nominal mass is to use a high-resolution mass spectrometer, which is capable of resolving species with similar nominal mass.[12] For example, the masses of ArO^+ and $^{56}Fe^+$ differ by 0.022 Da—a difference that is easily resolved using a high-resolution mass spectrometer.

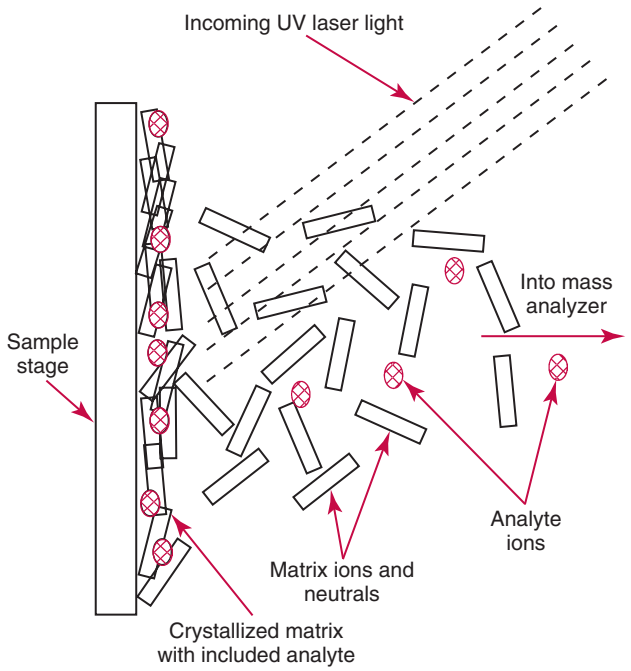

Figure 14-6 A generic view of the process of matrix-assisted laser desorption ionization. Cocrystallized matrix and analyte molecules are irradiated with an ultraviolet (UV) laser. The laser vaporizes the matrix, producing a plume of matrix ions, analyte ions, and neutrals. Gas-phase ions are directed into a mass analyzer.

Matrix-Assisted Laser Desorption/Ionization

MALDI and related techniques rely on energy transfer processes from a pulsed laser beam to the sample for ion generation. In most cases, the analyte is dissolved in a solution of matrix, a small molecular weight UV-absorbing compound, and this solution is placed on a target that is introduced into the mass spectrometer. A UV laser vaporizes small amounts of matrix and analyte into a plume of ions that is directed into a mass analyzer (Figure 14-6). MALDI is another of the "soft" ionization methods. Related techniques include atmospheric pressure matrix-assisted laser desorption/ionization, in which the MALDI process occurs at atmospheric pressure rather than reduced pressure, and surface-enhanced laser desorption ionization (SELDI), which uses a MALDI target surface modified with some type of affinity capture property [hydrophobic, ionic, immobilized metal affinity chromatography (IMAC), DNA, antibody, etc].

Ionization Methods of Potential Interest

Sonic spray ionization is one of the lesser used ionization methods with potential utility for clinical mass spectrometry.[53,54] It is as yet uncertain whether this technology has sufficient advantages over ESI and APCI to find frequent application, although it may find application for the analysis

of thermally labile compounds. Desorption electrospray ionization (DESI)[114] and direct analysis in real time (DART)[28] are two relatively new ionization methods that exemplify the generation of ions from surfaces at atmospheric pressure. Most applications of DESI and DART to date have been directed toward minimal sample preparation.

Ionization Methods of Historical Interest

The older literature includes several ionization methods or sample introduction methods that, although promising, or even widely used at one time, hold little interest for current practice in clinical chemistry. These include (1) *fast atom bombardment* (FAB), (2) *thermospray* (TSI), (3) *direct liquid introduction* (DLI), (4) *plasma desorption*, (5) *field ionization* (FI), (6) *field desorption* (FD), (7) *surface ionization mass spectrometry* (SIMS), (8) *laser desorption* (LD), and others. ESI and APCI ion sources have largely rendered these techniques obsolete.

Vacuum System

With the exception of certain ion trap mass spectrometers, ion separation in any of the mass analyzers requires that the ions do not collide with any other molecules during their interaction with magnetic or electric fields. This requires the use of a vacuum from 10^{-3} to 10^{-9} torr, depending on mass analyzer type. The length of the ion path in the analyzer must be less than the mean free path length, unless collisions play a role in mass analysis. Fourier transform ion cyclotron resonance (FT-ICR) requires the lowest pressure (10^{-9} torr). The quadrupole ion trap (QIT) tolerates the highest pressure (10^{-3} torr), a pressure range in which some collisions occur between ions and background gas. Routine quality assurance checks for vacuum leaks should include evaluation of air and water in the mass analyzer.

Efficient high-vacuum pumps generally do not operate well near atmospheric pressure. Thus the vacuum system must have a mechanical vacuum pump to evacuate the system to a pressure at which the high-vacuum pumps are effective. Mechanical pumps require routine maintenance, such as ballasting and replacing the pump oil. The diffusion pump is the least expensive and most reliable high-vacuum pump. Turbomolecular pumps and cryopumps are also used on mass analyzers, having largely replaced diffusion pumps. These high-vacuum pumps also require routine maintenance for optimal operation. A key consideration in construction of the vacuum system is pumping speed. The ability of the pump to maintain the vacuum by removing any gas (or solvent vapor) that enters the system determines the flow rate of gas or liquid that is introduced into the mass spectrometer. In general, higher pump capacities are associated with lower detection limits because noise arising from the gas background is reduced.

Mass Analyzers, Tandem Mass Spectrometers, and Ion Detectors

The term *mass spectrometry* is somewhat a misnomer because mass spectrometers do not measure molecular mass, but rather they measure mass-to-charge ratio. This fact is fundamental to the physical operating principles of mass spectrometers and consequently affects all aspects of instrumentation design and operation and interpretation of results. The symbol *m/z* is used to denote mass-to-charge ratio and conventionally has been defined as a dimensionless quantity.[97] However, a "dimensionless" mass-to-charge ratio is not consistent with equations of ion motion in the presence of electric and magnetic fields, which require units of mass divided by charge. Furthermore, the *m/z* scale sometimes is loosely discussed in terms of daltons (Da, also known as unified atomic mass units, u), although strictly speaking, Da is a unit of mass, not mass-to-charge ratio. Despite these nomenclature issues, the present chapter often follows conventional practices by discussing *m/z* in terms of mass and Da.

To help avoid some of the confusion surrounding the use of *m/z,* it has been proposed that it should be defined explicitly as quantity having units of mass-to-charge ratio, with mass specified in daltons and charge specified in elementary charges, and that this unit should be called the *Thomson* (Th) in honor of one of the pioneers of MS.[29,36] This terminology is sometimes seen in the literature but has not yet been widely adopted.

General Classes of Mass Spectrometers

Mass spectrometers are broadly classified into two groups: beam-type instruments and trapping-type instruments. In a beam-type instrument, the ions make one pass through the instrument and then strike the detector, where they are destructively detected. The entire process, from the time an ion enters the analyzer until the time it is detected, generally takes microseconds to milliseconds.

In a trapping-type analyzer, ions are held in a spatially confined region of space through a combination of magnetic and/or electrostatic and/or RF electrical fields. The trapping fields are manipulated in ways that allow *m/z* measurements to be performed. Trapping times may range from a fraction of a second to minutes, although most clinical applications are at the low end of this range. Detection of the ions in a trapping-type instrument may be destructive or nondestructive, depending on the specific type of mass spectrometer used. In this context, "destructive" means that ions are destroyed in the detection process. Additional discussions of mass analyzers, tandem mass spectrometers, and ion detectors are available,[35,107] and the CLSI document C-50A contains recommendations for matching the capabilities of different *m/z* analyzers to various application classes.[27]

Beam-Type Designs

The main beam-type mass spectrometer designs are (1) quadrupole, (2) magnetic sector, and (3) time-of-flight (TOF). It is convenient to categorize beam-type instruments into two broad categories, those that produce a mass spectrum by scanning the *m/z* range over a period of time (quadrupole and magnetic sectors) and those that acquire successive instantaneous snapshots of the mass spectrum (TOF). This categorization is not hard and fast. Certain instrument

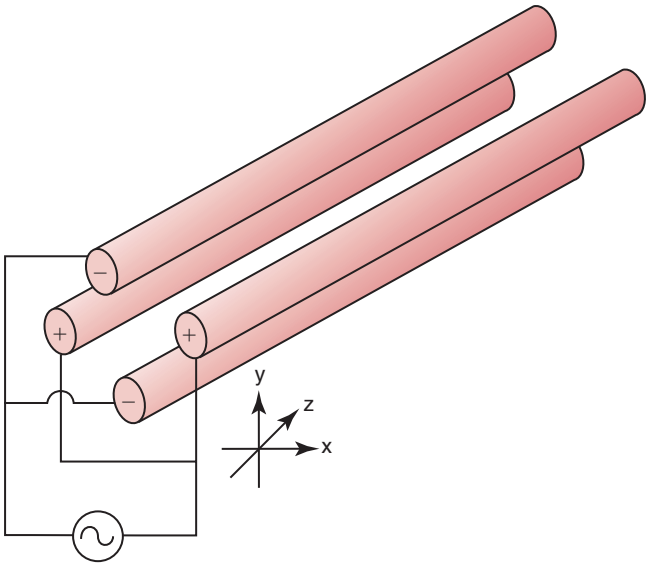

Figure 14-7 Diagram of quadrupole mass filter, including the radiofrequency (RF) part of voltages applied to the quadrupole rods.

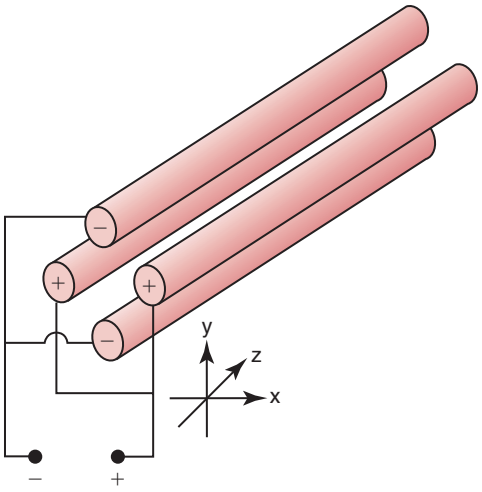

Figure 14-8 Direct current (DC) voltages applied to quadrupole rod assembly.

designs have been adapted to scanning or nonscanning operations. Nevertheless, the categorization is a useful one because it covers the majority of instruments currently available, and because scanning and nonscanning instruments are adapted for different optimal usages.

Quadrupole. Quadrupole mass spectrometers, sometimes known as quadrupole mass filters (QMFs), are currently the most widely used mass spectrometers, having displaced magnetic sector mass spectrometers as the standard instrument. Although these instruments lag behind magnetic sector instruments in terms of (1) sensitivity, (2) upper mass range, (3) resolution, and (4) mass accuracy, they offer an attractive and practical mix of features that accounts for their popularity, including (1) ease of use, (2) flexibility, (3) adequate performance for most applications, (4) relatively low cost, (5) noncritical site requirements, and (6) highly developed software systems.

A quadrupole mass spectrometer consists of four parallel electrically conductive rods arranged in a square array (Figure 14-7). The four rods form a long channel through which the ion beam passes. The beam enters near the axis at one end of the array, passes through the array in a direction generally parallel to the axis, and exits at the far end of the array. The ion beam entering the quadrupole array may contain a mixture of ions of various m/z values, but only ions of a very narrow m/z range (typically $\Delta m/z<1$) are successfully transported through the device to reach the detector. Ions outside this narrow range are ejected radially. The $\Delta m/z$ range represents a pass band, analogous to the pass band of an interference filter in optics (see Chapter 10), which is why quadrupole mass spectrometers are often referred to as *mass filters* rather than *mass spectrometers.*

Quadrupole mass spectrometers rely on a superposition of RF and constant direct current, or DC potentials applied to the quadrupole rods. DC voltages are applied to the electrodes in a quadrupolar pattern. For example, a positive DC potential is applied to electrodes 1 and 3, as indicated in Figure 14-8, and an equivalent negative DC potential is applied to electrodes 2 and 4. The DC potentials are relatively small, on the order of a few volts. Superimposed on the DC potentials are RF potentials, also applied in a quadrupolar fashion. RF potentials range up to the kilovolt range, and frequency is on the order of 1 MHz. The frequency is typically fixed and highly stable, although variable frequency operation is possible in principle.

The physical principles underlying the operation of a quadrupole mass spectrometer are rigorously described by solutions of a complicated differential equation, the Mathieu equation.[33] When an ion is subjected to a quadrupolar RF field, its trajectory is described qualitatively as a combination of fast and slow oscillatory motions. For descriptive purposes, the fast component will be ignored here. The slow component oscillates about the quadrupolar axis; this resembles the motion of a particle in a fictitious harmonic *pseudopotential.* The frequency of this oscillation is sometimes called the *secular frequency.*

The *effective force* associated with the pseudopotential is directed inward toward the quadrupolar axis and is proportional to the distance from the axis. It therefore acts as a confining force, preventing ions from being ejected radially from the quadrupolar assembly. Figure 14-9, *A*, shows an example of an ion confined by an RF-only quadrupole. Below a certain m/z cutoff frequency (which depends on the frequency and amplitude of the RF field), ions are ejected rather than confined. Figure 14-9, *B,* shows an example of an ion ejected by an RF-only quadrupolar field. This establishes the low mass cutoff for the m/z pass band. The effective confining force is strongest just above the low m/z cutoff, and then decreases asymptotically toward zero at high m/z.

The DC part of the quadrupolar potential is independent of m/z. Positive ions are attracted toward the negative poles.

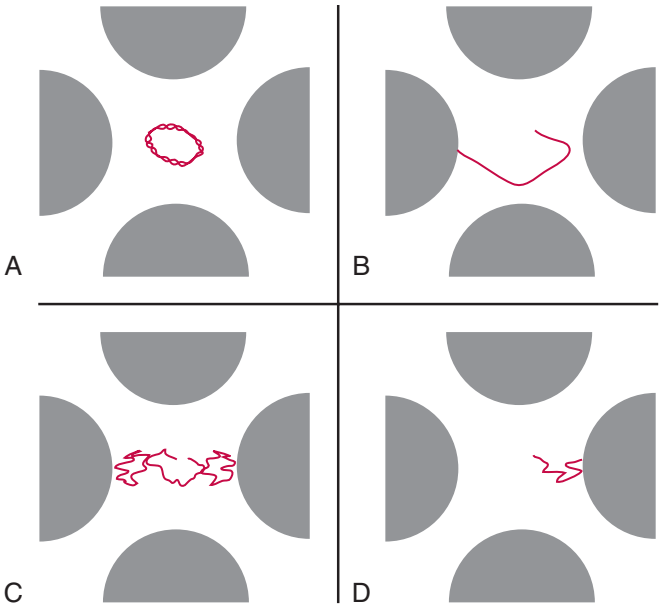

Figure 14-9 Ion trajectories showing confinement and ejection in quadrupole mass filters. A, Ion confinement by radiofrequency (RF)-only field. B, Ion ejection by RF-only field. C, Ion confinement with a combination of RF and direct current (DC) fields. D, Ion ejection with a combination of RF and DC fields. All trajectories were simulated using Simion software (Scientific Instrument Services, Inc., Ringoes, NJ).

Negative ions are attracted toward the positive poles. Attraction increases as the distance from the quadrupolar axis increases. Because a quadrupolar DC potential always has both negative and positive poles, the quadrupolar DC potential always contributes to ejection in at least one direction. Whether ejection of an ion of a particular *m/z* actually occurs depends on whether the ejecting force caused by the quadrupolar DC potential overcomes the effective confining force caused by the pseudopotential generated by the RF field. Above a certain *m/z* value, the DC part dominates, and ions are ejected radially from the device. This establishes an upper *m/z* limit for ion transmission. Figures 14-9, *C* and *D,* shows examples of ion trajectories under the influence of combined RF-DC fields, one being confined and the other being ejected. Trajectories in Figure 14-9 were calculated using the Simion ion optics computer program.[31]

A rigorous description of low- and high-mass cutoffs is found in so-called stability diagrams, which graphically describe the lower and upper *m/z* cutoffs of a quadrupole mass spectrometer in terms of parameters related to voltages, frequencies, and *m/z*. The third edition of this book presents an example of a stability diagram. However, to fully understand the meaning of the stability diagram, one must delve more deeply into a mathematical description than can be done here.

The combination of lower and upper *m/z* limits establishes a pass band ($\Delta m/z$), and ultimately a resolution [$(m/z)/(\Delta m/z)$]. With relatively few exceptions, quadrupole instruments are limited to a resolution of several thousand, which is sufficient to achieve isotopic resolution for singly charged ions of *m/z* as high as several thousand.

A quadrupole MS may be operated in an SIM mode or a scanning mode. In SIM mode, both DC and RF voltages are fixed. Consequently, both the center of the pass band and the width of the pass band are fixed. For example, the mass spectrometer may be set to pass ions of *m/z* 363 ± 0.5. Both the center *m/z* and the $\Delta m/z$ are adjusted by the appropriate choice of DC and RF.

In the scanning mode of operation, the RF and/or DC voltages are continuously varied to scan a range of *m/z* values. As with the SIM mode, the $\Delta m/z$ is determined by the RF and DC voltages. Usually the scan function is designed to maintain a constant $\Delta m/z$ across the full *m/z* range. Thus the resolution increases as *m/z* increases. The value of $\Delta m/z$ is frequently chosen in the range 0.5 to 0.7 to resolve isotopic peaks across the full *m/z* range.

Magnetic Sectors. Because magnetic sector mass spectrometers are rarely used in the clinical laboratory they will not be described in detail here. For an introduction to magnetic sector technology, refer to the third edition of this book. It should be noted, however, that these classic mass spectrometers are easy to understand (given a basic understanding of physics); are versatile, reliable, and highly sensitive; and in their "double focusing" variation are capable of very high *m/z* resolution and mass accuracy. However, they are typically expensive, large, and heavy. In addition, they have the reputation of being difficult to use. Consequently, other instruments have largely displaced magnetic sector mass spectrometers.

Time-of-Flight. TOF mass spectrometry (TOF-MS) is a nonscanning technique whereby a full mass spectrum is acquired as a snapshot rather than by sweeping through a sequential series of *m/z* values while sampling the sample. TOF mass spectrometers have several advantages, including (1) a nearly unlimited *m/z* range, (2) high acquisition speed, (3) high mass accuracy, (4) moderately high resolution, (5) high sensitivity, and (6) reasonable cost. They are also well adapted to pulsed ionization sources, which is an advantage in some applications, particularly with MALDI and related techniques.[14]

A major advantage of modern TOF mass spectrometers is that some of them produce so-called accurate mass measurements, sometimes loosely referred to as *exact mass,* which is typically accurate to a few parts per million (ppm). This allows TOF measurements to confirm the molecular formula of a compound. Unlike magnetic sector instruments, which are also capable of accurate mass measurements. TOF mass spectrometers are conceptually simple to understand because they are based on the fact that a lighter ion travels faster than a heavier ion, provided that both have the same kinetic energy. Figure 14-10 presents a simplified conceptual diagram of a TOF mass spectrometer. It resembles a long pipe. Ions are created or injected at the source end of the device and are then accelerated by a potential of several kilovolts. They travel down the flight tube and strike the detector at the far end of

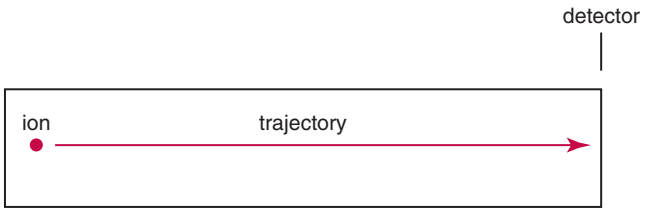

Figure 14-10 Diagram of simplified time-of-flight mass spectrometer.

the flight tube. The time it takes to traverse the tube is known as the flight time; this is related to the mass-to-charge ratio of the ion.

The flight time for an ion of mass m and kinetic energy E to travel a distance L in a region free of electric fields is given by

$$t = L\left(\frac{m}{2E}\right)^{1/2}$$

A sample calculation for an ion of molecular weight 200 Da (3.32×10^{-25} kg) with a kinetic energy of 10 keV (1.60×10^{-15} J), traveling through a distance of 1 m, yields a flight time of 10.18 ms, and an ion of molecular weight 201 takes just 25 ns longer. To accurately capture such fleeting signals, the data recording system must operate on a ≈1 ns or shorter time scale. Advances in signal processing electronics have made this practical at relatively modest cost, and this has been a major factor in the rise in popularity of TOF-MS.

TOF is inherently a pulsed technique; it couples readily to pulsed ionization methods, with MALDI being the most common example, although it is also possible to couple TOF with continuous ion sources such as EI, ESI, and APCI. However, the continuous nature of these sources causes a natural mismatch between continuous ion sources and TOF-MS, which is a pulsed technique. This mismatch is overcome by using a technique known as orthogonal acceleration TOF-MS (OA-TOF-MS), in which the ion beam is injected orthogonal to the axis of the TOF-MS.[32,78,106] During the injection period, the acceleration voltage is turned off. Once the injection region is filled with the traversing beam, the acceleration voltage is quickly turned on, and the TOF timing cycle starts. The process is cycled repeatedly. The overall duty cycle for this method can be more than 10%; this represents a vast improvement over the traditional method of gating the ion beam. For full spectrum capability with continuous ion sources, orthogonal injection TOF mass spectrometers are generally considered to have the lowest detection limits of all mass spectrometers. However, for the monitoring of a single m/z rather than a full mass spectrum, the use of SIM mode with a quadrupole MS provides superior limits of detection.

Improved resolution is an additional benefit conferred by orthogonal acceleration as applied to TOF-MS. Although a complete explanation is beyond the scope of this book, in brief, orthogonal acceleration reduces the resolution degrading effects that would normally accompany the kinetic energy variations of individual ions in the ion beam. Use of an ion mirror is a second technique often employed in TOF-MS design to improve resolution by compensating for kinetic energy variations.[82,101] Such instruments are known as *reflectrons*. To date, TOF-MS has had a lesser impact in clinical chemistry, but it seems read to take on a greater role in the future. For example, the full-spectrum capability, high resolution (up to 40,000 in some current instruments), high speed (10 to 100 stored spectra/s), and high mass accuracy of TOF-MS seem ideally suited to applications such as high-speed drug screens in toxicology when combined with fast chromatographic sample introduction.

Another area where TOF-MS provides an advantage is high-mass analysis, where its mass range is nearly unlimited. In MALDI-TOF, for example, it is not unusual to detect proteins with molecular weights exceeding 100,000. The ability for high-mass analysis is expected to increase in importance as clinical laboratories embrace proteomic-based diagnostic methods.

Trapping Mass Spectrometers

In contrast to beam-type designs, these mass spectrometers are based on the trapping of ions to capture and hold ions for an extended length of time in a small region of space. Trapping times vary from a fraction of a second to minutes. Compared with beam-type instruments, the division between scanning and nonscanning instruments has less meaning for ion-trapping instruments. The main practical difference between scanning and nonscanning instruments is related to distortions in chromatographic mass spectral data arising from the finite scan time of the mass spectrometer in relation to the chromatographic peak width of the chromatographic sample introduction scheme (peak skew). In terms of producing skewed spectra, trapping devices are more similar to nonscanning instruments, such as TOF (no skew), than to scanning instruments. This is because the sample is captured in an instant and then is analyzed at leisure. Because the sample is captured in an instant, no skewing of the spectra occurs, regardless of whether the m/z analysis is performed by a scanning procedure or a nonscanning procedure.

Traditionally, ion traps have been classified as (1) a quadrupole ion trap (QIT), which relies on RF fields to provide ion trapping; (2) a linear ion trap, which is closely related to the QIT in its operating principles; and (3) an ion cyclotron resonance (ICR) mass spectrometer, which relies on a combination of magnetic fields and electrostatic fields for trapping. A fourth, the orbitrap, is a more recent introduction into the field of ion trap mass spectrometry.[81A]

Quadrupole Ion Trap. QITs are relatively compact, inexpensive, and versatile instruments that are excellent for (1) exploratory studies, (2) structural characterization, and (3) sample identification. They are also used for quantitative analysis, although quantitative analysis is not the best use for these devices when compared with quadrupole-based instruments.

Operation of the QIT is based on the same physical principle as the quadrupole mass spectrometer described earlier. Both devices make use of the ability of RF fields to confine

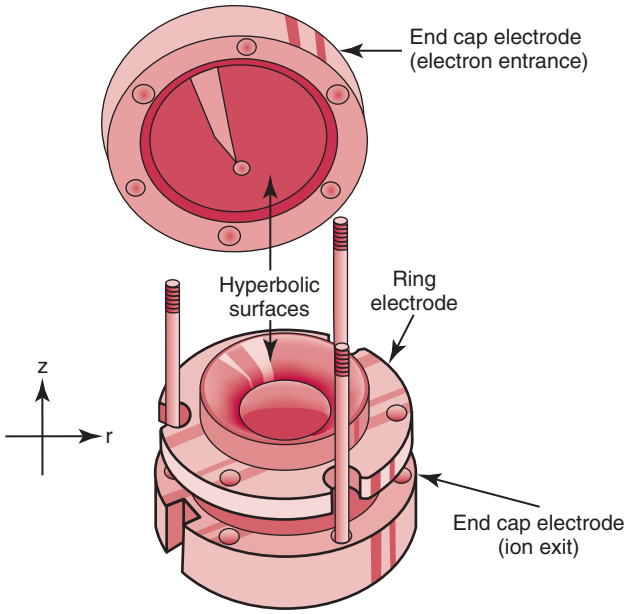

Figure 14-11 Diagram of quadrupole ion trap.

ions. However, the RF field of an ion trap is designed to trap ions in three dimensions rather than to allow the ions to pass through as in a QMF, which confines ions in only two dimensions. This difference has a large impact on the operation and limitations of the QIT.

The physical arrangement of a QIT is different from that of a QMF. If an imaginary axis is drawn through the *y*-axis of the quadrupole rods, and the rods are rotated around the axis, a solid ring with a hyperbolic inner surface results from the *x*-axis pair of rods. The two *y*-axis rods form two solid end caps. A diagram of an ion trap is given in Figure 14-11. The description of the fields within the electrodes must now include a radial component and an axial (between the end caps) component. This slightly changes the precise conditions required for ion confinement when compared with a QMF, although the qualitative description of ion confinement discussed previously is still valid.

A discussion of the several ways of scanning a QIT is beyond the scope of this chapter, except to mention that ions may be ejected from the trap in an *m/z*-dependent fashion for detection using an external electron multiplier.

QITs are among the most versatile of mass spectrometers, rivaled only in this respect by the ICR mass spectrometer. Notably, QITs are especially well adapted for performing multiple stages of tandem mass spectrometry (MS^n). The QIT also shares some advantages with TOF-MS. In particular, ion trap mass spectrometry is known for high sensitivity. Furthermore, sampling is decoupled from scanning, so no mass spectral peak skewing is seen in GC-MS and HPLC-MS. However, owing to ion-ion repulsion effects, which can reduce dynamic range and produce mass misassignments at high signal levels, QITs do not seem ideal for quantitative analysis applications that dominate clinical chemistry at the present time.

Linear Ion Trap. This is an RF ion trap that is based on a modified linear QMF. Rather than being a pass-through device, as in a normal linear QMF, electrostatic fields are applied to the ends to prevent ions from exiting out the ends of the device. When trapped in this manner, ions can be manipulated in many of the same ways as in a QIT. An advantage of the linear quadrupole trap is that the trapping field can be turned off at will and the device operated as a normal QMF. Thus a single device combines most of the features of a QIT and QMF and is extremely versatile. Commercial triple quadrupole mass spectrometers are being offered in which the third quadrupole is modified to function as a linear trap. Exploration of the capabilities of the linear ion trap is a very active field of research, and one can expect many new capabilities to be discovered in the next few years.

Ion Cyclotron Resonance. The ICR-MS excels in high-resolution and high-mass accuracy measurements.[84] Measurements at resolution exceeding 1 million are not unusual. ICR is a trapping technique that shares many of the advantages of RF ion traps. However, there are even more ways to manipulate ions in an ICR-MS than in QIT, and MS^n (multiple stages of MS/MS) measurements are easily done with an ICR-MS. Sensitivity of an ICR-MS is generally high. Furthermore, sampling is decoupled from spectral acquisition, so no peak skewing is seen in chromatographic experiments—a feature that ICR shares with TOF and QIT.

An ICR-MS is based on the principle that ions immersed in a magnetic field undergo circular motion (cyclotron motion). A typical ICR-MS uses a high-field (3 to 12 tesla) superconducting magnet. Within this field and within a high vacuum is mounted a "cell" typically composed of six metal electrodes, arranged as the faces of a cube. Ions are suspended inside the cell and undergo cyclotron motion, which keeps ions from being lost radially (the radial direction being defined as perpendicular to the magnetic field lines). A low (~1 V) potential is applied to the end caps to keep ions from leaving the trap axially. Thus the combination of electric and magnetic fields keeps ions confined within the cell.

Each *m/z* is associated with a specific cyclotron frequency. Ions circulating in the ICR cell induce an electrical current in detection electrodes, and after certain mathematical operations are performed on the signal (principally a Fourier transform), a mass spectrum is recovered. Each *m/z* value present in the sample produces a peak in the transformed signal. Because of the frequent use of FT in ICR, the technique is often referred to as FT-ICR, or FTMS.

Although this technique has many advantages, including (1) high mass accuracy, (2) ultrahigh resolution, and (3) the ability to perform MS^n, ICR-MS has several disadvantages, including (1) instrument costs are high; (2) site requirements, both in terms of space and in terms of access restrictions, are very demanding; (3) it uses a high-field superconducting magnet; and (4) its magnetic field introduces safety concerns, such as flying iron objects. Practical problems with this instrument include (1) the erasing of credit cards and other magnetically encoded strips; (2) costs of operation, care, and maintenance are high because the instruments consume liquid helium, and they must never be allowed to go dry; and (3) a highly skilled individual is necessary to operate it.

Orbitrap. The suitability of a new type of mass analyzer, the orbitrap, for clinical analysis has yet to be evaluated. However, the high resolution and mass accuracy of the orbitrap demand that its potential for clinical analysis be considered in the future. The orbitrap mass analyzer has similar resolution and mass accuracy to the ICR but does not require a magnetic field. This innovation minimizes many of the ICR disadvantages listed previously, although cost is still high. The analyzer is based on an early ion storage device—the Kingdon trap.[67] After many variations over the years, Makarov and associates produced a modified version that eventually was marketed in 2006.[79-81A] The commercial instrument can easily achieve resolutions up to 100,000 with sub-ppm mass accuracy, has a four orders of magnitude dynamic range, and has sampling decoupled from spectral acquisition (as in the ICR).

An orbitrap-MS is based on trapping within electrostatic fields.[96] The actual device is a rodlike central electrode surrounded by a barrel-like outer electrode.[59] When ions are introduced perpendicular to the central electrode and a radial potential is applied between electrodes, the ions spiral (orbit) around the central electrode and are effectively trapped in a radial direction. Trapping in the axial direction is an indirect result of the shape of the electrodes, together with the potentials that are applied to the electrodes. Ion trapping therefore involves both orbital motion around the central electrode and axial oscillations.

The trapping potential in the axial direction is of the form of a harmonic oscillator, and because the frequency of a harmonic oscillator is independent of oscillation amplitude, this frequency is very stable and well behaved. The *m/z* can be calculated from the frequency of axial oscillation

$$\omega = \left(\mathrm{kz/m}\right)^{0.5}$$

where *m* and *z* are the mass and charge, and *k* is the constant determined by trap geometry, dimensions, and applied potential. The image current made in the outer electrode by this motion is acquired in the time domain and can be Fourier-transformed to produce a frequency spectrum, which is then converted to *m/z* by the previous equation. With its ability to perform accurate mass measurements, especially when combined with a linear ion trap to form a hybrid tandem mass spectrometer, the orbitrap has excellent potential for proteomics research. However, the capabilities, advantages, and disadvantages of this new type of instrument are still an active area of research. For example, one recent publication noted anomalous isotope ratios observed under high-resolution operating conditions.[42] It is a curious point that the anomalies are compound dependent, and a theoretical explanation for them has yet to appear in the literature.

Tandem Mass Spectrometers

Tandem mass spectrometry, or mass spectrometry/mass spectrometry (MS/MS), has become a mainstay in clinical laboratories, where it has found extensive application in the quantitative analysis of routine samples.[20] However, it is also excellent for structural characterization and compound identification, and therefore useful for exploratory work, even when a final assay may be based on a different technology such as an immunoassay. The most important feature of this technique is its very high selectivity together with its ability to measure very low concentrations of analyte(s). When coupled with the added selectivity of a gas or liquid chromatograph, interferences in a well-designed MS/MS assay (and particularly an HPLC-MS/MS assay) are very low. Because of its (1) low interference rate, (2) low consumable cost (as with most MS methods), and (3) high sample throughput rates, more and more clinical laboratories are purchasing and using tandem mass spectrometers.

The physical principle of tandem mass spectrometry is based on the use of two mass spectrometers (mass filters) arranged sequentially in tandem, with a "collision cell" placed between the two mass filters. The first filter is used to select a *precursor ion* of a particular *m/z*. The precursor ion is directed into the collision cell, where ions collide with background gas molecules and are broken into smaller ions. These product ions of the dissociation process are referred to as *product ions* because they are products derived from the precursor ion. The second mass filter acquires the mass spectrum of the product ions. In the older literature, precursor and product ions are often referred to as parent and daughter ions, respectively.

A variety of scan functions are possible with tandem mass spectrometers. In practice, a product ion scan involves setting the first mass spectrometer or mass filter, MF1, to select a given *m/z,* and scanning through the full mass spectrum of product ions using the second mass spectrometer or mass filter, MF2. This scan function is often used for structural characterization.

A precursor ion scan reverses this relationship, with the second mass filter, MF2, set to select a specific product ion, and MF1 is scanned through the spectrum of precursor ions. The scan tells us which precursor ions produce a specific product ion—a capability that is often used to analyze for specific classes of compounds. For example, acylcarnitines are often analyzed by searching for the precursors to the *m/z* 85 product ion.

In a constant neutral loss scan, the two mass filters are scanned synchronously, with a constant *m/z* offset between precursor and product ion. This scan indicates which ions lose a particular neutral fragment. For example, an offset of 18 *m/z* units would select for ions losing H_2O in the dissociation process.

Another scan function is multiple reaction monitoring, or MRM. This is not actually a scan function but consists of a series of precursor/product ion pairs, with the mass spectrometer set to jump through the table of parent/product ion pairs in a cyclic fashion. This is primarily used for quantitative analysis of a few selected target compounds and is a close analog to SIM monitoring as used in GC-MS. MRM is also performed in a *static mode,* where the two mass filters are set to monitor just one precursor and one product ion. This is especially good for quantitative mass spectrometry.

The key to the high selectivity of MS/MS is that it characterizes a compound by two physical properties—precursor ion mass and product ion mass—rather than by a single property. If combined with chromatographic separation, retention time is added to the characterization, and the analytes are characterized by three physical properties. This imparts a very high degree of selectivity to the analysis and eliminates the vast majority of potential interferences.

As with single-stage mass spectrometers, tandem mass spectrometers are roughly categorized as beam-type instruments and trapping instruments. The most popular beam-type instrument is the triple quadrupole. In this instrument, the first quadrupole (Q1) functions as MF1, and the third quadrupole (Q3) functions as MF2. Between these two quadrupoles is another quadrupole, Q2, which functions as the collision cell. The pressure is raised in Q2 (e.g., greater than 10^{-3} torr) to the point that ions traversing Q2 undergo several collisions, leading to dissociation of precursor ions. The Q2 is operated as an "RF-only" quadrupole, ideally passing all ions regardless of *m/z,* although in reality the pass band may cover a ≈10 : 1 *m/z* range.

Two magnetic sector instruments have also been operated in tandem, with a collision cell placed between the two instruments. These instruments permit high-resolution selection of both precursor and product ions. However, they are now rarely used because they are expensive and cumbersome to operate. A single (as opposed to a pair in tandem) double-focusing mass spectrometer has also been used as a tandem mass spectrometer by a technique known as *linked scanning.* A product ion scan by linked scanning involves low resolution for the first *m/z* selection and high resolution for the second *m/z* selection.

So-called hybrid mass spectrometers include a combination of two different types of mass spectrometers in a tandem arrangement. The combination of a magnetic sector mass spectrometer with a quadrupole mass spectrometer was an early instrument of this type. More popular today is the combination of a quadrupole for the first stage of *m/z* selection and a TOF for the second *m/z* analyzer. Subsequently, a linear ion trap has been combined with an orbitrap. Hybrid instruments are presently used mainly for proteomics research. These instruments also have a problem in performing true precursor ion scans or constant neutral loss scans, though it is possible to mimic these functions by post-processing data, provided the full precursor-product ion map was generated in the experiment.

QIT, linear ion trap, and ICR mass spectrometers can also be used as tandem mass spectrometers. Unlike beam-type instruments, which are referred to as "tandem in space," trapping mass spectrometers are "tandem in time," meaning that ions are held in one region of space while the parent ion is selected and dissociated and the daughter ion analyzed sequentially in time. The ability to perform tandem mass spectrometry is inherent in the design of most trapping mass spectrometers. Generally, little or no additional hardware is required, and tandem capability is supplied via a software change. An exception is the orbitrap, which does not seem to be amenable to tandem mass spectrometry when used alone. However, when incorporated into a hybrid instrument, with a different type of mass spectrometer supplying the first stage of mass spectrometry (such as a linear ion trap), and with the orbitrap supplying the final stage of MS, tandem mass spectrometry is possible in an orbitrap-containing instrument. Most trap-based instruments are capable of multiple stages of mass spectrometry. Thus, product ions may be further dissociated to produce another generation of product ions (MS/MS/MS, or MS^3). In principle, any number of dissociation stages may be performed. This capability finds its greatest use in structural characterization, such as in the sequencing of peptides, and is less useful for quantitative analysis. Trapping designs are extremely versatile, but unlike triple quadrupoles, these instruments are unable to perform true precursor ion scans or constant neutral loss scans.

Detectors

With the exception of ICR-MS, orbitrap, and some ICP-MS instruments, most modern mass spectrometers use electron multipliers for ion detection. The main classes of electron multipliers used as MS detectors include the (1) discrete dynode multipliers; (2) continuous dynode electron multipliers (CDEMs), also known as channel electron multipliers (CEMs); and (3) microchannel plate (MCP) electron multipliers, also known as multichannel plate electron multipliers. Although different in detail, all three work on the same physical principle. Additional detectors used in mass spectrometers are the Faraday cup and image current detection.

Figure 14-12 presents a conceptual diagram of the operation of a discrete dynode electron multiplier. When an ion strikes the first dynode, it causes the ejection of one or more electrons ("secondary electrons") from the dynode surface. The electron is accelerated toward the second dynode by a voltage difference of ≈100 V. Upon striking the second dynode, this electron causes the ejection of additional electrons, typically 2 or 3 in number. The second group of electrons is then accelerated toward the third dynode and, upon striking the third dynode, causes the ejection of several more

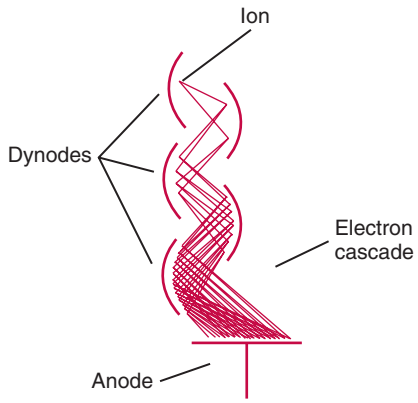

Figure 14-12 Discrete dynode electron multiplier showing dynode structure and generation of electron cascade.

electrons. This process is repeated through a chain of dynodes, numbering between 12 and 24 for most designs. The cascade process typically produces a gain of 10^4 to 10^8, meaning that the generation of one electron at the first dynode produces a pulse of 10^4 to 10^8 electrons at the end of the cascade. The duration of the pulse is very short, typically less than 10 ns.

Continuous dynode electron multipliers work on the same principle as discrete dynode electron multipliers but differ in their physical construction. The set of dynodes of a discrete dynode electron multiplier is replaced by a single continuous resistive surface that acts both as a (continuous) voltage divider to establish the potential gradient and as the secondary electron-generating surface. A microchannel plate electron multiplier is essentially a monolithic array of miniaturized CDEMs fabricated in a single wafer or disk of glass. Sometimes these are stacked into a "chevron" configuration for added gain.

The Faraday cup is not an electron-multiplying device, but rather a simple electrode that intercepts the ion beam directly. This current is amplified using electronic amplifiers. Because the Faraday cup measures signal intensity directly, rather than indirectly (as in saturation-prone electron multipliers), it provides an absolute measure of ion current and is useful when signal levels are too high for electron multiplier–based detection. Some instruments use both electron multiplier—and Faraday cup–based detection to provide for extended dynamic range—a capability that is especially useful for elemental analysis of trace metals in samples.

Detection in ICR occurs via image current detection. This is closely related to the Faraday detection cup in the sense that the ion current is detected directly. However, ions are not destroyed in the process of image current detection and are available for remeasurement. This feature is one of the keys to the versatility of ICR mass spectrometers. Image current detection is also used in the orbitrap.

Closely linked to the detection system is the electronic and signal processing system. In instruments that use electron multiplier detection (the vast majority of mass spectrometers), the raw signal from the detector is processed in one of two ways: (1) individual pulses (corresponding to individual ions) may be counted, as in so-called ion counting systems, or (2) the signal may be converted to a digital representation of the analog signal using an analog-to-digital converter, as in so-called analog detection.

Computer and Software

Because of their (1) mass resolution capabilities, (2) scanning functions, and (3) ability to automatically switch from positive to negative ionization modes, and (4) speed with which multiple *m/z* signals are acquired, modern MS instruments generate enormous quantities of raw data. In addition, the use of MS in such areas as (1) proteomics,[1A] (2) biomarker discovery, (3) synthetic combinatorial chemistry, (4) high-throughput drug discovery, (5) pharmacogenomics, (6) toxicology, and (7) therapeutic drug monitoring requires that MS manufacturers provide sophisticated computers and software programs.

In toxicology laboratories, one important function of the data system is library searching to assist in compound identification. Several commercial libraries, including the Wiley Registry of Mass Spectral Data (http://player.accuradio.com/player/slipstream/accuclassical/?channel=classical&sub=SubCrossover/accessed April 08, 2011), the NIST Mass Spectral Database (http://chemdata.nist.gov/accessed April 08, 2011), and the Pfleger, Maurer, and Weber drug libraries (http://www.sisweb.com/software/ms/wiley.htm/accessed April 08, 2011), are available. In addition, many laboratories generate their own libraries. The quality and quantity of available spectra, the search algorithm, and whether condensed or full spectra are searched are all important factors in spectral matching.

In proteomics and biomarker discovery, complex mass spectra from single proteins, protein mixtures, or protein digests are obtained. Data systems aid in characterization of spectral data to identify such properties as intact protein mass, amino acid subsequences, and post-translational modifications. Fragmentation information can also be compared with peptide databases to identify structural mutations that may be present.

The most important function of software in MS systems containing a chromatographic component is the generation and data processing of chromatograms from SIM or MRM data. Chromatographic peaks are integrated using automatic integration programs (with manual integration over-ride), and integrated peak intensities serve as the basis for quantitative analysis. Calibration curves are generated by the data processing programs, and quantitative results from individual samples are generated from the calibration curves created by the data system. Data systems also contain report generation capabilities, although in current MS instruments, the data reporting functions generally are not interfaced directly to laboratory information management systems.

Software programs are also available to locate and identify components in complex chromatographic separations. Deconvolution protocols have been developed that identify and characterize the mass spectra of coeluting compounds. In addition to proprietary deconvolution protocols embedded in the data systems of mass spectrometers supplied by some vendors, a popular deconvolution software program known as AMDIS (Association of Medical Directors of Information Systems, Lake Almanor, CA/ http://www.amdis.org/accessed April 08,2011) is available as a free download on the Internet.[1] In some cases, two separate sets of chromatographic data can be compared to evaluate similarities or unique differences (e.g., controls vs. disease state).

CLINICAL APPLICATIONS

Mass spectrometers coupled with gas or liquid chromatographs (GC-MS or LC-MS) serve as versatile analytical instruments that combine the resolving power of a chromatograph with the exquisite specificity and detection limits of a mass spectrometer. [102A] Such instruments are powerful analytical tools that are used by clinical laboratories to identify

and quantify organic analytes. They provide structural and quantitative information in real time on individual analytes as they elute from a chromatographic column. These coupled techniques require only nanogram or picogram quantities of an analyte for analysis. Specific applications of these coupled instruments are found in Chapters 34 and 35.

MALDI-TOF mass spectrometers and ICP ionization techniques have also enhanced the analytical capabilities of mass spectrometers. In addition, an important application of MS is its use as the primary analytical tool in the rapidly developing and expanding fields of proteomics and metabolomics.

Gas Chromatography–Mass Spectrometry

GC-MS has been used for the analysis of biological compounds for several decades. This technique is used by the U.S. National Institute of Standards and Technology for the development of definitive methods to qualify standard reference materials and to assign certified values to many clinical analytes, including cholesterol, glucose, creatinine, and urea nitrogen (see Chapter 9). One of the most common applications of GC-MS is drug testing for clinical or forensic purposes (see Chapter 35). Many drugs have relatively small molecular weights and nonpolar and/or volatile properties, making these compounds particularly suitable for analysis by GC. Electron impact ionization with full-scan mass detection is the most widely used approach for comprehensive drug screening. Unknown compounds can be identified by comparison of their full mass spectrum with a mass spectral library or database. In addition, vendors have recently reintroduced GC tandem quadrupole (GC-MS/MS) mass spectrometers, which should expand the capability of GC-MS to perform improved targeted analysis, thus enhancing existing screening and mass spectral identification properties of GC-MS.

GC-MS has many applications beyond drug testing. Numerous xenobiotic compounds are readily analyzed by GC-MS. Applications for anabolic steroids, pesticides, pollutants, and inborn errors of metabolism have been described.[64,90,109]

One important limitation to GC-MS is the requirement that compounds be sufficiently volatile to allow transfer from the solid phase to the mobile carrier gas and thus to elute from the analytical column to the detector. Although many biological compounds are amenable to chromatographic separation with GC, numerous compounds are too polar or too large to be analyzed with this technique. In many cases, chemical derivatization is necessary to create sufficiently volatile forms of compounds. Knapp's classic work on derivatization may be consulted for more information.[68]

Despite its limitations, GC-MS has several positive attributes. Fast and effective separations have been achieved with numerous commercial nonpolar columns. This technique has excellent limits of quantification and reproducibility. Last, some analytes, such as organic acids, are better suited to GC-MS because less interference may be present compared with atmospheric pressure ionization LC-MS.

Liquid Chromatography–Mass Spectrometry

As has been discussed earlier, several interface techniques have been developed for coupling a liquid chromatograph to a mass spectrometer, notably ESI and APCI, which have allowed LC-MS and LC-MS/MS to be successfully applied to a wide range of compounds. In theory, as long as a compound can be dissolved in a liquid, it can be introduced into an LC-MS system. Thus, in addition to low molecular weight polar and nonpolar analytes, large molecular weight compounds such as proteins can be analyzed using this technique.

LC-MS/MS has gained momentum in the arena of toxicology screening and confirmation.[38,88,89] Because a scan mode for MF1 looks for such a large range of potentially unnecessary precursor ions, many data acquisition protocols employ preselected sets of time-dependent targeted MRM precursor/product pairs that cover the drugs that are most often used by patients (Figure 14-13, *A*). For example, within the chromatographic time window of 1.5 to 2.0 minutes, the MRM transitions for selected sympathomimetic amines might be monitored (136→119 for amphetamine, 166→148 for pseudoephedrine, 220→84 for Ritalin). During the next defined time window, a new set of MRM transitions are monitored, and so on for the rest of the chromatographic run. A related approach is the use of targeted MRM, in which recognition of a chromatographic peak containing a preselected MRM transition triggers a product ion scan in a process called *information-dependent acquisition,* also known as *data-dependent acquisition*.

Although not presently widely applied to toxicology screening, coupling of TOF mass spectrometers to GC or LC provides a new approach to the identification of drugs. Because TOF is capable of achieving high mass resolution and has the ability of accurately measuring low quantities, the need for compound fragmentation may be minimized, allowing compound identification based on retention time and exact mass.[2]

The number of quantitative LC-MS/MS assays introduced for the measurement of clinically important compounds has markedly increased. For example, compounds that have been of special interest include (1) immunosuppressant drugs,[127] (2) biogenic amines,[37] (3) 25(OH)-vitamin D,[69] (4) antiretroviral drugs,[70,98] (5) psychoactive drugs,[34,110,124] (6) methylmalonic acid,[74,77] (7) thyroid hormones,[128] and (8) steroids.[75,108] When quantification of a specific compound is desired, the most effective approach is MRM analysis, as diagrammed in Figure 14-13, *B*. Both mass filters MF1 and MF2 are set in a static mode, whereby only a single precursor ion specific for the compound being measured is passed through MF1. This preselected precursor ion is then fragmented in the collision cell, and a specific product fragment ion derived from the compound of interest is passed by MF2 to the detector. Because only one ion is monitored in MF1 and one ion in MF2, as opposed to scanning for multiple ions, the MRM approach allows much greater specificity as well as lower limits of quantification.

Another area where MS/MS is used clinically is screening and confirmation of genetic disorders and inborn errors of

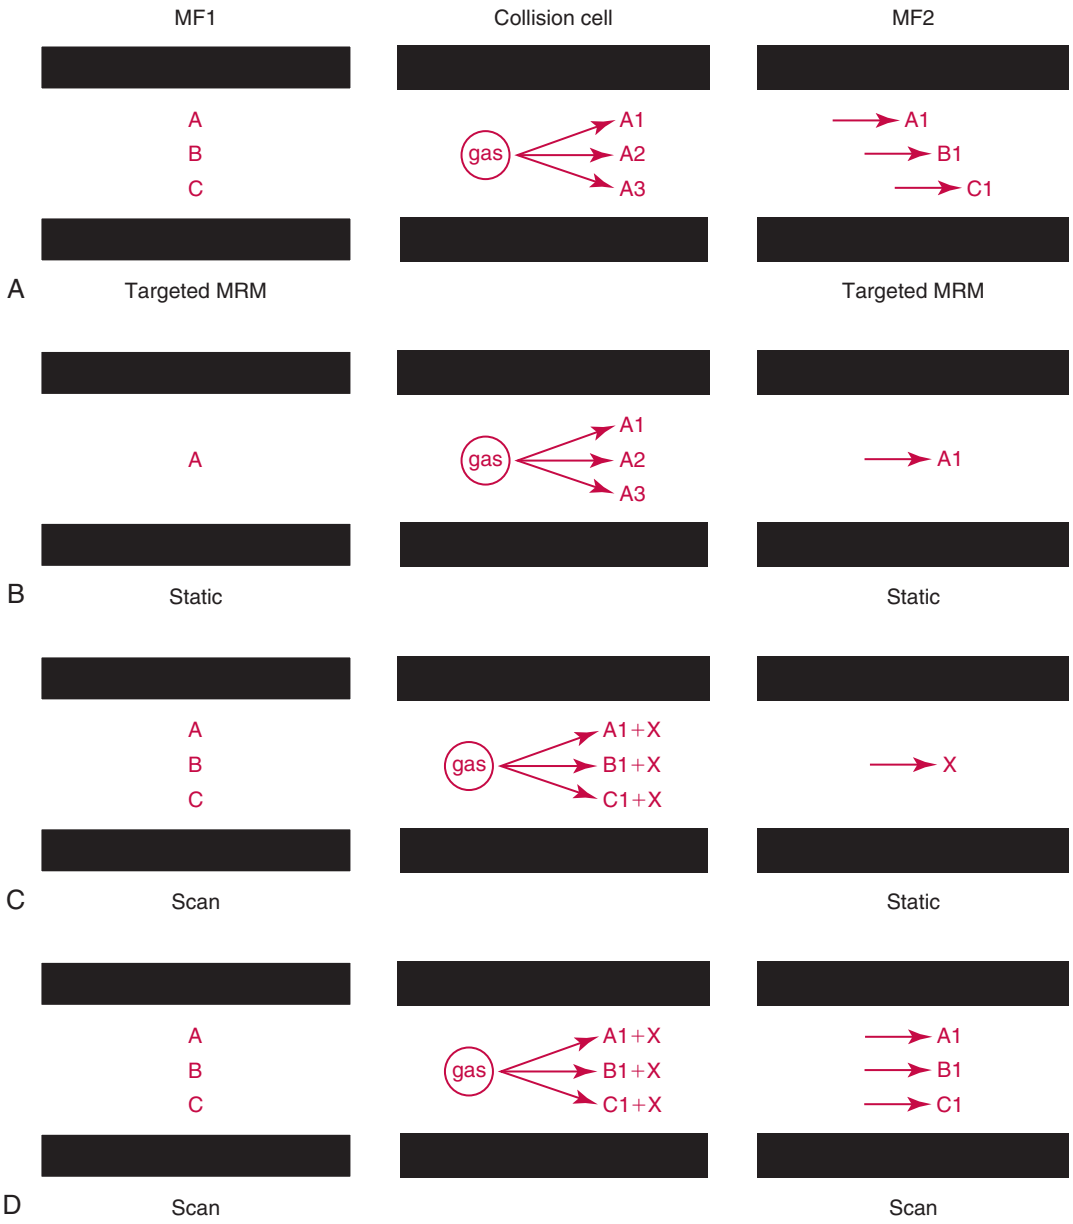

Figure 14-13 **Scan modes in mass spectrometry/mass spectrometry (MS/MS). A, Multiple reaction monitoring (MRM), where *A, B, C, A1, B1,* and *C1* are ions. Monitoring of MS/MS transitions $A \rightarrow A1$, $B \rightarrow B1$, and $B \rightarrow C1$ is multiplexed. For simplicity, only the dissociation of *A* is shown in a collision cell in the figure. B, MRM of a single compound, where only one MS/MS transition is monitored. C, Precursor ion scan, where *A, B, C,* and *X* are all ions. The second mass filter (MF2) is fixed to monitor the mass-to-charge ratio (*m*/*z*) corresponding to ionic species *X,* and the first mass filter (MF1) is scanned through a range of *m*/*z* values. D, Constant neutral loss scan, where *X* is uncharged and *A, B, C, A1, B1,* and *C1* are ions. The two mass filters are scanned with a constant *m*/*z* offset between the two corresponding to the mass of *X*.**

metabolism (see Chapter 58).[23,24] The ability to analyze multiple compounds in a single analytical run makes this technique an efficient tool for screening purposes. Often MS/MS is of sufficient selectivity to eliminate the need to incorporate LC separation, a simplification that can lead to considerable improvement in sample throughput. Electrospray-MS/MS has become the recognized reference method for carnitine and acylcarnitine analysis to identify organic acidemias and fatty acid oxidation defects.[22,51] In the case of acylcarnitine and amino acid analysis, these compounds vary widely in their polarity, which creates problems with consistency of response factors. To address this, most procedures employ a butyl ester derivatization of the carboxyl group to force cationic character upon the amino acids and thus yield similar

ionization efficiencies for these compounds.[18] Acylcarnitines can be analyzed without derivatization[25] but most often are monitored as butyl esters, where their identification is based on a data acquisition mode known as a *precursor ion scan* (see Figure 14-13, *C*).[21,99] This data acquisition mode makes use of the fact that acylcarnitines have a common collision-induced *m/z* 85 product ion (represented by *X* in Figure 14-13, *C*) that is selectively monitored in MF2. MF1 is set to full scan for any precursor *m/z* that fragmented to yield this product ion, thus identifying acylcarnitines present in the sample (see Figure 14-13, *C*).

Analysis of amino acids by LC-MS/MS has typically been performed using a data acquisition mode known as *constant neutral loss* (see Figure 14-13, *D*).[23] Alpha-amino acids share a common neutral product, butylformate, which has a mass of 102 Da (represented by *X* in Figure 14-13, *D*). By scanning for both product (MF2) and precursor (MF1) ions, and by keeping a constant offset between the two mass *m/z* analyzers (e.g., a difference of 102 *m/z* units), any *m/z* differences that equal 102 Da can be used to identify the presence of an amino acid.

One advantage of LC-MS/MS relative to GC-MS is that in many cases it is unnecessary to derivatize the target compounds. The example of butyl ester derivatization was discussed previously. In this example, the derivative has more favorable fragmentation properties than the underivatized compounds. Similarly, the dibutyl ester of methylmalonic acid, when run in positive ion mode ESI, has more favorable MS/MS spectra than the underivatized compound run in negative ion mode ESI; in addition, the dibutyl esters of dicarboxylic acids are more efficiently ionized in positive ion mode ESI than the underivatized compound run in positive ion mode ESI.[74] The most frequent reason for using derivatization in LC-MS and LC-MS/MS is to achieve improved ionization efficiency. Gao and colleagues have emphasized this issue in an extensive discussion of derivatization in ESI and APCI mass spectrometry.[48]

Not illustrated in Figure 14-13 is a product ion scan mode. In this scan mode, the first mass filter is fixed to pass a specific *m/z,* and the second mass filter is scanned over a range of *m/z* values. This scan mode is very useful for structural studies of targeted ions, such as in peptide sequencing applications by MS/MS, but is less useful for routine screening applications or quantitative analysis.

MALDI Mass Spectrometry

MALDI (usually coupled with a TOF analyzer) has been used to analyze many different classes of compounds. Notably, it has been widely applied in discovery applications for the detection and identification of proteins and peptides. Primary limitations include high background signal and a higher coefficient of variation that seems inherent in the MALDI ionization process. In addition, MALDI is essentially a batch-type process that does not interface naturally with online separation processes such as HPLC.

MALDI-TOF is often used to determine the identity of proteins through peptide mass fingerprinting (PMF). This technique has been used to identify a large number of two-dimensional (2D) gel spots for the bacterial pathogen *Pseudomonas aeruginosa*.[105] The procedure generally involves in-gel tryptic digestion followed by accurate mass measurement of the peptides. The generated mass list is then compared with theoretical tryptic masses for proteins in a database (Figure 14-14 and Table 14-1). This procedure, which works best for organisms with complete and annotated genomes, is very rapid (<2 min per sample) because 100 or more samples may be automatically processed and deposited on a single MALDI target plate. In the previous example,[105] the group rapidly identified a large number of proteins that were expressed differently between laboratory and pathogenic bacteria. In addition, it was found that some proteins were listed as "hypothetical," meaning they were previously undescribed or confirmed to be expressed, and that theoretical molecular weights and/or isoelectric points (pIs) in some cases were extremely different from those measured in the gel, indicating possible terminal clipping and/or post-translational modification. These observations are extremely useful in targeting areas of focus, given the large quantity of data generated by this technique.

An interesting emerging clinical application of MALDI-TOF involves identification of organisms, such as bacteria. A method has been described that attempts to identify bacteria by fingerprinting proteins that were extracted using gentle conditions.[120] The basis of this technique is that different bacteria should express unique proteins in the 2- to 20-kDa mass range, allowing classification according to the protein mass fingerprint. Problems[120] include lack of actual protein mass information for various bacteria and lack of investigation into different strains of the same bacteria. The

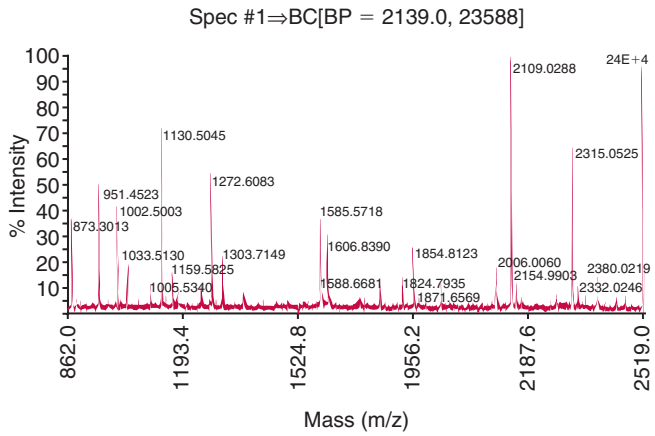

Figure 14-14 An example of a matrix-assisted laser desorption ionization (MALDI)–time-of-flight (TOF) spectrum showing peptides generated in a tryptic digest of a spot cored from a two-dimensional (2D) sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). The 16 most abundant *m/z* values were submitted to the MS-Fit database for searching against the nonredundant database. The results for this search are shown in Table 14-1.

protein mass fingerprints must be catalogued for each bacterium and determined to be completely reproducible for a given extraction method.

Some of these drawbacks were addressed in a MALDI technique that targets ribosomal proteins.[40] This technique was evaluated using 1116 isolates collected in a routine clinical microbiology laboratory and was described as being fast, reliable, and easy to use. More than 95% of clinical isolates were correctly identified, and most of the incorrectly identified isolates were placed in the correct genus or a closely related genus.

MALDI mass spectrometry has the reputation of being a nonquantitative technique. However, some progress has been made toward its use as a quantitative technique.[113] If this application becomes routine, it could have major benefits for clinical mass spectrometry because the time to acquire a mass spectrum by MALDI is only a few seconds. This could dramatically improve throughput. However, it seems likely that this application would require off-line separation prior to loading of the MALDI target, to obtain sufficient selectivity for clinical applications.

ICP Mass Spectrometry

ICP-MS is used for the determination of trace and toxic elements in many types of samples (see Chapters 31 and 36).[9,10] and references 9 and 10). However, it is known that the toxicity of an element may depend on the organic or inorganic state in which the element is present. In these cases, it is more important to ascertain the concentrations of toxic species rather than the total concentration of the element. To extend the usefulness of this technique, GC and HPLC systems have been coupled to ICP-MS to separate individual elemental species before ICP-MS analysis.[83]

Proteomics, Genomics, and Metabolomics

The past 20 years have seen tremendous progress in genomics, with hundreds of genomes completed or near completion and many now parsed and annotated. However, this information has often failed to provide vast new understanding into cellular function, mainly because of the myriad changes that occur to proteins produced from the genome throughout the life cycle of a cell.[1A] In the mid 1990s, MS came to the forefront of analytical techniques used to study proteins, and the term *proteomics* was coined. Although the definition of proteomics is still debated, for the present discussion it is taken to encompass knowledge of the structure, function, and expression of all proteins in the biochemical or biological contexts of all organism.[65] In a more basic and practical sense, proteomics refers to the identification and quantification of proteins and their post-translational modifications in a given system or systems. This is a challenging task in that a given gene may have many distinct chemical protein

isoforms. In addition, many other molecules (metals, lipids, etc.) interact with proteins in a noncovalent fashion. Therefore in a genome, such as the human genome, a repertoire of more than a million "proteins" may require identification and quantification. Proteome analysis is a powerful tool for investigating (1) biomarkers of disease, (2) antigens of pathogens, (3) drug target proteins, and (4) post-translational modifications, as well as for other investigations.

Two foundations are necessary to begin this daunting challenge. The first is the basic sequence expected for each possible protein in a cell (i.e., a completed genome). The second is instrumentation, which currently consists of advanced mass spectrometers that identify and quantify protein isoforms in an automated fashion at very low limits of detection. Both foundations are now essentially in place, and the field of proteomics has leapt forward over the past several years. However, the goal previously stated is far from being met, and considerable advances will have to be made before we truly examine all the proteins in a cell.

Currently, MS is routinely used to accomplish many tasks in proteomics. The most basic task is protein identification. The typical approach is known as the *bottom-up* method, whereby proteins are separated—by gel electrophoresis or by solution-based methods—and then digested. The resulting enzymatic fragments are analyzed and used to identify the protein(s) present. This process is time consuming and has many pitfalls. Increasingly, much research has been devoted to analysis of mixtures of proteins. These mixtures are derived from cellular compartments, tissue, or immunoprecipitation. Although it solves many problems associated with analysis of proteins isolated by gels, this technique suffers one major drawback: complexity. Currently, both instrumentation and analysis software are not sufficiently advanced to allow easy identification of all the proteins in truly complex mixtures. As a result, much emphasis has been placed on separation methods for proteins and/or peptides. Many groups have introduced methods to begin handling this level of complexity. The most popular approaches include subcellular fractionation, multidimensional chromatography, and affinity labeling and/or purification. By combining these approaches, several thousand protein species can be identified routinely. Obviously these numbers are better than those obtained through bottom-up methods from gels, but they still fall far short of those necessary for complete proteomics.

Two additional areas that have to be addressed are quantification and de novo sequencing and/or post-translational modification. First, most identified proteins must be quantified in relation to changes in cell state or cell type. Quantification in MS for these purposes is relative comparing a standard condition to a perturbed one. Current techniques in this area involve labeling a subset of peptides (isotope-coded affinity tagging) or all peptides (metabolic labeling). Although some problems exist with the labeling, the g reatest—as with identification—involves the sheer complexity of the sample to be analyzed. Label-free approaches for LC-MS/MS quantitative proteomics have also appeared in the literature.[103] The second problem is both separate and related. Post-translational modifications clearly are the major control mechanisms in cells.[94,95] For example, in the field of phosphoproteomics, mass spectrometry has become a powerful technology for the analysis of in vivo phosphorylation in signaling pathways.[94,95] Mass spectrometry is unique as a technique because it will both identify and exactly locate a modification. However, the software needed to automate this process lags far behind the ability to collect data. What is lacking is software for de novo sequencing that will reliably interpret a mass spectrum with little or no user intervention, especially in the area of post-translational modification. Currently, highly skilled mass spectrometrists manually interpret most modified spectra, adding days or even weeks of analysis time per sample. These two problems, in addition to sample complexity, will have to be solved before proteomics evolves into a mature field.

The term *proteomics* is often used in the context of biomarker discovery. To date, very few markers discovered using proteomics methods have migrated to the clinical laboratory. Some of the reasons for the dearth of new protein biomarkers have recently been discussed.[16] From a broader view, however, proteomics may also include the application of mass spectrometry for the analysis of previously recognized proteins and peptides. For example, mass spectrometric methods for the analysis of carbohydrate-deficient transferrin have been developed, including a reference method[93] and a method for routine patient testing. Additional areas of application of mass spectrometry include analysis of the proteome of the pathogenic mold *Aspergillus fumigatus* with the aim of identifying vaccine candidates and new allergens.[6]

A method of analysis of thyroglobulin, a well-known tumor marker, has been described.[56] Although the limit of quantification of this thyroglobulin method still needs to be improved before it is suitable for routine clinical application, it represents substantial progress in the application of mass spectrometry for practical analysis of proteins.

Promising proof-of-principle research has been performed on the characterization of hemoglobinopathies by mass spectrometry.[8,122,123] Most hemoglobin methods using mass spectrometry do not detect the intact tetramer but rather detect separate hemoglobin chains or peptides products from enzymatic digests of hemoglobin. However, as shown by Rockwood and coworkers,[102] and shortly thereafter by Ganem and associates,[46,47] the retention of higher order structure, such as noncovalent complexes, is possible when ions are transferred from solution to gas phase, and hemoglobin tetramers have been observed by mass spectrometry.[5] Another hemoglobin application, a reference method for hemoglobin A_{1c} using mass spectrometry, has been approved by the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC).[62] A method used for hepcidin, a recently discovered peptide hormone believed to be a master regulator of iron status, has been published.[71]

Genetic applications for clinical mass spectrometry are beginning to emerge. For example, MALDI-TOF has been used for mutation detection in myeloproliferative disorders,[45] DNA methylation analysis,[61,119] and gene expression analysis.[7]

A very promising genomic approach for pathogen identification uses polymerase chain reaction amplification of selected regions of a pathogen genome, followed by accurate mass measurement using ESI-TOF-MS. From the accurate mass information, a DNA base composition is computed, and the results are matched to pathogen DNA base compositions in a database.[39,55]

A burgeoning area where MS plays a role is the emerging field of *metabolomics*. This scientific area involves the investigation and characterization of small molecules, including byproducts, present in biological fluids under different conditions that include (1) normal homeostasis, (2) disease states, (3) stress, (4) dietary modification, (5) treatment protocols, (6) aging, and (7) others. In a fashion similar to a mass spectrum providing a fingerprint signature for a specific molecule, it has been speculated that compounds identified and evaluated in metabolomic studies may provide a fingerprint signature for a current physiologic state.

In practice, metabolites are identified through comparison with (1) known reference materials if available, (2) commercial or in-house developed mass spectral libraries or metabolite databases, (3) interpretation of mass spectra, or (4) ancillary techniques such as nuclear magnetic resonance (NMR). As with other applications of MS, both GC-MS and LC-MS have a place in such studies. GC-MS has some potential advantages that were described earlier. To use GC-MS, however, the metabolites in the sample must be volatile, or a separate derivatization step is needed to observe additional compounds. Furthermore, the molecular ion, reflecting the mass of a compound, may not be observed.

LC-MS has its own usefulness in metabolomics because it has potentially wider applicability to polar and nonpolar compounds. LC-MS allows observation of the pseudomolecular ion. However, because reference materials or isotope-labeled internal reference materials do not exist for validating ionization efficiencies or recoveries for newly identified unknown compounds, the effects of ion suppression (discussed later) remain a potential confounding factor. Compared with proteomic research, metabolomic research faces the added difficulties that the MS/MS spectra are more difficult to interpret, no "sequence information" is found in the MS/MS spectra, and DNA and protein sequence databases are of no use in interpreting the results.

Mass spectral imaging of tissue sections is another emerging technology intended for clinical applications that holds great promise. The most common approach is to apply MALDI mass spectrometry to image tissue sections.[26,30] A mass spectrum is acquired at each spot on a regularly spaced array on the sample. From these data, an image is constructed for each *m/z*. The images provide a spatial map of chemical composition (primarily peptides) from the sample. Another approach uses laser ablation, followed by ICP-MS, to provide a spatial map of the inorganic elemental composition of the sample.[11] This technique can be extended to immunohistochemical imaging by using metal-labeled antibodies.[104] With this scheme, it is possible to use different labels on different antibodies to do multiplexed imaging of several different targets on the same sample.

Practical Aspects of Mass Spectrometry—Logistics, Operations, and Quality

In many respects, the logistics, operations, and quality processes for clinical mass spectrometry laboratories follow well-established clinical laboratory standards and processes. However, mass spectrometers are complex instruments and most manufacturers of instrumentation are still learning how to best support their clients in the clinical laboratory. Consequently, the adoption of mass spectrometry, and especially the more complex technologies such as LC-MS/MS, places added demands on training, competency, and service beyond those of more familiar and well-established technologies used in clinical laboratories.

In contrast to techniques such as optical spectrophotometry, mass spectrometers tend to require more frequent tuning, calibration, and optimization, and the laboratory inspection checklist of the College of American Pathologists specifies that mass spectrometers be tuned daily.[15] In addition, the frequency of calibrations and optimizations needed to maintain instruments in fit-for-purpose condition will vary, depending on the requirements of the assays being performed, the instrumentation used, and other factors.

The term *calibration* is used in at least two distinct ways in mass spectrometry. The first is calibration of the *m/z* scale of the instrument, usually referred to as *mass calibration*. The other is calibration for quantitative analysis.

Schedules for mass calibration vary between laboratories, types of instruments used, and types of assays being run. For example, if accurate mass measurements are an important part of a method, as with many assays that employ TOF mass spectrometry, then very frequent mass calibration is typically required. In some cases, internal mass reference materials are included within each run, or even within each sample. For applications that are less dependent on mass accuracy, such as most quantitative methods that rely on a quadruple mass filter, mass calibration may be performed less frequently. For example, mass calibration may be performed every few weeks, with verification of mass calibration performed more frequently—as often as daily in some laboratories.

Based on validation results obtained in individual laboratories, schedules for calibration for quantitative analysis may vary. For example, some laboratories calibrate an assay daily, while others calibrate every run.

One advantage of mass spectrometry is that most methods in the mass spectrometry laboratory avoid the use of highly specialized reagents such as antibodies. Consumables are mostly generic items, such as solvents, chromatography columns, and sample vials or 96-well plates. This tends to buffer the laboratory from supply disruptions of specialized reagents, and in some cases can decrease consumable costs as well. However, consumables must be carefully selected and monitored for quality, and some laboratories have experienced intermittent cases of contaminated supplies. Solvent

quality is of particular concern. For example, one study documented wide variations in methanol quality from different suppliers, which can lead to large differences in ionization efficiency in ESI sources.[4]

Whenever possible, a quantitative method should use isotopically labeled internal reference materials of the same chemical composition (except for the isotope labels) for each target analyte. However, it is not always possible to obtain isotopically labeled versions of each target analyte, in which case one should select a closely related chemical analog as an internal standard.

Mass spectrometry provides several opportunities for enhancing analytical quality, and therefore improving patient care. The high degree of selectivity of mass spectrometry, particularly when included as a part of hyphenated techniques (GC-MS, LC-MS, LC-MS/MS, etc.) reduces the likelihood of interference compared with immunoassays or simple separation-based techniques (GC or LC), particularly for small molecule analysis, where cross-reactivity is a concern.[57] Perhaps as important as a high degree of selectivity, mass spectrometry provides a means to detect the presence of interferences when they occur. With methods that produce fragmentation, in the ion source (as in EI) or in a collision cell (as in MS/MS), fragment ions are produced in reproducible intensity ratios. By monitoring one or more ion ratios, and by comparing these ratios to ratios obtained from authentic reference materials measured in the same run, it is possible to detect many occurrences of interfering compounds on a sample-by-sample basis.[76]

In addition, accurate mass measurements are useful for detecting interferences if one is using an instrument capable of such measurements, such as a TOF mass spectrometer. To illustrate, the accurate mass of protonated cortisol ($C_{21}H_{31}O_5^+$) is 363.2166 Da, whereas the accurate mass of one of the isotope peaks of protonated fenofibrate ($C_{20}H_{22}ClO_4^+$) is 363.1180 Da—a difference of 270 ppm. Therefore, an interference of even a few percent by fenofibrate in a cortisol analysis would be detectable as a shift in mass of the cortisol peak on an instrument capable of low single-digit ppm mass accuracy.

Obviously, detection of interferences by mass measurement alone becomes more difficult as the mass of the interfering compound approaches that of the target compound, but given the ability to detect interferences at a ≈20% level or better, and assuming a mass spectrometer of ≈3 ppm mass accuracy, a reasonable estimate is that one could detect interferences for all compounds with $|\Delta m/z|$ >30 ppm relative to the target compound. Given the cortisol example discussed earlier, 22 chemical formulas for ions are within 30 ppm of the mass of protonated cortisol, provided we limit our list to the composition constraints listed earlier. Interferences from these would be difficult or impossible to detect by mass measurement alone, but for the other 131 chemical formulas discussed that are outside of the 30 ppm window interference, detection by mass measurement alone is feasible. Thus, accurate mass would likely detect the majority of possible interferences, but a non-negligible minority of potentially interfering compounds would be difficult or impossible to detect.

In developing methods using MS/MS, it is important to carefully assess which MS/MS transitions are to be used. Not all are created equal, particularly with regard to selectivity. In preliminary studies in method development, it is useful to first develop a list of possible MS/MS transitions, based on product ion spectra of pure reference materials . It is generally advisable at this point to strike those transitions from the list that are likely to be nonspecific. Water loss peaks are prime candidates for exclusion, although exclusion of water loss peaks is not always a feasible option if no other high-abundance peaks are available. In the case of methods that rely on derivatization, it is usually best to remove those ions from the list that are products of the derivatization reagent rather than the original target molecule, as these often lack specificity. More transitions can be struck from the list by running a series of patient samples. Those MS/MS transitions that show high background or other interferences are best eliminated from consideration. If pure reference materials of related compounds show similar MS/MS transitions, they may also be candidates to be struck from the list, although if the method is an LC-MS/MS method and the related compounds have different retention times from the target compounds, they may be acceptable. It is also often useful to optimize the collision energy during method development to minimize the likelihood of interferences.

Ion suppression is another quality issue that should be evaluated during method validation.[3] First described in 1993,[63,116] ion suppression is a matrix effect that results from the presence of coeluting nonvolatile or less volatile compounds that change the efficiency of spray droplet formation, ionic properties, and evaporation. These nonvolatile materials, which include salts, ion-pairing agents, endogenous compounds, drugs, and/or metabolites, compete with analyte ions for access to the droplet surface or transfer to the gas phase, which, in turn, affects the amount of charged ion in the gas phase that ultimately reaches the detector.[66] Anions, such as phosphate or borate in buffers, can also neutralize the effective ionization of an analyte. Phospholipids present in blood have been demonstrated to be a major contributor to ion suppression.[125] Impurities in solvents can result in ion suppression.[4]

The presence of ion suppression, or other deleterious matrix effects, can be evaluated via several experimental protocols.[27] One involves comparison of (1) the instrument response for reference materials (including any internal standards) injected directly in the mobile phase, and (2) the same amount of compound spiked into preextracted samples.[86] Data for the standard in the mobile phase provide a relative 100% response value. Data for the same amount of compound spiked into preextracted samples show the effects of sample matrix on MS response (ion suppression).

A second protocol involves postcolumn continuous infusion of compound into the MS detector.[13,58,91] The

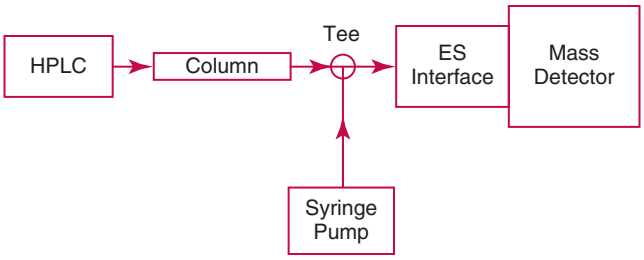

Figure 14-15 Postcolumn infusion system. Mobile phase or specimen extracts are injected into the high-performance liquid chromatography (HPLC) system. The analyte being evaluated is continuously infused, post column, and is mixed with the column effluent through a tee before entering the electrospray interface.

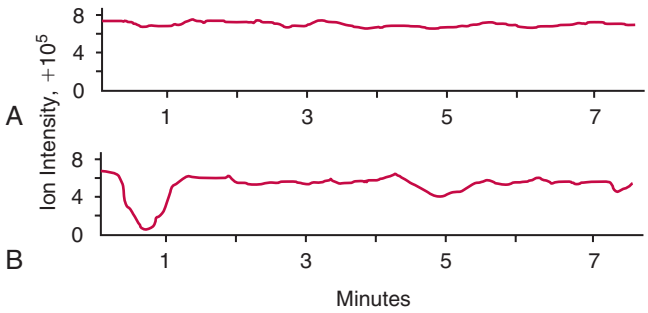

Figure 14-16 Infusion chromatograms for hypothetical analytes. A, Mobile-phase injection. B, Serum liquid-liquid extract injection. These profiles illustrate that ion suppression can be greater than 90%, that a recovery time may exist, and that suppression is not limited to the solvent front region. For a comprehensive presentation of these types of effects, the reader is referred to References 13, 58, and 91.

instrumental setup includes a syringe pump connected via a tee to the column effluent (Figure 14-15). Because the compound being tested is introduced into the mass detector at a constant rate, a constant electrospray ionization response should ideally be observed (Figure 14-16, *A*) if no ionization interferences occur when an extract from a biological specimen, such as serum, is injected into the HPLC portion of the instrument. In actuality, it is common to see suppression of the signal at the time point that corresponds to the void volume of the column (see Figure 14-16, *B*). The degree of ion suppression and the recovery time to full response can vary from compound to compound[13] and from sample to sample and can be dependent on the sample preparation method. Because endogenous compounds from the specimen matrix can continue to elute at any time during the chromatographic run, ion suppression is not limited to the column void. The observed degree of ion suppression can also be dependent on the injection volume and the concentration of the analyte being monitored,[118] which is related to the matrix-to-analyte ratio.[52] It should be noted that the degree of the matrix effect might differ even between different samples of the same biological material, as has been amply shown by Matuszewski et al.[85,87]

Ion suppression is not limited to HPLC-MS or ESI interfaces. For MALDI analysis, arginine-containing peptides have been reported to dominate the peptide pattern for protein digests,[73] the extent of which depends on the matrix used. The presence of ionic detergents, such as Triton X-100 and Tween 20, has been shown to cause signal suppression in MALDI experiments, which can be countered by modifications to the matrix.[49]

CHAPTER 15

Enzyme and Rate Analyses

*Renze Bais, Ph.D., A.R.C.P.A., and Mauro Panteghini, M.D.**

Enzymes are proteins with catalytic properties; *clinical enzymology* is the application of the science of enzymes to the diagnosis and treatment of disease. The principles of clinical enzymology will be introduced and discussed in this chapter, as will information on how enzymes are measured and how they are used as analytical reagents in various types of rate analysis. Individual topics include basic principles, enzyme kinetics and analytical enzymology, and rate analyses.

BASIC PRINCIPLES

This section begins with a presentation of enzyme nomenclature, which is followed by a discussion of enzymes as proteins and catalysts.

Enzyme Nomenclature

Historically, individual enzymes were identified using the name of the substrate or group upon which they act and then adding the suffix *-ase*. For example, the enzyme hydrolyzing urea was ure*ase*. Later, the type of reaction involved was also identified, as in carbonic anhydrase, D-amino acid oxidase, and succinate dehydrogenase. In addition, some enzymes had been given empirical names such as trypsin, diastase, ptyalin, pepsin, and emulsin.

Because this combination of trivial common names and semisystematic names was found to be inadequate, in 1955 the International Union of Biochemistry (IUB) appointed an Enzyme Commission (EC) to study the problem of enzyme nomenclature. Its subsequent recommendations, with periodic updating, provide a rational and practical basis for identifying all enzymes now known and enzymes that will be discovered in the future (http://www.chem.qmw.ac.uk/iubmb/enzyme/accessed May 6, 2011).[11]

With the IUB system, a systematic and trivial name is provided for each enzyme. The systematic name describes the nature of the reaction catalyzed and is associated with a unique numeric code. The trivial or practical name, which may be identical to the systematic name but is often a simplification of it, is suitable for everyday use. The unique numeric designation for each enzyme consists of four numbers, separated by periods (e.g., 2.2.8.11), and is prefixed by the letters *EC,* denoting *Enzyme Commission.* The first number defines the class to which the enzyme belongs. All enzymes are assigned to one of six classes, characterized by the type of reaction they catalyze: (1) oxidoreductases, (2) transferases, (3) hydrolases, (4) lyases, (5) isomerases, and (6) ligases. The next two numbers indicate the subclass and the sub-subclass to which the enzyme is assigned. For example, these may differentiate the amino-transferring subclass from the phosphate-transferring category, or the ethanol acceptor sub-subclass from that accepting acyl groups. The last number is the specific serial number given to each enzyme within its sub-subclass.

To illustrate how this system is used to name an enzyme, consider the enzyme creatine kinase, which catalyzes the following reaction:

$$\text{ATP} + \text{creatine} \rightleftharpoons \text{ADP} + \text{creatine phosphate}$$

Its system number is

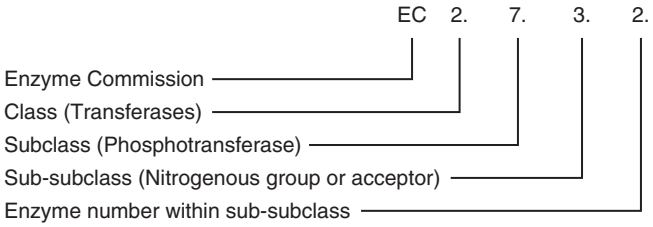

Table 15-1 lists some selected enzymes of clinical interest, identified by trivial, abbreviated, and systematic names and by their code numbers.

Although it is not recommended by the EC, it is a common and convenient practice to use capital letter abbreviations for the names of certain enzymes, such as ALT (formerly GPT) for alanine aminotransferase. Other examples are AST for aspartate aminotransferase, LD for lactate dehydrogenase, and CK for creatine kinase (see Table 15-1).

Enzymes as Proteins

All enzyme molecules possess the primary, secondary, and tertiary structural characteristics of proteins (see Chapter 21).

**The authors gratefully acknowledge the original contributions by Drs. A. Ralph Henderson and Donald W. Moss upon which portions of this chapter are based.*

tahir99-VRG & vip.persianss.ir

TABLE 15-1 Enzyme Commission (EC) Numbers, Systematic and Trivial Names, Together With Frequently Adopted Abbreviations of Enzymes of Major Clinical Importance

EC Number	Systematic Name	Trivial Name	Abbreviation
1.1.1.27	L-Lactate: NAD^+ oxidoreductase	Lactate dehydrogenase	LD
1.4.1.3	L-Glutamate: $NAD(P)^+$ oxidoreductase (deaminating)	Glutamate dehydrogenase	GLD
2.3.2.2	(γ-Glutamyl)-peptide: amino acid γ-glutamyltransferase	γ-Glutamyltransferase	GGT
2.6.1.1	L-Aspartate: 2-oxoglutarate aminotransferase	Aspartate aminotransferase (transaminase)	AST
2.6.1.2	L-Alanine: 2-oxoglutarate aminotransferase	Alanine aminotransferase (transaminase)	ALT
2.7.3.2	ATP: creatine *N*-phosphotransferase	Creatine kinase	CK
3.1.1.3	Triacylglycerol acylhydrolase	Lipase	LPS
3.1.1.7	Acetylcholine acetylhydrolase	Acetylcholinesterase, true cholinesterase, choline esterase I	—
3.1.1.8	Acylcholine acylhydrolase	Pseudocholinesterase, butyryl cholinesterase, choline esterase II (serum cholinesterase)	CHE
3.1.3.1	Orthophosphoric-monoester phosphohydrolase (alkaline optimum)	Alkaline phosphatase	ALP
3.1.3.2	Orthophosphoric-monoester phosphohydrolase (acid optimum)	Acid phosphatase	ACP
3.1.3.5	5′-Ribonucleotide phosphohydrolase	5′-Nucleotidase	NTP
3.2.1.1	1,4-α-D-Glucan glucanohydrolase	Amylase	AMY
3.4.21.4		Trypsin	TRY
4.1.2.13	D-Fructose-1,6-bisphosphate D-glyceraldehyde-3-phosphate-lyase	Aldolase	ALD

In addition, most enzymes exhibit quaternary structure. The *primary* structure, the linear sequence of amino acids linked through their α-carboxyl and α-amino groups by peptide bonds, is specific for each type of enzyme molecule. Each polypeptide chain is coiled up into three-dimensional secondary and tertiary structure. *Secondary* structure refers to the conformation of limited segments of the polypeptide chain, namely α-helices, β-pleated sheets, random coils, and β-turns. The arrangement of secondary structural elements and amino acid side chain interactions that define the three-dimensional structure of the folded protein is referred to as its *tertiary* structure. In many cases, biological activity, such as the catalytic activity of enzymes, requires two or more folded polypeptide chains (subunits) to associate to form a functional molecule. The arrangement of these subunits defines the *quaternary* structure. The subunits may be copies of the same polypeptide chain (e.g., the MM isoenzyme of creatine kinase, the H_4 isoenzyme of lactate dehydrogenase), or they may represent distinct polypeptides.

The application of physical methods, such as x-ray crystallography and multidimensional nuclear magnetic resonance (NMR), has provided structural insights upon which enzyme mechanisms have been built. Furthermore, the tools of molecular biology, such as molecular cloning, have enabled the purification and characterization of enzymes that previously were available only in minute amounts. Molecular biology also enables the manipulation of the amino acid sequence of enzymes, and site-directed mutagenesis (substituting one amino acid residue for another) and deletion mutagenesis (eliminating sections of the primary structure) have enabled the identification of chemical groups that participate in ligand binding and in specific chemical steps during catalysis.

In general, no feature of primary structures, such as repetition of particular amino acid sequences, is common to all enzyme molecules. However, considerable homologies of sequence are found between enzymes that appear to share a common evolutionary origin, such as the proteases, trypsin and chymotrypsin, and similarities of sequence are even more marked among the members of a family of isoenzymes. The amino acid sequence in the immediate neighborhood of the active center of the enzyme (discussed later) is often closely similar in enzymes of related function (e.g., the *serine proteases* are so called because they all have this amino acid in the active center).

Enzyme molecules differ in the proportion of secondary structures—such as α-helices—they contain, although no enzyme molecule so far studied approaches the large proportion of α-helices found in myoglobin and hemoglobin. The tertiary structures of different types of enzyme molecules are as individually characteristic as their primary structures;

tahir99-VRG & vip.persianss.ir

nevertheless, some common features exist. Enzyme molecules are roughly globular in overall shape, with a preponderance of polar amino acid side chains on the outside of the molecule and nonpolar side chains in the interior. The ionizable residues in contact with the surrounding medium are responsible for many of the properties of the enzyme molecules in solution, such as their migration in an electric field and their solubility. Covalent disulfide bridges may link different parts of the polypeptide chains in some enzyme molecules, but the three-dimensional structure is mainly stabilized by the large number of hydrophobic interactions that are formed between the nonpolar side chains in the interior of the molecule.

The biological activity of a protein molecule depends generally on the integrity of its structure, and any disruption of its structure is accompanied by loss of activity, a process known as *denaturation*. If the process of denaturation is minimal, it may be reversed with the recovery of enzyme activity upon removal of the denaturing agent. However, prolonged or severe denaturing conditions result in an irreversible loss of activity. Denaturing conditions include elevated temperatures, extremes of pH, and chemical addition. Heat inactivation of most enzymes takes place at an appreciable rate at room temperature and in most cases becomes almost instantaneous above 60 °C. The polymerases are an exception and retain activity at temperatures as high as 90 °C—a property that has been made use of in the polymerase chain reaction (see Chapter 17). Low temperatures are used to preserve enzyme activity, especially in aqueous solutions, such as serum (see Chapter 22). Extremes of pH also cause unfolding of enzyme molecular structures and, except for a few exceptions, should be avoided when enzyme samples are preserved. Addition of chemicals, such as urea and detergents, disrupts hydrogen bonds and hydrophobic interactions so that exposure of enzymes to strong solutions of these reagents results in inactivation.

Specificity and the Active Center

With the exception of enzymes such as proteases, nucleases, and amylases, which act on macromolecular substrates, enzyme molecules are considerably larger than the molecules of their substrates. Consideration of the structure of an enzyme's active site and its relationship to the structures of the enzyme's substrate(s) in its ground and transition states is necessary to understand the rate enhancement and specificity of the chemical reactions performed by the enzyme. The active site of an enzyme will vary between enzymes but in general,[5]

1. The active site of an enzyme is relatively small compared with the total volume of the enzyme molecule because its structure may involve less than 5% of the total amino acids in the molecule.
2. The active sites of enzymes are three-dimensional structures that are formed as a result of the overall tertiary structure of the protein. This results when the amino acids and cofactors in the active site of an enzyme are spatially structured in an exact, three-dimensional relationship with respect to one another and the structure of the substrate molecule.
3. Typically, the attraction between the molecules of the enzyme and its substrate molecules is noncovalent binding. Physical forces used in this type of binding include hydrogen bonding, electrostatic and hydrophobic interactions, and van der Waals forces.
4. Active sites of enzymes typically occur in clefts and crevices in the protein. This excludes bulk solvent and reduces the catalytic activity of the enzyme.
5. The specificity of substrate binding is a function of the exact special arrangement of atoms in the enzyme active site that complements the structure of the substrate molecule.

Isoenzymes and Other Multiple Forms of Enzymes

An *isoenzyme* is defined as "one of a group of related enzymes catalyzing the same reaction but having different molecular structures and characterized by varying physical, biochemical, and immunologic properties." However, the IUB recommends that use of the term *isoenzyme* be restricted to forms that originate at the level of the genes that encode the structures of the enzyme proteins in question.[4]

Isoenzymes may occur within a single organ or even within a single type of cell. The forms can be distinguished on the basis of differences in various physical properties, such as electrophoretic mobility and resistance to chemical or thermal inactivation. They often have significant quantifiable differences in catalytic properties, but all forms of a particular enzyme retain the ability to catalyze its characteristic reaction.

The existence of multiple forms of enzymes in human tissue has important implications in the study of human disease. The presence in different organs of isoenzymes with distinctive properties helps in our understanding of organ-specific patterns of metabolism, but genetically determined variations in enzyme structure between individuals account for such characteristics as differences in sensitivity to drugs and differences in metabolism, which manifest themselves as hereditary metabolic diseases. For diagnostic enzymology, the existence of multiple forms of enzymes, whether due to genetic or nongenetic causes, provides opportunities to increase the diagnostic specificity and sensitivity of enzyme assays in body fluid samples.

Similar to other proteins, enzymes usually elicit the production of antibodies when they are injected into animals of a species other than those in which they originate. Even small structural differences between closely similar molecules, such as the members of a family of isoenzymes, are often sufficient to render them antigenically distinct, allowing antibodies to be produced specific to a single type of molecule. The availability of enzyme-specific antisera opens up a wide range of methods in enzyme analysis, some of which—such as immunoassay—do not depend on the catalytic activity of the enzyme molecules. The availability of immunochemical methods has been particularly important in the analysis of

tahir99-VRG & vip.persianss.ir

isoenzyme mixtures. Many commercial immunoassays now use monoclonal antibodies to increase specificity.

Genetic Origins of Enzyme Variants

True isoenzymes result from the existence of more than one gene locus coding for the structure of the enzyme protein. Many human enzymes (perhaps more than one third) are known to be determined by more than one structural gene locus. Genes at the different loci have undergone differential modifications during the course of evolution, so that the enzyme proteins coded by them no longer have identical structures, although they are recognizably similar; in other words, they are isoenzymes.

The multiple genes that determine a particular group of isoenzymes are not necessarily closely linked on one chromosome. For example, the structural genes that code for human salivary and pancreatic amylases both are located on chromosome 1, whereas the genes that code for cytoplasmic and mitochondrial malate dehydrogenase are carried on chromosomes 2 and 7, respectively. Among the enzymes of clinical importance that exist as isoenzymes because of the presence of multiple-gene loci are lactate dehydrogenase, creatine kinase, α-amylase, and some forms of alkaline phosphatase.

An enzyme can exist in molecular forms that differ from one individual to another because of the existence of alternative alleles that are inherited according to mendelian laws. These give rise to gene products with the same function, and isoenzymes that result from the existence of allelic genes are termed *allozymes*. The proportion of human gene loci subject to allelic variation is considerable, and the probability that individual human beings will differ to some degree in their isoenzyme patterns is correspondingly high.

The number of allelic variants and the frequency with which particular variants occur within the population vary considerably from one enzyme to another. For example, mutations at either of the two principal loci that determine human lactate dehydrogenase are extremely rare, but a high incidence of mutant alleles occurs at the single locus that determines the structure of placental alkaline phosphatase. More than 400 mutations in the glucose-6-phosphate dehydrogenase gene have now been identified on the X chromosome [up-to-date genetic information on this and other enzymes can be obtained from the Online Mendelian Inheritance in Man (OMIM) database at http://www.ncbi.nlm.nih.gov/Omim/searchomim.html/accessed May 6, 2011]. Some of these alleles are extremely rare, whereas others occur with appreciable frequency in particular populations or geographical locations. When isoenzymes, because of variation at a single locus, occur with appreciable frequency in a human population, the population is said to be *polymorphic* with respect to the isoenzymes in question.

Another category of multiple molecular forms can arise when enzymes are oligomeric and consist of molecules made up of subunits. The association of different types of subunits in various combinations gives rise to a range of active enzyme molecules. When the subunits are derived from different structural genes—multiple loci or multiple alleles—the hybrid molecules so formed are called *hybrid isoenzymes*. The ability to form hybrid isoenzymes is evidence of considerable structural similarities between the different subunits. Hybrid isoenzymes can be formed in vitro, but they are also formed in vivo in cells in which different types of constituent subunits are present in the same subcellular compartment.

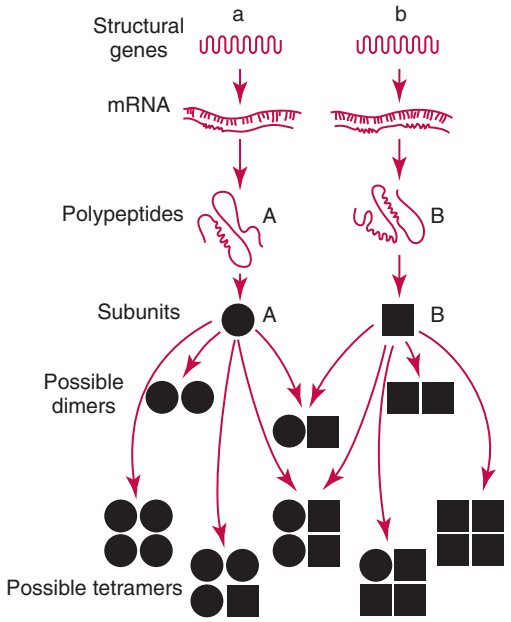

Figure 15-1 Diagram showing the origin of isoenzymes, assuming the existence of two distinct gene loci. When the active enzymes are polymers containing more than one subunit, hybrid isoenzymes consisting of mixtures of different subunits may be formed. One such isoenzyme can be formed in the case of a dimeric enzyme, such as creatine kinase, and three if the enzyme is a tetramer (e.g., lactate dehydrogenase). In both cases, two homopolymeric isoenzymes can also exist. *(From Moss DW. Isoenzyme analysis. London: The Chemical Society, 1979. Reprinted by permission of The Royal Society of Chemistry. Reproduced by permission of The Royal Society of Chemistry.)*

The number of different hybrid isoenzymes that can be formed from two nonidentical protomers depends on the number of subunits in the complete enzyme molecule. For a dimeric enzyme, one mixed dimer (hybrid isoenzyme) can be formed. If the enzyme is a tetramer, three heteropolymeric isoenzymes may be formed (Figure 15-1). Examples of hybrid isoenzymes include the mixed MB dimer of creatine kinase and the three hybrid isoenzymes—LD-2, LD-3, and LD-4—of lactate dehydrogenase.

Nongenetic Causes of Multiple Forms of Enzymes

Post-translational modifications of enzyme molecules give rise to multiple forms known as *isoforms* (Figure 15-2).

Modifications of residues in the polypeptide chains of enzyme molecules takes place in living cells to yield multiple forms. For example, removal of amide groups accounts for some of the heterogeneity of amylase and carbonic anhydrase (each of these enzymes also exists as a true isoenzyme). Modification can also take place as a result of extraction

tahir99-VRG & vip.persianss.ir

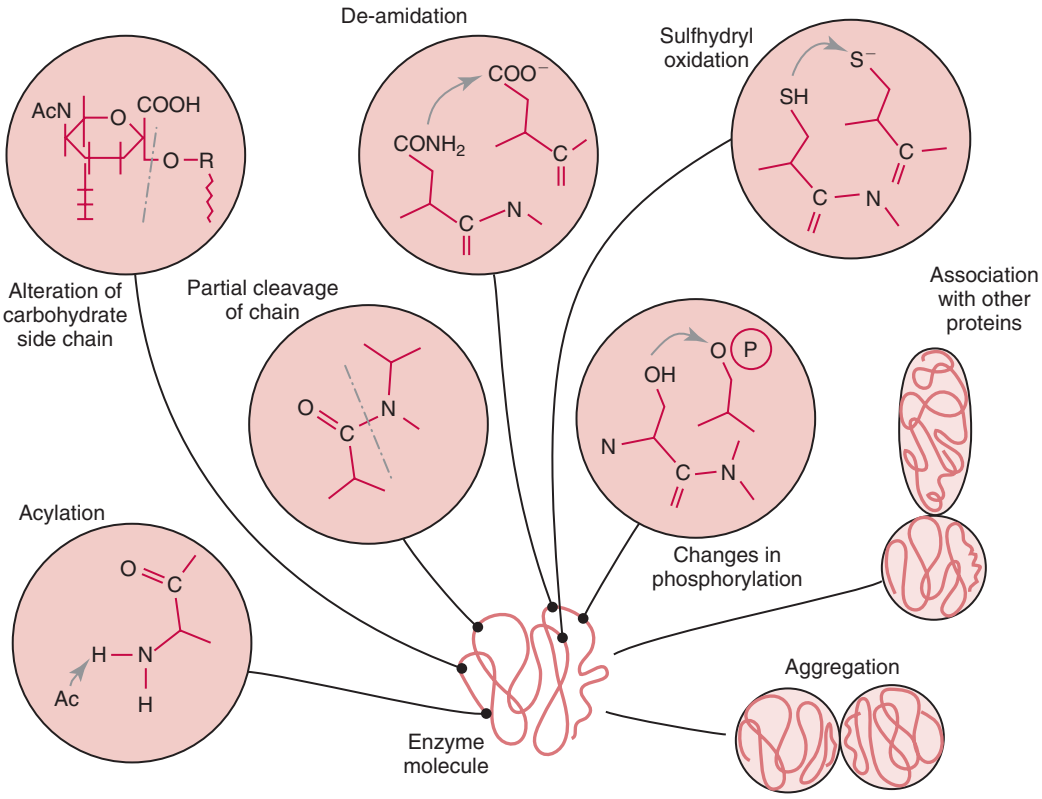

Figure 15-2 Nongenetic modifications that may give rise to multiple forms of enzymes. *(From Moss DW. Isoenzymes. London: Chapman & Hall, 1982.)*

procedures. Many erythrocyte enzymes, including adenosine deaminase, acid phosphatase, and some forms of phosphoglucomutase, contain sulfhydryl groups that are susceptible to oxidation. In hemolysates, oxidation may be brought about by the action of oxidized glutathione, although in intact cells, this compound is present in its reduced form. Thus, variant enzyme molecules with altered molecular charge may be generated.

Serum isoforms of creatine kinase are formed as part of the normal clearance process of the cell. Human myocardial and skeletal muscle tissues have the CK-MM and CK-MB isoenzymes, which are modified upon release into the circulation. This modification is due to sequential removal of the C-terminal amino acid, lysine, by the action of carboxypeptidase (see Chapter 22 for additional details).

Modifications affecting nonprotein components of enzyme molecules may also lead to molecular heterogeneity. Many enzymes are glycoproteins, and variations in carbohydrate side chains are a common cause of nonhomogeneity of preparations of these enzymes. Some carbohydrate moieties, notably *N*-acetylneuraminic acid (sialic acid), are strongly ionized and consequently have a profound effect on some properties of enzyme molecules.[1] For example, removal of terminal sialic acid groups from human liver and/or bone alkaline phosphatase with neuraminidase greatly reduces the electrophoretic heterogeneity of the enzyme.

Aggregation of enzyme molecules with each other or with nonenzymatic proteins may give rise to multiple forms that can be separated by techniques that depend on differences in molecular size. For example, four catalytically active cholinesterase components with molecular weights ranging from about 80,000 to 340,000 are found in most sera, with the heaviest component, C_4, contributing most of the enzyme activity. Other enzyme forms are also occasionally present, but it appears that the principal serum cholinesterase fractions can be attributed to different states of aggregation of a single monomer.

A specific form of interaction between enzymatic and nonenzymatic proteins is the cause of unusual enzyme components noted when some samples of human plasma are fractionated by electrophoresis or chromatography. These components are the result of the combination of apparently normal enzyme or isoenzyme molecules with plasma immunoglobulins. The enzyme–protein complexes *(macrocomplexes)* thus formed may themselves be heterogeneous. Since the identification of *macroamylase,* the first such enzyme–immunoglobulin complex to be identified, similar complexes have been observed involving lactate dehydrogenase, creatine kinase, alkaline phosphatase, and other enzymes.

A single polypeptide chain in theory exists in an infinite number of different conformations. However, one specific conformation generally appears to be the most stable for any given sequence of amino acids, and this conformation is assumed by the chain as it is synthesized within the cell. Thus, the primary structure of the polypeptide chain also determines its three-dimensional secondary and tertiary structures. It is

tahir99-VRG & vip.persianss.ir

conceivable that in some cases, several alternative conformations ("conformers") of a single chain that are almost equally stablel may be present, and therefore these alternative forms may coexist. This possibility was first suggested to account for the heterogeneity noted in preparations of the cytoplasmic and mitochondrial isoenzymes of malate dehydrogenase and has also been proposed as an explanation for the multiple electrophoretic zones of erythrocyte acid phosphatase. However, no multiple-enzyme forms have been shown unequivocally to be due to conformational isomerism.

Distribution of Isoenzymes and Other Multiple Forms of Enzymes

The existence of multiple-gene loci and the isoenzymes derived from them has presumably conferred an evolutionary advantage on the species and has thus become part of its normal metabolic pattern. Some of these adaptations are related to the division of function between and within different types of specialized cells and tissues. Thus, the distribution of isoenzymes is not uniform throughout the body, and wide variations in the activities of different isoenzymes are found at the organ, cellular, and subcellular levels. Tissue-specific differences are also found in the distributions of some multiple forms of enzymes that are not due to the existence of multiple-gene loci. The tissue-specific distribution of isoenzymes and other multiple forms of enzymes provides the basis for organ-specific diagnosis through isoenzyme measurements.

Certain gene loci may be expressed almost exclusively in a single tissue, perhaps at a particular stage in development. In addition to the two gene loci that determine the two most common subunits of lactate dehydrogenase, a third locus is active only in mature testes. It determines the structure of a third type of subunit, X or C, which makes up a specific isoenzyme, LD-X or LD_C, found only in testes. The isoenzyme of ALP that occurs in the human placenta is the product of a single structural gene locus, which is distinct from the loci that specify the structures of other forms of ALP, and the product of the placental phosphatase locus is normally detectable only in the placenta.

A particularly striking example of the local expression of multiple-gene loci is provided by distinct isoenzymes that occur exclusively in specific subcellular organelles. Differences between mitochondrial isoenzymes and their functionally analogous counterparts in the cytoplasm have been demonstrated in several cases (e.g., for aspartate aminotransferase and malate dehydrogenase).

Changes in Isoenzyme Distribution During Development and Disease

The patterns of several sets of isoenzymes change during normal development in tissues from many species. For example, during the embryonic development of skeletal muscle, the proportions of the electrophoretically more cathodal isoenzymes—both LD and CK—progressively increase in this tissue until approximately the sixth month of intrauterine life, when the pattern resembles that of differentiated muscle.

The liver also shows characteristic changes in the patterns of several isoenzymes during embryogenesis. In early fetal development, three aldolase isoenzymes—A, B, and C—together with various hybrid tetramers, can be detected in extracts of liver. However, at birth as in the adult liver, aldolase B is the predominant isoenzyme. Striking changes in the distribution of isoenzymes of alcohol dehydrogenase also occur in human liver during prenatal development.

Changes in isoenzyme patterns during development result from changes in the relative activities of gene loci within developing cells of a particular type (e.g., muscle cells). Other alterations in the balance of isoenzymes within the whole organism may derive from changes in the number or activity of cells that contain large amounts of a characteristic isoenzyme. An example of this is the increased number and activity of the osteoblasts, which are responsible for mineralization of the skeleton between the early postnatal period and the beginning of the third decade of life. An excess of ALP from active osteoblasts enters the circulation, where its presence can be recognized by its characteristic properties, and where it elevates the total serum ALP activity of young people to above that of skeletally mature adults. An ALP from the liver also contributes to the total activity of this enzyme in the plasma of healthy people, and the amount of this isoenzyme in plasma shows a small, progressive increase with age. The reason for the latter age-dependent change is not known, but it may result from increased synthesis of the isoenzyme by hepatocytes in response to continuing exposure to inducing factors.

Certain diseases, such as the progressive muscular dystrophies, appear to involve failure of the affected tissues to mature normally or to maintain a normal state. Cancer cells show progressive loss of the structure and metabolism of the healthy cells from which they arise. Therefore, the pattern of isoenzymes of mature, differentiated tissue may be lost or modified if normal differentiation is arrested or reversed, and many examples of isoenzyme changes accompanying such processes have been reported.

The distributions of isoenzymes of aldolase, LD, and CK in the muscles of patients with progressive muscular dystrophy have been found to be similar to those in the earlier stages of development of fetal muscle. Isoenzyme abnormalities in dystrophic muscle have been interpreted as failure to reach or maintain a normal degree of differentiation. Isoenzyme patterns seen in regenerating tissues may also show some tendency to approach fetal distributions. This tendency may result from relaxation or modification of control systems in rapidly dividing cells and may account for some of the isoenzyme changes noted (e.g., in muscle in acute polymyositis).

Reemergence of fetal patterns of isoenzyme distribution is a feature of malignant transformation in many tissues. This phenomenon was first studied extensively in the case of lactate dehydrogenase isoenzymes. Malignant tumors in general show a significant shift in the balance of isoenzymes toward electrophoretically more cathodal forms such as LD-4 and LD-5. The decline in activity of the LD-1 and LD-2 isoenzymes results in patterns that are reminiscent of those occurring in

tahir99-VRG & vip.persianss.ir

embryonic tissues. Tumors of prostate, cervix, breast, brain, stomach, colon, rectum, bronchus, and lymph nodes are among those that show this transformation. In contrast, comparatively benign gliomas show a relative increase in anionic isoenzymes. A relative increase in the proportion of cathodal isoenzymes of LD has also been observed in tissue adjacent to malignant tumors (e.g., the colon), although the cells in these regions are morphologically normal.

Differences in Properties Between Multiple Forms of Enzymes

Structural differences between the multiple forms of an enzyme give rise to greater or lesser differences in physicochemical properties, such as electrophoretic mobility, resistance to inactivation, and solubility, or in catalytic characteristics, such as the ratio of reaction with substrate analogs or response to inhibitors. Methods of isoenzyme analysis have therefore been designed to investigate a wide range of catalytic and structural properties of enzyme molecules.[9] However, it is usually possible to make only limited deductions about the nature of the underlying structural differences between isoenzymes that are responsible for the dissimilar properties. Equally, the changes in catalytic and other properties that may result from specific structural alterations in enzyme molecules are difficult to predict from current theoretical knowledge of the relationship between structure and function of proteins.[22]

Techniques of molecular biology, such as gene cloning and sequencing, have revolutionized the investigation of the primary structures of isoenzymes. Differences in primary structures between isoenzymes, whether derived from multiple-gene loci or from different alleles, are now known to exist in a growing number of cases. Furthermore, many questions have been answered about whether multiple-enzyme forms represented true (genetically determined) isoenzymes or arose from post-translational modification.

Isoenzymes caused by the existence of multiple-gene loci usually differ quantitatively in catalytic properties. These differences may be manifested in such characteristics as molecular activity, K_m values for substrate(s), sensitivity to various inhibitors, and relative rates of activity with substrate analogs (when the specificity of the isoenzymes allows the substrate to be varied), underscoring the biological importance of isoenzymatic variation. In contrast, multiple-enzyme forms that arise by such post-translational modifications as aggregation usually have similar catalytic properties.

Multilocus isoenzymes also usually differ in terms of antigenic specificity, although these differences may be less pronounced among isoenzymes that have emerged relatively recently in evolutionary history and are closely related in structure. Immunological cross-reaction is not uncommon among multilocus isoenzymes. Multiple-enzyme forms caused by postsynthetic modification frequently have common antigenic determinants. Isoenzymes derived from allelic genes (allozymes) are often antigenically similar, even to the extent that they may cross-react with antisera to the common isoenzyme even when a mutation has abolished enzyme activity altogether. The capacity for detecting differences between antigenically similar isoenzyme molecules depends on the extent of monoclonal antibody specificity.

Differences in resistance to denaturation (e.g., by heat, concentrated urea solutions, detergents) are commonly found between true isoenzymes, whether these are the products of multiple loci or multiple alleles. Other multiple forms of enzymes often do not differ or differ only slightly in this respect. The most commonly exploited difference between isoenzymes is the difference in net molecular charge that results from the altered amino acid compositions of the molecules; this forms the basis of separation by zone electrophoresis, ion-exchange chromatography, or isoelectric focusing. Separation methods that depend on differences in molecular size, such as gel filtration, do not distinguish between the small size differences that often exist between true isoenzyme molecules but are important in the detection of multiple forms that involve aggregation or association of enzyme molecules with other proteins.

Enzymes as Catalysts

A *catalyst* is a substance that modifies and increases the rate of a particular chemical reaction without being consumed or permanently altered; enzymes are *protein catalysts* of biological origin. *Metabolism* is a coordinated series of chemical reactions that occur within a living cell to provide energy and accomplish biosynthesis. The process can be regarded as an integrated series of enzymatic reactions, and some diseases as a derangement of the normal pattern of metabolism. Apart from these fundamental considerations, it is the remarkable properties of enzymes that make them such sensitive indicators of pathologic change.

Because of their remarkable catalytic activity, a given number of enzyme molecules convert an enormous number of substrate molecules to products within a short time. This property is used to measure increased amounts of enzymes in the bloodstream, although the amount of enzyme protein released from damaged cells is small compared with the total quantity of nonenzymatic proteins in blood. Thus a change in the quantity of a particular enzyme is recognized by its characteristic effect on a given chemical reaction.

Units for Expressing Enzyme Activity

When enzymes are measured by their catalytic activities, the results of such determinations are expressed in terms of the concentration of the number of activity units present in a convenient volume or mass of specimen. The unit of activity is the measure of the rate at which the reaction proceeds (e.g., the quantity of substrate consumed or product formed in a chosen unit of time). In clinical enzymology, the activity of an enzyme is generally reported in terms of unit of volume, such as activity per 100 mL or per liter of serum or per 1.0 mL of packed erythrocytes. Because the rate of the reaction depends on experimental parameters, such as pH, type of buffer, temperature, nature of substrate, ionic strength, concentration of activators, and other variables, these parameters must be specified in the definition of the unit.

tahir99-VRG & vip.persianss.ir

To standardize how enzyme activities are expressed, the EC proposed that the unit of enzyme activity should be defined as the quantity of enzyme that catalyzes the reaction of 1 µmol of substrate per minute, and that this unit should be termed the *international unit* (U). Catalytic concentration is to be expressed in terms of U/L or kU/L, whichever gives the more convenient numeric value. In this chapter, the symbol U is used to denote the international unit. In those instances in which there is some uncertainty about the exact nature of the substrate, or when difficulty is encountered in calculating the number of micromoles reacting (as with macromolecules such as starch, protein, and complex lipids), the unit is to be expressed in terms of the chemical group or residue measured in the following reaction (e.g., glucose units, amino acid units formed).

The International System of Units (SI)-derived unit for catalytic activity (see Chapter 9) is the *katal,* defined as moles converted per second. The name *katal* had been used for this unit for decades but did not become an official SI-derived unit until 1999 with Resolution 12 of the 21st French Conférence Général des Poids et Mesures (CGPM), on the recommendation of the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC). Both the International Union of Pure and Applied Chemistry (IUPAC) and the IUB now recommend that enzyme activity be expressed in moles per second, and that the enzyme concentration be expressed in terms of katals per liter (kat/L).[8] Thus, 1 U = 10^{-6} mol/60 s = 16.7 × 10^{-9} mol/s, or 1.0 nkat/L = 0.06 U/L.

ENZYME KINETICS

The Enzyme–Substrate Complex

Enzymes act through the formation of an enzyme–substrate (*ES*) complex, in which a molecule of substrate is bound to the *active center* of the enzyme molecule. The binding process transforms the substrate molecule to its activated state. The energy required for this transformation is provided by the free energy of binding of *S* to *E*. Therefore, activation takes place without the addition of external energy, so that the energy barrier to the reaction is lowered and the breakdown to products is accelerated (Figure 15-3). The ES complex breaks down to give the reaction products *(P)* and free enzyme *(E)*:

$$E + S \rightleftharpoons ES \longrightarrow P + E \qquad (1)$$

All reactions catalyzed by enzymes are in theory reversible. However, in practice, the reaction is usually found to be more rapid in one direction than in the other, so that an equilibrium is reached in which the product of the forward or the backward reaction predominates, sometimes so markedly that the reaction is virtually irreversible.

If the product of the reaction in one direction is removed as it is formed (e.g., because it is the substrate of a second enzyme present in the reaction mixture), the equilibrium of the first enzymatic process will be displaced so that the reaction will proceed to completion in that direction. Reaction sequences in which the product of one enzyme-catalyzed reaction becomes the substrate of the next enzyme and so on, often through many stages, are characteristic of biological processes. In the laboratory also, several enzymatic reactions may be linked together to provide a means of measuring the activity of the first enzyme or the concentration of the initial substrate in the chain. For example, the activity of CK is usually measured by a series of linked reactions, and the concentration of glucose is determined by consecutive reactions catalyzed by hexokinase and glucose-6-phosphate dehydrogenase.

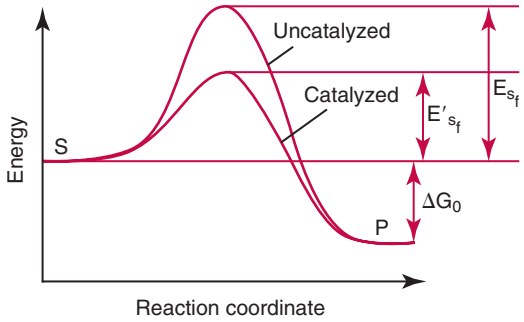

Figure 15-3 Activation energy barrier and reaction course, with and without enzyme catalysis. E_{sf} is the activation energy for the forward reaction (S → P) in the absence of a catalyst, and E'_{sf} is the activation energy in the presence of a catalyst. ΔG_0 is the change in free energy for the reaction.

When a secondary enzyme-catalyzed reaction, known as an *indicator reaction,* is used to determine the activity of a different enzyme, the primary reaction catalyzed by the enzyme to be determined must be the rate-limiting step. Conditions are chosen to ensure that the rate of reaction catalyzed by the indicator enzyme is directly proportional to the rate of product formation in the first reaction.

Factors Governing the Rate of Enzyme-Catalyzed Reactions

Factors that affect the rate of enzyme-catalyzed reactions include enzyme and substrate concentration, pH, temperature, and the presence of inhibitors, activators, coenzymes, and prosthetic groups.

Enzyme Concentration

The simplest enzymatically catalyzed reaction for converting substrate S into product P with the intermediate formation of an ES complex is as follows:

$$E_f + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} E_f + P \qquad (2)$$

where

E_f = free enzyme
k_1 = rate constant for the association of the complex
k_1 = rate constant for the dissociation of the complex
ES = enzyme–substrate complex
k_2 = rate constant for breakdown of ES to E_f and P
P = product

tahir99-VRG & vip.persianss.ir

Michaelis and Menten assumed that equilibrium is attained rapidly among E, S, and ES, with the effect of product formation (ES → P) on the concentration of ES being negligible. In addition, the formation of product is written as an irreversible process because there is no product in the solution under initial conditions. Therefore the overall rate of the reaction under otherwise constant conditions is proportional to the concentration of the ES complex.

Provided that an excess of free substrate molecules is present, addition of more enzyme molecules to the reaction system increases the concentration of the ES complex and thus the overall rate of reaction. This accounts for the observation that the rate of reaction is generally proportional to the concentration of enzyme present in the system and is the basis for the quantitative determination of enzymes by measurement of reaction rates. Reaction conditions are selected to ensure that the observed reaction rate is proportional to enzyme concentration over as wide a range as possible.

Substrate Concentration

In addition to explaining the dependence of reaction rate on enzyme concentration under conditions in which excess substrate is present, the formation of an ES complex accounts for the hyperbolic relationship between reaction velocity and substrate concentration (Figure 15-4). In this section, single-substrate, two-substrate, and consecutive enzyme reactions will be discussed.

Single-Substrate Reactions

If the enzyme concentration is fixed and the substrate concentration is varied, the rate of reaction is first order with respect to substrate concentration and proportional to substrate concentration at low values of the latter. Under these conditions, only a fraction of the enzyme is associated with substrate, and the rate observed reflects the low concentration of the ES complex. At high substrate concentrations, variation in substrate concentration has no effect on rate, and the reaction is zero order with respect to substrate concentration. Under these conditions, all the enzyme is bound to the substrate, and a much higher rate of reaction is obtained. Moreover, because all the enzyme is now present in the form of the complex, no further increase in complex concentration and no further increment in reaction rate are possible. The maximum possible velocity for the reaction has been reached. The significance of substrate-rate curves was first emphasized by Michaelis and Menten, and such curves are referred to as *Michaelis-Menten plots*.

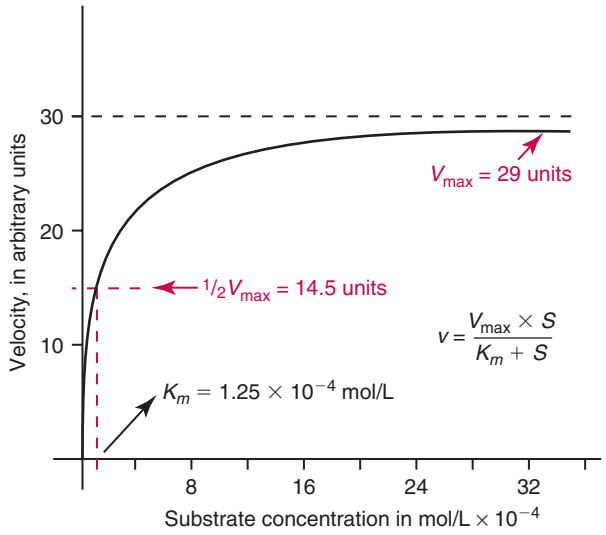

Figure 15-4 Michaelis-Menten curve relating velocity (rate) of an enzyme-catalyzed reaction to substrate concentration. The value of K_m is given by the substrate concentration at which one half of the maximum velocity is obtained.

Referring again to equation (2), the overall rate of the reaction (v) is determined by the rate at which product is formed:

$$v = \frac{d[P]}{dt} = k_2[ES] \tag{3}$$

The formation of ES will depend on the rate constant k_1 and the availability of enzyme and substrate. If it its assumed the system is in a steady state with the ES complex being formed and broken down at the same rate so that overall [*ES*] is constant, then the steady-state equation is

$$k_1[E][S] = k_{-1}[ES] + k_2[ES] \tag{4}$$

This equation can be rearranged to

$$[ES] = \frac{k_1[E][S]}{k_{-1} + k_2} \tag{5}$$

when these rate constants are combined into a single term; writing the Michaelis constant (K_m) as

$$K_m = \frac{k_{-1} + k_2}{k_1} \tag{6}$$

and then substituting this into equation (5) gives

$$[ES] = \frac{[E][S]}{K_m} \tag{7}$$

Because the total amount of enzyme in the system does not change,

$$[E_t] = [ES] + [E] \tag{8}$$

and upon substituting equation (3) into equation (7) and eliminating (ES) using equation (8),

$$v = k_2 \times \frac{[E_t] \times [S]}{K_m + [S]} \tag{9}$$

For a given amount of enzyme, the maximum reaction velocity (V_{max}) is reached when all of the enzyme is saturated with substrate (i.e., [*ES*] = [*Et*]), and therefore, $V_{max} = k_2 \times [Et]$. Substituting this in equation (9) gives

$$v = \frac{V_{max}[S]}{K_m + [S]} \tag{10}$$

A plot of v against [*S*] gives a section of a rectangular hyperbola (see Figure 15-4), and this is the shape of the curve

tahir99-VRG & vip.persianss.ir

that is found experimentally for most enzymes. When $[S] = K_m$, it can be shown with manipulation of equation (10) that K_m is the substrate concentration at which the reaction proceeds at one half of its maximum velocity. In practice, it is now customary to restrict K_m to the experimentally determined substrate concentration at which $v = 0.5 V_{max}$ and to use the symbol K_s to represent the true ES association constant, where this is known.

Although it is simple to set up an experiment to determine the variation of v with $[S]$, the exact value of V_{max} is not easily determined from hyperbolic curves. Furthermore, many enzymes deviate from ideal behavior at high substrate concentrations and indeed may be inhibited by excess substrate, so the calculated value of V_{max} cannot be achieved in practice. In the past, it was common practice to transform the Michaelis-Menten equation (10) into one of several reciprocal forms [equations (11) and (12)], and either $1/v$ was plotted against $1/[S]$, or $[S]/v$ was plotted against $[S]$.

$$\frac{1}{v} = \left(\frac{K_m}{V_{max}} \times \frac{1}{[S]}\right) + \frac{1}{V_{max}} \qquad \textbf{(11)}$$

$$\frac{[S]}{v} = \left(\frac{1}{V_{max}} \times [S]\right) + \frac{K_m}{V_{max}} \qquad \textbf{(12)}$$

Equation (11), for example, when plotted, results in a *Lineweaver-Burk* plot that gives a straight line with intercepts at $1/V_{max}$ on the ordinate and $-1/K_m$ on the abscissa. For illustrative purposes, the data for Figure 15-4 are replotted in Lineweaver-Burk form in Figure 15-5.

It is now routine practice to determine kinetic constants such as K_m and V_{max} using a software package. A large number of such packages are available; these vary from specialized routines for kinetic simulations or for data fitting to general mathematical, statistical, or graphical packages (http://med.umich.edu/biochem/enzresources/software.ttm/ accessed March 30, 2011). These packages are free (public domain, shareware, or free license) or are commercially available. An example of the former is the ENCORA 1.2 freeware package available from R.J.W. Slats and colleagues at the Delft University of Technology (http://www.bt.tudelft.nl/ http://med.umich.edu/biochem/enzresources/software.ttm/ accessed March 30, 2011), which was developed for an enzymatic kinetic parameter fitting using progressive curve analysis. DynaFit is an example of a commercially available routine (http://www.biokin.com/dynafit/accessed March 30, 2011) that performs nonlinear least-squares regression of chemical kinetic, enzyme kinetic, or ligand receptor binding data. The data can be initial reaction velocities for different concentrations of varied species (e.g., inhibitor concentration vs. velocity), or reaction progress curves (e.g., time vs. absorbance). SigmaPlot 11 is another example of commercially available software that will compute and plot enzyme kinetic data (http://www.sigmaplot.com/products/sigmaplot/enzyme-mod.php/accessed March 30, 2011).

The value of K_m has been used to compare the binding of homologous or related substrates to the same enzyme. Also, if measured against the same substrate under defined conditions, the K_m value can be used to compare the properties of similar enzymes from different sources. Isoenzymes

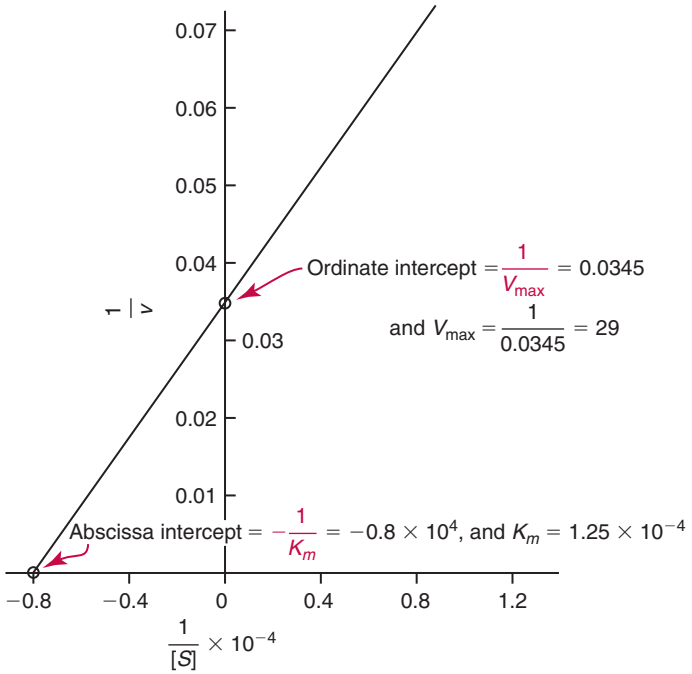

Figure 15-5 Lineweaver-Burk transformation of the curve in Figure 15-4, with $1/v$ plotted on the ordinate (y-axis), and $1/[S]$ on the abscissa (x-axis). The indicated intercepts permit calculation of V_{max} and K_m. The units of v and $[S]$ are those given in Figure 15-4.

tahir99-VRG & vip.persianss.ir

determined by distinct genetic loci typically differ in their K_m (e.g., for the isoenzymes of lactate dehydrogenase).

When setting up methods of enzyme assay, it is necessary to (1) explore the relationship between reaction velocity and substrate concentration over a wide range, (2) determine K_m, and (3) detect any inhibition at high substrate concentrations. Zero-order kinetics is maintained if the substrate is present in large excess (i.e., concentrations at least 10 and preferably 100 times that of the value of K_m). When $[S] = 10 \times K_m$, v is approximately 91% of the theoretical V_{max}. The K_m values for the majority of enzymes are on the order of 10^{-5} to 10^{-3} mol/L; therefore substrate concentrations are usually chosen to be in the range of 0.001 to 0.10 mol/L. On occasion, the optimal concentrations of substrate cannot be used (e.g., when the substrate has limited solubility, or when the concentration of a given substrate inhibits the activity of another enzyme needed in a coupled reaction system).

Two-Substrate Reactions

Most enzymes catalyze reactions with two or more interacting substrates symbolized by the following equation:

$$\underset{S_1}{Substrate\,1} + \underset{S_2}{Substrate\,2} \overset{E}{\rightleftharpoons} \underset{P_1}{Product\,1} + \underset{P_2}{Product\,2} \qquad \textbf{(13)}$$

When one of the substrates is water (i.e., when the process is one of hydrolysis), with the reaction taking place in aqueous solution, only a fraction of the total number of water molecules present participates in the reaction. The small change in the concentration of water has no effect on the rate of reaction and these pseudo-one substrate reactions are described by one-substrate kinetics. More generally, the concentrations of both substrates may be variable, and both may affect the rate of reaction. Among the bisubstrate reactions important in clinical enzymology are the reactions catalyzed by dehydrogenases, in which the second substrate is a specific coenzyme, such as the oxidized or reduced forms of nicotinamide adenine dinucleotide (NADH), or nicotinamide adenine dinucleotide phosphate (NADPH), and the amino-group transfers catalyzed by the aminotransferases.

If a bisubstrate reaction proceeds by way of intermediate ES complexes, so that

$$E + S_1 \rightleftharpoons ES_1 \qquad \textbf{(14)}$$

followed by

$$ES_1 + S_2 \rightleftharpoons ES_1S_2 \longrightarrow P_1 + P_2 + E \qquad \textbf{(15)}$$

and if S_1 and S_2 combine with separate sites on the enzyme molecule, the rate of reaction is given by

$$v = \frac{V_{max} \times [S_1][S_2]}{[S_1][S_2] + [S_2]K_m^1 + [S_1]K_m^2 + K_S^1 K_m^2} \qquad \textbf{(16)}$$

$K^1{}_m$ and $K^2{}_m$ are the K_m values for the two substrates, and $[S_1]$ and $[S_2]$ are their concentrations. $K^1{}_s$ is the equilibrium constant for the reversible reaction between the enzyme and S_1. If the equation is rearranged into the double reciprocal form

$$\frac{1}{v} = \frac{1}{[S_1]}\left(\frac{K_m^1}{V_{max}} + \frac{K_m^2 K_S^1}{[S_2]V_{max}}\right) + \frac{1}{V_{max}}\left(1 + \frac{K_m^2}{[S_2]}\right) \qquad \textbf{(17)}$$

a plot of $1/v$ against $1/[S_1]$ gives a straight line, but both the slope of the line and its intercept on the ordinate are dependent on $[S_2]$, the concentration of the second substrate (Figure 15-6, *A*). Similarly, a plot of $1/v$ against $1/[S_2]$ is rectilinear but with the slope and intercept dependent on $[S_1]$.

Values of K_m and V_{max} for each substrate are derived from experiments in which the concentration of the first substrate is held constant at saturating quantities while the concentration of the second substrate is varied, and vice versa. There is no reason why the K_m values for the two substrates should be the same or even similar (e.g., pyruvate and NADH, the two-substrate pair in the reaction catalyzed by lactate dehydrogenase of beef heart, have K_m values of 2×10^{-5} mol/L and 3×10^{-6} mol/L, respectively).

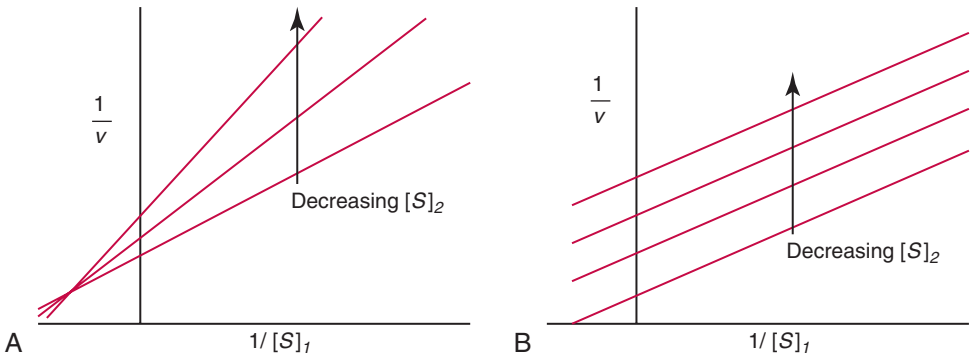

Figure 15-6 Double-reciprocal plots of $1/v$ against $1/[S_1]$ for two-substrate reactions, showing the effect of falling concentration of the second substrate, $[S_2]$. A, In a dehydrogenase reaction in which a ternary complex is formed. B, In a *ping-pong bi-bi* reaction mechanism (e.g., aminotransferase) in which no ternary complex is formed. *(From Moss DW. Measurement of enzymes. In: Hearse DJ, de Leiris J, eds. Enzymes in cardiology: diagnosis and research. New York: John Wiley & Sons Inc, 1979. Reprinted by permission of John Wiley & Sons, Inc.)*

In some bisubstrate reactions, no ternary complex ES_1S_2 is formed, because the binding of the first substrate is followed by release of the first product before the second substrate is bound and the second product is released. This sequence is described as a *ping-pong bi-bi* type of reaction. It occurs in reactions catalyzed by aminotransferases.

The relationship between reaction velocity and the concentrations of the two substrates in *ping-pong bi-bi* reactions reduces to the form

$$v = \frac{V_{max} \times [S_1][S_2]}{[S_1][S_2] + [S_2]K_m^1 + [S_1]K_m^2} \quad \textbf{(18)}$$

The reciprocals of v and $[S_1]$ are related by the equation

$$\frac{1}{v} = \frac{1}{[S_1]} \times \frac{K_m^1}{V_{max}} + \frac{1}{V_{max}}\left(1 + \frac{K_m^2}{[S_2]}\right) \quad \textbf{(19)}$$

so that a plot of $1/v$ against $1/[S_1]$ is unchanged in slope by variation in $[S_2]$, but the intercept on the ordinate and therefore the value of V_{max} changes as $[S_2]$ is varied (see Figure 15-6, *B*). Similar equations describe the variation of V_{max} with $[S_1]$ when $1/v$ is plotted as a function of $1/[S_2]$.

The selection of reaction conditions for the measurement of enzymatic activity involving two substrates is approached empirically by varying the concentration of the first substrate and keeping the concentration of the second substrate constant until maximum activity is reached. The process is then repeated with the concentration of the first substrate held at the value thus determined, while the concentration of the second substrate is varied.

In practice, the choice of substrate concentrations is limited by such considerations as the solubility of the substrates, the viscosity and initial absorbance of concentrated solutions, and the relative costs of the reagents. Furthermore, the selection of appropriate substrate concentrations is only one of the factors to be considered in formulating an optimal assay system for the measurement of a specific enzyme activity. Critical choices must also be made with respect to other, frequently interdependent factors that affect reaction rate, such as the concentrations of activators and the nature and pH of the buffer system.

Consecutive Enzymatic Reactions

As discussed previously, an enzymatic reaction is usually found to be more rapid in one direction than the other, so that the reaction is essentially irreversible. If the product of the reaction in one direction is removed as it is formed (i.e., because it is the substrate of a second enzyme present in the reaction mixture), the equilibrium of the first enzymatic process is displaced so that the reaction may continue to completion in that direction. Reaction sequences in which the product of one enzyme-catalyzed reaction becomes the substrate of another enzyme, often through many stages, are characteristic of metabolic processes. Analytically, as indicated earlier, several enzymatic reactions also may be linked together to provide a means of measuring the activity of the first enzyme or the concentration of the initial substrate in the chain.

When a linked enzyme assay, known as an *indicator reaction,* is used to determine the activity of a different enzyme, it is essential that the primary reaction be the rate-limiting step. For example, in the determination of aspartate aminotransferase activity, the indicator reaction is the reduction of the 2-oxoglutarate formed in the aminotransferase reaction to malate by malate dehydrogenase and NADH. The activity of the indicator enzyme must be sufficient to ensure the virtually instantaneous removal of the product of the first reaction so as to prevent significant reversal of the first reaction. The measured enzyme typically is acting under conditions of saturation with respect to its substrate; however, the concentration of the substrate of the indicator enzyme (i.e., the product of the first reaction) remains in the region of the Michaelis-Menten curve in which v is directly proportional to $[S]$. Therefore the rate of reaction catalyzed by the indicator enzyme is directly proportional to the rate of product formation in the first reaction.

During a lag period that occurs after the start of the first reaction, the concentration of its product reaches a steady state. Because the rate of the second reaction depends on the activity of the indicator enzyme and on the concentration of its substrate (the product of the primary reaction), the duration of the lag period is reduced by increasing the concentration of the indicator enzyme, thus lowering the steady-state concentration of the product of the primary reaction.

The rate of the indicator reaction, v_i, is related to substrate concentration and therefore to the product concentration $[P]$ by the Michaelis-Menten equation

$$v_i = \frac{V_{max}^i \times [P]}{[P] + K_m^i} \quad \textbf{(20)}$$

in which V^i_{max} and K^i_m are the maximum velocity and K_m of the indicator enzyme, respectively. For the rate of the indicator reaction not to be the rate limiting factor, v_i must at least equal the limiting velocity of the primary reaction, v_t, which the assay system is expected to measure. Therefore, the minimum activity of indicator enzyme needed is given by

$$v_t = \frac{V_{max}^i \times [P]}{[P] + K_m^i} \quad \textbf{(21)}$$

or is rearranged as

$$V_{max}^i = v_t\left(1 + \frac{K_m^i}{[P]}\right) \quad \textbf{(22)}$$

The ratio of activities of the indicator and primary enzymes varies from one assay method to another, depending on (1) the range of activity measured, (2) the K_m of the indicator enzyme, and (3) the lag period that is considered acceptable. Nevertheless the catalytic concentration of the indicator enzyme in the reaction mixture must always be much greater than that of the enzyme being determined.

Effect of pH

The rate of enzyme-catalyzed reactions typically shows a marked dependence on pH (Figure 15-7). Many of the

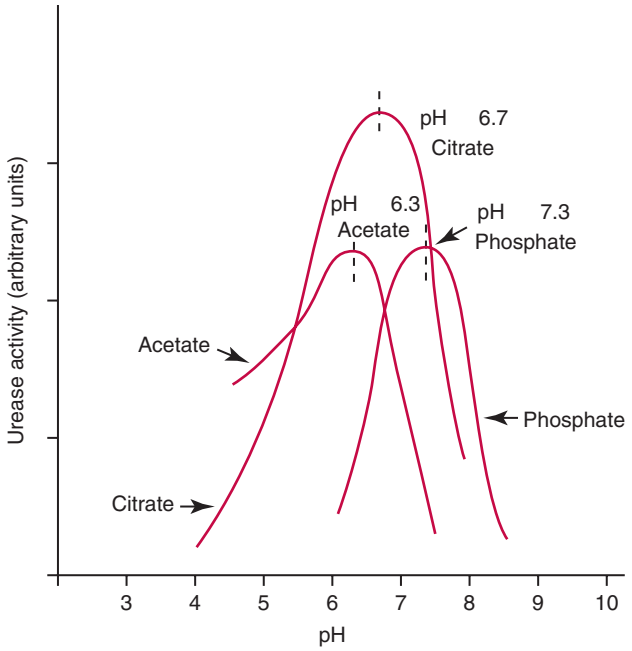

Figure 15-7 The pH activity curves for urease show the effects of buffer species on pH optimum. *(Modified from Howell SF, Sumner JB. The specific effects of buffers upon urease activity. J Biol Chem 1934;104:619.)*

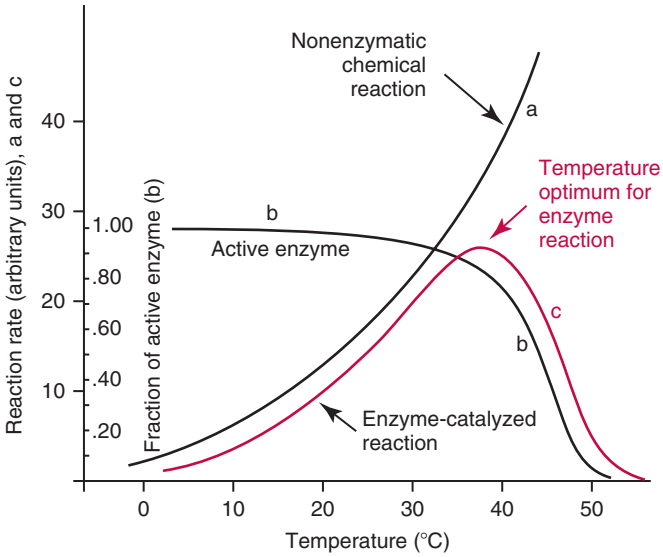

Figure 15-8 Schematic diagram showing effects of temperature on the rate of non–enzyme-catalyzed and enzyme-catalyzed reactions.

enzymes in blood plasma show maximum activity in vitro in the pH range from 7 to 8. However, activity has been observed at pH values as low as 1.5 (pepsin) and as high as 10.5 (ALP). The optimal pH for a given forward reaction may be different from the optimal pH found for the corresponding reverse reaction. The form of the pH-dependence curve is the result of a number of separate effects, including ionization of the substrate and the extent of dissociation of certain key amino acid side chains in the protein molecule, both at the active center and elsewhere in the molecule. Both pH and ionic environment will also have an effect on the three-dimensional conformation of the protein and therefore on enzyme activity to such an extent that enzymes may be irreversibly denatured at extreme values of pH.

The pronounced effects of pH on enzyme reactions emphasize the need to control this variable by means of adequate buffer solutions. Enzyme assays should be carried out at the pH of optimal activity, because the pH-activity curve has its minimum slope near this pH, and a small variation in pH will cause a minimal change in enzyme activity. The buffer system must be capable of counteracting the effect of adding the specimen (e.g., serum itself is a powerful buffer) to the assay system, as well as the effects of acids or bases formed during the reaction (e.g., formation of fatty acids by the action of lipase). Because buffers have their maximum buffering capacity close to their pK_a values, whenever possible a buffer system should be chosen with a pK_a value within 1 pH unit of the desired pH of the assay (see Chapter 11). Interaction between buffer ions and other components of the assay system (e.g., activating metal ions) may eliminate certain buffers from consideration.

Temperature

The rate of an enzymatic reaction is proportional to its reaction temperature. For most enzymatic reactions, values of Q_{10} (the relative reaction rates at two temperatures differing by 10 °C) vary from 1.7 to 2.5. However, an increase in the rate of the catalyzed reaction is not the only effect of increasing temperature on an enzymatic reaction. In theory, the initial rate of reaction measured instantaneously will increase with a rising temperature. In practice, however, a finite time is needed to allow the components of the reaction mixture, including the enzyme solution, to reach temperature equilibrium and to permit the formation of a measurable amount of the product. During this period, the enzyme is undergoing thermal inactivation and denaturation, a process that has a very large temperature coefficient for most enzymes and thus becomes virtually instantaneous at temperatures of 60 to 70 °C. The counteracting effects of the increased rate of the catalyzed reaction and more rapid enzyme inactivation as the temperature increases account for the existence of an apparent *optimal temperature* for enzyme activity (Figure 15-8).

As stated earlier, at some critical temperature, an enzyme will undergo thermal inactivation influenced by a number of factors. These include the presence of substrate and its concentration, the pH, and the nature and ionic strength of the buffer. The presence of other proteins, as in serum samples, may help to stabilize enzymes. Storage of serum samples at low temperatures is necessary to minimize loss of enzyme activity while awaiting analysis, although repeated freezing and thawing should be avoided. However, individual enzymes vary in their stability characteristics, and appropriate storage conditions vary correspondingly. Amylase, for example, is stable at room temperature (22 to 25 °C) for 24 hours, whereas acid phosphatase is exceedingly unstable, even when refrigerated, unless kept at a pH below 6.0. ALP exhibits an unusual property: the

tendency for the activity of frozen, partially purified preparations of the enzyme to increase after thawing over a period of 24 hours or longer. This effect is shared by reconstituted, lyophilized preparations of the enzyme and affects their use for quality control purposes. A few enzymes are inactivated at refrigerator temperatures; a clinically important example is the liver-type isoenzyme of lactate dehydrogenase, LD-5, which appears to be less stable at lower temperatures. As a result, sera for lactate dehydrogenase determinations should be kept at room temperature and not refrigerated.

Historically, the choice of temperature for the assay of enzymes of clinical importance was the subject of extensive debate. The choice of reaction temperature has become a nonissue because most analytical systems operate at 37 °C. Reference methods for several clinically relevant enzymes have now been developed at 37 °C.[14-21] In practice, accurate temperature control to within ±0.1 °C during the enzymatic reaction is essential.

Inhibitors and Activators

The rates of enzymatic reactions are often affected by substances other than the enzyme or substrate. These modifiers may be inhibitors because their presence reduces the reaction rate, or activators because they increase the rate of reaction. Activators and inhibitors are usually small molecules (compared with the enzyme itself) or even ions. They vary in specificity from modifiers that exert similar effects on a wide range of different enzymatic reactions at one extreme, to substances that affect only a single reaction. Reagents, such as strong acids or multivalent anions and cations that denature or precipitate proteins, destroy enzyme activity and thus may be regarded as extreme examples of nonspecific enzyme inhibitors. These effects usually are not included in discussions of enzyme inhibition, although they have obvious practical implications in the treatment and storage of specimens in which enzyme activity is to be measured. The activity of some enzymes depends on the presence of particular chemical groups, such as reduced sulfhydryl (–SH) groups, in the active center. Reagents that alter these groups (e.g., oxidants of SH groups) therefore act as general inhibitors of such enzymes.

Some phenomena of enzyme activation or inhibition are caused by interactions between the modifier and a nonenzymatic component of the reaction system, such as the substrate (e.g., Mg^{2+} combining with ATP to form MgATP, the required substrate for the creatine kinase reaction). In most cases, however, the modifier combines with the enzyme itself in a manner analogous to the combination of enzyme and substrate.

Inhibition of Enzyme Activity

Inhibitors are classified as reversible or irreversible. *Reversible inhibition* implies that the activity of the enzyme is fully restored when the inhibitor is removed from the system in which the enzyme acts by some physical separative process, such as dialysis, gel filtration, or chromatography. An *irreversible inhibitor* combines covalently with the enzyme so that physical methods are ineffective in separating the two. For example, organophosphorous compounds are extremely potent irreversible inhibitors of esterases, including acetylcholinesterase. The enzyme breaks one of the bonds in the inhibitor, but part of the molecule is left bound to the active center of the enzyme, preventing further activity. In some cases, enzymes that have combined with irreversible inhibitors can be reactivated by a chemical reaction that removes the blocking group (e.g., the phosphoryl enzymes formed with organophosphorous compounds sometimes can be reactivated by treatment with oximes or hydroxamic acids).

Reversible Inhibition. Reversible inhibition is characterized by the existence of equilibrium between enzyme, *E*, and inhibitor, *I:*

$$E + I \rightleftharpoons EI \tag{23}$$

The equilibrium constant of the reaction, K_i (the *inhibitor constant*), is a measure of the affinity of the inhibitor for the enzyme, just as K_m generally reflects the affinity of the enzyme for its substrate.

A *competitive* inhibitor is usually a structural analog of the substrate that can combine with the free enzyme in such a way that it competes with the normal substrate for binding at the active site. The actual rate of the reaction is strictly dependent on the relative concentrations of substrate and inhibitor. Two equilibriums are therefore possible:

$$E + S \rightleftharpoons ES \longrightarrow E + Products \tag{24}$$

and

$$E + I \rightleftharpoons EI \tag{25}$$

The equation that relates the observed reaction velocity to the concentrations of substrate, [*S*], and inhibitor, [*I*], is as follows:

$$v = \frac{V_{max}[S]}{[S] + K_m\left(1 + \frac{[I]}{K_i}\right)} \tag{26}$$

This is the Michaelis-Menten equation, but with K_m modified by a term including the inhibitor concentration and the inhibitor constant, V_{max} is unaltered. Therefore, curves of v against [*S*] in the presence and absence of inhibitor reach the same limiting value at high substrate concentrations, but when the inhibitor is present, K_m is apparently greater. Plots of $1/v$ against $1/[S]$ with and without inhibitor intersect the ordinate at the same point but have different slopes and intercepts on the abscissa (Figure 15-9).

Competitive inhibition is responsible for the inhibition of some enzymes by excess substrate because of competition between substrate molecules for a single binding site. In two-substrate reactions, high concentrations of the second substrate may compete with binding of the first substrate. For example, aspartate aminotransferase is inhibited by excess concentrations of the substrate 2-oxoglutarate, and this inhibition is competitive with respect to L-aspartate. Therefore, to maintain a given velocity at high 2-oxoglutarate concentrations, the concentration of L-aspartate has to be

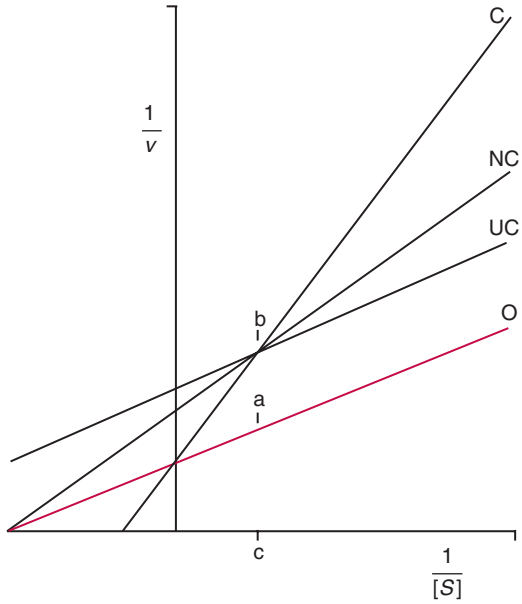

Figure 15-9 Effects of different types of inhibitors on the double-reciprocal plot of 1/*v* against 1/[*S*]. Each of the inhibitors has been assumed to reduce the activity of the enzyme by the same amount, represented by the change in 1/*v* from *a* to *b* at a substrate concentration of *c*. *Line O* is the plot for enzyme without inhibitor, *C* with a competitive inhibitor, *NC* with a noncompetitive inhibitor, and *UC* with an uncompetitive inhibitor. *(From Moss DW. Measurement of enzymes. In: Hearse DJ, de Leiris J, eds. Enzymes in cardiology: diagnosis and research. New York: John Wiley & Sons Inc., 1979. Reprinted by permission of John Wiley & Sons, Inc.)*

increased above the value needed at lower concentrations of 2-oxoglutarate.

Competitive inhibition also contributes to the reduction in the rate of an enzymatic reaction over time. For example, a rate reduction can occur because increasing concentrations of reaction products tend to drive the reaction backward, if it is freely reversible. A product may itself be an inhibitor of the forward reaction, so even if the reaction is not readily reversible, it proceeds against a rising concentration of inhibitor. A familiar example of *product inhibition* is the release of the competitive inhibitor, inorganic phosphate, by the action of ALP on its substrates. In this case, both organic phosphates and inorganic phosphates bind to the active center of the enzyme with similar affinities (i.e., K_m and K_i are of the same order of magnitude).

Product inhibition is a cause of nonlinearity of reaction progress curves during fixed-time methods of enzyme assay. For example, oxaloacetate produced by the action of aspartate aminotransferase inhibits the enzyme, particularly the mitochondrial isoenzyme. The inhibitory product may be removed as it is formed by a coupled enzymatic reaction: malate dehydrogenase converts the oxaloacetate to malate and at the same time oxidizes NADH to NAD^+.

Competitive inhibition by metal ions occurs when two metal ions compete for the same binding site on the enzyme. Sodium and lithium are potent inhibitors of pyruvate kinase, for which potassium is an obligatory activator.

A *noncompetitive* inhibitor is usually structurally different from the substrate. It is assumed to bind at a site on the enzyme molecule that is different from the substrate-binding site; thus, there is no competition between inhibitor and substrate, and a ternary enzyme–substrate–inhibitor (ESI) complex is formed. Attachment of the inhibitor to the enzyme does not alter the affinity of the enzyme for its substrate (i.e., K_m is unaltered), but the ESI complex does not break down to give products. Because the substrate does not compete with the inhibitor for binding sites on the enzyme molecule, increasing the substrate concentration does not overcome the effect of a noncompetitive inhibitor. Thus, V_{max} is reduced in the presence of such an inhibitor, whereas K_m is not altered, as the Lineweaver-Burk plot shows (see Figure 15-9).

Uncompetitive inhibition is produced by a combination of the inhibitor with the ES complex. It is more common in two-substrate reactions, in which a ternary ESI complex forms after the first substrate has combined with the enzyme. In uncompetitive inhibition, parallel lines are obtained when plots of $1/v$ against $1/[S]$ with and without the inhibitor are compared (see Figure 15-9), that is, both K_m and V_{max} are decreased.

Irreversible Inhibition. Irreversible inhibitors render the enzyme molecule inactive by covalently and permanently modifying a functional group required for catalysis. An irreversible inhibitor is not in equilibrium with the enzyme. Its effect is progressive with time, becoming complete if the amount of inhibitor present exceeds the total amount of enzyme. The rate of the reaction between enzyme and inhibitor is expressed as the fraction of the enzyme activity that is inhibited in a fixed time by a given concentration of inhibitor. The velocity constant of the reaction of the inhibitor with the enzyme is a measure of the effectiveness of the inhibitor.

When the inhibitor is added to the enzyme in the presence of its substrate, the reaction between the enzyme and the inhibitor may be delayed because some of the enzyme molecules are combined with the substrate and are therefore protected from reacting with the inhibitor. However, as the substrate molecules react chemically, the active centers become available, and inhibition eventually will become complete, even though an excess of substrate may have been present initially. Furthermore, the addition of more substrate is ineffective in reversing the inhibition in contrast to its effect on reversible competitive inhibition.

Irreversible inhibitors have been useful in mapping active sites by covalently modifying different types of functional groups in the enzyme molecule to establish whether such groups are necessary for catalytic activity.

A physiologically important category of irreversible enzyme inhibition is exemplified by various trypsin inhibitors. These are proteins that bind to trypsin irreversibly, nullifying its proteolytic activity. One such inhibitor is present in the α_1-globulin fraction of serum proteins; others are found in soybeans and lima beans. Similar proteolysis inhibitors

present in plasma prevent the accumulation of excess thrombin and other coagulation enzymes, thus keeping the coagulation process under control.

Inhibition by Antibodies. The combination of enzyme molecules with specific antibodies often has no effect on catalytic activity, which is retained by the enzyme–antibody complex.[2] However, in some cases, the reaction of the enzyme and antibody reduces or even abolishes enzymatic activity. The most probable explanation for this type of inhibition is that the antibody molecule restricts access of the substrate molecules to the active center by steric hindrance or, in extreme cases, completely masks the substrate-binding site. However, it appears that some examples of enzyme inhibition by combination with antibodies are caused by a conformational change induced in the enzyme molecule.

Inhibition of the activity of an enzyme molecule labeled with a hapten (e.g., morphine) as a result of combination with a specific antibody forms the basis for a homogeneous enzyme immunoassay (EMIT, Siemens Healthcare Diagnostics, Deerfield, Ill; http://www.medical.siemens.com/accessed March 30, 2011). See Chapter 16 for additional details.

Enzyme Activation

Activators increase the rates of enzyme-catalyzed reactions by promoting formation of the most active state of the enzyme itself or of other reactants, such as the substrate. This generalization covers a wide variety of mechanisms of activation.

Many enzymes contain metal ions as an integral part of their structures (e.g., zinc in ALP and carboxypeptidase A). The function of the metal may be to stabilize tertiary and quaternary protein structures. Removal of divalent metal ions by treatment with an appropriate quantity of ethylenediaminetetraacetic acid (EDTA) solution is accompanied by conformational changes and inactivation of the enzyme. The enzyme often can be reactivated by dialysis against a solution of the appropriate metal ion or simply by addition of the ion to the reaction mixture. Reactivation may take some time, because rearrangement of polypeptide chains into the active conformation is not instantaneous.

When the activator ion is an essential part of the functional enzyme molecule, whether as a purely structural element or with an additional catalytic role, it is usually incorporated quite firmly into the enzyme molecule. Therefore it is not usually necessary to add the activator to reaction mixtures, and an excess of the ion may even have an inhibitory effect. However, in some cases, the activating ion is attached only weakly or transiently to the enzyme (or its substrate) during catalysis. Enzyme samples therefore may be deficient in the ion, so that addition of the ion increases the reaction rate or indeed may be essential for the reaction to take place. For example, all phosphate transfer enzymes (kinases), such as creatine kinase, require the essential presence of Mg^{2+} ions. Other common activating cations are Mn^{2+}, Fe^{2+}, Ca^{2+}, Zn^{2+}, and K^{+}. More rarely, anions may act as activators. Amylase functions at its maximal rate only if Cl^{-} or other monovalent anions, such as Br^{-} or NO_3^{-}, are present. Addition of 5 mmol/L of chloride increases amylase activity almost threefold, at the same time shifting the pH optimum from 6.5 to 7.0. The chloride ion may combine with a positively charged group in the enzyme, changing the ionization constant of a group important in catalysis. However, other anions—such as bromide—are less effective activators of amylase, so some degree of specificity is involved in the process of activation. Some enzymes require the obligate presence of two activating ions. K^{+} and Mg^{2+} are essential for the activity of pyruvate kinase, and both Mg^{2+} and Zn^{2+} are required for ALP activity.

The velocity of the reaction depends on the concentration of a reversible activator in a fashion similar to its dependence on substrate concentration, and an activator constant, K_a, analogous to K_m, can be determined from data relating enzyme activity to increasing activator concentration in the presence of excess substrate. The simplest interpretation of K_a is that it is the dissociation constant of the equilibrium between E and the activator, A. However, this is true only when the combination of enzyme and activator is independent of the reaction between E and S, and the same value for K_a is obtained at all concentrations of the substrate. If the free enzyme and the enzyme–substrate complex have different affinities for the activator, the value for K_a varies with $[S]$.

Apparent activation of an enzyme may be observed whenever a substance that can counteract the presence of some inhibiting agent is added.

Coenzymes and Prosthetic Groups

Coenzymes are usually more complex molecules than activators, although they are smaller molecules than the enzyme proteins themselves. Some compounds, such as the dinucleotides NAD and NADP, are classified as coenzymes and are specific substrates in two-substrate reactions. Their effects on the rate of reaction follow the Michaelis-Menten pattern of dependence on substrate concentration. The structures of these two coenzymes are identical except for the presence of an additional phosphate group in NADP; nevertheless, individual dehydrogenases, for which these coenzymes are substrates, are predominantly or even absolutely specific for one or the other form.

Coenzymes such as NAD and NADP are bound only momentarily to the enzyme during the course of the reaction, as is the case for substrates in general. Therefore no reaction takes place unless the appropriate coenzyme is present in solution (e.g., by adding it to the reaction mixture in the assay of dehydrogenase activity). In contrast to these entirely soluble coenzymes, some coenzymes are more or less permanently bound to the enzyme molecules, where they form part of the active center and undergo cycles of chemical change during the reaction. When bound, the coenzyme is known as a prosthetic group.

The active *holoenzyme* results from the combination of the inactive *apoenzyme* with the *prosthetic group.* An example of a prosthetic group is pyridoxal-5′-phosphate (P-5′-P), a component of AST and ALT. The P-5′-P prosthetic group undergoes a cycle of conversion of the pyridoxal moiety to pyridoxamine and back again during the transfer of an amino

group from an amino acid to an oxo-acid. Prosthetic groups, such as activators with a structural role, do not usually have to be added to elicit full catalytic activity of the enzyme unless previous treatment has caused the prosthetic group to be lost from some enzyme molecules. However, both normal and pathologic serum samples contain appreciable quantities of apo-aminotransferases, which are converted to active holoenzymes through a suitable period of incubation with P-5′-P.

A study of the formulas of coenzyme and prosthetic groups shows that many contain structures derived from the vitamins (see Chapter 31). Thus, the nicotinamide portion of NAD and NADP derives from the vitamin niacin, whereas the P-5′-P prosthetic group of the aminotransferases is a derivative of pyridoxine, vitamin B_6. Other derivatives of the B-group vitamins participate in enzymatic reactions.

ANALYTICAL ENZYMOLOGY

Analytically, the clinical laboratorian is concerned with measuring the activity or mass in serum or plasma of enzymes that are predominantly intracellular and that are physiologically present in the serum in low concentrations only. By measuring changes in the concentrations of these enzymes in disease, it is possible to infer the location and nature of pathologic changes in the tissues of the body.

Measurement of Reaction Rates

The rate of an enzyme-catalyzed reaction is directly proportional to the amount of active enzyme present in the system. Consequently, determination of the rate of reaction under defined and controlled conditions provides a measurement of the amount of enzyme in a sample such as serum.

Determination of reaction rate involves the kinetic measurement of the amount of change produced within a defined time interval.[6,23A] Both *fixed-time* and *continuous-monitoring* methods are used to measure reaction rates. In the fixed-time method, the amount of change produced by the enzyme is measured after the reaction is stopped at the end of a fixed-time interval. In the continuous-monitoring method, the progress of the reaction is monitored continuously. These two methods have different advantages and limitations. To appreciate them, it is necessary to consider the way in which the rate of an enzymatic reaction varies with time.

The progress of conversion of the substrate into products in the presence of an enzyme is monitored by measuring the decreasing concentration of the substrate or the increasing concentration of the products. Measurement of product formation is preferable, as determination of the increase in concentration of a substance above an initially zero or low concentration is analytically more reliable than measurement of a decline from an initially high concentration.

At the moment when the enzyme and the substrate are mixed, the rate of the reaction is zero. The rate then typically rises rapidly to a maximum value, which remains constant for a period of time (Figure 15-10). During the period of constant reaction rate, the rate depends only on enzyme concentration and is completely independent of substrate concentration. The reaction is said to follow zero-order kinetics, because its rate is proportional to the zero power of the substrate concentration. Ultimately, however, as more substrate is consumed, the reaction rate declines and enters a phase of first-order dependence on substrate concentration. Other factors that contribute to the decline in reaction rate include accumulation of products that may be inhibitory, the growing importance of the reverse reaction, and even enzyme denaturation. Although it is possible to compare the rates of reaction produced by different amounts of an enzyme under first-order conditions, it is obviously easier to standardize such comparisons when the enzyme concentration is the only variable that influences the reaction rate. Therefore, enzyme assays are usually made under conditions that are initially saturating with respect to substrate concentration. The rate of reaction during the zero-order phase is determined by

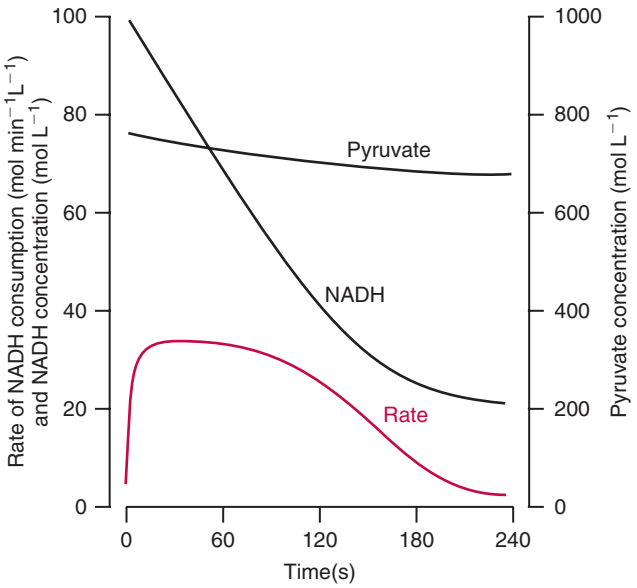

Figure 15-10 Changes in substrate concentrations and rates of reaction during an assay of lactate dehydrogenase activity at 37 °C in phosphate buffer, with pyruvate and nicotinamide adenine dinucleotide (NADH) as substrates. The reaction is followed by observing the fall in absorbance at 340 nm as NADH is oxidized to NAD^+. The rate of reaction rises rapidly to a maximum value, from which it declines only slightly until about half the NADH has been used up. During this phase of the reaction, the rate is essentially zero order with respect to substrate concentration. At the point at which the rate falls below about 90% of its maximum value, NADH concentration is approximately 10 × K_m. The K_m for NADH is on the order of 5×10^{-6} mol/L, whereas for pyruvate it is 9×10^{-5} mol/L. Thus an initial pyruvate concentration approximately 10 times that of NADH is used. (Concentrations are per liter of reaction mixture.) *(From Moss DW. Measurement of enzymes. In: Hearse DJ, de Leiris J, eds. Enzymes in cardiology: diagnosis and research. New York: John Wiley & Sons Inc., 1979. Reprinted by permission of John Wiley & Sons, Inc.)*

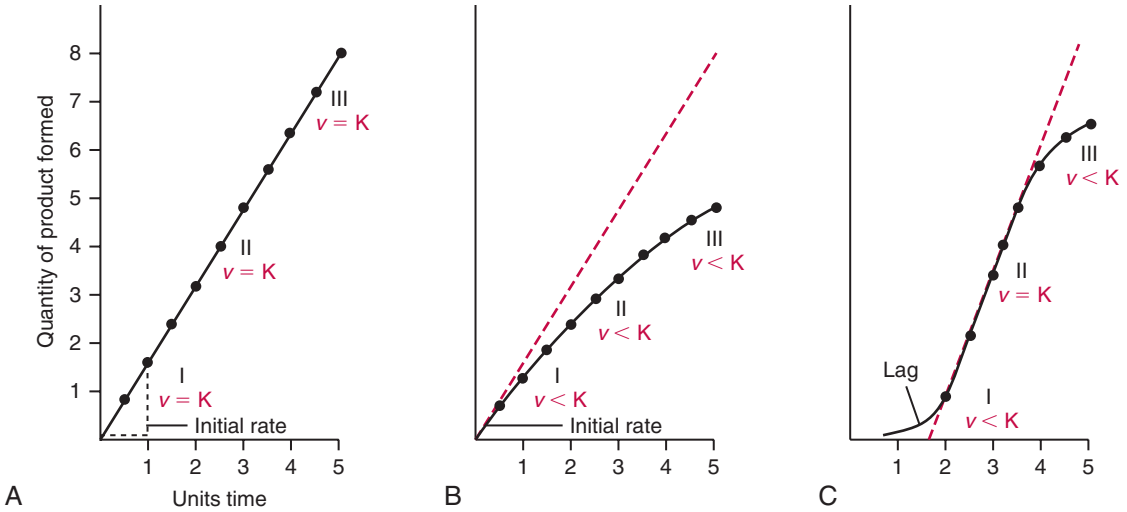

Figure 15-11 Forms of graphs showing change in enzyme reaction rate as a function of time. In A, the rate is constant during the entire run, and rates calculated as *I, II,* and *III* will be identical to the initial rate. In B, the rate falls off continuously; rates calculated at *I, II,* and *III* will be different and less than the true initial rate. In C, a measurement at *II* will be representative of the maximum rate, but at *I* (lag period) and *III* (substrate depletion), it will be less than at *II*.

measuring the product formed during a fixed period of incubation where the rate remains constant. This is illustrated in Figure 15-11. Measurement of reaction rates at any portion of curve A gives results that are identical to the true *initial rate.* However, curve B deviates from linearity over its entire course, and rates fall off with time. From curve C, correct results are obtained only if the rate is measured along segment II. Incorrect results are obtained if the rate is measured during the lag phase (I) or during phase III.

Careful selection of reaction conditions, such as the concentrations of substrates and cofactors, improves the reaction progress curves, eliminating lag phases and prolonging the period of linearity, so that fixed-time methods of analysis become feasible. Improvements in optical techniques, leading to more reliable and sensitive measurement of product formation, have also allowed the duration of incubation to be shortened compared with older assays. This has resulted in a corresponding increase in the interval over which enzyme activity is measured. Nevertheless, an upper limit of activity exists in all fixed-time methods, above which progress curves will no longer be linear. In this case, the amount of change measured over the fixed-time interval no longer represents true zero-order rate conditions.

The upper limit of activity acceptable in the unmodified method must be chosen so that samples with activities below it are presumed with a high degree of certainty to give linear progress curves; alternatively, if the limit is set too low, many samples will be reanalyzed unnecessarily. Samples that are above the limit should ideally be reassayed by shortening the incubation period until a constant reaction rate is obtained. However, this is difficult or impossible in some automated methods, in which the duration of incubation is fixed by the configuration of the apparatus. It then becomes necessary to dilute the specimen; however, dilution may not always result in a proportional change in activity.

The initial rate of reaction theoretically increases without limit as enzyme concentration increases, as long as no other factor, such as substrate concentration, becomes limiting. In practice, the reaction rate becomes so rapid at high enzyme activities that it is impossible to measure the initial rate of reaction, even with continuous-monitoring methods. Therefore, an upper limit of activity that is measurable without modification of the assay procedure exists even in continuous-monitoring methods, but this limit is usually much higher than that applicable in corresponding fixed-time methods. Fewer samples therefore require special treatment. Furthermore, continuous monitoring allows identification of the appropriate zero-order portion of the progress curve for each sample and identification of samples that require special treatment. Continuous-monitoring methods therefore provide a decisive advantage in enzyme assay and should be used whenever possible.

Measurement of Substrates

The amount of substrate transformed into products during an enzyme-catalyzed reaction can be measured with any appropriate analytical method, such as spectrophotometry, fluorometry, or chemiluminescence.[8A] For example, if an enzyme reaction is accompanied by a change in the absorbance characteristics of some component of the assay system, in the visible or ultraviolet spectrum, it can be photometrically observed while it is proceeding. *Self-indicating* reactions of this type are particularly valuable, as they allow continuous monitoring. Important examples of self-indicating reactions

are determination of dehydrogenase activity by monitoring the change in absorbance at 339 (340) nm of the coenzyme NADH or NADPH during oxidation or reduction, and measurement of ALP activity by the generation of the yellow *p*-nitrophenolate ion from the substrate *p*-nitrophenyl phosphate in alkaline solution. These indicator reactions are so versatile that coupled reactions are frequently used to provide an observable optical change accompanying a primary reaction in which such a change is not present.

The introduction of prism or diffraction-grating spectrophotometers capable of isolating a narrow beam of monochromatic light in the ultraviolet or visible spectrum and with stable and sensitive photomultipliers as detectors has greatly improved the reproducibility of photometric measurements (see Chapter 10). Consequently, it is customary to make use of the known molar absorptivity of well-defined reaction products (such as NADH) when calculating changes in their concentrations based on measurements made with spectrophotometers. However, the absorbance and wavelength accuracy of the spectrophotometer should be checked regularly. (See Chapter 10 for details on validating the performance of a spectrophotometer.)

Optimization, Standardization, and Quality Control

To measure enzyme activity reliably, all factors that affect the reaction rate—other than the concentration of active enzyme—need to be optimized and rigidly controlled. Furthermore, because the reaction velocity is at or near its maximum under optimal conditions, a larger analytical signal is obtained that can be more accurately and precisely measured than a smaller signal obtained under suboptimal conditions. Much effort therefore has been devoted to determining optimal conditions for measuring the activities of enzymes of clinical importance.

Optimization

Optimization of reaction conditions for enzyme assays traditionally has been carried out by varying a single factor and studying its effect on the reaction rate, then repeating the experiment with a second factor and so on, until effects of all the variables have been tested. An optimal combination of variables is selected on the basis of these experiments, and the validity of the chosen conditions is verified. Not only is this approach labor intensive, it also is difficult to adapt in situations in which the effects of different variables are interdependent, as is frequently the case in enzyme analysis. This traditional empirical approach to optimization has been replaced by newer techniques of simplex co-optimization and response-surface methodology.[13]

Standardization

Despite considerable effort, the goal of a single universally used procedure to measure the catalytic activity of a given enzyme has not been achieved. Consequently, current enzyme standardization efforts are focused on the development of a system that allows comparability of test results, independent

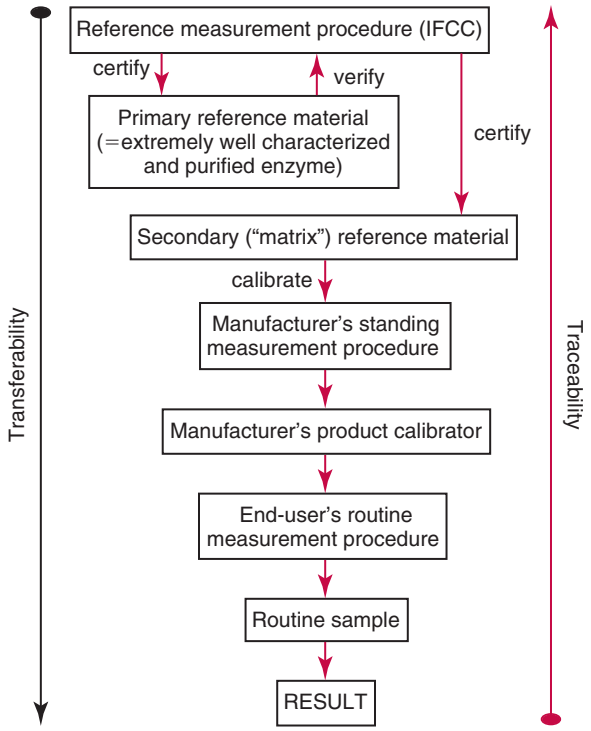

Figure 15-12 The proposed reference system for enzyme measurement showing the traceability of the laboratory result to the reference measurement procedure. *(From Panteghini M, Ceriotti F, Schumann G, Siekmann L. Establishing a reference system in clinical enzymology. Clin Chem Lab Med 2001;39:795-800. Reprinted with permission of Walter de Gruyter.)*

of the measurement method. To achieve this, a "reference system" based on the concepts of metrologic traceability and on the hierarchy of analytical methods has been proposed.[7,12,24] A reference procedure and certified reference materials form the basis of the metrological traceability chain (Figure 15-12).[1,3] As part of this hierarchy, reference procedures at 37 °C for the most common enzymes have been developed, and a group of reference laboratories are being selected to perform enzyme measurements at an appropriately high metrologic level.[14-21]

Reference procedures set standards of precision and accuracy against which the relative performance of methods intended for routine use are judged. The reference procedure is used to assign a certified value to the reference material. This certified material is then used by the manufacturers to assign values to commercial calibrators, resulting in traceability of the value obtained in the laboratory.

Several studies have demonstrated that enzyme preparations with reproducible properties and purity and having assured stability can be made. These may be derived from animal sources in which the enzymes closely resemble their human counterparts, although new possibilities have been created by gene-transfer and recombinant techniques.

For a reference system to be capable of standardizing the results of different assays of a given enzyme activity, some conditions must be satisfied.[10] First, the reference procedure

used to assign the value of the reference material and the routine method(s) to be calibrated must have identical specificities for the analyte enzyme isoenzyme or isoform under study. Second, the properties of the calibrator material must be the same as or closely similar to those of the analyte enzyme in its natural matrix and, "commutable" and capable of being exchanged for another or for something else that is equivalent with human serum samples for that particular method.

Quality Control

The application of quality control programs is as essential in enzyme analysis as in other forms of clinical analysis if the results obtained are to be useful in diagnosis and treatment.

Lyophilized and liquid preparations containing various enzymes are available from commercial sources, and these have a useful function in quality control.

Measurement of Enzyme Mass Concentration

Many immunoassays for human enzymes and isoenzymes measuring protein mass instead of catalytic activity have been described. To develop such assays, purified enzyme protein has to be prepared to (1) act as a calibrator, (2) be labeled, and (3) be used to raise the enzyme-specific antibody. These methods identify all molecules with the antigenic determinants necessary for recognition by the antibody, so that inactive enzyme molecules that are immunologically unaltered are measured along with active molecules. This has been found to be significant in the determination of some digestive enzymes, such as trypsin, when inactive precursors and inhibitors of catalytic activity are present in plasma. In the majority of cases, however, no degradation or changes in the active enzyme occur in blood so that the clinical equivalence of the different measurement approaches (i.e., estimation of catalytic activity and mass concentration) is obtained.

Immunoassays typically are not used for determination of total activities for the more important diagnostic enzymes, as these assays generally cannot compete in terms of speed, precision, and cost with automated measurements of catalytic activity. Furthermore, several enzyme activities in serum are due to mixtures of immunologically distinct forms, so an assay using a single type of antibody usually determines only one of the enzyme forms. However, this disadvantage in the determination of total enzyme activity becomes a marked advantage in the measurement of specific isoenzymes and isoforms, and immunologic methods have assumed great importance in isoenzyme analysis for diagnostic purposes.

Enzymes as Analytical Reagents

Enzymes are used as analytical reagents for the measurement of several metabolites and substrates and in immunoassays to detect and quantify immunologic reactions.

Measurement of Metabolites

The use of enzymes as analytical reagents to measure metabolites frequently offers the advantage of great specificity for the substance being determined. This high specificity typically removes the need for preliminary separation or purification stages, so the analysis can be carried out directly on complex mixtures such as serum. Uricase (urate oxidase), urease, and glucose oxidase are examples of highly specific enzymes used in clinically important assays, such as the measurement of uric acid, urea, and glucose in biological fluids. However, high specificity cannot always be achieved in practice, and knowledge of the substrate specificities of reagent enzymes is therefore essential to allow possible interferences with the assay to be anticipated and corrected. Coupled reactions are often used to construct an enzymatic analytical system for determining a particular compound. An example of this is the determination of glucose by the hexokinase reaction. Hexokinase converts sugars other than glucose to their 6-phosphate esters. However, the indicator reaction used to monitor this change is catalyzed by glucose-6-phosphate dehydrogenase, an enzyme that is highly specific for its substrate; so the overall process is highly specific for glucose.

In practice, both equilibrium and kinetic (rate) methods have been developed that use enzymes as reagents.[23]

Equilibrium Methods

Most assays used to determine the amount of a substance enzymatically are allowed to continue to completion, so that all substrate has been converted into a measurable product. These methods are called *end point* or, more correctly, *equilibrium* methods, because the reaction ceases when equilibrium is reached. Reactions in which the equilibrium point corresponds virtually to complete conversion of the substrate are obviously preferable for this type of analysis. However, an unfavorable equilibrium can often be displaced in the desired direction by additional enzymatic or nonenzymatic reactions that convert or "trap" a product of the first reaction (e.g., in measuring lactate with lactate dehydrogenase, the pyruvate formed can be trapped by the addition of hydrazine, with which it forms an irreversible hydrazone).

Theoretically, the time required to transform a fixed quantity, Q, of substrate into products is inversely proportional to the amount of enzyme, $[E]$, present:

$$Q = k_1 + [E] \times t \tag{27}$$

and

$$[E] = \frac{Q}{k_1} \times \frac{1}{t} \tag{28}$$

where k_1 is the rate constant and t is the elapsed time. Equilibrium methods therefore may require the use of appreciable amounts of enzyme for each sample, to avoid inconveniently long incubation periods. As the substrate concentration falls to low quantities toward the end of the reaction, the K_m of the enzyme becomes important in determining the reaction rate. Enzymes with high affinities for their substrates (low K_m values) therefore are most suitable for equilibrium analysis. Equilibrium methods are largely insensitive to minor changes in reaction conditions. It is not necessary to have exactly the same amount of enzyme in each reaction mixture or to maintain the pH or temperature absolutely constant, provided that

the variations are not so great that the reaction is not completed within the fixed time allowed.

Kinetic Methods

First-order or pseudo–first-order reactions are the most important reactions for the kinetic determination of substrate concentration. For any first-order reaction, the substrate concentration [*S*] at a given time *t* after the start of the reaction is given by

$$[S] = [S_0] \times e^{-kt} \quad \textbf{(29)}$$

where $[S_0]$ is the initial substrate concentration, *e* is the base of the natural log, and *k* is the rate constant.

The change in substrate concentration $\Delta[S]$ over a fixed-time interval, t_1 to t_2, is related to $[S_0]$ by the equation

$$[S_0] = \frac{-\Delta[S]}{e^{-kt_1} - e^{kt_2}} \quad \textbf{(30)}$$

As this equation indicates, the change in substrate concentration over a fixed-time interval is directly proportional to its initial concentration. This is a general property of first-order reactions.

For an enzymatic reaction, first-order kinetics is followed when [*S*] is small compared with K_m. Thus,

$$v = \frac{V_{\max}}{K_m} \times [S] \quad \textbf{(31)}$$

or

$$v = k[S] \quad \textbf{(32)}$$

Therefore, the first-order rate constant, *k,* is equal to $\frac{V_{\max}}{K_m}$.

Methods in which some property related to substrate concentration (such as absorbance, fluorescence, chemiluminescence, etc.) is measured at two fixed times during the course of the reaction are known as *two-point* kinetic methods. Theoretically, they are most accurate for the enzymatic determination of substrates. However, these methods are technically more demanding than equilibrium methods, and all factors that affect reaction rate, such as pH, temperature, and amount of enzyme, must be kept constant from one assay to the next, as must the timing of the two measurements. These conditions can readily be achieved in automatic analyzers. A reference solution of the analyte (substrate) must be used for calibration. To ensure first-order reaction conditions, the substrate concentration must be low compared with the K_m (i.e., on the order of less than $0.2 \times K_m$). Enzymes with high K_m values therefore are preferred for kinetic analysis to obtain a wider usable range of substrate concentrations.

Immunoassay

In enzyme immunoassay, enzyme-labeled antibodies or antigens first are allowed to react with ligand; then an enzyme substrate is added. Enzymes such as (1) ALP, (2) horseradish peroxidase, (3) glucose-6-phosphate dehydrogenase, and (4) β-galactosidase all have been used as enzyme labels. A modification of this methodology is the enzyme-linked immunoabsorbent assay (ELISA), in which one of the reaction components is bound to a solid-phase surface. In this technique, an aliquot of sample is allowed to interact with the solid-phase antibody. After washing, a second antibody labeled with enzyme is added to form an Ab–Ag–Ab–enzyme complex. Excess free enzyme–labeled antibody then is washed away, and the substrate is added; the conversion of substrate is proportional to the quantity of antigen. In immunoassays, it is not the specificity of labeled enzymes that is important, but their sensitivity.

Analytical Applications of Immobilized Enzymes

For some types of enzymatic analyses, enzyme consumption is reduced by the use of immobilized enzymes that are reused for several analyses. Immobilized enzymes have been chemically bonded to adsorbents, such as (1) microcrystalline cellulose,(2) diethylaminoethyl (DEAE) cellulose, (3) carboxymethyl cellulose, and (4) agarose. Diazo, triazine, and azide groups are used to join the enzyme protein to the insoluble matrix, forming particles in contact with the substrate solution or a surface in contact with substrate solution, such as a membrane or a coating on the inner surface of a vessel holding the substrate solution. Among enzymes available in such immobilized form are (1) urease, (2) hexokinase, (3) α-amylase, (4) glucose oxidase, (5) trypsin, and (6) leucine aminopeptidase. Stability to heat and other forms of inactivation is considerably increased compared with enzymes in solution. Immobilized proteolytic enzymes are not subject to autodigestion. However, some properties of the enzyme, such as its K_m or its pH optimum, may be altered.

Electrochemical techniques such as (1) potentiometry, (2) polarography, and (3) microcalorimetry have been chosen in exploiting the benefits of immobilized enzymes (see Chapter 11). Enzymes incorporated into membranes form part of enzyme electrodes. The surface of an ion-sensitive electrode is coated with a layer of porous gel in which an enzyme has been polymerized. When the electrode is immersed in a solution of the appropriate substrate, the action of the enzyme produces ions to which the electrode is sensitive. For example, an oxygen electrode coated with a layer containing glucose oxidase has been used to determine glucose from the amount of oxygen consumed in the reaction. Urea has been estimated by the combination of a selective ammonium ion–sensitive electrode and a urease membrane.

Measurement of Isoenzymes and Isoforms

A number of analytical techniques have been used to measure isoenzymes or isoforms. They include (1) electrophoresis (see Chapter 12), (2) chromatography (see Chapter 13), (3) chemical inactivation, and (4) differences in catalytic properties, but the most widely used methods are now based on immunochemical methods.

Electrophoresis

Various forms of electrophoresis have been used to separate isoenzymes, but generally they are not used routinely because

they are time-consuming, difficult to quantify, and relatively expensive. Isoelectric focusing (see Chapter 12) has been used successfully to separate isoforms that differ in the amount of covalently bound sugar residues, such as sialic acid.

Chromatography

Ion-exchange chromatography makes use of differences in net molecular charge at a given pH to separate isoenzymes. A typical ion-exchange material is DEAE cellulose, in which ionizable DEAE groups are attached to an inert cellulose matrix. Ion-exchange chromatography is not in general as highly resolving of closely similar proteins as is zone electrophoresis, but relatively large quantities of proteins can be separated with good recovery of enzymatic activity, so the method is of great value in enzyme purification.

Other forms of chromatography that have been applied to fractionation of isoenzyme mixtures include high-performance liquid chromatography (HPLC) and affinity chromatography. The latter makes use of differences between isoenzymes in their affinities for a specific ligand that is attached to an inert insoluble support used as the stationary phase in a chromatography column or in a batch technique.

Chemical Inactivation and Differences in Catalytic Properties

Selective inactivation under controlled conditions has been used in isoenzyme characterization. The method is based on differences in stability that result from small changes in the structure of protein molecules. Elevated temperatures or concentrated solutions of urea or other reagents were used to denature the enzyme. Rates of enzyme inactivation by these agents are critically dependent on the conditions of the experiment, which therefore must be strictly controlled if reliable comparisons between samples are to be made.

Differences in catalytic properties, such as (1) differences in K_m, relative rates of reaction with substrate analogs (when the specificity of the enzyme allows for variation in the structure of the substrate), (2) pH optima, and (3) response to inhibitors, typically exist between isoenzymes that are the products of multiple-gene loci. These differences can serve as the basis of methods of identification and measurement of particular isoenzymes.

These techniques generally are not used routinely, as they have been largely superseded by other, more convenient methods such as immunoassay methods.

Immunochemical Assays

Immunochemical methods of isoenzyme analysis are particularly applicable to isoenzymes derived from multiple-gene loci, because these are usually most clearly antigenically distinct. However, the greater discriminating power of monoclonal antibodies has potentially brought all multiple forms of an enzyme within the scope of immunochemical analysis. Some of these methods make use of catalytic activity of the isoenzymes. For example, residual activity may be measured after reaction with antiserum. Radioimmunoassays in which isoenzyme labeled with a radioactive tracer competes with unlabeled isoenzyme for antibody-binding sites have also been applied to isoenzyme measurement. These methods do not depend on the catalytic activity of the isoenzyme being determined. However, with the development of automated immunoassay systems, the most common routine methods for measuring isoenzymes, such as CK-MB, are solid-phase ELISAs.

The choice and application of various methods of isoenzyme analysis in clinical enzymology in relation to specific isoenzyme systems are discussed in Chapter 22.

CHAPTER 16

Principles of Immunochemical Techniques

*Larry J. Kricka, D.Phil., F.A.C.B., C.Chem., F.R.S.C., F.R.C.Path., and Jason Y. Park, M.D., Ph.D., F.A.C.P.**

Immunochemical reactions form the basis of a diverse range of sensitive and specific clinical assays. In a typical immunochemical analysis, an antibody is used as a reagent to detect an antigen of interest. The exquisite specificity and the high affinity of antibodies for their antigens, coupled with the ability of antibodies to cross-link antigens, allow the identification and quantitation of specific substances by a variety of methods. The principles of the methods most commonly used in the clinical laboratory are discussed in this chapter. This introduction is intended to acquaint the reader with the structure and function of antibodies (immunoglobulins) in relation to their use as reagents in immunoanalyses.

BASIC CONCEPTS

The binding of antibodies and their complementary antigens forms the basis of all immunochemical techniques.

Antibodies

Antibodies are immunoglobulins that are capable of binding specifically to a wide array of natural and synthetic antigens, including proteins, carbohydrates, nucleic acids, lipids, and other molecules. Immunoglobulins consist of five general classes designated as immunoglobulin (Ig)G, IgA, IgM, IgD, and IgE. IgG is used most commonly in immunochemical reagents. A schematic diagram of the IgG molecule is shown in Figure 16-1. IgG is a glycoprotein [molecular weight (MW), 158,000 Da] composed of two heavy (γ) and two light (κ or λ) chains joined by disulfide bonds. Each chain (H or L) is the product of three (L) or four (H) distinct gene segments. These are the constant (C), joining (J), diversity (D), and variable (V) genes that undergo combinatorial joining during B-cell development. Several hundred germline V genes, 5 to 10 J genes, 15 D genes (H chain only), and a single C gene have been identified for each heavy or light chain class. During B-cell development, the V, D, and J (H chain) or V and J (L chain) undergo random rearrangement and splicing, and this recombined product then is spliced to the constant region gene. This combinatorial diversity, along with somatic mutations that occur at the splicing sites, generates a tremendous diversity of antibody specificities. When a B-cell clone expressing a particular antibody specificity on its surface is "selected" by an antigen, it expands and differentiates into a plasma cell that secretes the specific antibody. For more information on immunoglobulins, see Chapter 21.

The variable amino acid sequence at the amino terminal end (≈105 amino acids) of each chain determines the antigenic specificity of the particular antibody. Each unique variable region is a product of a single plasma cell line or clone. A complex antigen is capable of eliciting a multiplicity of antibodies with different specificities that are derived from different cell lines. Antibodies derived in this manner are termed *polyclonal* and exhibit diverse specificities in their reactivity with the immunogen. Each unique region of the antigen molecule that will bind a complementary antibody is termed an *epitope* (antigenic determinant).

Immunogens

An *immunogen* is a protein or a substance coupled to a carrier that when introduced into a foreign host is capable of inducing the formation of an antibody in the host. The antibody produced may be circulating *(humoral)* or tissue bound *(cellular)*.

A *hapten* is a small, chemically defined determinant that when conjugated to an immunogenic carrier stimulates the synthesis of antibody specific for the hapten. It is capable of binding an antibody but cannot by itself stimulate an immune response.

*The author gratefully acknowledges the original contribution by Dr. Gregory Buffone, upon which portions of this chapter are based.

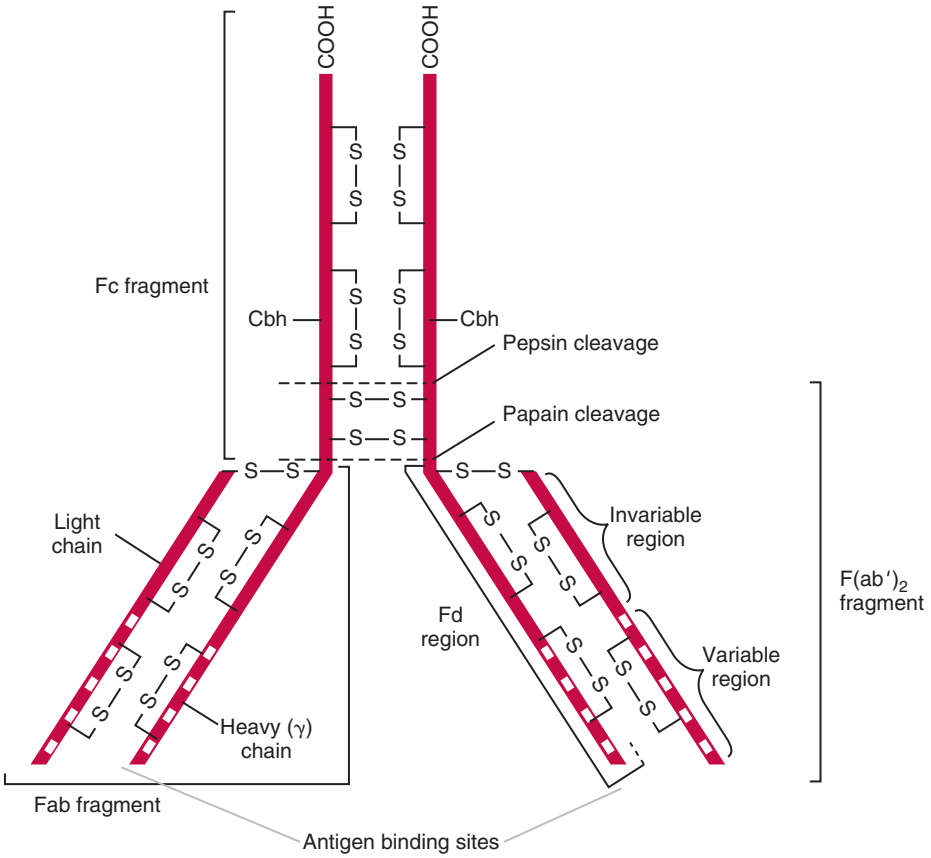

Figure 16-1 Schematic diagram of immunoglobulin (Ig)G antibody molecule showing carbohydrate (Cbh), disulfide bonds (—S—S—), and major fragments produced by proteolytic enzyme treatment (F[ab′]$_2$, Fc, Fab, Fd).

Continued stimulation by an immunogen results in increased production of immunoglobulins of different types and of high-affinity binding characteristics for antigens. After the first exposure to an immunogen, a latent period (induction) occurs during which no antibody is present in serum; this period may last from 5 to 10 days.

The strength or energy of interaction between the antibody and the antigen is described by two terms. *Affinity* refers to the thermodynamic quantity defining the energy of interaction of a single antibody-combining site and its corresponding epitope on the antigen. *Avidity* refers to the overall strength of binding of an antibody and its antigen and includes the sum of the binding affinities of all the individual combining sites on the antibody. For example, IgG has two antigen-binding sites, whereas IgM has 10 antigen-binding sites per antibody molecule. Thus affinity is a property of the substance bound (antigen), and avidity is a property of the binder (antibody). For polyclonal antibodies, avidity is difficult to determine primarily because of the diversity of the antibody population.

Polyclonal antiserum is raised in a normal animal host in response to immunogen administration. In contrast, *monoclonal antibodies* are produced in a very different manner and represent the product of a single clone or plasma cell line, rather than a heterogeneous mixture of antibodies produced by many plasma cell clones in response to immunization. Monoclonal antibodies are now widely used as reagents in immunoassay techniques.[44,59] The usual method of production of monoclonal antibodies involves fusing antibody-producing plasma cells from the spleens or lymph nodes of mice that have been immunized several times over a 2- to 4-week period with a murine myeloma cell line from tissue culture in the presence of polyethylene glycol (PEG)(PEG promotes membrane and thus cell fusion through an unknown mechanism). The murine myeloma cell line is an immortalized plasma cell line. The murine myeloma cell lines most commonly used are deficient in the enzyme hypoxanthine guanine phosphoribosyl transferase (HGPRT) and therefore cannot synthesize purine bases from thymidine and hypoxanthine in the presence of aminopterin. Following fusion, the cells are placed into a selection medium containing hypoxanthine, aminopterin, and thymidine (HAT medium) to grow *fused hybrid cell* lines selectively. The fused hybrid cells can survive in a HAT medium, because these cells combine the immortality of the myeloma cell with the genetic material of the splenic plasma cell necessary for synthesis of thymidine in the presence of aminopterin. The unfused myeloma cells are killed by the HAT medium because they do not have the HGPRT gene, and the unfused spleen cells cannot be maintained in the culture. Colonies arising from

tahir99-VRG & vip.persianss.ir

the fused cells are then screened for antibody production, and cell lines secreting antibody of the desired specificity are cloned in subcultures. In this way, a single clonal line can be isolated that produces an antibody with a selected specificity and affinity for a single antigen.

Because of the unique ability of a monoclonal antibody to react with a single epitope on a multivalent antigen, the majority of monoclonal antibodies will not cross-link and precipitate macromolecular antigens. Consequently, monoclonal antibodies have not found broad applicability in traditional precipitin methods. A practical advantage of using monoclonal antibodies is that two different antibody specificities can be used in a single incubation step. A solid phase antibody specific for a unique epitope and another labeled antibody specific for a different epitope can react with an antigen in a single step. This eliminates the incubating and washing steps that usually would be required for polyclonal antibodies.

Phage display technology provides a new in vitro approach for producing antibodies (single chain Fv fragments, Fab fragments, and whole antibody molecules) that mimic the immune system but do not require B-cell immortalization.[15,89] V genes coding for the heavy and light chain variable domains of immunoglobulin isolated from lymphocytes are amplified by the polymerase chain reaction and ligated into a filamentous bacteriophage vector to form combinatorial libraries of V_H and V_L genes. Individual bacteriophages display copies of a specific antibody on their surface, and the phage library can be screened for the antibody of a defined specificity using immobilized antigen ("panning"). Large libraries displaying antibodies formed from more than 10^{12} different V_H and V_L combinations can be constructed; this provides a rich source of antibodies with binding constants of 10^8 to 10^9 L/mol. Soluble antibody from selected bacteriophages can be secreted from infected bacteria (e.g., *Escherichia coli*) in yields greater than 500 mg/L.

ANTIGEN-ANTIBODY BINDING

Binding Forces

The strength of the binding of an antigen to an antibody depends on several forces acting cooperatively. These include van der Waals-London dipole-dipole interaction, hydrophobic interaction, and ionic coulombic bonding.[42]

Van der Waals-London Dipole-Dipole Interactions

Van der Waals-London binding is caused by the attraction between atoms when they are brought together in close proximity. These interactions are basically electrostatic in nature and are applicable to polarizable, noncharged molecules, whose structure allows the electron cloud around the molecule to be distorted by outside forces in such a way that a transient dipole is produced. Such polarization results in the formation of an instantaneous dipole moment, which in turn induces a dipole moment in adjacent molecules. The induced dipole moment is oriented in an antiparallel fashion with respect to the original dipole moment, such that a net attractive force is produced. These forces operate over short distances (4 to 6 nm) and are more significant for larger molecules. Because polarizability varies inversely with temperature, the attractive force is inversely proportional to the temperature.

Hydrophobic Interaction

Hydrophobic interactions result because the association of nonpolar groups is energetically favored in aqueous or other polar solutions. In proteins, hydrophobic interactions serve to bend and fold a molecule in a way that brings nonpolar R groups inside to the less polar interior; polar R groups are oriented outside toward the more polar aqueous environment. Thus hydrophobic bonding forms an interior, hydrophobic protein core, where most hydrophobic side chains can closely associate and weakly bind. Hydrophobic interaction enhances or stabilizes antigen-antibody binding but is not necessarily the major force in such binding.[76]

Coulombic Bonds

Coulombic bonding results from the attraction between charged groups on the antigen and the antibody, primarily COO^- and NH_4^+. The attraction between the charged groups is greatest in a medium with a low dielectric constant caused by reduced interaction of the solvent or other solute (salts) with the macromolecular ions. In a medium of high dielectric constant (aqueous solutions containing added salt), a diffuse double layer of charged particles will tend to shield the attraction of the charged species in the reactive sites of the antigen and antibody. This inhibition under certain circumstances can considerably reduce the binding constant for many antigen-antibody systems.

Given these forces, one would predict that changing pH, temperature, and ionic strength of the reaction medium should influence the binding of antigen and antibody. However, given a lower and upper limit of pH of 6 and 8 and an incubation temperature between 25 °C and 35 °C, these variables have only minimal effect on the rate of association and immune complex formation.[58,78] In fact, extremes in pH (less than 4.0 and greater than 8.0) can cause inhibition of binding or dissociation of already formed antigen-antibody complexes. Changes in ionic strength will produce a significant effect on the rate of binding of antigen and antibody. This concept is studied further in the following sections.

Reaction Mechanism

The binding of antigen to antibody is not static but is an equilibrium reaction that proceeds in three phases. The initial reaction (phase 1) of a multivalent antigen (Ag_n) and a bivalent antibody (Ab) occurs very rapidly in comparison with subsequent growth of the complexes (phase 2) and is depicted by the following equation:

$$Ag_n + Ab \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ag_nAb \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Ag_aAb_b \qquad (1)$$

where $k_1 >>> k_2$, n is the number of epitopes per molecule, and a and b are the numbers of antigen and antibody molecules per complex. Phase 3 of the reaction involves

tahir99-VRG & vip.persianss.ir

precipitation of the complex after a critical size is reached. The speed of these reactions depends on electrolyte concentration, pH, and temperature, and on antigen structure and antibody class and the binding affinity of the antibody. The concentration of NaCl is important, and in most cases saline (NaCl, 0.15 mol/L) is used. Higher concentrations of NaCl can lead to smaller amounts of precipitate; this is due not to increased solubility of the antigen-antibody complex, but to an equilibrium shift causing a given amount of antigen to combine with smaller amounts of antibody. Decreasing the NaCl concentration can lead to increased precipitation of other proteins.

It is best to use dilute Ab and Ag solutions for determining the influence of such factors as (1) ionic species, (2) ionic strength, and (3) pH. Use of dilute solutions slows the growth of antigen-antibody complexes, and a more stable and more homogeneous population of complexes results.

Factors Influencing Binding

Factors that influence the strength of binding between an antigen and an antibody include ion species, ionic strength, and polymers used in the solution.

Ion Species and Ionic Strength Effects

Cationic salts produce an inhibition of the binding of antibody with a cationic hapten.[30] The order of inhibition by various cations is $Cs^+ > Rb^+ > NH_4^+ > K^+ > Na^+ > Li^+$. This order corresponds to the decreasing ionic radius and the increasing radius of hydration. Similar results were found for anionic haptens and anionic salts. For example, the order of inhibition of binding for anionic salts is $CNS^- > NO^-3 > I^- > Br^- > Cl^- > F^-$, which again is in the order of decreasing ionic radius and increasing radius of hydration. If the competition theory as suggested by these experiments is correct, one would expect the degree of inhibition to be a concentration-dependent phenomenon, and indeed the rate of formation of immune complexes is slower in normal saline (NaCl, 0.15 mol/L) than the same reaction carried out in deionized water. Given the previous observation, F^- should be the anion of choice for immunochemical reaction buffers. In fact, F^- does provide a modest improvement over Cl^-, but the advantage is so small that laboratories rarely substitute toxic fluoride ion for innocuous chloride ion in buffer solutions. A small but measurable difference in the initial rate of combination of antigen and antibody can be seen for phosphate as compared with tris buffer. In general, the most notable differences in reaction rates for the various anionic species evaluated are seen when t is less than 5 minutes. When reactions are evaluated at longer times (i.e., t greater than 5 minutes), the difference in the rate of Ag-Ab complex formation is relatively small for different anionic species.[58]

Polymer Effect[54]

In general, the solubility of a protein in the presence of different linear polymers is inversely proportional to the molecular weight of the polymer (i.e., the higher the molecular weight of the polymer, the lower is the solubility of the protein). For example, in the presence of Dextran 500, the solubility of α-crystalline < fibrinogen < γ-globulin < albumin <<< tyrosine.[52,53] Laurent thus proposed a steric exclusion mechanism to explain the effects of polymers on protein solubility.[53] Assuming a fixed total volume (V_T) of solvent being occupied by both polymer and protein and defining the volume occupied by polymer as V_E (excluded volume, i.e., volume not accessible to proteins) and the volume occupied by protein as V', then the relation

$$V_T = V' + V_E \quad (2)$$

implies that any increase in V_E caused by an increase in number or size of polymer molecules forces a decrease in V' and an effective increase in the concentration of protein molecules. Hence, as V_E is increased, the *effective* protein concentration is increased, the probability of collision and self-association of protein molecules is increased, and large insoluble aggregates are formed.

Studies by Hellsing[34,35] have provided support for the steric exclusion model and have demonstrated that (1) the *composition* of the immune complex formed is not affected by the presence of a polymer; (2) no complex is formed between the polymer and the antigen, antibody, or immune complex; (3) the polymer effect is dependent on the molecular weight of both antigen and polymer; and (4) the use of polymer in a reaction mixture can increase the precipitation of an immune complex with low-avidity antibody. Addition of polymer to a mixture of antigen and antibody causes a notable increase in the rate of immune complex growth, especially during the early phase of the reaction. Numerous polymer species have been tested (Box 16-1) for applications in immunochemical methods. The most desirable characteristics of the polymer are high molecular weight, a high degree of linearity (minimal branching), and high aqueous solubility. Most investigators have found PEG 6000 in concentrations of 3 to 5 g/dL to be most useful.

BOX 16-1 Linear Polymers Used to Enhance Antigen-Antibody Reactions

Polyvinyl pyrrolidone

Types of Reactions

Types of antigen-antibody reactions that are of analytical importance include the precipitin reaction and those noted at a solid-liquid interface.

The Precipitin Reaction

If the number of antibody-combining sites is notably greater than the antigen-epitope sites ([Ab] >>> [Ag]), then antigen-binding sites are quickly saturated by antibodies before

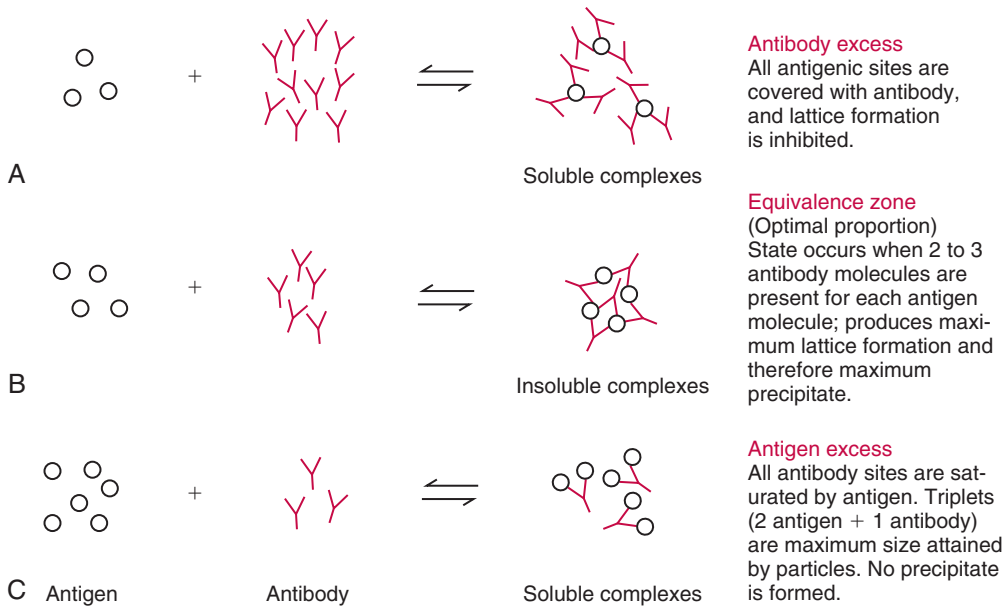

Figure 16-2 Schematic diagram for precipitin reaction.

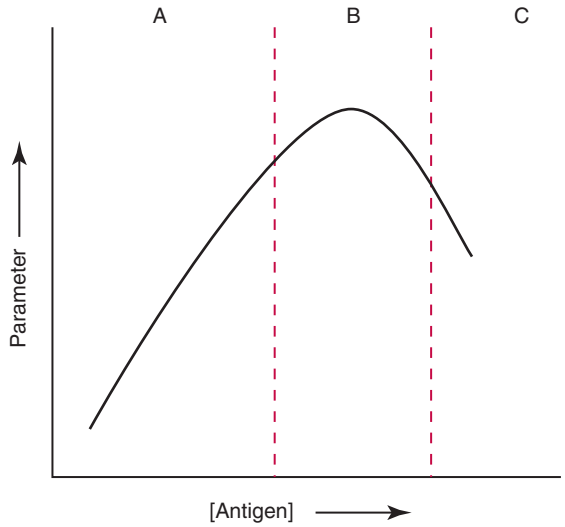

Figure 16-3 Schematic diagram of precipitin curve illustrating zones of antibody excess *(A)*, equivalence *(B)*, and antigen excess *(C)*. The parameter measured may be the quantity of protein precipitated, light scattering, or another measurable parameter. Antibody concentration is held constant in this example.

cross-linking can occur, along with the formation of small insoluble antigen-antibody complexes (Figure 16-2, *A*). When an antibody is in moderate excess (i.e., [Ab] > [Ag]), the probability of cross-linking of Ag by Ab is more likely, and hence large insoluble complex formation is favored (Figure 16-2, *B*). When [Ag] is in great excess, large complexes would be less probable (Figure 16-2, *C*). This model describes the results observed when antigens and antibodies are mixed in various concentration ratios. The curve shown in Figure 16-3 is a schematic diagram of the classical precipitin curve. Although the concentration of total antibody is constant, the concentration of free antibody $[Ab]_f$ (i.e., not bound to antigen) and free antigen $[Ag]_f$ varies throughout the range for any given Ag/Ab ratio. A low Ag/Ab ratio exists in *A* of Figure 16-3 (zone of antibody excess). Under these conditions, $[Ab]_f$ exists in solution, but $[Ag]_f$ does not. As total antigen increases, the size of the immune complexes increases up to equivalence (Figure 16-3, *B*), where little or no $[Ab]_f$ or $[Ag]_f$ exists. This is the zone of maximum immune complex size. This equivalence zone does not represent a ratio of exact molar equivalence of reactants but is the optimal combining ratio for cross-linking in the particular system under evaluation. As Ag/Ab increases (Figure 16-3, *C*), the immune complex size will decrease and $[Ag]_f$ will increase (zone of antigen excess). No $[Ab]_f$ should exist in this area of the curve. However, for a given Ag/Ab ratio, the population of immune complexes formed at equilibrium will be heterogeneous with respect to size and composition.

Reactions at a Solid-Liquid Interface

If the antigen or antibody of interest is bound to a solid phase such as a synthetic particle (polystyrene or cellulose), the protein will exist in a microenvironment that is different from that of a protein in free solution. Water surrounding the protein is more highly ordered near the surface of the solid phase, and the condition that results is more favorable for van der Waals-London dipole-dipole interaction and coulombic bonding. This situation favors the formation of both low- and high-avidity antigen-antibody complexes, and hence can provide lower detection limits for analytical applications.

Because of the exquisite specificity and the high affinity of antibodies for specific antigens, thousands of immunoassays have been developed to detect and measure a wide variety of biological analytes. In the next two sections, qualitative and quantitative immunotechniques are discussed.

tahir99-VRG & vip.persianss.ir

QUALITATIVE METHODS

Various types of immunotechniques have been used for qualitative purposes; these include passive gel diffusion, immunoelectrophoresis (IEP), and Western and dot blotting.

Passive Gel Diffusion

Many qualitative and quantitative immunochemical methods are performed in a semisolid medium, such as agar or agarose. The primary advantage of using a gelatinous medium is that the diffusion process is stabilized with regard to mixing caused by vibration, and visualization of precipitin bands is allowed for qualitative and quantitative evaluation of the reaction. Antigen-to-antibody ratio, salt concentration, and polymer enhancement have the same influence on the antigen-antibody reaction in gels that they have on reactions in solution.

The initial concentration of antigen and antibody is critical. Each molecule in the system will achieve a unique concentration gradient with time. When the leading fronts of antigen and antibody diffusion overlap, the reaction will begin, but formation of a precipitin line will not occur until moderate antibody excess is achieved. A precipitin band may form and be dissolved many times by an incoming antigen before equilibrium is established, and the position of the precipitin band becomes stable. Because heavier molecules diffuse more slowly, the position of the precipitin band is in part a function of the molecular masses of both antigen and antibody. The precipitin band acts as a specific barrier; neither specific antigen nor antibody can penetrate without being precipitated by the other, but unrelated molecules can cross the band of precipitation freely. Basic approaches to passive diffusion include simple diffusion and double diffusion. With simple diffusion, a concentration gradient is established for only a single reactant. *Single immunodiffusion* usually depends on diffusion of an antigen into agar impregnated with antibody. A quantitative technique based on this principle is radial immunodiffusion (RID), which is discussed later. The second approach is double diffusion, in which a concentration gradient is established for both reactants (antigen and antibody).

Double immunodiffusion in two dimensions is a historical immunotechnique known as the Ouchterlony method. It allows direct comparison of two or more test materials and provides a simple method for determining whether the antigens in the test specimens are identical, cross-reactive, or nonidentical.

The simplest method uses an agar dish or slide with holes cut as shown in Figure 16-4. When the same antigen is in adjacent wells, the lines of precipitation fuse and are continuous—this is a reaction of identity (Figure 16-4, *A*). When the precipitin bands cross each other, this is a reaction of nonidentity (Figure 16-4, *B*); if the two antigens are related but are not identical, a reaction of partial identity is observed (Figure 16-4, *C*). Here the cardinal point is that the precipitate serves as a barrier that does not block unrelated diffusing reactants. As shown in Figure 16-4, *D*, when two related

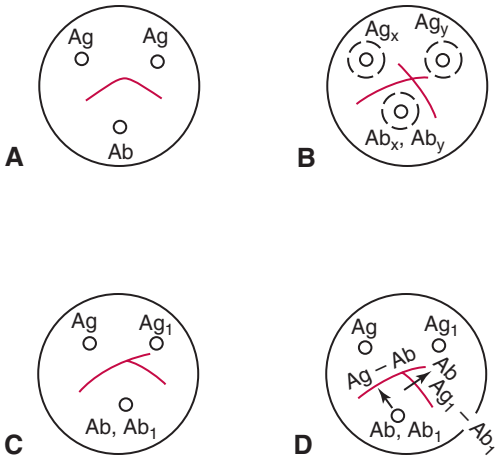

Figure 16-4 Double immunodiffusion in two dimensions by the Ouchterlony technique. A, Reaction of identity; B, reaction of nonidentity; C, reaction of partial identity; D, scheme for spur formation. *Ab,* Antibody; *Ag,* antigen.

antigens, Ag and Ag_1, are in separate wells, and the respective antibodies, Ab and Ab_1, are in the third well, an AgAb precipitate forms on one side and blocks further diffusion of Ab from the antibody well. However, on the other side, the Ag_1Ab_1 precipitate does not stop Ab from migrating further and forming an AgAb spur.

Note that a negative reaction does not necessarily imply absence of antibody or antigen. A negative reaction can result from using amounts of material too small for the detection limit of the method, or the antibody may be nonprecipitating.

Immunoelectrophoresis (IEP)

If several antigens of interest exist in a solution (e.g., spinal fluid or serum), the various protein species can be separated and identified by IEP. This technique has been used extensively for the study of antigen mixtures and for evaluation of the specificity of antiserum.[43]

The procedure is performed using an agarose gel medium poured onto a thin plastic sheet. The sample to be analyzed is placed in a reservoir in the gel, and an electrical field is applied across the gel surface. During electrophoresis, the proteins in the serum are separated according to their electrophoretic mobilities (Figure 16-5). Following electrophoresis, an antiserum against the protein of interest is placed in a trough parallel and adjacent to the electrophoresed sample. Simultaneous diffusion of the antigen from the separated sample and the antibody from the trough leads to the formation of precipitin arcs, whose shape and position are characteristic of individual separated proteins within the specimen. By comparison with a known control separated on the same plate, individual proteins can be tentatively identified.

Crossed Immunoelectrophoresis (CRIE)

This technique, also known as two-dimensional IEP, is a variation of IEP wherein electrophoresis is also used in the second

tahir99-VRG & vip.persianss.ir

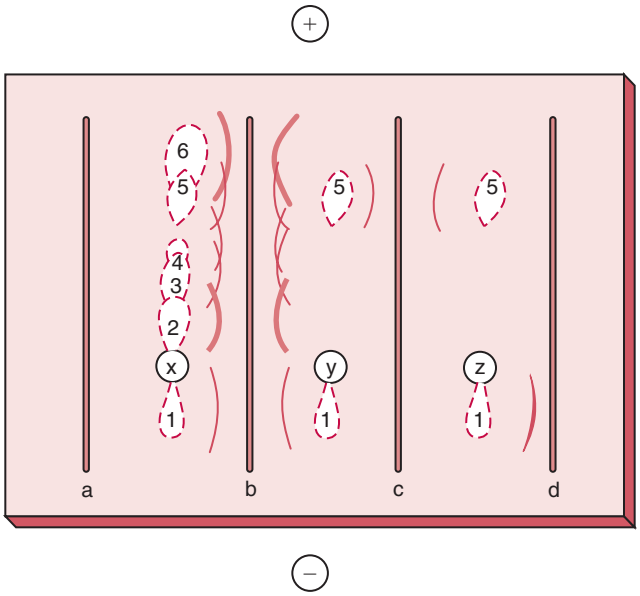

Figure 16-5 Configuration for immunoelectrophoresis. Sample wells are punched in the agar and/or agarose, sample is applied, and electrophoresis is carried out to separate the proteins in the sample. Antiserum is loaded into the troughs and the gel incubated in a moist chamber at 4 °C for 24 to 72 hours. Track *x* represents the shape of the protein zones after electrophoresis; tracks *y* and *z* show the reactions of proteins 5 and 1 with their specific antisera in troughs *c* and *d*. Antiserum against protein *1-6* is present in trough *b*.

dimension to drive the antigen into a gel containing antibodies specific for the antigens of interest.[50] This technique is more sensitive and produces higher resolution than IEP. For more information on CRIE, see the previous edition of this textbook.

Counterimmunoelectrophoresis (CIE)

With CIE, two parallel lines of wells are punched in the agar. One row is filled with antigen solution, and the opposing row is filled with antibody solution (Figure 16-6). If the solutions were allowed to passively diffuse, a precipitin line would form between the opposing wells in 18 to 24 hours. With CIE, this process is accelerated by applying a voltage across the gel so that the antigen and the antibody move toward each other. Qualitative information (i.e., identification of antigen) is provided within 1 to 2 hours. Historically, this method has found application in the detection of bacterial antigens in blood, urine, and cerebrospinal fluid.

Immunofixation (IF)

This technique has gained widespread acceptance as an immunochemical method for identifying proteins.[3] As in IEP and CRIE, a first-dimension electrophoresis is performed in agarose gel to separate proteins in the sample. Subsequently, antiserum spread directly on the gel causes the protein(s) of interest to precipitate. The immune precipitate is trapped within the gel matrix, and all other nonprecipitated proteins are removed by washing the gel. The gel may then be stained for identification of the proteins. IF is technically more efficient than IEP or CRIE, and it produces patterns that are interpreted more easily. The usefulness of IF, which is now widely used for the evaluation of myeloma proteins, is illustrated in Figure 16-7.

Western Blotting

The techniques discussed previously use direct evaluation of the immunoprecipitation of the protein(s) in a gel. However, certain media, such as polyacrylamide, do not lend themselves to direct immunoprecipitation, nor is there always sufficient antigen concentration to produce an immunoprecipitate that will be retained in the gel during subsequent processing. Under these circumstances, a technique termed *Western blotting* can be used (see Chapter 12).[11,26] This technique involves an electrophoresis step followed by transfer of separated proteins onto an overlying strip of nitrocellulose or a nylon membrane by a process called *electro-blotting*. Once the proteins are in the membrane, they can be detected using antibodies labeled with probes, such as radioactive isotopes or enzymes. When such probes are used, the limits of detection can be 10 to 100 times lower than when direct immunoprecipitation and staining of proteins are conducted. This technique is analogous to *Southern blotting* (electrophoresed DNA blotted onto a membrane), and *Northern blotting* (electrophoresed RNA blotted onto a membrane).

An example of this technique applied to the detection of human immunodeficiency virus type 1 (HIV-1) antibodies is shown in Figure 16-8. HIV-1 antigens are separated according to molecular weight by gel electrophoresis and then are transferred to a nitrocellulose membrane by electro-blotting. A serum sample is then incubated with a strip of the membrane. HIV-1 antibodies in the sample bind to the viral antigens transferred to the strip as discrete bands. After washing, the strip is incubated with an alkaline phosphatase antihuman immunoglobulin conjugate. After a further washing step, the nitrocellulose strip is incubated with an alkaline phosphatase substrate solution (5-bromo-4-chloro-3-indolyl phosphate and nitroblue tetrazolium) to reveal where anti–HIV-1 antibody is bound to specific viral antigens fixed in the membrane.

Protein transfer and immobilization following separation by electrophoresis, isoelectric focusing, sodium dodecyl sulfate polyacrylamide electrophoresis (see Chapter 12 for further discussion of these techniques), or other methods provide a powerful tool for the analytical study of proteins present in low concentrations in cell culture or body fluids. When applied to antigen assays, concentrations of antigen as low as 500 ng/mL or 2.5 ng/band in the gel can be detected by this method. The detection limit of the technique can be lowered to approximately 100 pg by using chemiluminescence labels on the antibody.[10,47]

Dot Blotting

A similar technique that bypasses the electrophoretic separation step is known as *dot blotting*. A protein sample to be analyzed is applied to a membrane surface as a small "dot" and is dried. The membrane is then exposed to a labeled antibody specific for the test antigen contained in the dotted protein mixture. After washing, bound labeled antibody is detected with a photometric or chemiluminescent detection system.

QUANTITATIVE METHODS

Several immunochemical techniques have been used to quantify analytes of clinical interest. They include radial immunodiffusion (RID) and electroimmunoassays, turbidimetric and nephelometric assays, and labeled immunochemical antibody assays.

Radial Immunodiffusion and Electroimmunoassay

Typically, the two most commonly encountered gel-based methods for quantitative immunochemical studies are RID immunoassay and electroimmunoassay ("rocket" technique).

Radial Immunodiffusion Immunoassay

With this technique, a concentration gradient is established for a single reactant, usually the antigen. The antibody is

tahir99-VRG & vip.persianss.ir

uniformly dispersed in the gel matrix. Antigen is allowed to passively diffuse from a well into the gel, and immune precipitation occurs until antibody excess exists. The antigen-antibody interaction is manifested by a defined ring of precipitation around the antigen well, and ring diameter will increase with increased antigen concentration. Calibrators are run at the same time as the sample, and a calibration curve of ring diameter versus concentration is plotted. Under equilibrium conditions, a linear relationship exists between antigen concentration and the square of the precipitin ring diameter.[57] In addition, the precision of the measurement of the ring diameter is better when equilibrium is established. However, quantitative data can also be derived by reading the ring diameter before equilibrium is established.[23] This approach, although less precise, is often more practical for a clinical laboratory if time is at a premium. Antigen concentrations are calculated in both the preequilibrium and equilibrium methods[23,57] by plotting the square of the precipitin ring diameter against calibrating antigen concentrations. RID can be made more sensitive by using PEG to enhance precipitin line formation or by using ^{125}I- or enzyme-labeled reagents.[33,61,69]

Electroimmunoassay

In *electroimmunoassay,* as in RID, a single concentration gradient is established for the antigen, but in this case, an applied voltage is used to drive the antigen from the application well into a homogeneous suspension of antibody in the gel (Figure 16-9).[51] Unlike RID, this produces a unidirectional migration of antigen and results in a lower limit of detection for electroimmunoassay methods. The height of the resulting rocket-shaped precipitin line is proportional to the antigen concentration. Quantitation is affected by using calibrators on the same plate and estimating the concentrations of unknowns from the heights of the "rockets" obtained. The calibration curve is linear only over a narrow concentration range, so samples may have to be diluted or concentrated as necessary. Electroimmunoassay methods produce the best results, with antigens having a strong anodic mobility and intermediate to low molecular weight. Proteins such as transferrin, C3, or IgG, with low anodal mobility or virtually no net charge at pH 8.6 (the most common pH used for the method), can be modified by carbamylation or can be run at a lower pH to make their measurements by electroimmunoassay feasible. Other modifications, such as use of an intermediate gel that causes precipitation of C3, allow measurement of C3d in human serum and illustrate the exceptional versatility of this method.[9]

Turbidimetric and Nephelometric Assays

Turbidimetry and nephelometry are convenient techniques for measuring the rate of formation of immune complexes in vitro. Instrumental principles for these methods are described in Chapter 10. It has been found that the reaction between antigen and antibody begins within milliseconds and continues for hours.[30] Both turbidimetric and nephelometric immunochemical methods using rate and pseudoequilibrium protocols have been described for proteins, antigens, and haptens. In rate assays, measurements are usually made within the first few minutes of the reaction, when the largest change *(dIs/dt)* in intensity of scattered light *(Is)* with respect to time occurs. For so-called equilibrium assays, it is necessary to wait 30 to 60 minutes. For the purpose of this discussion, such conditions are referred to as *pseudoequilibrium,* because true equilibrium is not reached within the time allowed for these assays. Measurement of the *rate* of immune complex formation can also be used for quantitative immunochemical studies. Either *dIs*/*dt* or the time required to reach peak rate can be related to antigen concentration in a manner analogous to any other rate methodology. Rate nephelometric assays have the advantage that blank correction is not required, and that several samples can be assayed in a few minutes instead of the 30 to 60 minutes required for pseudoequilibrium methods.[6,14,37] The analytical performance of nephelometric or turbidimetric assays can be significantly improved by increasing the reaction rate by adding water-soluble linear polymers. This allows the use of much lower reactant concentrations and results in more stable immune complexes.[13]

Nephelometric methods in general are more sensitive than turbidimetric assays and have an average lower limit of detection of 0.1 to 10 mg/L for a serum protein. Lower detection limits are obtained in cerebrospinal fluid and urine because of their lower lipid and protein concentrations, resulting in a better signal-to-noise ratio. In addition, for low molecular weight proteins [e.g., myoglobin (MW, 17,800 Da)], assay

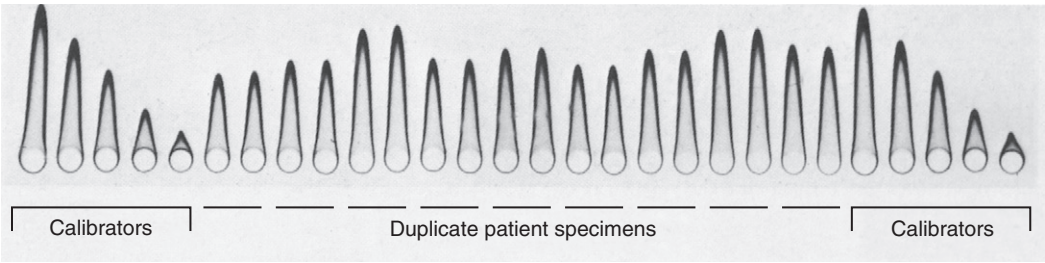

Figure 16-9 Rocket immunoelectrophoresis of human serum albumin. Patient samples were applied in duplicate. Standards were placed at opposite ends of the plate.

tahir99-VRG & vip.persianss.ir

detection limits can be lowered using a latex-enhanced procedure based on antibody-coated latex beads.[29]

Nephelometric and turbidimetric assays have also been applied to the measurement of drugs (haptens) using *inhibition techniques*. The reagent is made by attaching the drug of interest to a carrier molecule, such as bovine serum albumin. The hapten-bound albumin then competes with free hapten (drug introduced in sample) for the antihapten antibody. In the presence of free hapten, immune complex formation is decreased, because more antibody sites are saturated; thus light scattering is decreased. This decrease in light scattering is related to the concentration of free hapten. Both kinetic and pseudoequilibrium methods have been described.[25]

Particle-enhanced turbidimetric inhibition immunoassay (PETINIA) is another type of agglutination immunoassay that measures decreasing agglutination in the presence of increasing concentrations of analyte. The reagents comprise an antibody to the analyte of interest and a reagent analyte of interest linked to a latex bead. In the absence of analyte in a specimen, reagent antibody binds to the reagent analyte linked to the latex bead, resulting in increased turbidity. When a specimen with high analyte levels is added to the reagents, the reagent antibody is bound by the analyte in the specimen and not to the reagent analyte linked to the latex bead. Thus, the presence of specimen analyte results in less turbidity.

Labeled Immunochemical Assays

The previously discussed methods rely on immune complex formation as an index of antigen-antibody reaction. As demonstrated previously in equation (1), the overall reaction occurs in sequential phases, and only the final phase is the formation of the immune complex. However, the initial binding of the antibody and antigen has been demonstrated to be very useful analytically and has been used with labeled antigens and antibodies to develop many sensitive and specific immunochemical assays. The reaction describing this initial binding and the kinetic constant for the overall reaction are shown in equations (3a) and (3b), respectively:

$$\mathrm{Ab} + \mathrm{Ag} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{AbAg} \qquad \textbf{(3a)}$$

$$K = \frac{[\mathrm{AbAg}]}{[\mathrm{Ab}][\mathrm{Ag}]} \qquad \textbf{(3b)}$$

where

k_1 = the rate constant for the forward reaction

k_{-1} = the rate constant for the reverse reaction

K = the equilibrium constant for the overall reaction

As would be predicted from the law of mass action, the concentration of Ab, Ag, and AbAg will be dependent on the magnitude of k_1 and k_{-1}. For polyclonal antiserum, the average avidity of the antibody populations will determine *K* (typically 10^8 to 10^{10} L/mol), and the magnitude of k_1 in comparison with k_{-1} will determine the ultimate limit of detection attainable with a given antibody population.

The original assays used radioactive labels, but concerns about safe handling and disposal of radioactive reagents and waste have led to the development of alternative nonisotopic labels (Table 16-1).[47,66] In this section, the methodologic principles on which these assays are based and the factors that affect their analytical sensitivity are discussed. In addition, specific examples of these assays and the types of labels that are used in them are evaluated. Commercial versions and applications of these assays are discussed in other chapters (see Chapters 10 and 19).

TABLE 16-1 Labels Used for Nonisotopic Immunoassay

Chemiluminescent	Acridinium ester, sulfonyl acridinium ester, isoluminol
Cofactor	Adenosine triphosphate, flavin adenine dinucleotide
Enzyme	Alkaline phosphatase, marine bacterial luciferase, β-galactosidase, firefly luciferase, glucose oxidase, glucose-6-phosphate dehydrogenase, horseradish peroxidase, lysozyme, malate dehydrogenase, microperoxidase, urease, xanthine oxidase
Fluorophore	Europium chelate, fluorescein, phycoerythrin, terbium chelate
Free radical	Nitroxide
Inhibitor	Methotrexate
Metal	Gold sol, selenium sol, silver sol
Particle	Bacteriophage, erythrocyte, latex bead, liposome, quantum dot
Phosphor	Upconverting lanthanide-containing nanoparticle
Polynucleotide	DNA
Substrate	Galactosyl-umbelliferone

Methodologic Principles

To exploit the exquisite specificity and the enhanced sensitivity that are possible with immunochemical assays, various methodological principles have been applied in their development. These include competitive and noncompetitive reaction formats and different processing schemes for performing the assays.

Competitive versus Noncompetitive Reaction Formats

The two major reaction formats that are used in immunochemical assays (Figure 16-10) are termed *competitive* (limited reagent assays) and *noncompetitive* (excess reagent, two-site, or sandwich assays).

Competitive Immunoassays. In a *competitive* immunochemical assay, all reactants are mixed together *simultaneously* or *sequentially*. In the simultaneous approach, the labeled antigen (Ag*) and the unlabeled antigen (Ag) compete for binding to the antibody. In such a system, the avidity of

tahir99-VRG & vip.persianss.ir

Competitive (limited reagent)

Simultaneous

$$Ab + Ag + Ag{-}L \rightleftharpoons Ab{:}Ag + Ab{:}Ag{-}L$$
(free) (bound)

Sequential

$$\text{Step 1 } Ab + Ag \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ab{:}Ag + Ab$$

$$\text{Step 2 } Ab{:}Ag + Ab + Ag{-}L \rightleftharpoons Ab{:}Ag + Ab{:}Ag{-}L + Ag{-}L$$

Noncompetitive (excess reagent, two-site, sandwich)

Figure 16-10 Immunoassay designs. *L*, Label.

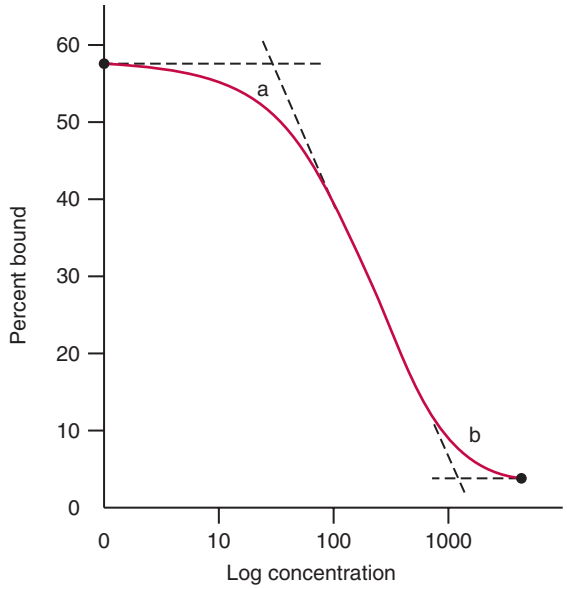

Figure 16-11 A schematic diagram of the dose-response curve for a typical competitive immunoassay. The analytically useful portion of the curve is bracketed by points *a* and *b*.

the antibody for both labeled and unlabeled antigen must be the same. Under these conditions, the probability of the antibody binding the labeled antigen is inversely proportional to the concentration of unlabeled antigen; hence, bound label is inversely proportional to unlabeled antigen concentration.

In a *sequential* competitive assay, unlabeled antigen is first mixed with excess antibody, and binding is allowed to reach equilibrium (see Figure 16-10, step 1). Labeled antigen is then sequentially added (step 2) and is allowed to equilibrate. After separation, the bound labeled antigen is determined and is used to calculate the unlabeled antigen concentration. Using this two-step method, a larger fraction of the unlabeled antigen is bound by the antibody than in the simultaneous assay, especially at low antigen concentrations. Consequently, this strategy provides a twofold to fourfold improvement in the detection limit of provided $k_1 >> k_{-1}$. This improvement in detection limit results from an increase in AgAb binding (and thus a decrease in Ag* binding), which is favored by the sequential addition of Ag and Ag*. If $k_1 >> k_{-1}$, dissociation of AgAb becomes more likely, resulting in increased competition between Ag* and Ag. A typical competitive immunochemical assay binding curve is shown in Figure 16-11.

Noncompetitive Immunoassays. In a *noncompetitive immunochemical assay*, a capture antibody first is passively adsorbed or covalently bound to the surface of a solid phase. Various approaches for attaching the capture antibody are shown in Box 16-2. The simplest involves direct attachment to the solid phase. However, this can lead to some loss of antibody-binding capacity because of steric factors or attachment of the antibody via its Fab region. To protect the binding properties of the antibody, more complex sequences have been devised. For example, the solid support is coated with an antispecies antibody, and then the antispecies antibody used to immobilize the capture antibody via an antigen-antibody reaction.

In the first stage of the assay, the antigen from the sample is allowed to react with the solid phase, capture antibody; other proteins are washed away, and a labeled antibody (conjugate) is added that reacts with the bound antigen through a second and distinct epitope. After washing again, the bound label is determined, and its concentration or activity is directly proportional to the concentration of the antigen.

In noncompetitive assays, the capture and labeled antibody are polyclonal or monoclonal. If monoclonal antibodies having specificity for distinct epitopes are used, it is possible to incubate the sample and conjugate simultaneously with the capture antibody, thus simplifying the assay protocol.

Noncompetitive immunoassays are performed in a simultaneous (one-step) or sequential (two-step) mode. However, in the simultaneous mode, a situation can occur in which a high concentration of analyte can saturate both capture and labeled antibodies. When this occurs, the calibration curve of the assay exhibits a "hook effect," in which the assay response drops off at high analyte concentrations. Under these conditions, the analyte is present in such high concentrations that it reacts simultaneously with the capture antibody and the labeled antibody. This reduces the number of complexes formed and produces a falsely low result. Assays for analytes for which the normal pathologic concentration range is very wide (e.g., tumor markers) are particularly prone to this problem. Dilutions of a sample are usually reanalyzed to

BOX 16-2 Immobilization Schemes for Preparation of Solid Phase Antibodies for Use in Immunoassay

AB, Capture antibody.

tahir99-VRG & vip.persianss.ir

check for this type of analytical interference. The hook effect can be eliminated by adopting a sequential assay format[64] and by ensuring that the concentrations of capture and labeled antibody are sufficiently high to cover analyte concentrations over the entire analytical range of the assay.

Heterogeneous versus Homogeneous Immunochemical Assays

Immunochemical assays that require separation of free from bound labels are termed *heterogeneous;* those that do not are called *homogeneous.*
