Heterogeneous Assays. Heterogeneous assays implicitly assume that $k_1 >> k_{-1}$ and that a variety of physical separation techniques are used to separate the free-label (Ag*) from the bound-label antigen (Ag*Ab). The most widely used of these techniques are precipitation and solid phase adsorption.

Precipitation of the bound-labeled antigen (Ag*Ab) from the reaction mixture can be achieved chemically by the addition of a protein-precipitating chemical, such as $(NH_4)_2SO_4$, or immunologically by the addition of a second, "precipitating" antibody. In the latter approach, if the primary antibody was obtained from rabbit antiserum, the precipitating antibody would be contained in a goat or sheep antiserum raised against rabbit globulin. This approach has the advantage that it can be used for practically any assay; however, it has the disadvantage that it usually requires longer assay times and additional processing steps.

Solid phase adsorption is the separation technique that currently is the most popular and widely used in both manual and automated immunoassays (see Chapter 19). In this technique, the binding and competition of labeled and unlabeled antigens for the binding sites of the antibody occur on the surface of a solid support onto which the capture antibody has been attached by physical adsorption or covalent bonding. Several different types of solid support have been used, including the inner surface of plastic tubes or wells of microtiter plates and the outer surface of insoluble materials, such as cellulose or magnetic latex beads or particles. With the tubes and microtiter plates, the solid surface containing the attached antibody and the bound antigen is washed "in place," and indicator reagents are subsequently added to complete the assay. When beads or particles are used, they are added directly to the reaction mixture and after incubation are removed by centrifugation or magnetic separation. After the supernatant has been removed by siphoning or decanting, the beads or particles are washed and indicator reagents subsequently added to complete the assay.

Homogeneous Assays. The development of homogeneous assays that do not require separation of bound- and free-labeled antibody or antigen was a major advance in the field of immunochemical analysis. In this type of assay, the activity of the label attached to the antigen is directly modulated by antibody binding, with the magnitude of the modulation being proportional to the concentration of the antigen or antibody being measured. Consequently, in practice it is necessary to incubate only the sample containing the analyte antigen with the labeled antigen and antibody and then to directly measure the activity of the label "in place," thus making these assays technically easier and faster. The original homogeneous immunoassay was developed for drug analysis and used a nitroxide spin label; this was termed a *free radical immunoassay technique.*[55] The electron spin resonance spectrum of this label was modulated when the nitroxide-labeled drug was bound by a drug-specific antibody. This procedure was quickly superseded by homogeneous immunoassays that used enzyme labels and could be performed on spectrophotometric analyzers [see subsequent descriptions of enzyme multiplied immunoassay technique (EMIT) and cloned enzyme donor immunoassay (CEDIA)].[36,70] A homogeneous sandwich format chemiluminescent immunoassay has also been developed that expands the scope of homogeneous assays to large molecules [see subsequent description of luminescent oxygen channeling immunoassay (LOCI)].[80]

Analytical Detection Limits

The analytical detection limits of competitive and noncompetitive immunoassays are determined principally by the affinity of the antibody and the detection limit of the label used, respectively.[21,39,40,67] Calculations have indicated that a lower limit of detection of 10 fmol/L (i.e., 600,000 molecules of analyte in a typical sample volume of 100 μL) is possible in a competitive assay using an antibody with an affinity of 10^{12} L/mol. Table 16-2 illustrates theoretical detection limits for isotopic and nonisotopic labels. A radioactive label, such as ^{125}I, has low specific activity (7.5 million labels necessary for detection of 1 disintegration/s) compared with enzyme labels and chemiluminescent and fluorescent labels. Enzyme labels provide an amplification (each enzyme label produces many detectable product molecules), and the detection limit for an enzyme can be improved by replacing the conventional photometric detection reaction by a chemiluminescent or bioluminescent reaction. The combination of amplification and an ultrasensitive detection reaction makes noncompetitive chemiluminescent immunoassays among the most sensitive types of immunoassay. Fluorescent labels also have high specific activity, and a single high-quantum yield fluorophor can produce 100 million photons/s. In practice, several factors degrade the detection limit of an immunoassay; these include background signal from the detector, assay reagents, and nonspecific binding of the labeled reagent.

Secondary labels, such as biotin, can be used to introduce amplification into an immunoassay. The binding constant of the biotin-avidin complex is extremely high (10^{15} L/mol); capitalizing on this system allows immunoassay systems to be devised that are even more sensitive than simple antibody systems. A biotin-avidin system uses a biotin-labeled soluble antibody. Biotin can be attached to the antibody in relatively high proportion without loss of immunoreactivity.[5,31] When an avidin-conjugated label is added, a complex of Ag:Ab-biotin:avidin label is formed. Further amplification can be achieved by a biotin:avidin:biotin linkage, because the binding ratio of biotin : avidin is 4 : 1. If the label is an enzyme, then large numbers of enzyme molecules in the complete complex provide a large increase in enzymatic activity coupled with

TABLE 16-2 Detection Limits for Isotopic and Nonisotopic Immunoassay Labels

Label	Detection Limit in Zeptomoles* (10^{-21} moles)	Method
Alkaline phosphatase	50,000	Photometry
	300	Time-resolved fluorescence
	100	Fluorescence
	10	Enzyme cascade
	1	Chemiluminescence

the small amount of antigen being determined, and the assay is correspondingly more sensitive.

Examples of Labeled Immunoassays

In the decade following the pioneering developments of Yalow and Berson,[93] all competitive and noncompetitive immunoassays used a radioactive label in a competitive assay format. Since the introduction of enzyme immunochemical assays in the 1970s,[55,70] a vast array of sophisticated immunochemical assays have evolved. Specific examples of several of these assays follow; others are briefly described in Box 16-3.

Radioimmunoassay

Radioimmunoassays (RIAs) were developed in the 1960s and used radioactive isotopes of iodine (^{125}I, ^{131}I) and tritium (^{3}H) as labels.[20,93] Radiolabeling of antigen with an isotope can cause changes in reactivity with the antibody. Therefore labeled and unlabeled antigens always need to be evaluated when a competitive assay is used to ensure that the antibody reacts equally with each form. Labeled antibody noncompetitive assays (immunoradiometric or "sandwich" assay) have the advantage of not requiring a quantity of purified antigen because the antigen does not have to be labeled. This also obviates potential problems that may be caused by iodination of labile antigens. Antibodies are relatively stable proteins that are less difficult to label without damaging the function of the protein. Combinations of labels (e.g., ^{57}Co and ^{125}I) have been used for simultaneous assays of lutropin and follitropin,[87] and thyrotropin and free thyroxine.

Enzyme Immunoassay (EIA)

Enzyme immunoassays use the catalytic properties of enzymes to detect and quantify immunologic reactions. In practice, enzyme-labeled antibodies or antigens (i.e., conjugates) are first allowed to react with ligands. Bound label is then separated and enzyme substrates are subsequently added. Measurement of the resultant decrease in substrate concentration or increase in product concentration is used to detect or quantify the antigen-antibody reaction. Alkaline phosphatase, horseradish peroxidase, glucose-6-phosphate dehydrogenase, and β-galactosidase enzyme labels predominate in EIA.[27,28] Enzyme-labeled antibody and antigen conjugates are prepared by covalent coupling procedures using bifunctional reagents [e.g., glutaraldehyde, *N*-succinimidyl-3-(pyridyl) propionate].[4]

Various detection systems have been used to monitor and quantify EIAs. Assays that produce compounds that can be monitored photometrically are very popular, because compact, high-performance photometers are available. However, EIAs that use fluorescent- or chemiluminescent-labeled substrates or products are often preferred to photometry-based assays owing to the inherent sensitivity of fluorescent and chemiluminescent measurements (see Chapter 10 and Table 16-2). Immunoassays that incorporate horseradish peroxidase as a label can be assayed by chemiluminescence using a mixture of (1) luminol, (2) peroxide, and an (3) enhancer such as *p*-iodophenol, or by using an acridan derivative.[2] Umbelliferone phosphate is a nonfluorescent substrate that is converted to the highly fluorescent umbelliferone by alkaline phosphatase.[24] A very sensitive assay for alkaline phosphatase labels uses a chemiluminescent adamantyl 1,2-dioxetane aryl phosphate substrate.[10] The enzyme dephosphorylates the substrate, which decomposes with a concomitant long-lived glow of light [detection limit for alkaline phosphatase using this assay is ≈1 zeptomole (10^{-21} moles)]. Enzyme cascade reactions have also been applied to the detection of enzyme labels in EIA; the principle of a cascade assay for alkaline phosphatase is illustrated in Figure 16-12. The advantage of such an assay is that it combines the amplification properties of two enzymes—the alkaline phosphatase label and the alcohol dehydrogenase in the assay reagent—thus producing a very sensitive assay (see Table 16-2).

BOX 16-3 Examples of Other Nonisotopic Immunoassays

Bioluminescent Immunoassays[66]
Native or recombinant apoaequorin (from the bioluminescent jellyfish *Aequorea*) is used as the label. It is activated by reaction with coelenterazine, and light emission at 469 nm is triggered by reaction with calcium ions (calcium chloride).

Erenna Immunoassay[72,74,79,91]
The Erenna Immunoassay System utilizes a modified microparticle-based sandwich immunoassay and single-molecule counting technology. It integrates capillary flow, laser-induced fluorescence, a highly sensitive detection optics module, and a 384-well plate format for sample analysis.

Fluorescence Excitation Transfer Immunoassay[81]
Homogeneous competitive assay in which a fluorophore (donor)-labeled antigen competes with an antigen in the sample for binding sites on an antibody labeled with a fluorescent dye (acceptor). The fluorescence of the donor is quenched when it is bound to the acceptor-labeled antibody.

Immuno-PCR[71]
Heterogeneous immunoassay in which a piece of single- or double-stranded DNA is used as a label for an antibody in a sandwich assay. Bound DNA label is amplified using the polymerase chain reaction (PCR). The amplified DNA product is separated by gel electrophoresis and quantitated by densitometric scanning of an ethidium-stained gel.

Nanotechnology-Based Assays[6,17,18,49,92-95]
A variety of immunoassays that employ nanoparticles, spheres, or tubes as solid phases.

Phosphor Immunoassay[60,96]
Heterogeneous immunoassay in which an upconverting phosphor nanoparticle is used as a label. The nanoparticle (200- to 400-nm diameter) is a crystalline lanthanide oxysulfide. It absorbs two or more photons of infrared light (980 nm) and produces light emission at a shorter wavelength (anti-Stokes shift). The phosphorescence is not influenced by reaction conditions (e.g., temperature, buffer), and no upconverted signal is received from biological components in the sample (low background). Multiplexing is possible because different types of particles produce different wavelengths of phosphorescence [e.g., yttrium/erbium oxysulfides are green (550 nm), yttrium/thulium oxysulfide particles are blue (475 nm)].

Quantum Dot Immunoassay[16,32,68]
Heterogeneous immunoassay in which a nanometer-sized (less than 10 nm) semiconductor quantum dot is used as a label. A quantum dot is a highly fluorescent nanocrystal composed of CdSe, CdS, ZnSe, InP, or InAs or a layer of ZnS or CdS on, for example, a CdSe core. Multiplexing is possible with these labels because the emission properties can be modulated by changing the size and composition of the nanocrystal (e.g., CdS emits blue light, InP emits red light).

Solid Phase, Light-Scattering Immunoassay[65]
Indium spheres are coated on glass to measure an antibody binding to an antigen. Binding of antibodies to antigens increases dielectric layer thickness, which produces a greater degree of scatter than in areas where only an antigen is bound. Quantitation is achieved by densitometry.

Surface Effect Immunoassay[75]
An antibody is immobilized on the surface of a waveguide (a quartz, glass, or plastic slide, or a gold- or silver-coated prism), and binding of an antigen is measured directly by total internal reflection fluorescence, surface plasmon resonance, or attenuated total reflection.

Types of enzyme-linked immunoassay include (1) enzyme-linked immunosorbent assay (ELISA), (2) EMIT, and (3) CEDIA.

Enzyme-Linked Immunosorbent Assay. ELISA is a heterogeneous EIA technique that is widely used in clinical analyses.[22,83] In this type of assay, one of the reaction components is nonspecifically adsorbed or covalently bound to the surface of a solid phase, such as a microtiter well, a magnetic particle, or a plastic bead. This attachment facilitates separation of bound- and free-labeled reactants. In the most common approach to using the ELISA technique, an aliquot of sample or calibrator containing the antigen to be quantitated is added to and allowed to bind with a solid phase antibody. After washing, enzyme-labeled antibody is added and forms a "sandwich complex" of solid phase Ab-Ag-Ab enzyme. Unbound antibody is then washed away, and enzyme substrate is added. The amount of product generated is proportional to the quantity of antigen in the sample. Specific antibodies in a sample can also be quantified using an ELISA procedure, in which antigen instead of antibody is bound to a solid phase and the second reagent is an enzyme-labeled antibody specific for the analyte antibody. Also, ELISA assays have been used extensively for detection of antibodies to viruses and autoantigens in serum or whole blood.[84] In addition, enzyme conjugates coupled with substrates that produce visible products have been used to develop ELISA-type assays with results that can be interpreted visually. Such assays have been found to be very useful in screening, point-of-care, and home testing applications.

Enzyme Multiplied Immunoassay Technique. EMIT is a homogeneous EIA that is very widely used in clinical analyses, an illustration of which is shown in Figure 16-13. Because EMIT does not require a separation step, it is simple to perform and has been used to develop a wide variety of drug, hormone, and metabolite assays.[70] Because of their operational simplicity, EMIT-type assays are easily automated and are included in the repertoire of many automated clinical and immunoassay analyzers (see Chapter 19). In this technique, antibody against the analyte drug, hormone, or metabolite is added together with substrate to the patient's sample. Binding

of the antibody and analyte occurs. An aliquot of the enzyme conjugate of the analyte is then added as a second reagent; the enzyme hapten (analyte) conjugate binds with the excess analyte antibody, forming an antigen-antibody complex. This binding of the analyte antibody with the enzyme analyte conjugate affects enzyme activity by physically blocking access of the substrate to the active site of the enzyme, or by changing the conformation of the enzyme molecule and thus altering its activity. To complete the assay, the resultant enzyme activity is measured. The relative change in enzyme activity resulting from the formation of the antigen-antibody complex is proportional to the hapten concentration in the patient's sample. Concentration of the analyte is calculated from a calibration curve prepared by analyzing calibrators that contain known quantities of the analyte in question.

Cloned Enzyme Donor Immunoassay. As shown in Figure 16-13, CEDIA is a homogeneous EIA; it was the first EIA designed and developed using genetic engineering techniques.[36] Inactive fragments (the enzyme donor and acceptor) of β-galactosidase are prepared by manipulation of the Z gene of the *lac* operon of *E. coli.* These two fragments spontaneously reassemble to form active enzyme even if the enzyme donor is attached to an antigen. However, binding of antibody to the enzyme donor antigen conjugate inhibits reassembly, and no active enzyme is formed. Thus competition between the antigen and the enzyme donor antigen conjugate for a fixed amount of antibody in the presence of the enzyme acceptor modulates the measured enzyme activity (high concentrations of the analyte antigen produce the least inhibition of enzyme activity; low concentrations produce the greatest inhibition).

Fluoroimmunoassay

Examples of fluorophores that are used as labels in *fluoroimmunoassay* and their properties are listed in Table 16-3.[90] Initially, background fluorescence from drugs, drug metabolites, and protein-bound substances, such as bilirubin, limited the usefulness of this technique. However, this problem has largely been overcome by the use of rare earth (lanthanide) chelates and background rejection (time-resolved) procedures (see Chapters 10 and 19).[19,73] Fluorescent emissions from lanthanide chelates (e.g., europium, terbium, samarium) are long lived (greater than 1 μs) compared with the typical background fluorescence encountered in biological specimens. In a time-resolved fluoroimmunoassay, a europium chelate label is excited by a pulse of excitation light (0.5 μs), and the long-lived fluorescence emission from the label is measured after a delay (400 to 800 μs). By this time, any short-lived background signal has decayed.

Fluorescent polarization immunoassay is a type of homogeneous fluoroimmunoassay that is widely used to measure drugs and other small molecules (Figure 16-14).[41,63] The polarization of the fluorescence from a fluorescein-antigen conjugate is determined by its rate of rotation during the lifetime of the excited state in solution. A small, rapidly rotating fluorescein antigen conjugate has a low degree of polarization; however, binding to a large antibody molecule slows

TABLE 16-3 Properties of Fluorescent Labels

Fluorophore	Excitation, nm	Emission, nm	Fluorescence Quantum Yield*	Lifetime, ns
Fluorescein isothiocyanate	492	520	0.0-0.85	4.5
Europium (β-naphthoyl trifluoroacetone)	340	590, 613	–	500,000
Phycobiliprotein	550-620	580-660	0.5-0.98	–
Rhodamine B isothiocyanate	550	585	0.0-0.7	3.0
Umbelliferone	380	450	–	–

down the rate of rotation and increases the degree of polarization. Thus binding to antibody modulates polarization, and a homogeneous assay is possible.[42,56] As listed in Box 16-3, other types of homogeneous fluoroimmunoassays have been described in the literature.[28,46,64,81]

Chemiluminescence Immunoassay

Chemiluminescence is the name given to light emission produced during a chemical reaction (see Chapter 10). Isoluminol and acridinium esters are important examples of chemiluminescent labels used in *chemiluminescent immunoassay.* Oxidation of isoluminol by hydrogen peroxide in the presence of a catalyst, such as microperoxidase, produces a relatively long-lived light emission at 425 nm, and oxidation of an acridinium ester by alkaline hydrogen peroxide in the presence of a detergent (e.g., Triton X-100) produces a rapid flash of light at 429 nm. Acridinium and sulfonyl acridinium esters are high specific activity labels (detection limit for the label is 800 zeptomoles) that can be used to label both antibodies and haptens (Figure 16-15, *A*).[1,86]

Luminescent oxygen channeling immunoassay (LOCI) is a particularly important type of chemiluminescent immunoassay (Figure 16-16). It is one of the few homogeneous immunoassays that operate in a noncompetitive ("sandwich") format and can be used to assay large molecules. LOCI utilizes two reagent particles (sensitizer and chemiluminescer particles) that form a complex with the analyte of interest.[81] The presence of analyte links the two reagent latex particles in close proximity. The first particle contains a photosensitizer (e.g., phthalocyanine) and in the presence of light converts oxygen to singlet oxygen. The second chemiluminescer particle contains a chemiluminescent agent (e.g., olefin) that reacts with singlet oxygen to form a dioxetane that decomposes and emits light. This reaction occurs only if the two particles are in close proximity and the singlet oxygen can

diffuse efficiently from the sensitizer particle to the chemiluminescer particle. Singlet oxygen does not react with unbound chemiluminescer particles because of the short lifetime of this transient species in an aqueous environment.

An example of a sandwich immunoassay for thyroid-stimulating hormone (TSH) is illustrated in Figure 16-17. TSH binds to a biotinylated anti-TSH antibody, and this complex links the streptavidin-coated sensitizer particle to the anti-TSH antibody–coated chemiluminescer particle. Exposure of light results in emission of singlet oxygen from the photosensitive particle. The singlet oxygen activates the chemiluminescent particle to emit light that is then measured.[81]

Electrochemiluminescence Immunoassay

Ruthenium (II) tris(bipyridyl) (see Figure 16-15, *B*) undergoes an electrochemiluminescent reaction (620 nm) with tripropylamine at an electrode surface, and this chelate is now used as a label in competitive and sandwich *electrochemiluminescence immunoassays*. Using this label, various assays have been developed in a flow cell using magnetic beads as the solid phase. Beads are captured at the electrode surface, and an unbound label is washed out of the cell by a wash buffer. Label bound to the bead undergoes an electrochemiluminescent reaction, and the light emission is measured by an adjacent photomultiplier tube.[7,38]

Simplified Immunoassays

Integration of the technical advances made in molecular immunology with those made in the material and processing sciences has resulted in the development of a number of "simplified" immunoassays for use in physicians' offices or the home (i.e., the so-called point-of-care market). Early efforts were directed toward pregnancy and fertility testing and were based on agglutination and inhibition of agglutination using labeled red blood cells or latex particles in a slide format. Subsequently, sandwich immunoassays have been adapted for similar applications. For example, as listed in the package insert, the ICON II pregnancy test (Beckman Coulter, Fullerton, Calif) is an operationally simple and sensitive assay for human chorionic gonadotropin (hCG) that detects hCG down to 10 mIU/mL for serum and 20 mIU/mL for urine. As shown in Figure 16-18, the ICON II test is a sandwich EIA device that uses a murine monoclonal antibody, which is immobilized onto the surface of a microporous nylon

membrane located on top of an adsorbent pad.[82] The pad functions as a capillary pump to draw liquid through the membrane. To perform an analysis, an aliquot of urine is added to the surface of the membrane; hCG is removed as liquid is drawn through it, resulting in removal of hCG from the sample by its binding to the capture antibody on the membrane. Next, a matched murine monoclonal anti-hCG antibody alkaline phosphatase conjugate is added and is allowed to drain into the adsorbent pad. Wash solution is then added, followed by an indoxyl phosphate substrate. Bound conjugate converts this to an insoluble indigo dye, which appears as a discrete blue spot. The second generation of the ICON test includes two additional control zones. An immobilized anti–alkaline phosphatase zone acts as a procedural control; it binds the alkaline phosphatase conjugate and appears as a blue spot. Another zone contains an immobilized irrelevant murine monoclonal antibody; this detects the presence of heterophile antibodies in samples, particularly human antimouse antibodies.[8] These mimic antigen and bridge the capture and conjugated mouse antibodies, thus yielding what appears to be a positive result.

Newer tests require only the addition of sample, thus simplifying the assay protocol and minimizing possible malfunction resulting from operator error. Numerous one-step pregnancy tests are now available.[62] One uses a colloidal selenium particle (160-nm diameter) labeled with monoclonal anti–α-hCG antibody, which is red and easily visible. Sample (urine) is applied to the sample well and soaks into a glass fiber pad containing the conjugate. Any hCG in the urine sample combines with the selenium-labeled antibody, and the mixture migrates along a nitrocellulose track to a region where a line of polyclonal anti-hCG antibody and an orthogonal line of anti–α-hCG:hCG complex has been immobilized. The complex captures unreacted selenium-labeled anti–α-hCG to form a minus sign visible in the viewing window. If hCG is present in the urine sample, then the selenium-labeled anti–α-hCG:hCG complexes bind to the immobilized polyclonal anti-hCG, and a plus sign is formed, denoting a positive result. The remainder of the reaction mixture migrates to the end of the track and reacts with a Quinaldine Red pH indicator in an "end-of-assay" window to signal that the flow in the device has functioned correctly.

Another test device uses an absorbent strip that contains blue beads attached to an anti-hCG monoclonal antibody. As urine moves by capillary action through the strip, labeled antibodies are mobilized and move up the test strip, which contains regions of immobilized antibodies loaded with a blue dye. Each strip has separate windows for the positive, negative, and procedural controls. If hCG is present at a level of 25 mIU/mL or greater, a blue line becomes visible in the test region window. This region remains clear if the test is negative. A blue line appears in the reference region of the result window to show the test is complete and has worked correctly.

Simultaneous multianalyte immunoassays in which two or more analytes are detected in a single assay represent a further means of work simplification in immunoassay. Two different strategies have been developed based on discrete reaction zones or combinations of different labels. In the triage panel for a drugs of abuse point-of-care testing device (Biosite Incorporated, San Diego, Calif), simultaneous detection of up to nine drugs is achieved using discrete test zones on a small piece of nylon membrane.[12] Each test zone consists of antibodies for a specific drug immobilized on the membrane surface. This zone captures free gold-drug conjugate from the sample, antidrug antibody, and gold-drug conjugate reaction mixture and appears as a purple band. Combinations of distinguishable labels, such as europium (613 nm; emission lifetime, 730 μs) and samarium (643 nm; emission lifetime 50 μs) chelates, provide the basis of quantitative simultaneous immunoassays. These two chelates have different fluorescence emission maxima and different fluorescence decay times and thus can be easily distinguished by making measurements at 613 nm, delay time 0.4 ms (europium), and 643 nm, delay time 0.05 ms (samarium). An assay for free and bound prostate-specific antigen and an assay for myoglobin and carbonic anhydrase III are examples of tests combined in this simultaneous assay format.[54,85]

Protein Microarrays

Arrays of hundreds or thousands of micrometer-sized dots of antigens or antibodies immobilized on the surface of a glass or plastic chip are emerging as an important tool in proteomic studies and in assessing protein-protein interactions. This format facilitates simultaneous multianalyte immunoassays using, for example, enzyme or fluorophore-labeled conjugates. The arrays are made by printing or spotting 1-nL drops of protein solutions onto a flat surface, such as a glass microscope slide. In a typical sandwich assay, the array on the surface of the slide is incubated with sample and then with conjugate. Bound conjugate is detected with chemiluminescence or fluorescein using a scanning device. The pattern of the signal provides information on the presence and amount of individual analytes in the sample or the reactivity of a single analyte with the range of proteins arrayed on the surface of the slide.[77] (Such devices are discussed in greater detail in Chapter 10.)

Interferences in Immunoassays

Immunological assays are prone to interferences, in spite of the use of highly specific antibodies for molecular recognition of the analyte. Falsely low results can occur because of the hook effect at high antigen concentrations (see earlier discussion). False-negative or false-positive results are encountered if the sample contains anti–animal immunoglobulin antibodies. For example, in a two-site sandwich assay for hCG based on mouse antibodies, any human antimouse antibodies (HAMA) present in the specimen will recognize the immobilized mouse capture and mouse conjugate antibodies and will form a complex that is indistinguishable from an immobilized capture antibody:hCG:conjugate complex. This leads to a false-positive result. A false-negative result will be obtained if the HAMA react with the capture antibody or the conjugate to such an extent that specific antibody binding to

hCG is prevented. Many different types of circulating anti–animal immunoglobulin antibodies have been detected (e.g., human antigoat, human antibovine antibodies) and shown to interfere in immunoassays. In practice, this type of interference is minimized by including additives in the immunoassay reagents such as nonimmune serum or IgG from the species used to raise the antibodies used in the assay.[8,45,48]

CELL AND TISSUE-BASED IMMUNOCHEMICAL TECHNIQUES

Other analytical methods of clinical interest that employ antibodies include immunohistochemistry and agglutination assays.

Immunohistochemistry

The use of labeled antibody reagents as specific probes for protein and peptide antigens allows the researcher and the pathologist to evaluate single cells or pieces of tissue for their synthetic capability and/or phenotypic identity. Immunohistochemistry has been rapidly expanded by immunoenzymatic methods, especially with regard to the use of horseradish peroxidase–labeled (immunoperoxidase) assays. Using enzyme labels provides several advantages over fluorescent labels. They permit the use of fixed tissue embedded in paraffin, which provides excellent preservation of cell morphology and eliminates the problem of autofluorescence from tissue. In addition, immunoperoxidase stains are permanent, and only a standard light microscope is necessary to identify labeled features. The immunoperoxidase methods are also applicable to electron microscopy. Several approaches for immunoenzymatic assays have been used, including direct, indirect, peroxidase-antiperoxidase, and enzyme bridge methods.

Agglutination Assays

Agglutination assays have been used for many years for the qualitative and quantitative measurement of antigens and antibodies. In an agglutination method, the visible clumping of particulates, such as cells and latex particles, is used as an indicator of the primary reaction of antigen and antibody. Agglutination methods require stable and uniform particulates, pure antigen, and specific antibody. IgM antibodies are more likely to produce complete agglutination than are IgG antibodies because of the size and valence of the IgM molecule. Therefore, when only IgG antibodies are involved, it may be necessary to use chemical enhancement or an antiglobulin agglutination method. As with all immunochemical reactions in which aggregation is the measured end point, the ratio of antigen to antibody is critical. Extremes in antigen or antibody concentration will result in inhibition of aggregation.

An incomplete agglutination reaction is one in which the primary reaction occurs, but no or only minimal aggregation of the particles occurs. Many particles, such as erythrocytes and bacteria in solution, have a net negative charge (zeta potential), which causes mutual repulsion.[88] For successful agglutination, the antigen-antibody reaction must overcome this normal resistance. In the case of a weak antigen-antibody reaction, or one in which only IgG is involved, this mutual repulsion may be sufficient to inhibit agglutination completely or partially. In systems in which incomplete agglutination results, enhancement may be achieved by lowering the ionic strength or by introducing polymeric molecules, such as polymerized albumin (5% to 30%), dextran, polybrene, polyvinylpyrrolidone, or PEG.[88]

Hemagglutination refers to agglutination reactions in which the antigen is located on an erythrocyte. Erythrocytes not only are good passive carriers of antigen, they also are easily coated with foreign proteins and can be easily obtained and stored.

Direct testing of erythrocytes for blood group, Rh, and other antigenic types is used widely in blood banks; specific antisera, such as anti-A, anti-C, and anti-Kell, are used to detect such antigens on the erythrocyte surface.

In *indirect* or *passive* hemagglutination, the erythrocytes are used as a particulate carrier of foreign antigen (and in some tests of antibodies); this technique has wide applications. Other materials available in the form of fine particles, such as bentonite and latex, also have been used as antigen carriers, but they are more difficult to coat, standardize, and store. In a related variation of this technique, known as *hemagglutination inhibition,* the ability of antigens, haptens, or other substances to specifically inhibit hemagglutination of sensitized (coated) cells by antibody is determined.

In general, agglutination methods are sensitive but are not as quantitative as other immunochemical methods discussed thus far. Nonisotopic immunoassays, especially EIAs, are as convenient as agglutination reactions and therefore are replacing agglutination methods in many laboratories.

CHAPTER 17

Nucleic Acid Techniques

Carl T. Wittwer, M.D., Ph.D., and Noriko Kusukawa, Ph.D.

Molecular diagnostics requires techniques to detect extremely low concentrations of nucleic acids in a background of complex genomic structure. This chapter begins by considering the enzymes that allow us to process nucleic acids into forms suitable for analytical interrogation. We briefly touch on chemical and other processes that aid us in handling nucleic acids (nucleic acid isolation is discussed in detail in Chapter 39). We then discuss amplification techniques that are often necessary to observe or quantify nucleic acid sequences of interest. The tools used to detect or visualize nucleic acids are discussed. Finally, specific methods are described that allow identification, quantification, and/or segregation of individual nucleic acid species.

Molecular diagnostics is a highly competitive field, both in academics and in industry. Those using particular techniques, instruments, or probe designs may defend their choices with a commitment that approaches religious fervor. In this chapter, cute trade names and commercial references are avoided. To misquote the Bard's fool, "if you think our presentation less familiar, please accept that our intent was not to offend, perhaps inspection of the references will mend."

ENZYMES THAT ACT ON NUCLEIC ACIDS

Nucleic acid enzymes are critical tools for the techniques used in molecular diagnostics. Common enzymes that act on nucleic acids include those that synthesize nucleic acid polymers and those that process them into shorter fragments. These enzymes are critical for DNA replication and RNA transcription and must be present in all cells that replicate. In addition, a variety of unique enzymes found in bacteria and viruses act on specific nucleic acid sequences. Many of these enzymes have been purified and synthesized in vitro, sometimes "engineered" with alterations that improve their performance or stability. Our ability to manipulate nucleic acids in vitro with these enzymes has made modern molecular biology possible. Enzymes are used extensively in nucleic acid diagnostics, including sample preparation, probe labeling, signal generation, and amplification of targets and probes.

Nucleases are enzymes that hydrolyze one or more phosphodiester bonds in nucleic acid polymers.[67] Nucleases may require a free hydroxyl end *(exonucleases),* with specificity for the 3′ or 5′ end, or may act only on internal bonds *(endonucleases).* Nucleases can be DNA or RNA specific and may act only on double- or single-stranded polymers. For example, DNAse I digests double-stranded DNA (dsDNA), and S1 nuclease acts only on single-stranded DNA (ssDNA). DNase I can be used to specifically degrade DNA in nucleic acid mixtures when only RNA is of interest. RNAses are very stable enzymes that are common laboratory contaminants.

DNA glycosylases are enzymes that remove damaged nitrogenous bases while leaving the sugar-phosphate backbone of DNA intact. Uracil *N*-glycosylase (UNG) from the bacterium *Escherichia coli* is commonly used in molecular diagnostics to prevent carryover contamination of DNA from previous amplification reactions (see Contamination Control to Avoid False-Positive Results later in this chapter for details).

Restriction endonucleases are found in bacteria; these enzymes prevent replication of foreign DNA.[99] Their action is sequence specific, requiring recognition sequences of usually 4 to 10 nucleotides on a dsDNA molecule. Often, these recognition sequences are palindromic (meaning that the same sequence occurs on both of the complementary DNA strands). At each location where these sequences are found, the enzyme cuts both strands in a reproducible manner, resulting in staggered or blunt-end cuts. For example, *Eco*RI is a restriction enzyme from *E. coli* that recognizes the six-base sequence GAATTC and cuts between the G and the A on both strands, producing a staggered cut:

5′ … G/AATTC … 3′
3′ … CTTAA/G … 5′

Note that "blunt-end" cuts would be produced if an enzyme hydrolyzed the bond between A and T. Some restriction enzymes recognize nonpalindromic asymmetric sequences and cut outside of the recognition sequence. An example is *Fok*I, which recognizes the sequence 5′GGATG, and then cuts the two DNA strands 9 and 13 bases downstream of the recognition sequence, generating a four-base 5′ overhang.

Restriction enzymes are used for digesting large strands of DNA into smaller fragments and for preparing DNA from different sources to be joined together in cloning procedures. *Nicking enzymes* are restriction enzymes that cut only one strand of double-stranded nucleic acid. *Methylation-sensitive enzymes* are restriction enzymes that distinguish between

cytosine and 5-methylcytosine in the recognition sequence. In humans, methylation of cytosine is a common epigenetic modification of DNA and is important because it affects gene expression.

Ligases catalyze the formation of phosphodiester linkages between two nucleic acid chains.[48] DNA ligases are not sequence specific but require the presence of a complementary template. In contrast, RNA ligases used in mRNA processing do not require a template but are sensitive to sequence.

Polymerases catalyze the synthesis of complementary nucleic acid polymers using a parent strand as a template.[48] In vitro, these enzymes can extend an oligonucleotide primer that is annealed to a template strand. Extension requires that the 3′-OH of the extending end is free, and that nucleotide triphosphates (NTPs) are present in the reaction mixture. Extension stops if you run out of template or NTPs, or if no 3′-OH groups are available at the extending end. DNA polymerases generate DNA strands from a DNA template, whereas RNA polymerases generate RNA strands from a DNA template. Thermostable polymerases, such as *Thermus aquaticus (Taq)* DNA polymerase, are essential reagents for the automation of many nucleic acid amplification procedures because of their stability at the high temperatures used in these procedures. Some DNA polymerases also have exonuclease activity that can be 3′ to 5′, 5′ to 3′, or both. A polymerase with 3′ to 5′ exonuclease activity can correct mismatched base pairs at the 3′-end of the extending chain. Such *proofreading activity* increases polymerase *fidelity* by decreasing the number of errors or misincorporated bases. A polymerase with 5′ to 3′ exonuclease activity can increase polymerase *processivity* by cleaving any blocking probes or secondary structures, thereby increasing the number of bases incorporated for each extension.

Reverse transcriptase is found in retroviruses and catalyzes the synthesis of DNA from an RNA (or DNA) template.[2] Retroviruses have RNA genomes, and reverse transcriptase activity is required as part of their replication. Reverse transcriptases do not have proofreading activity and therefore are error prone compared with polymerases. This, however, allows viruses to mutate quickly and develop drug resistance. In vitro, reverse transcriptase is used to make complementary DNA (cDNA) copies of RNA in samples and may be used for cloning, probe preparation, and nucleic acid assays.

NUCLEIC ACID TREATMENTS THAT DO NOT USE ENZYMES

Sometimes nonenzymatic methods are used to process nucleic acids before amplification and/or analysis. This is not an exhaustive list, and others are discussed during various parts of the remainder of this chapter.

Sonication, shearing, or *chemical cleavage* can be used to cut DNA or RNA into smaller fragments so as to make the analytical processes that follow more efficient. Sonication generates nucleic acid fragments of 100 to 1000 bases in length, depending on the conditions used. Shearing can be performed by a compressed air device known as a *nebulizer.* For chemical cleavage, several metal-ion–catalyzed chemistries can cleave single-stranded and double-stranded nucleic acids. Some alkylating compounds can cleave and label nucleic acids at the same time. One example is 5-(bromomethyl)-fluorescein, which is catalyzed by metal ions to fragment RNA or DNA, and then labels those fragments with fluorescein.[10] This can be used in nucleic acid preparation for microarray analysis.

Bisulfite treatment of DNA is used to analyze the methylation status of cytosine (C) residues in DNA. Sodium bisulfite ($NaHSO_3$),[36] optionally used together with ammonium bisulfite,[97] converts C into uracil (U), but does not affect 5-methylcytosine. The chemical process of bisulfite treatment is shown in Figure 17-1. The process works effectively only on single-stranded DNA, and so the sample needs to be denatured by heat, alkali, or chaotropic agents such as urea or formamide. Analysis of the bisulfite-treated DNA is usually performed after nucleic acid amplification. DNA polymerases used for amplification will treat 5-methylcytosine as C (no change in sequence), but they will treat unmethylated C that is converted to U as a T (thus a sequence change of C to T). Many methods can be used to detect and quantify the altered sequences that result from bisulfite treatment of methylated DNA, including preferential amplification, detection with probes, melting techniques, and sequencing.[49] One limitation of bisulfite treatment is that it significantly degrades DNA.

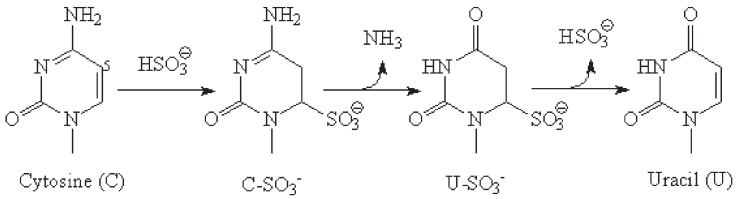

Figure 17-1 Bisulfite-mediated conversion of cytosine (C) to uracil (U) occurs in three steps. The first step is the addition of bisulfite to C. This reaction occurs at acid pH. The second step is the deamination of cytidine-bisulfite (C-SO_3^-) to produce uracil-bisulfite (U-SO_3^-), which is optimal at pH 5 to 6. Prior to analysis, U-SO_3^- is converted to U by adjusting the pH to alkali. The majority of methylation on the C residue in mammalian cells occurs at the carbon 5 position (shown in the structure of C), resulting in 5-methylcytosine, which is resistant to bisulfite-mediated conversion.

Depending on the protocol, as much as 90% of the DNA can be lost.

Affinity enrichment of methylated DNA is an alternative to bisulfite treatment that may provide higher yields. One example is to enrich methylated DNA by immunoprecipitation with an antibody raised against DNA containing 5-methylcytosine.[117] Up to 90-fold enrichment in methylated DNA can be achieved by immunoprecipitation. Another method is to use methylated DNA binding protein to capture double-stranded methylated DNA on an affinity column or other solid support.[83]

Reversal of formalin (formaldehyde) cross-linking is required before DNA or RNA can be analyzed from tissues prepared in formalin-fixed paraffin-embedded (FFPE) blocks. Formalin modifies nucleic acids with monomethylol groups, which cause nucleic acids to cross-link by forming methylene bridges to amino groups.[63] These cross-links interfere with many processes, including reverse transcription and polymerase reactions. Heating the DNA or RNA reverses cross-linking, and most protocols use alkali (pH 9 to 12) conditions to reverse formalin cross-linking in DNA and acid (pH 3 to 6) conditions for RNA. Depending on the age of the FFPE specimen, nucleic acid can be degraded into short fragments.

AMPLIFICATION TECHNIQUES

Achieving adequate detection limits is a central concern for clinical applications of nucleic acid analysis. Techniques that increase the amount of the nucleic acid target, the detection signal, or the probe are referred to as *amplification methods.* Examples of amplification methods are listed in Table 17-1. In *target amplification,* a well-defined segment of the nucleic acid region of interest (the target sequence) is copied many times by in vitro methods. Areas outside the target are not amplified. In *signal amplification,* the amount of target stays the same, but the signal is increased by one of several methods, including sequential hybridization of branching nucleic acid structures and continuous enzyme action on substrate that may be recycled. Finally, in *probe amplification,* the probe (or a product of the probe) is amplified only in the presence of the target. Amplification techniques often can achieve more than a million-fold amplification in less than an hour.

Polymerase Chain Reaction (PCR)—Target Amplification

When the amount of target nucleic acid is increased by synthetic in vitro methods, target amplification occurs. PCR[90] is the best known and most widely applied of the target amplification methods. Because of the commercial availability of thermostable DNA polymerases, kits, and instrumentation, this method has been widely adopted in research and is routinely used in the clinical laboratory.

Details of the PCR Process

PCR requires a thermostable DNA polymerase, (deoxy) nucleotides of each base (collectively referred to as *dNTPs*), the target sequence, and a pair of oligonucleotides (referred to as *primers*) complementary to opposite strands flanking the sequence to be amplified (the target sequence). In the first step, target duplexes are denatured into single strands by heat (Figure 17-2). When the mixture is cooled, primers provided in great excess (usually over a million times the concentration of the initial target) specifically anneal to complementary sequences on the target. Once the primers are annealed, the action of the polymerase synthesizes two new DNA strands by extending each of the two primers at their 3′ end. The primers are designed to recognize sequences of the target that

TABLE 17-1 Common Amplification Techniques

Techniques	Amplifies	Enzymes Used	Thermal Cycling
Polymerase chain reaction (PCR)[90]	Target	DNA polymerase (thermostable)	Yes
Transcription-mediated amplification (TMA)[46]	Target	Reverse transcriptase; RNA polymerase; RNase H	No
Self-sustained sequence replication (3SR)[32]			
Nucleic acid sequence–based amplification (NASBA)[15]			
Strand displacement amplification (SDA)[114]	Target	*Hinc*II; DNA polymerase I (exonuclease deficient)	No
Loop-mediated amplification (LAMP)[75]	Target	DNA polymerase	No
Whole genome amplification (WGA) or multiple displacement amplification (MDA)[19]	Target	Φ29 DNA polymerase	No
Ligase chain reaction (LCR)[120]	Target	DNA ligase (thermostable)	Yes
Antisense RNA amplification (aRNA)[80]	Target	T4 DNA polymerase; Klenow; S1 nuclease; T7 polymerase	No
Branched DNA (bDNA)[14]	Signal	Alkaline phosphatase	No
Serial invasive signal amplification[35]	Signal	Cleavase	No
Rolling circle amplification (RCA)[3,60]	Probe	T4 gene 32 protein; Φ29 DNA polymerase; DNA ligase (RAM)	No
Ramification amplification (RAM)[131]			

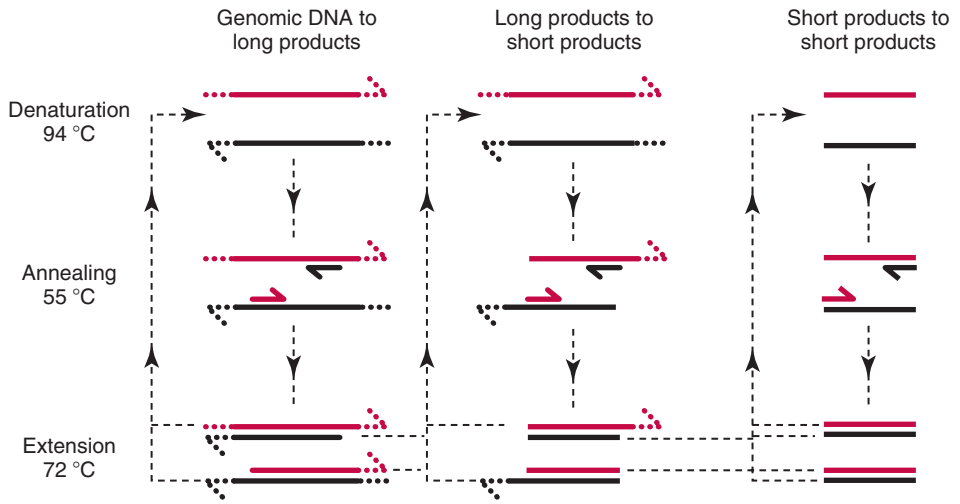

Figure 17-2 Schematic diagram of the polymerase chain reaction (PCR). Repetitive cycles of denaturation, annealing, and extension are paced by temperature cycling of the reaction. Two primers (indicated as short segments) anneal to opposite template strands *(long red and black lines)* to define the region to be amplified. Extension occurs from the 3′-ends *(indicated with half arrowheads)*. In each cycle, genomic DNA is denatured and annealed to primers that extend in opposite directions across the same region, producing long products of undefined length. Long products generated by extension of one of the primers anneal to the other primer during the next cycle, producing short products of defined length. Any short products present produce more short products. After n cycles, 2^n new copies of the amplified region (n long products + $[2^n - n]$ short products) are generated from each original genomic copy. A similar approach can be used to amplify RNA targets by initial reverse transcription of the RNA template to produce the DNA template.

are close enough together that the polymerase extends each strand far enough to include the priming site of the other primer. Usually, the optimal temperature for polymerization (or DNA synthesis) is an intermediate temperature between the annealing temperature (at which primer hybridizes to its target) and the denaturation temperature (at which the newly generated DNA strand dissociates from its template). The second cycle also begins with denaturation, but now twice as many strands (the original genomic DNA and the extension products from the first cycle) are available for primer annealing and subsequent extension. Temperature cycling (typically) employs three temperatures: a high temperature sufficient to denature the target sequence, a low temperature that allows annealing of the primers to the target, and a third temperature optimal for polymerase extension. The instrument that takes samples through the multiple steps of changing temperature is known as a *thermocycler.*

Repetitive thermocycling results in the exponential accumulation of the short product (consisting of primers and all intervening sequences). If the efficiency of each cycle is optimal, the number of target sequences doubles each cycle (the efficiency is 100% or 1.0). PCR efficiency depends on the primers and the temperature-cycling conditions, along with the presence or absence of polymerase inhibitors. Amplified products accumulate exponentially in the beginning cycles of PCR. At some point, however, the efficiency of amplification falls and eventually the amount of product plateaus (Figure 17-3) as the result of exhaustion of components or competition between primer and product annealing (i.e., the single strands of product are at such high concentrations that they anneal to each other rather than to the primers). The S-curve shape is similar to the logistical model for population growth. In a typical PCR reaction using 0.5 μmol/L of each primer, the maximum DNA concentration achievable is about 100 billion copies/μL.

With the addition of an initial reverse transcriptase step to form cDNA from RNA in the sample, RNA targets can be successfully amplified into DNA copies. Reverse transcription and DNA amplification steps usually are catalyzed by two different polymerases, but some thermostable enzymes (such as the *Tth* polymerase) have both DNA polymerase and reverse transcription activities, so that both steps can be performed in the same tube with the same enzyme.

After amplification, the products can be detected by various methods. Gel electrophoresis with ethidium bromide staining is a classical qualitative method that may suffice for many applications. When greater accuracy is required, one of the primers can be fluorescently labeled so that after PCR, the fragments can be sized on a *DNA sequencing* device. Alternatively, some form of hybridization assay can be used to verify or analyze the amplified product. Automated methods are always attractive, and closed-tube methods are particularly advantageous in the clinical laboratory. Adding a fluorescent dye or probe before amplification allows thermocyclers

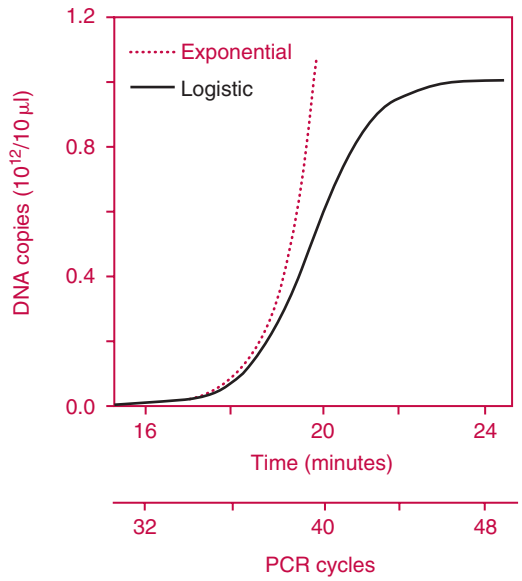

Figure 17-3 Exponential and logistic curves for DNA amplified by polymerase chain reaction (PCR). A doubling time of 30 seconds is assumed for PCR, that is, given the equation $N_t = N_0e^{rt}$, in which N_t is the amount of DNA at time t and N_0 is the initial amount of DNA, r is 1.386 min^{-1} for PCR. A carrying capacity of 100 billion copies of PCR product per µL was used, assuming that the reaction is primer limited at one-third the primer concentration (initially at 0.5 µmol/L, or 300 billion primer pairs per µL). Starting with only one target copy, it takes 23 minutes (46 cycles) to amplify the target to saturation. *(Modified with permission of the publisher from Wittwer CT, Kusukawa N. Real-time PCR. equipped with optical detection to analyze the reaction as it progresses (real-time PCR) or after the reaction is complete (end point melting) without the need to process the sample for a separate analysis step.

PCR Kinetics and Rapid Cycling

It is natural to think about PCR in terms of three events—denaturation of double-stranded target, annealing of primers to their targets, and extension of the DNA strand from the primer—that occur at three temperatures, each requiring a certain amount of time. Indeed, it is common to perform PCR by holding the reaction mixture at three different temperatures (e.g., denaturation at 94 °C, annealing at 55 °C, and extension at 72 °C). Standard thermocycling instruments that use conical tubes focus on accurate temperature control of the heating block at equilibrium, not on the dynamic control of the sample temperature. As a result, sample temperatures are not well defined during transitions, and long cycle times have become standard to ensure that samples reach target temperatures. Reproducibility between instruments and manufacturers is poor, and PCR may require hours to complete 30 cycles of amplification.

The kinetics of PCR suggests that *rapid transitions* between temperatures with minimal or no pauses (temperature plateaus) provide a better paradigm of PCR amplification (Figure 17-4). Denaturation, annealing, and extension are very rapid reactions as shown by experiments in capillaries.[125] The use of temperature "spikes" at denaturation and annealing, instead of extended temperature plateaus, allows for rapid cycling with the appropriate instrumentation.[129] The actual time required for PCR depends on the size of the product, but when it is less than 500 base pairs (bp), 30 cycles are easily completed in 15 minutes. Furthermore, rapid amplification improves specificity. Figure 17-5 shows PCR amplification of the same product amplified at different cycling speeds. With conventional slow cycling, many nonspecific products are generated (cycling profile A). These products disappear as the cycling time is decreased (profiles B, C, and D). In fact, amplification yield and product specificity are optimal when denaturation and annealing times are minimal.

Requirements for denaturation, annealing, and extension in PCR have been reviewed.[128] Initial denaturation of genomic DNA may be required before PCR cycling, depending on how the DNA sample was prepared. Boiling of the sample or an initial denaturation step of 5 to 10 seconds before PCR cycling may be necessary. During PCR, however, denaturation occurs very rapidly. Even for long PCR products, denaturation is complete in less than 1 second after the denaturation temperature is reached. Anything greater than a denaturation time of "0" serves only to degrade the polymerase. If longer denaturation times are required, either the sample is not reaching temperature or heat-activated polymerases are being used. Product specificity is optimal when annealing times are less than 1 second. Longer annealing times may be required if the primer concentrations are low. The required extension time for each cycle depends on the length of the PCR product. Extension is not instantaneous, although it is much faster than common practice would suggest. Extension rates of *Taq* polymerase under optimal conditions are 50 to 100 bases per second. Despite its common use, a 5 to 10 minute final extension is not necessary to complete extension. Products can be as small as 40 bp to about 40 kilobases (kb). To amplify products longer than 2 kb, mixtures of polymerases that include some 3′-exonuclease activity to edit mismatched nucleotides are usually used. Instead of separate annealing and extension temperatures, both processes can be carried out at the same temperature, resulting in two-temperature, instead of three-temperature, cycling. Although this simplifies the demand on instrumentation and programming, it limits the choice of primers and requires a longer extension time at suboptimal temperatures.

PCR Optimization and Primer Design

In addition to the temperature-cycling conditions, the specificity of PCR depends on the choice of primers and the Mg^{2+} concentration. The choice of primers often dictates the quality and success of the amplification reaction. To select primers, the sequence of the target must be known. Some guidelines for primer selection are intuitive and helpful:

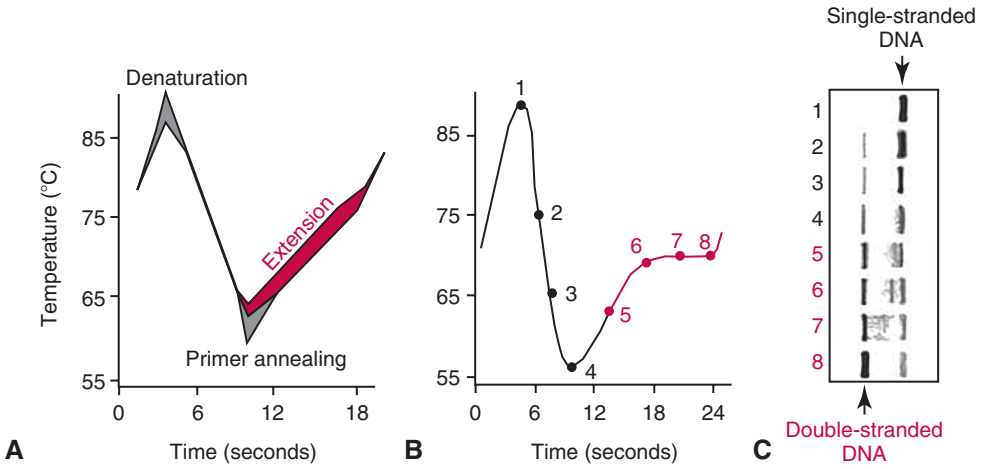

Figure 17-4 A visual demonstration of polymerase chain reaction (PCR) kinetics. The three phases of PCR (denaturation, annealing, and extension) occur as the temperature is continuously changing (A). Toward the end of PCR temperature cycling, the reaction contains single- and double-stranded PCR products. When different points of the cycle are sampled (by snap-cooling the mixture in ice water, (B) and analyzed, the transition from denatured single-stranded DNA to double-stranded DNA is revealed as a continuum (C). Progression of the extension reaction can be followed by additional bands appearing between the single- and double-stranded DNA (time points 5 to 7). *(Modified with permission from Wittwer CT, Herrmann MG. Rapid thermal cycling and PCR kinetics. In: Innis M, Gelfand D, Sninsky J, eds. PCR applications. San Diego: Academic Press, 1999:211-29. © 1999 Academic Press.)*

1. Avoid primers that anneal to themselves or to other primers. Particularly avoid complementation at the 3′-end of primers, and especially do not use a primer that has reciprocal 3′-end complementation.
2. Choose primers that are specific to the target. Avoid simple sequence repeats and common repeated sequences, such as *Alu* repeats. If your target has close relatives, design your primers so that they will anneal only to your intended target. Targets that need to be avoided include pseudogenes (for genomic DNA) and related bacterial or viral strains (for microorganisms).
3. One should avoid primers that have sequence complementary to internal sequences of the intended product, especially at the 3′-ends of the primers.
4. Primers should have between 18 and 25 bases that are matched in melting temperature (Tm) to each other. A primer greater than 17 bases long has a good chance of being unique in the human genome.
5. Unless there is a reason to amplify longer targets, product length should be less than 500 bps. Even shorter products (<200 bps) amplify with the highest efficiency.
6. It is important to search for sequences similar to the candidate primers that are present in the background DNA likely to be present in your assay (http://www.ncbi.nlm.nihgov/BLAST/). Many primer selection programs are available commercially and others can be freely obtained over the Internet. However, very few if any of the selection rules have been empirically tested.

For exponential PCR, priming sites must be oriented appropriately within a close distance. The desired target can be favored by choosing a small product size and rapid cycling.

Detection Limits of PCR

When PCR is performed under optimal conditions, a single copy of the target can be detected. In practice, however, the statistical probability of distributing at least a single copy from a dilute template solution into the PCR must be considered. The Poisson distribution indicates that if, on average, one target copy is present per tube, 37% of the tubes will have no target, 37% will have one target, and the remainder will have more than one target. About three copies on average are necessary for 95% of the tubes to include at least one copy. Therefore, the limit of detection (95% probability) of any single PCR cannot be lower than three copies per reaction. This limitation of low copy analysis holds true for any amplification technique.

3′-End of PCR Products

Taq DNA polymerase and other polymerases have a terminal transferase activity that may add a single unpaired nucleotide on the 3′-end of PCR product strands. In the presence of all four dNTPs, dATP is preferentially added. This means that some percentage of the double-stranded products generated by PCR will have a protruding A at one or both ends. Although this does not influence most detection protocols, it can complicate some systems with high size resolution. On the other

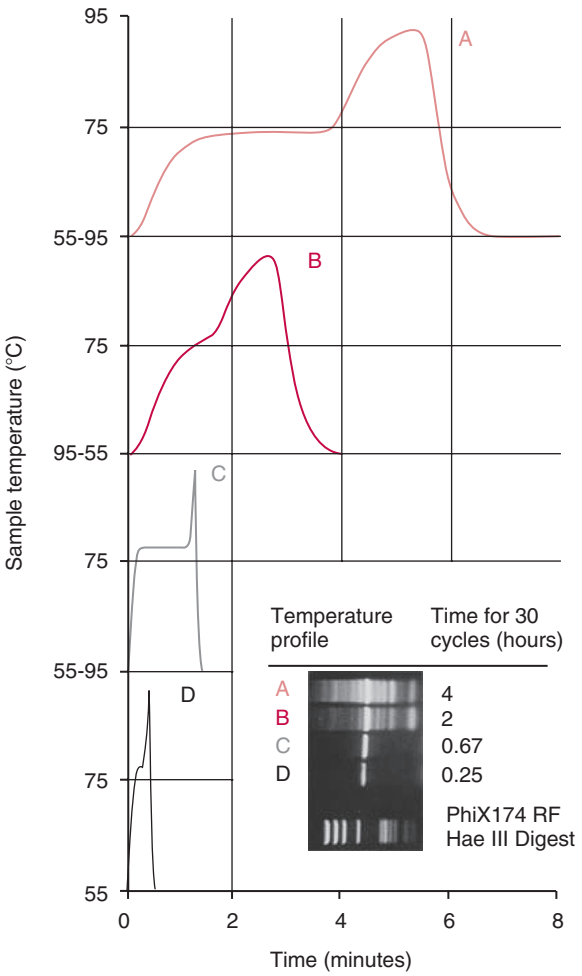

Figure 17-5 Rapid polymerase chain reaction (PCR) improves product specificity. Human genomic DNA samples were cycled 30 times through temperature profiles *A, B, C,* and *D*. Increased specificity of amplification of the 536 bp β-globin fragment is seen with faster cycling (*C* and *D*). *(Reprinted by permission of the publisher from Wittwer CT, Garling DJ. Rapid cycle DNA amplification: time and temperature optimization. BioTechniques 1991;10:76-83. © 1991 Eaton Publishing.)*

hand, this feature is useful for high-efficiency cloning and ligation of PCR products.[134]

Contamination Control to Avoid False-Positive Results

Because PCR can detect a single molecule of target sequence, a small amount of contamination in a sample can easily produce a false-positive result. The greatest potential for contamination comes from the product of the amplification reaction, referred to as the *amplicon* (used interchangeably with *PCR product*). After amplification, each reaction mixture may contain as many as one trillion copies of the amplicon. Thus, minute aerosol droplets contain more than enough target for robust amplification. Amplicon can contaminate reagents, pipettes, and glassware. It is easy to turn a laboratory into a Dr. Seuss fiasco.[95] Experience has dictated the use of laboratory procedures that minimize contamination by amplicons.[52] These include physically separated areas for preamplification and postamplification steps, positive-displacement or filter barrier pipettes to minimize aerosol contamination, and the use of prealiquoted reagents. The most effective way of all is to not let the product out of the tube. Methods that perform amplification, detection, and characterization in a closed tube virtually eliminate the risk of product contamination. Even with these precautions, a negative control or blank (all reactants minus target DNA) is one of the most important controls for PCR.

In combination with the precautions listed previously, chemical modifications can be made to the amplicon so it becomes an unsuitable template for further amplification. One of the commonly practiced chemical modifications is to substitute deoxyuridine 5′-triphosphate (dUTP) for deoxythymidine 5′-triphosphate (dTTP) in amplification reactions, which results in incorporation of U in place of T in the amplified product. A bacterial enzyme, UNG, degrades DNA that contains U. Because U is not normally found in DNA, only amplicons will be susceptible to degradation by UNG treatment, and a new target DNA will not be affected. During a brief incubation step before amplification, uracil-containing DNA strands that are carried over from previous amplifications are enzymatically degraded such that they cannot serve as substrates for further amplification. UNG is then inactivated during the first denaturation cycle, so newly formed amplicon can accumulate normally during the reaction. However, UNG may regain activity, even after multiple cycles of amplification, if the temperature of the reaction mixture drops to below 55 °C. Residual UNG activity may also affect the detection limit (and the sensitivity of quantitative PCR assays) if amplified products are held at room temperature before detection. Often, PCR is carried out with dUTP but not with UNG until amplicon contamination is suspected.

An inexpensive method for reducing contamination in PCR consists of exposing the amplicon to ultraviolet (UV) light (such as a transilluminator) for a certain amount of time (usually 15 minutes) immediately after the amplification procedure. UV light creates unamplifiable pyrimidine dimers in the amplicon molecules. However, this procedure may not be compatible with all detection methods.

Inhibition Control to Avoid False-Negative Results

PCR is a resilient process that does not require highly purified nucleic acid. In practice, however, clinical samples may contain impurities that can inhibit polymerase activity. To ensure reliable amplification, some form of nucleic acid purification is often used. The idiosyncratic nature of PCR inhibitors contained in clinical specimens requires demonstration that the sample (or preparation of nucleic acid purified from it) will allow amplification. A control nucleic acid sequence, usually different from the target, can be added to the sample (or to the extract from the sample). Failure to amplify this control indicates that further purification of the sample is required to remove inhibitors of PCR.

Hot Start Techniques

PCR sensitivity and specificity can be compromised by the formation of unintended low molecular weight artifacts. This process is initiated before PCR, when the primers, template, and polymerase are all together at temperatures below the annealing temperature of PCR. Even at low temperatures, if a primer momentarily anneals to another primer or to an undesired target region, *Taq* DNA polymerase may extend the complex. If the extension product, in turn, is primed and extended, then unintended, double-stranded products can be formed (e.g., primer-dimers) that serve as amplification templates throughout the reaction. Primer-dimers can be distinguished from the intended target by their molecular weight or melting temperature, but they also influence the efficiency of the intended amplification and decrease the sensitivity of the assay.

The formation of primer-dimers can be minimized in several ways. All limit the activity of polymerase until the temperature is increased (thus the strategy is often collectively called *hot start*). One method of hot start involves the use of antibody (or an aptamer) to bind and inactivate the polymerase at room temperature. The binding agent is released upon heating, allowing polymerase activation. Another method uses wax or paraffin to create a physical barrier between the essential components in the reaction. This barrier may be created by putting some of the reaction components into the bottom of the tube and overlaying them with molten wax. Cooling solidifies the wax, and the missing components (usually the polymerase, or magnesium, which is essential for polymerase activity) can be placed on top. The wax melts when the temperature reaches 60 to 80 °C, and all components are mixed together by convection while the molten wax floats on top and prevents evaporation of the sample. Various commercial wax beads encasing one or more critical components are available. Finally the polymerase, primers, or dNTPs can be chemically blocked so that extension cannot occur until activation by heat, usually requiring an extended initial denaturation period of 10 to 20 minutes.

Asymmetric PCR and Allele-Specific PCR

Conventional PCR uses primers that are present in equal amounts, thereby ensuring that most of the products are double-stranded amplicons. *Asymmetric PCR* uses different concentrations of the two primers to generate more of one strand than of the other. For instance, the use of primer A at 0.5 µmol/L and primer B at 0.005 µmol/L produces mostly single-stranded DNA extended off the more abundant primer. This is useful for sequencing or making single-stranded probes. Yield of the product, however, may be low. With less extreme ratios (e.g., primer A at 0.5 µmol/L and primer B at 0.2 µmol/L), the yield is mostly preserved, with one strand produced in enough excess to make it more available for probe hybridization.

Another variant method called *allele-specific PCR* enables preferential amplification of one genetic allele over another. The 3′-end of one primer is placed at the polymorphic site and is extended readily only if it is completely complementary to the target. This strategy is used for distinguishing a gene from its pseudogenes and for genotyping of single-nucleotide polymorphisms (SNPs). Allele-specific PCR can also be used to determine haplotypes.[66]

Single-Molecule PCR or Digital PCR

Conventional PCR averages the amplification results of the many individual template molecules in a reaction. Because of this averaging, certain questions are difficult to answer. For example, quantification of copy number variants and minor allele fractions in the background of wild-type DNA, although possible, is difficult by bulk PCR. It is also difficult to determine whether multiple variants are on the same or different chromosomes. Single-molecule PCR (sometimes also called *digital PCR*) is a technique that uses a dilute solution of template that is distributed across many reaction compartments such that each of those compartments will have no template or a single molecule of template. Instead of conventional tubes, these compartments may be minute aqueous droplets in a water-in-oil emulsion *(emulsion PCR),*[102] PCR colonies *(polonies)* on a thin film of acrylamide gel,[68] or clusters on the surface of a planar flowcell generated by bridge amplification,[4] or they may be found on beads with clonally amplified template attached to their surface.[62,96] When amplification is observed in one of the massively parallel reactions, this means that clonal amplification occurred from a single template molecule. By analyzing each of these clonal reactions, it is possible (1) to determine whether multiple sequence variants are carried on one chromosome or split among two chromosomes, (2) to detect hemizygous gene or exon level deletions, and (3) to count minority events such as a mutation in a gene that is present in a very small fraction of cells in the specimen. Single-molecule PCR is used as the first step for many of the high-throughput sequencing methods reviewed later in this chapter.

Other Forms of Target Amplification

Several other methods for target amplification have been developed and are described briefly here.

Transcription-Based Amplification Methods

Transcription-based amplification methods are modeled after the replication of retroviruses. These methods are known by various names, including transcription-mediated amplification (TMA),[30,43] nucleic acid sequence–based amplification (NASBA),[15] and self-sustained sequence replication (3SR) assays.[32] They amplify their target without temperature cycling (isothermally) and use the collective activities of reverse transcriptase, RNase H, and RNA polymerase. The most widely used is TMA, illustrated in Figure 17-6. Two primers, a reverse transcriptase, and an RNA polymerase are used. The primer complementary to the RNA target has a 5′-tail that includes a promoter sequence for RNA polymerase. This primer anneals to the target RNA and is extended by the reverse transcriptase, creating an RNA/DNA duplex. The RNA strand is degraded by the RNAse H activity of the reverse transcriptase, allowing the second primer to anneal.

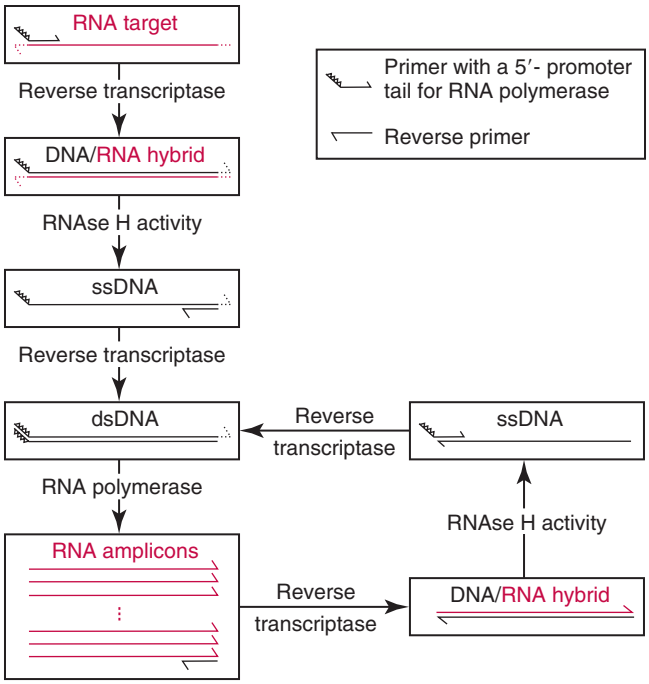

Figure 17-6 Schematic diagram of transcription-mediated amplification (TMA). Starting with a single-stranded RNA target, a primer with an RNA polymerase promoter on its 5′-end is extended by reverse transcriptase to form a DNA/RNA hybrid. The reverse transcriptase also has RNAse H activity that subsequently degrades the RNA strand to leave single-stranded DNA (ssDNA). A second primer then binds to the ssDNA, and extension forms double-stranded DNA (dsDNA) with the attached RNA polymerase promoter. RNA polymerase then makes 100 to 1000 copies of RNA, some of which are again primed by the second primer. Repeated cycles of reverse transcription, DNA/RNA hybrid degradation by RNAse H activity, dsDNA formation by reverse transcriptase, and further transcription by RNA polymerase exponentially produce ssRNA amplicons. Single-stranded targets are amplified isothermally, while double-stranded targets are first denatured to single strands.

The reverse transcriptase then extends the second primer to create double-stranded DNA that includes the promoter. RNA polymerase recognizes the promoter and initiates transcription, producing 100 to 1000 copies of RNA. Each strand of RNA then binds and extends the second primer, forming a RNA/DNA hybrid; the RNA in the hybrid is degraded, the promoter primer binds and extends to produce double-stranded DNA that can be transcribed, and the cycle repeats. As in PCR, all reagents are included and amplification is exponential with completion in less than an hour. Unlike PCR, these methods do not require temperature cycling (except for an initial heat denaturation if a DNA template is used). They are particularly advantageous when the target is RNA (e.g., human immunodeficiency virus [HIV] and hepatitis C virus [HCV] in blood bank nucleic acid testing).

Strand Displacement Amplification

Another isothermal amplification technique is strand displacement amplification (SDA).[114] After heat denaturation of DNA in the presence of four primers—dCTP, dGTP, dUTP, and a modified deoxynucleotide (dATPαS)—two enzymes are added: an exonuclease-deficient polymerase and a restriction enzyme. The two flanking primers that enter into exponential amplification have a restriction site added to their 5′-end and get nicked by the restriction enzyme, allowing displacement of strands that in turn can be primed, extended, and nicked. Deoxy-ATPαS is used so that restriction sites include a hemiphosphorothioate linkage to allow single-strand nicking, instead of cutting through the double strands.

Loop-Mediated Amplification Methods

The target amplification methods presented so far produce a defined length of RNA or DNA according to primer placement. In contrast, loop-mediated methods produce a wide range of different length concatemers of the target sequence. Primer design includes tails at the 5′-end of some of the primers that are complementary to the target sequence. After replication of complementary strands, these ends become free 3′-ends capable of extension. By forming a loop, these 3′-ends prime and extend the hairpin (self-priming) initiating concatemer formation. After initial DNA denaturation, the process can be isothermal if strand displacement primers are included. In the basic version, two strand displacement primers and two loop-forming primers recognize six segments in the target.[75] In another version, allele-specific amplification with five primers and one competitive probe recognizes seven segments in the target.[1] In both versions, a variety of product concatemers are formed, and the reactions can be completed in less than 1 hour.

Whole Genome and Whole Transcriptome Amplification

Instead of specific amplification of one target to improve sensitivity, methods that amplify all genomic DNA or mRNAs are useful when the target is in short supply. For example, *multiple-displacement amplification* uses exonuclease-resistant random hexamers and a highly processive polymerase to amplify DNA nonspecifically.[19] Initial DNA denaturation is not necessary, and the reaction proceeds isothermally. Similarly, messenger RNA can be generically amplified with a poly(T) primer modified with an RNA polymerase promoter.[80] After reverse transcription, second-strand DNA synthesis, and transcription, antisense RNA is produced. Both whole genome and antisense RNA amplification are also useful as nucleic acid purification methods before amplification or detection.

Other Approaches to Amplification

It is not always necessary to amplify the target DNA or cDNA sequence. Instead of target amplification, signal amplification or probe amplification can be used.

Branched-Chain DNA: Signal Amplification

Instead of increasing the concentration of target, signal amplification techniques use nucleic acids to magnify the

detection signal. The branched-chain DNA (bDNA) method is one of these techniques in common use. The bDNA approach hybridizes the target nucleic acid to multiple capture probes affixed to a microtiter well.[108] This is followed by hybridization to a series of "extender," "preamplifier," and amplifier probes. The final, highly branched amplifier probe includes multiple copies of signal-generating enzymes that act on a chemiluminescent substrate to produce light. Nucleotide analogs isoC and isoG (isomers of C and G that are complementary to each other but not to other nucleotides) are often used to increase the specificity of the signaling cascade.

Serial Invasive Amplification: Signal Amplification

When two probes overlap on one target, an "invasive" cleavage reaction can be catalyzed by certain structure-specific nucleases. The cleaved fragment, in turn, can cause invasive cleavage of a secondary probe in the shape of a hairpin. The hairpin probe can be designed as a fluorogenic indicator by using a reporter/quencher pair of dyes that are separated by cleavage. This serial sequence of events (primary invasion and cleavage, followed by secondary invasion and cleavage of an indicator probe) is known as the serial invasive signal amplification reaction.[35] After DNA denaturation, cooling, and the addition of enzymes, the reaction is run at a temperature at which both the primary and secondary reactions recycle.

Rolling Circle Amplification: Probe Amplification

If a primer is annealed to a closed circle of DNA in the presence of a processive, displacing polymerase, the complement of the circle will be synthesized over and over again with displacement of the tandem repeats.[60] If two primers are used in opposite orientation, progressively more complex branches will be formed in an exponential reaction. The rolling circle can be formed by ligation of the two ends of a linear probe on template DNA. Ligation may happen directly, after polymerization through a gap, or after annealing of an additional, allele-specific oligonucleotide.

End Point Quantification in Amplification Assays

Molecular diagnostic assays may be qualitative (presence/absence of a target or genotype identification) or quantitative (the original concentration of a target sequence in the sample). When amplification is part of the assay, many variables need to be carefully controlled for accurate and precise quantification. Variation in extraction efficiency, the presence of enzyme inhibitors, lot-to-lot variation in enzyme and reagent performance, and day-to-day variation in reaction and detection conditions need to be addressed by methods that attempt quantification.

Quantitative analysis at the end point of amplification is usually carried out with the use of calibrators with known amounts of target or a target mimic. Sample nucleic acid may be quantified by comparison with an *internal standard* of known amount that is added at the time of sample processing to control for efficiency of nucleic acid purification. These internal standards can be DNA fragments, plasmids, or RNA packaged into synthetic phage or virus particles to mimic real viruses (so-called *armored RNA*[115]). One such strategy uses a *competitor* template, which is amplified by the target primers but generates an amplicon with sequence or size different from that of the expected amplicon. This competitor template is added in varying amounts to replicates of the sample before amplification. When the target and the competitor are present in equal concentrations, the amounts of the two different products will also be the same. The competitor is present in the same tube as the sample, so any variation in enzyme activity affects both products identically. This method is not used frequently in clinical applications because of the requirement for multiple assays on each patient sample.

Real-time (continuous) analysis is simpler and more powerful for quantification than end point assays. Reactions are monitored over time, and the profiles of the curves are used to calculate initial target concentrations. Real-time PCR is described in later sections of this chapter.

DETECTION TECHNIQUES

Molecular diagnostics uses both generic and specific methods of nucleic acid detection. Nucleic acids can be quantified in bulk by optical techniques, and specific methods of detection and quantification use sequence-specific primers and/or probes.

Generic Measurement and Visualization of Nucleic Acids

To measure or visualize nucleic acids generically, two approaches are commonly used: UV absorbance and fluorescent dyes.

UV Absorbance

Nucleic acid molecules absorb ultraviolet light maximally at 260 nm owing almost entirely to the constituent bases. This property can be used to measure the nucleic acid content of a solution. DNA double helices have lower UV absorbance than an equivalent number of nucleotide monomers, and when DNA is denatured into single strands (ssDNA) (e.g., by heat or pH), UV absorbance increases.[6] If a double-stranded DNA preparation is pure, a 50 mg/L solution has an absorbance of 1.0 at 260 nm. RNA has a greater absorbance, so only about 30 mg/L gives an absorbance of 1.0. More precise estimates for oligonucleotides are based on dinucleotide contributions.[8] It is common to assess the purity of a nucleic acid preparation by its ratio of absorbances at 260 nm and 280 nm *(260:280 ratio)*. In contrast to nucleic acids, proteins absorb maximally at 280 nm. A pure preparation of nucleic acid should have a 260:280 ratio between 1.7 and 2.0 that depends on base content. Lower values suggest significant protein contamination.

Fluorescent Staining of Nucleic Acids

Although absorbance measurements are simple and precise, they are not sensitive. Fluorescent stains that bind to nucleic acid are 1000 to 10,000 times more sensitive than absorbance

measurements. The best known example of a nucleic acid dye is ethidium bromide, a positively charged, intercalating dye for double-stranded DNA and to a lesser extent, single-stranded DNA and RNA. Cyanine dyes are also popular stains for nucleic acids; they do not fluoresce unless they are bound to nucleic acids, thus providing very low background. With the appropriate optics, single molecules of DNA can be visualized with cyanine-based nucleic acid stains.[79] Nucleic acid dyes can detect DNA and RNA in gels or in solution (such as in real-time PCR).

Reporter Molecules and Labeled Probes

Ultraviolet absorbance and fluorescent dyes in themselves do not discriminate between different nucleic acid sequences (i.e., they are not sequence specific). Specificity in nucleic acid assays almost always comes from the hybridization of two complementary nucleic acid strands. Many reporter molecules can be covalently attached or incorporated into nucleic acid probes. Use of these probes can reveal the physical presence or location of sequences complementary to the nucleic acid portion of the probe.

Radioactivity

The first probes used in nucleic acid detection were radioactively labeled. Radioactive labels are still favored in some research settings because of the sensitivity attained with probes of high specific activity. The most frequently used isotopic labels are ^{32}P and ^{33}P, which are incorporated into the probe by enzymatic reactions. *Nick translation* is a classical method of labeling double-stranded DNA fragments. Nicks are introduced randomly into each strand of DNA by DNase I, and the resulting 3′-OH groups form priming sites for DNA polymerase. Labeled nucleotides are incorporated as the polymerase extends the strand by digesting and removing the unlabeled strand. Another method of labeling double-stranded DNA is *random priming,* in which the nucleic acid is denatured and is allowed to anneal with short oligonucleotides of random sequence. The 3′-end of an annealed primer forms an initiation site for the DNA polymerase, which incorporates labeled nucleotides using single-stranded regions of the DNA as the template. Labeled nucleic acid can also be synthesized by PCR, or if a labeled RNA is desired, it can be prepared with the use of a double-stranded DNA fragment containing a promoter sequence for RNA polymerase and incorporating radiolabeled ribonucleotides by transcription.

Additional enzymatic reactions are useful for labeling oligonucleotides. T4 polynucleotide kinase may be used to label the 5′-end of an oligonucleotide. Alternatively, terminal deoxynucleotidyl transferase (TdT) can add labeled nucleotides onto the 3′-end in a *tailing* reaction. No template is required, and the number and type of nucleotides can be controlled by the reaction conditions. A somewhat longer probe than the original oligonucleotide is obtained with additional labeled bases at the 3′-end. The sensitivity that is achieved with radioactive nucleic acid probes is determined by the radioactivity of the label, its extent of incorporation, and the detection time. Radioactively labeled probes have a short shelf life limited by isotopic decay and radiolysis of the nucleic acid. This inherent instability, along with concerns of radioisotope safety and disposal, restricts the use of radioactive probes in the clinical laboratory.

Indirect Probe Detection

The first practical example of nonradioactive probes used a biotin-labeled analog of dUTP.[53] Despite the altered steric configuration, this nucleotide is incorporated by both DNA polymerase and terminal transferase. Other functional groups, such as digoxigenin, may also be used as affinity labels through chemical linkage to a dUTP and incorporation into polynucleotides. Alternatively, oligonucleotide probes can be labeled during synthesis with biotin or amino linkers for subsequent attachment to indicator molecules. Labels at the 5′- or 3′-end of the molecule are usually preferred because central modifications may interfere with hybridization.

Biotin and other affinity labels do not generate detectable signals on their own. However, they can initiate signal amplification mediated by high-affinity binding with antibodies, or in the case of biotin, with avidin or streptavidin. These binding molecules can be linked to enzymes—such as alkaline phosphatase, peroxidase, or luciferase—connecting a single target to a single enzyme. Enzyme activity is monitored by detecting catalytic turnover of enzyme substrates that result in colorimetric, fluorescent, or chemiluminescent signals.

Affinity labels can be used to capture and localize targets to an area of a solid support. For example, biotinylated probes can be affixed to a streptavidin-coated surface. After incubation with the target nucleic acid, a second probe is added, which may be directly labeled with fluorescence or conjugated through another affinity label to an enzyme. Any background or nonspecific localization of reagents results in amplification of an undesired signal along with the desired signal, and these methods usually require multiple separation and washing steps to decrease the background.

Electronic detection of nucleic acids is attractive for its simplicity. Hybridization events can be detected by redox indicators that recognize the DNA duplex, or by other hybridization-induced changes in electrochemical parameters, such as conductivity or capacitance.[78,107] However, it is difficult to make electronic methods sensitive and specific enough that nucleic acid amplification is not required.

Fluorescent Labels

Advances in oligonucleotide synthesis and fluorescence detection have made fluorescently labeled probes the preferred reporter for nucleic acid analysis. Many fluorescent labels are now available, allowing color multiplexing for applications such as DNA sequencing, fragment length analysis, DNA arrays, and real-time PCR as reviewed later in this chapter. Techniques such as fluorescence polarization, fluorescence resonance energy transfer (FRET), and fluorescence quenching can provide additional detection specificity. Fluorescence polarization can be used to distinguish free from bound label, if the molecular rotation of the probe changes

upon binding.[51] Molecular rotation primarily depends on the size of the molecule, so binding of a small probe onto a large target results in a polarization increase that can be measured. FRET techniques depend on the distance between two spectrally distinct fluorescent labels. Two labeled probes may be brought closer together by adjacent hybridization. Alternatively, two labels on the same probe may end up farther apart by hydrolysis or hybridization. Fluorescence quenching or augmentation does not always require FRET. For example, fluorescence may change merely by hybridization of a fluorescent oligonucleotide to its target. The effect depends on the dye and on inherent quenching from G residues in the target and/or probe.[16,72] Alternatively, quenching moieties can be purposely incorporated into probes.[55,106]

DISCRIMINATION TECHNIQUES

Nucleic acid discrimination techniques are divided into three categories:

1. Electrophoretic methods that physically separate nucleic acids based on molecular size and/or shape.
2. Alternatives to electrophoresis that determine the size, base content, and/or sequence of nucleic acids without electrophoresis. Examples include high-performance liquid chromatography (HPLC), mass spectrometry, and high-throughput sequencing.
3. Hybridization assays that identify specific nucleic acids by annealing or melting of complementary nucleic acids.

Some techniques use both electrophoresis and hybridization.

Electrophoresis

Electrophoresis is the most commonly used method for DNA and RNA analysis. Both DNA and RNA are negatively charged and will migrate toward the positively charged electrode when an electrical field is present within an appropriately buffered solution. Separation of different nucleic acids occurs when mixtures are allowed to travel through a neutral sieving polymer under the electrical field. Separation is based primarily on molecular size, with smaller molecules traveling faster through the polymer than larger ones (Figure 17-7). When very large molecules (≥50 kb) have to be separated, pulsed electrical fields are used to help move these molecules through the polymer matrix.[64] Separation also occurs based on the physical conformation, or shape, of the molecule. For instance, (1) single-stranded molecules may fold into secondary structures or they may stay as flexible linear structures; (2) linear double-stranded molecules may form heteroduplexes with mismatched bases or they may stay in their original homoduplex forms; and (3) circular double-stranded nucleic acids may be nicked and take a relaxed open-circular structure or they can be in a more compact superhelical structure. Under nondenaturing conditions, each of these shapes may influence the way nucleic acid molecules travel through the electrophoretic matrix. Separation based on shape can provide useful information, but it can also confuse size-based analysis. Electrophoresis of DNA is performed under nondenaturing or denaturing conditions depending on the application.

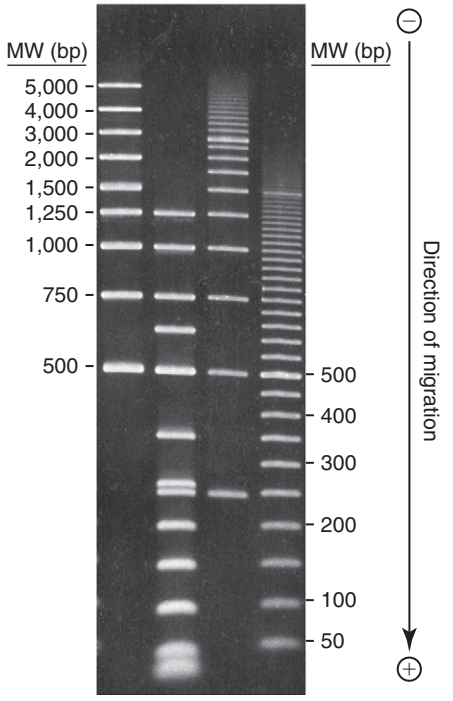

Figure 17-7 A photograph of multiple DNA fragments after agarose gel electrophoresis (1% w/v, SeaKem LE agarose gel) showing the separation of double-stranded DNA molecules by size. *(Photograph courtesy of Lonza Rockland Inc, Rockland, Maine.)*

RNA electrophoresis is commonly performed as a quality control check before transcript quantification or microarray expression analysis. RNA can be degraded easily by tissue or environmental RNAses, so it is important to assess the quality of the RNA used in these methods. Because RNA often has secondary structure, electrophoresis is usually performed under denaturing conditions to abolish these structures. Microfluidic chips with integrated microelectrophoresis are commercially available to rapidly assess RNA integrity by inspection of ribosomal RNA peaks (Figure 17-8). Although specific transcripts are not detected by this method, only small amounts of starting RNA are needed.

Agarose and *polyacrylamide* are the two types of polymers commonly used in electrophoresis. Several chemical variants of the polymers are commercially available and are tailored for different separation ranges and applications. The choice of polymer and polymer concentration (usually expressed as % w/v) is dictated by (1) the size of nucleic acid to be separated, (2) the resolution that is required, and (3) how the result will be visualized and analyzed. Using various concentrations, an agarose gel can separate nucleic acid fragments as small as 20 bp to over 10 Mb (10,000 kb), including chromosomes of yeast, fungi, and parasites. However, the resolution of agarose is limited, usually to a size difference of 2 to 5%. Agarose polymers are cast in trays (sometimes commercially supplied as precast gels) and submerged in buffer. The

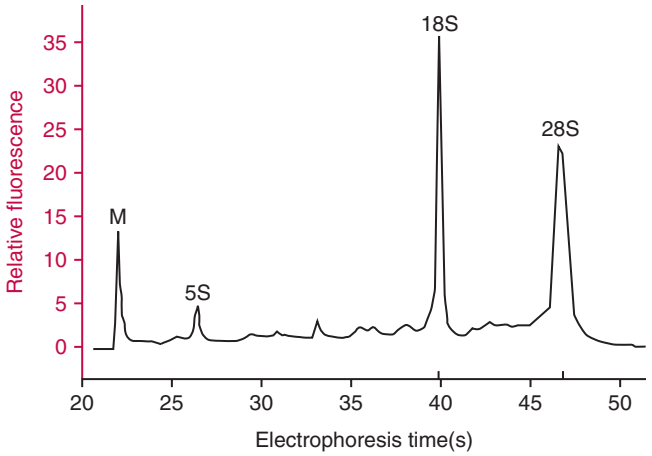

Figure 17-8 Microelectrophoresis of human white blood cell RNA. After isolation of white blood cells and extraction of total RNA, samples were denatured, stained with a fluorescent dye, and applied to a commercial microelectrophoresis platform for assessment of RNA quality. Prominent 18S and 28S bands of ribosomal RNA suggest the RNA is largely intact. Also indicated are a reference marker (M) and the 5S ribosomal band. Note that electrophoresis was performed in less than 1 minute.

gels are permeable to fluorescent nucleic acid–binding dyes, and results may be recorded as a photographic image of the stained gel under ultraviolet illumination.

Polyacrylamide polymers are suited for high-resolution separation (down to about 0.1% size differences) of short molecules (up to about 2 kb) and are the primary polymer for single-stranded nucleic acid separation, such as dideoxy-termination sequencing. Polyacrylamide may be used as a linear polymer solution, which is filled in capillaries *(capillary electrophoresis),* or as cross-linked gels, which are cast between two plastic or glass plates *(slab gel electrophoresis).* Polyacrylamide gels are permeable to fluorescent stains, and nucleic acids can also be silver stained. In addition, the optical clarity of polyacrylamide polymers makes them ideal for visualizing emission signals from fluorescently labeled fragments using laser-induced fluorescence detection.

Table 17-2 lists common electrophoresis-based techniques described further in this section.

Restriction Fragment Length Polymorphism

DNA extracted from a cell is extremely long and is usually cut into shorter fragments before electrophoresis to enhance mobility. Restriction endonucleases cut double-stranded DNA into fragments of reproducible size; the same enzyme produces the same fragments in different specimens if they contain the same DNA sequence. If an alteration in the DNA abolishes or creates a cleavage site recognized by the enzyme (or changes the spacing between two cleavage sites), then different sized fragments will be produced. These changes in fragment lengths (or polymorphisms) that result from restriction digestion are called *restriction fragment length polymorphisms* (RFLPs). However, restriction digestion produces thousands of fragments. To be useful, specific fragments need to be visualized.

TABLE 17-2 Commonly Used Electrophoresis-Based Techniques

Techniques Using Electrophoresis	Abbreviation	Primary Application
PCR/Restriction fragment length polymorphism	RFLP	Detection
PCR (RT-PCR) fragment analysis		Detection
Southern blotting		Detection
Northern blotting		Detection
Dideoxy-termination sequencing		Detection
Single-nucleotide extension assay	SNE	Detection
Oligo ligation assay	OLA	Detection
Multiplex ligation-dependent probe amplification	MLPA	Quantification
Heteroduplex migration assay	CSGE	Scanning
Single-strand conformation polymorphism analysis	SSCP, SSCA	Scanning
Denaturing gradient gel electrophoresis	DGGE	Scanning
Temperature-gradient electrophoresis	TGGE, TGCE	Scanning

CSGE, Conformation-sensitive gel electrophoresis; *PCR*, polymerase chain reaction; *RT-PCR*, reverse-transcriptase PCR.

Southern and Northern Blotting

Southern blot analysis (Figure 17-9) separates restriction fragments by agarose gel electrophoresis and transfers (blots) them to a membrane for easier manipulation in the following steps and for selective visualization by labeled probes. It reveals polymorphisms in the DNA sequence based on the RFLP profile. After electrophoresis, acid treatment fragments the DNA to make it easier to blot, and base treatment denatures the DNA to single strands for better binding to the membrane and probe hybridization. After neutralization, the DNA is transferred to a nitrocellulose or nylon membrane and immobilized. The membrane is then incubated with one or more probes that hybridize to the fragments of interest. The hybridized probes then are visualized by autoradiography or chemiluminescence. Southern blotting detects RFLPs, including large structural alterations such as deletions, duplications, insertions, and rearrangements. The procedure was named after its inventor, E. M. Southern,[100] and was the first

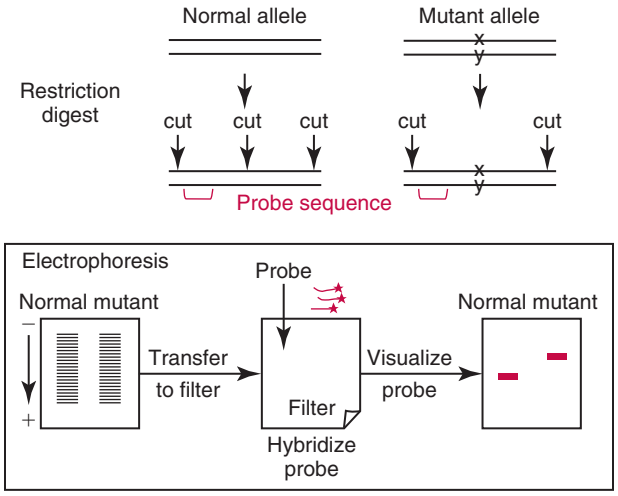

Figure 17-9 Schematic of Southern blotting. Genomic DNA is isolated from a normal specimen and from a mutant specimen that carries the polymorphic allele *(x,y)*. The normal specimen has a site in the middle that is recognized by a restriction enzyme, while the mutant allele disrupts this site. After restriction enzyme digestion of genomic DNA, both samples are separated by agarose electrophoresis. At this point, no discrete bands are visible over the background of many fragments that are generated by the enzyme. DNA is transferred to a filter and is hybridized with a short DNA probe that is labeled. This probe hybridizes to the genomic sequence on one side of the polymorphic site. After visualization of the probe on film, a larger fragment is seen in the specimen with the mutant allele compared with the smaller digested fragment seen in the normal specimen.

discrimination method with adequate sensitivity and specificity for DNA analysis of single-copy genes in complex genomes. However, it requires large amounts of DNA (10 to 50 µg/lane) and is very labor intensive and time consuming. Today, it has largely been replaced by PCR.

Northern blotting was named not for its inventor but as a companion technique that uses RNA rather than DNA as the test nucleic acid. After electrophoresis, RNA is transferred from the gel onto a membrane followed by hybridization with a specific labeled probe. Because RNA molecules have defined lengths and are much shorter than genomic DNA, it is not necessary to cleave RNA before electrophoresis. However, because of the secondary structure of RNA, it is necessary to perform electrophoresis under denaturing conditions, usually formaldehyde/formamide buffers in agarose gels. RNA extracted from cells consists primarily of ribosomal and transfer RNA. Messenger RNA makes up only 1 to 2% of total cellular RNA. After electrophoresis and staining, intact RNA reveals two clearly visible bands of ribosomal RNA. Electrophoresis of about 10 µg of RNA is usually sufficient to allow visualization of the mRNA of interest after hybridization with a probe. Northern blotting provides information about the size of mRNA transcripts. Although only partly quantitative, the relative concentration of a particular transcript can be estimated by reference to a constitutively expressed control transcript, such as β-actin mRNA.

PCR Product Length

PCR product analysis by electrophoresis is frequently used to query the quality and specificity of PCR amplification. PCR products are visualized by staining the gel with a fluorescent DNA-binding dye, such as ethidium bromide. In some cases, the presence of an amplification product is directly diagnostic (e.g., detection of sequences found only in a bacterium, virus, or fungus in a human sample). The specificity of the amplification reaction is verified by the known size of the fragment. Internal negative and positive controls are used to control for potential contamination and to establish detection sensitivity.

Small insertions, deletions, rearrangements, and changes in the number of repeated sequences can also be detected by monitoring PCR product length on gels. Length differences may be large and easily picked up with agarose gel electrophoresis, or they may be small enough to require a denaturing polyacrylamide matrix. Fluorescent primers may be incorporated into the product during PCR to simplify detection of fragment lengths. These techniques are commonly used in the diagnosis of inherited diseases and in identity assessment.

PCR/RFLP

Many sequence alterations (e.g., single base substitutions) do not change the length of DNA. However, they can be amplified easily by PCR and usually are detected as RFLPs after treatment with restriction enzymes. After PCR, the products are digested with one or more enzymes and analyzed by electrophoresis. For example, if a sample has a mutation that disrupts an enzyme recognition site, this can be distinguished from a sample that does not have the mutation. Such an assay will produce one uncut PCR fragment when the mutation is present and two shorter fragments when the mutation is absent (Figure 17-10). If the mutation is present as a heterozygote (one normal and one mutant copy of DNA), then one long and two shorter fragments will be observed. Usually it is possible to design the assay so that the fragments can be easily resolved by agarose electrophoresis. One variant of this method uses reverse-transcribed mRNA, which lacks the introns that would be present in the DNA. In this way, multiple exons can be analyzed in a single PCR reaction.

Heteroduplex Migration

Heteroduplex migration analysis [also called *conformation-sensitive gel electrophoresis (CSGE)*] reveals the presence of sequence variants by the altered electrophoretic mobility of a double-stranded DNA fragment that contains one or more mismatched bases (a heteroduplex) versus one that is perfectly matched (a homoduplex). Originally described as a PCR artifact,[71] heteroduplex migration analysis has become a popular mutation-scanning technique, primarily because of its technical simplicity. With this technique, dsDNA generated by PCR is denatured, is allowed to re-anneal, and then is separated by electrophoresis under slightly denaturing

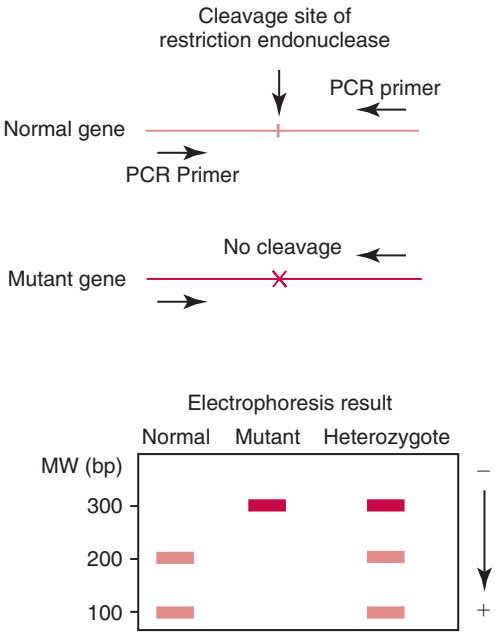

Figure 17-10 An example of polymerase chain reaction–restriction fragment length polymorphism (PCR-RFLP). A DNA fragment amplified by PCR carries a site (a unique sequence of generally four or more bases) that is recognized and cleaved by a restriction endonuclease. If a mutation is present, this site is altered and is no longer recognized by the enzyme. Electrophoresis reveals that the fragment from a normal specimen was indeed cut by the enzyme, generating two fragments shorter than the original length, while the fragment from a homozygous mutant was not cut, and the original length of the amplicon is preserved. In a heterozygous mutant, both the original fragment and the shorter fragments are visible.

conditions (e.g., 15% urea, 40 °C) on polyacrylamide gels. Detection is performed by silver staining of the gel or by fluorescence detection if one of the PCR primers is labeled. Heteroduplexes usually migrate more slowly than homoduplexes during electrophoresis (Figure 17-11). Although mutant alleles are often present as heterozygotes in a clinical specimen, homozygous mutations require mixing with wild-type DNA for mutations to be detected.

Heteroduplex migration detects single-nucleotide polymorphisms in fragments as large as 600 bp. The principal factor influencing sensitivity is the combination of the mismatched bases. Greater mobility differences (relative to the homoduplex) occur in the order of G:G/C:C > A:C/T:G = A:G/T:C > A:A/T:T.[39] This technique and other variant-scanning methods are useful when a wide variety of sequence alterations might be present. Particularly when most of the samples tested are wild-type ("normal"), it is more economical to scan for the presence of variants before performing specific genotyping or DNA sequencing.

Single-Strand Conformation Polymorphism

Single-strand conformation polymorphism analysis (SSCP or SSCA) is another electrophoresis technique used to scan for unknown variants in nucleic acid sequence. Similar to heteroduplex migration, it first requires PCR amplification. The amplicon is diluted and is denatured with heat and formamide; the resulting single-stranded DNA is separated by nondenaturing polyacrylamide electrophoresis (usually run at 4 °C). During electrophoresis, the single-stranded molecules fold into three-dimensional structures according to their primary sequence. Electrophoretic mobility then becomes a function of size and shape of the folded single-stranded molecules. If the sequence of a reference sample

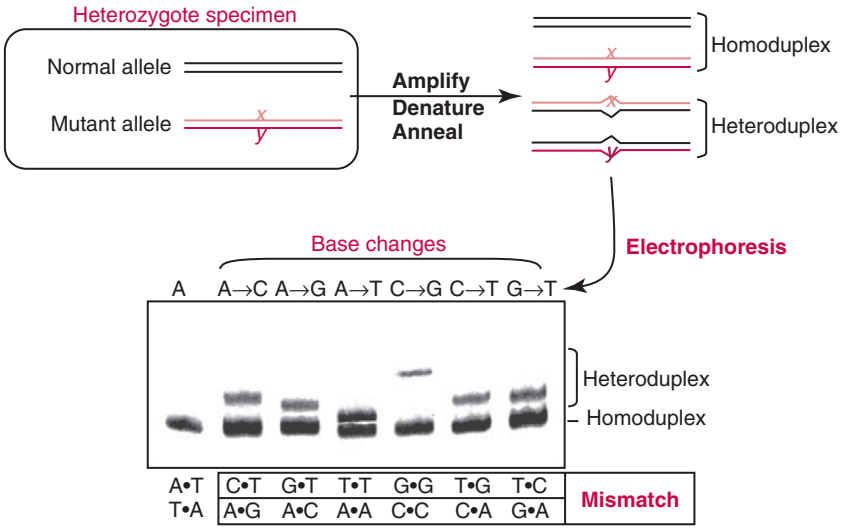

Figure 17-11 A schematic of heteroduplex migration analysis. When amplified DNA from a heterozygous specimen is denatured and cooled, the fragments re-anneal in four combinations. Electrophoresis on a specialized polyacrylamide gel reveals the presence of heteroduplexes by extra band(s) appearing above the homoduplex band.

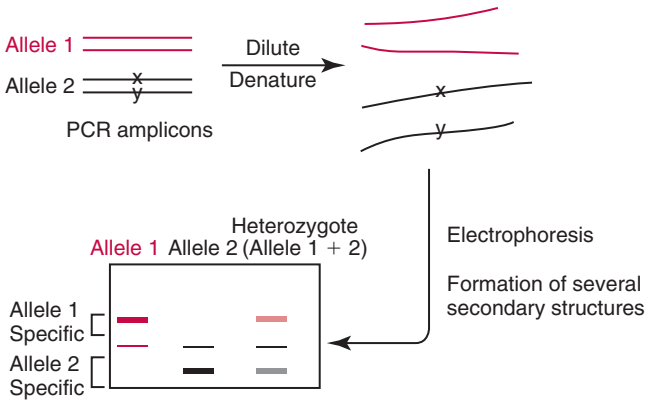

Figure 17-12 A schematic of single-strand conformation polymorphism analysis (SSCP). Polymerase chain reaction (PCR) amplicons carrying the polymorphic site *(shown as x and y)* are diluted and then denatured to form single-stranded fragments. During electrophoresis, they assume secondary structures. When conditions are right, polymorphisms are detected by differential band patterns compared with a known sample.

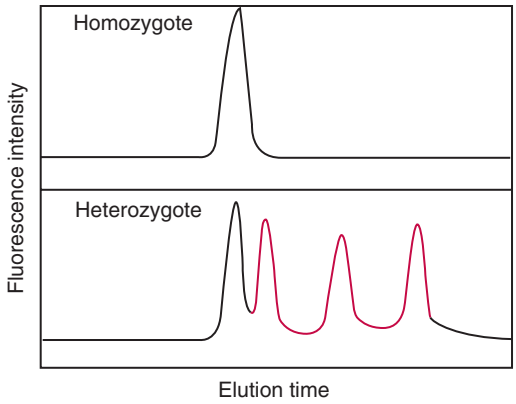

Figure 17-13 An ideal elution profile from temperature-gradient capillary electrophoresis (TGCE). The polymerase chain reaction (PCR) fragments are denatured and then cooled before electrophoresis (see diagram in Figure 17-11). Only one peak is visible for the PCR product of a normal homozygous specimen, whereas all four possible duplexes are visible and are separated from each other in a heterozygous mutant specimen. The shape of the elution profile (rather than the elution time) is used to compare unknowns with control samples.

differs from that of the fragment being tested, even by only a single nucleotide, often at least one of the strands, if not both, will adopt different conformations and exhibit a unique banding pattern (Figure 17-12). Since its introduction in 1989,[76] SSCP has emerged as a popular strategy used to detect sequence variants. Results can be visualized by silver staining of the gel or by fluorescent detection using labeled PCR primers. Unlike heteroduplex migration, there is no need to mix reference materials to detect the presence of homozygous variants. The sensitivity of SSCP depends on the GC content of the fragment and the assay conditions.[40] GC content is the amount of guanine and cytosine in a polynucleic acid usually expressed as percentage of total bases. Different conditions may be required to detect all mutations, sometimes making multiple runs necessary for a single target sequence. Furthermore, the results of SSCP are difficult to interpret when one sequence gives rise to multiple single-stranded conformations, some of which may be difficult to see, depending on amplification and electrophoresis conditions. It is also difficult to establish reliable protocols for fragments greater than ≈200 bp.

Denaturing Gradient Gel Electrophoresis

Denaturing gradient gel electrophoresis (DGGE) is yet another technique used to scan for unknown variants in nucleic acid sequence. Separation of PCR products is performed at a constant temperature within a gel that includes a concentration gradient of denaturants, such as urea, along the direction of electrophoresis. If the sequence of the PCR product is known, the detection rate of variants can approach 100%. However, only variants in the first melting domain are detected, so it may be necessary to limit the length of the PCR product and/or attach an artificial GC-rich sequence *(GC clamp)* to one end of the fragment to provide adequate separation.[12]

Temperature Gradient Electrophoresis

Temperature gradient gel electrophoresis (TGGE) is similar to DGGE. However, instead of using chemical denaturants, a temporal or spatial temperature gradient is used to provide the denaturing effect. For example, if the electrophoresis gel is in contact with a metal plate, a linear temperature gradient can be established perpendicular or parallel to the direction of electrophoresis.[86] Separation occurs according to size, shape, and thermal stability of the nucleic acids. If the temperature gradient is perpendicular to the direction of electrophoresis, intramolecular conformational changes show up as continuous transition curves, while strand separation leads to discontinuous transitions. Heteroduplexes are detected by a shift of the transition curves to lower temperatures.

Temperature gradients over time have been applied during capillary electrophoresis.[56] The temperature of the capillary array is increased by 0.5 to 0.7 °C/min and nucleic acid migration monitored by fluorescence in the presence of an intercalating dye. Heteroduplexes are detected by a change in the peak profile, which, under ideal conditions, may show all four possible duplexes as peaks[27] (Figure 17-13). Multiple samples can be run at the same time. However, as with heteroduplex techniques, homozygous variants are difficult to discriminate from a homozygous normal sample without mixing the two together to form heteroduplexes.

Dideoxy-Termination Sequencing

DNA sequencing[26] is routinely performed in the clinical laboratory. RNA is sequenced by first converting RNA to DNA by reverse transcriptase. Nucleic acid sequence is determined and compared with a reference sequence with an error rate

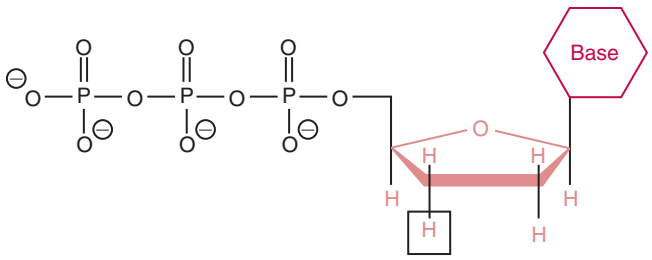

Figure 17-14 A dideoxynucleotide. Notice the absence of the 3′-OH that is usually present in standard deoxynucleotides. This lack of a 3′-OH prevents polymerase extension because no phosphoester bond can form. Incorporation of a dideoxynucleotide forces termination of polymerase extension.

of 0.1% (one misidentified base in 1000). Often the sequence is analyzed on both strands (sense and antisense) for even greater accuracy. Any deviation from the reference sequence is identified by using computer programs to match the sequences. Base changes resulting in an altered amino acid code, stop codons, deletions, or insertions can be identified. The most common sequencing strategy uses PCR in the first step to amplify the region of interest, followed by a variable chain-termination reaction developed by F. Sanger in the late 1970s.[91] This reaction (also referred to as *Sanger sequencing*) generates fragments that are terminated at various lengths by incorporation of one of the four dideoxynucleotide base analogs (Figure 17-14) during extension from a sequencing primer (Figure 17-15). Dideoxynucleotides lack both 3′- and 2′-hydroxyl groups on the pentose ring. Because DNA chain growth requires the addition of deoxynucleotides to the 3′OH group, incorporation of dideoxynucleotides terminates chain growth. The most common method for generating these terminated fragments is *cycle sequencing,* repeating the steps of annealing, chain extension-termination, and denaturation by temperature cycling, similar to PCR. The fragments generated are tagged with a fluorescent dye (with the use of labeled primers or labeled terminator dideoxynucleotides), are separated by electrophoresis, and are detected by fluorescence as the fragments travel past a detector (Figure 17-16). When fluorescently labeled primers are used, four tubes are needed, each with one of the four dideoxy-terminators. If four colors are used, then the termination reactions can be combined before electrophoresis, and only one capillary is necessary. Alternatively, the use of four terminators of different colors makes it possible to streamline the process down to one tube for the termination reactions and one capillary. After PCR and cycle sequencing, about 600 bases can be resolved in less than 2 hours by capillary electrophoresis, and 96 of 384 samples can be run in parallel. DNA sequencing in the clinical laboratory is commonly used in viral genotyping such as HIV for drug resistance and HCV to establish prognosis and appropriate therapy. Sequencing is also used for bacterial speciation by analysis of ribosomal DNA and to identify mutations in many genetic diseases.

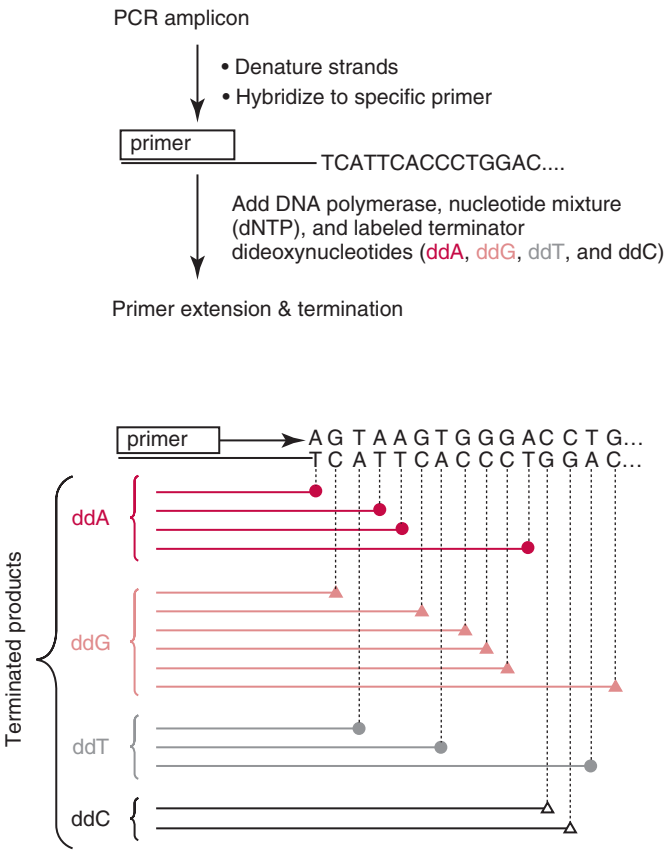

Figure 17-15 The dideoxy-termination reaction for sequencing. A polymerase chain reaction (PCR) amplicon is denatured and then hybridized to a specific oligonucleotide primer. As the DNA polymerase extends the primer by incorporating bases [(deoxy)nucleotides (dNTPs)] complementary to the template, it occasionally incorporates a terminator base analog (ddA, ddG, ddT, or ddC) that stops further extension. The result is a mixture of extended products of varying lengths. Each terminator base may be labeled with one of four different fluorescent tags (shown as different symbols in the diagram). Alternatively, the primer can carry four different fluorescent tags in individual chain-termination reactions [containing only one dideoxynucleoside triphosphate (ddNTP)] performed in separate tubes. The original procedure incorporated a radioactive dNTP during extension, allowing monochromatic detection of the truncated fragments in four electrophoresis lanes.

New technology now allows high-throughput sequencing of entire organisms in one operation. Massively parallel amplification in microscopic reactions (such as emulsion droplets) is followed by extension or ligation reactions that are observed with fluorescence (see next section). However, complete sequencing of only one gene (exons and splice sites) in the clinical laboratory for the detection of disease-causing mutations is still an expensive proposition by targeted dideoxy-termination sequencing. This is especially true for population screening (in which most samples will not have a

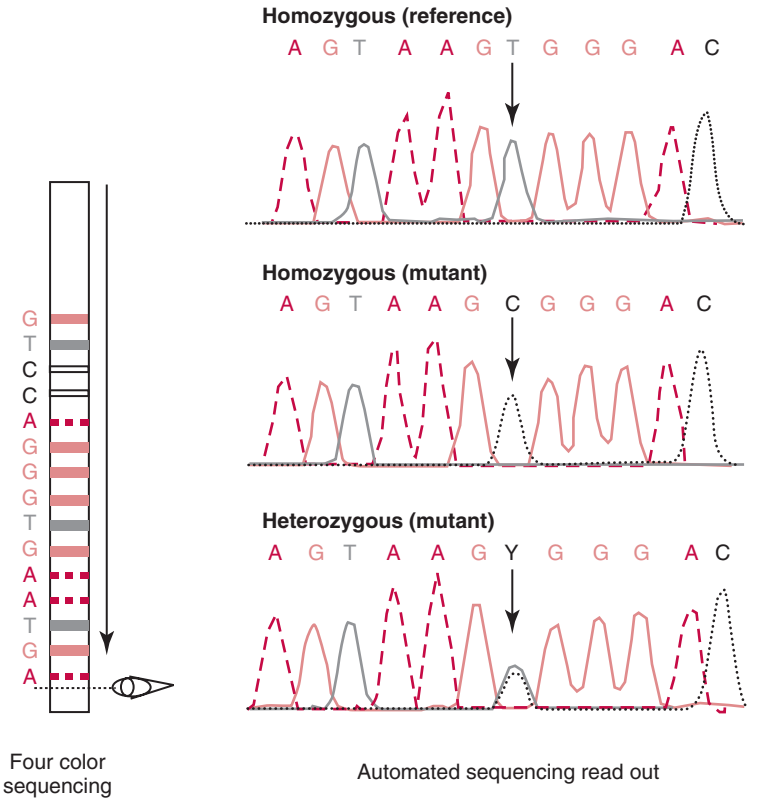

Figure 17-16 Schematic of DNA sequencing. Extension products (see Figure 17-15) are labeled with different color dyes for each of the four terminator reactions and are separated by electrophoresis. The four-color strategy allows automated end point fluorescence detection *(shown by the eye icon)*. The direction of fragment migration is from top to bottom. The sequence is read from left to right in the electropherogram generated by the sequencer. Examples of a reference sample (homozygous T at the polymorphic site), a mutant sample (homozygous C), and a heterozygous mutant sample (T and C, reported as Y) are shown.

mutation), but also for patients with symptoms of the disease. Therefore, in genetic testing, DNA sequencing is often performed after a negative result is obtained from targeted analysis of common mutations, or after a *mutation scanning assay* has determined the exons that need to be sequenced or otherwise genotyped.

Single Nucleotide Extension (SNE)

Also known as *single-base primer extension* or *minisequencing,* single nucleotide extension (SNE) assays involve the annealing of an oligonucleotide primer to a single-stranded PCR amplicon at a location that is immediately adjacent to, but does not include, the site of the single base variant, followed by enzymatic extension of the primer in the presence of polymerase and dideoxynucleotide terminators. For example, each of the four terminators can be labeled with a unique fluorescent label so that it is possible to detect which base was incorporated. SNE assays can be multiplexed on capillary electrophoresis instruments by varying the lengths of the primers so that each SNP is resolved by size in one electrophoresis run. Many SNE detection methods are available other than electrophoresis, including (1) photometric detection on microtiter plates, (2) product capture detection systems on DNA microarrays, (3) bead hybridization assays detected by flow cytometry, (4) solution-based fluorescence polarization detection systems, and (5) mass spectrometry. SNE assays are particularly useful when the target of interest contains 5 to 50 disease-causing single base variants. SNE assays do not work well if polymorphisms are present in the primer-binding site. Nor are they usually designed to detect polymorphisms at a position other than immediately adjacent to the 3′-end of the primer.

Oligo Ligation

Another assay format frequently used for SNP detection is the oligo ligation assay (OLA). Two oligonucleotide probes are hybridized to adjacent sequences of amplified target DNA, with the variation site positioned at the end of one probe (Figure 17-17). DNA ligase covalently joins the two probes only if both probes are perfectly hybridized to the target, including the polymorphic base. A probe matching the normal base and another probe matching the variant base are usually prepared. These two can be discriminated through differential electrophoretic mobility by varying the length of

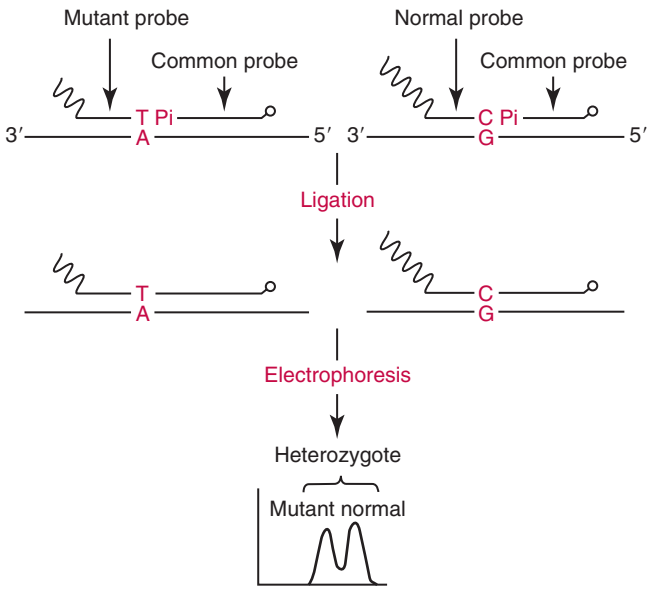

Figure 17-17 Oligo ligation assay of a heterozygous single-nucleotide polymorphism (SNP). A mutant probe with a 3′-T *(upper left)* hybridizes to the mutant DNA with an opposing *A,* while a normal probe with a 3′-C *(upper right)* hybridizes to the normal DNA with an opposing *G*. The probes are also attached to mobility modifying tails of different lengths *(wavy lines)*. Hybridized next to these probes is the common probe with a 5′-phosphate (Pi) and a 3′-fluorescent tag. In the presence of ligase, adjacent probes are covalently joined to generate longer probes, each with a fluorescent tag and a mobility-modifying tail. Probes that are mismatched to the target at their 3′-ends may hybridize, but they are not ligated. Electrophoresis and end point, laser-induced detection of ligated probes reveal the different alleles by their different mobility. Multiple SNP sites can be analyzed in one electrophoresis assay by varying tail lengths and/or by using multicolor fluorescence tags.

their 5′-tails. These tails can be noncomplementary poly A or poly C tails or pentaethylene oxide (PEO) units. The probe hybridizing to both alleles (the *common probe*) provides the reporter molecule, usually a fluorescent label. Multiplexing of SNP detection is achieved by attaching different fluorescent labels to the common probes and by varying the length of the tails on the allele-specific probes. Following ligation, probes for multiple SNP sites are separated by denaturing capillary electrophoresis.

Multiplex Ligation-Dependent Probe Amplification

Muliplex ligation-dependent probe amplification (MPLA)[7] is a convenient method for relative quantification of up to 10 to 50 targets. This method is particularly useful in screening for deletions or duplications of multiple exons within a gene. For each target, two probes are designed that hybridize adjacent to each other so that they can be ligated. The two probes have unique tails that do not hybridize to the target and that are the same between targets. After hybridization and ligation, the probes are amplified by PCR with a common primer pair (complementary to the tails). One of the primers is fluorescently labeled at its 5′-end. Because probes of different lengths are used, multiple PCR products of different sizes are produced and separated on a sequencing gel. Relative peaks heights or areas are compared for relative quantification.

Alternatives to Electrophoresis

Electrophoresis is not required to determine the size, base content, and/or sequence of nucleic acids. Some of these alternatives to electrophoresis are attractive in the clinical laboratory because of compatibility with automation and capacity for high throughput. Some examples include pyrosequencing, mass spectrometry, HPLC, and high-throughput sequencing.

Pyrosequencing

Pyrosequencing[89] is a sequencing-by-synthesis method that does not require dideoxy-termination or electrophoresis. A sequencing primer is hybridized to a single-stranded template generated by PCR. Four enzymes, a DNA polymerase, ATP sulfurylase, luciferase and apyrase, and two substrates—adenosine 5′-phosphosulfate and luciferin—are included in the reaction mixture (Figure 17-18). One of the four dNTPs is added to the reaction, with dATPαS substituted for dATP because it is incorporated by the polymerase but is not a luciferase substrate. If the base is complementary to the template strand, DNA polymerase catalyzes its incorporation. Each incorporation event is accompanied by release of a pyrophosphate (PPi) so that the quantity of PPi produced is equimolar to the amount of incorporated nucleotide. The release of PPi is monitored by conversion of PPi and adenosine 5′-phosphosulfate into adenosine triphosphate (ATP) by ATP sulfurylase, and ATP in turn drives conversion of luciferin into oxyluciferin, which generates visible light. The light produced is proportional to the number of nucleotides incorporated. Apyrase, which is a nucleotide-degrading enzyme, continuously degrades ATP and unincorporated dNTP. This switches off the light in preparation for the next dNTP addition. As the process is repeated by adding one dNTP at a time, the complementary DNA strand is built and the nucleotide sequence is determined. Because the technique can be automated, it is useful when the sequences of a large number of short segments need to be determined.

Mass Spectrometry

Matrix-assisted laser-desorption ionization time-of-flight (MALDI-TOF) mass spectrometry can be used to genotype sequence polymorphisms.[9,82] With mass spectrometry, no label is necessary because the alleles differ in mass. After isolation of genomic DNA, a specific DNA fragment including the polymorphic site is amplified by PCR. Heat-labile alkaline phosphatase is added to the reaction to dephosphorylate any residual nucleotides, preventing future incorporation and interference with the primer extension assay. Samples are then heated to inactivate the alkaline phosphatase. An extension primer is hybridized directly or closely

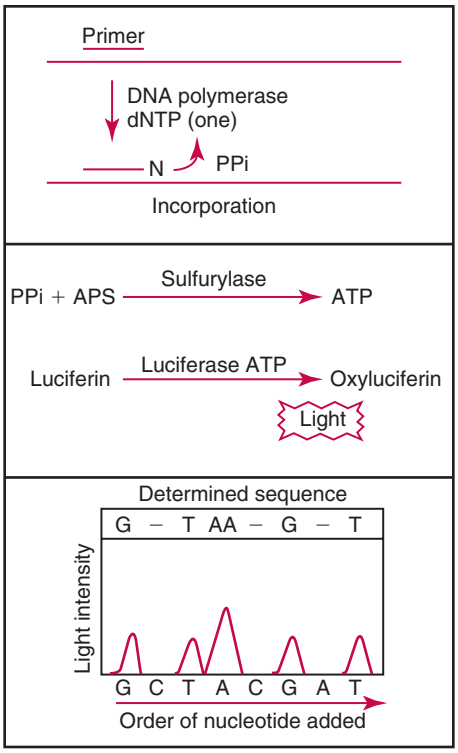

Figure 17-18 Schematic of pyrosequencing. Individual (deoxy)nucleotides (dNTPs) are added one by one to the single-stranded template, a primer, and a polymerase. Pyrophosphate is generated if the dNTP is complementary to the next base on the template *(top)*. Any pyrophosphate produced reacts with adenosine-5′-phosphosulfate (APS) to produce adenosine triphosphate (ATP), which in turn generates light in the presence of luciferase *(middle)*. The sequence can be determined from the order of dTNP addition and from the intensity of light produced *(bottom)*.

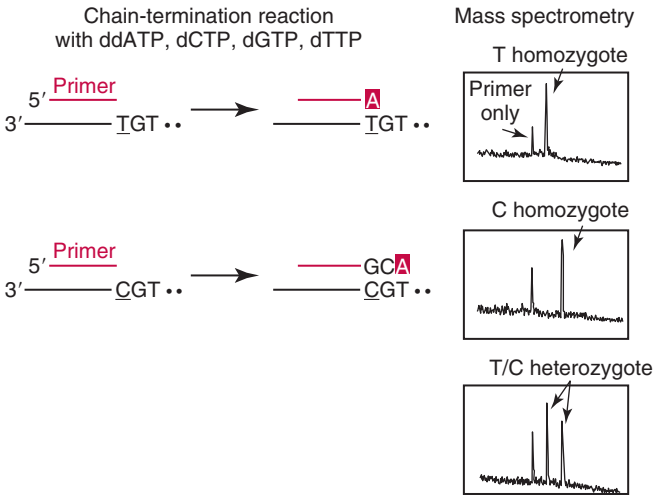

Figure 17-19 Sequence polymorphism analysis by mass spectrometry. The *underlined* base is the polymorphic site in the template (T or C). The single-stranded template is primed and extended in the presence of three (deoxy)nucleotides (dNTPs) and one dideoxynucleoside triphosphate (ddNTP), producing fragments of different mass depending on the sequence. The boxed "A" in this example indicates the incorporated terminator adenine base. The mass of terminated products is precisely measured by matrix-assisted laser-desorption ionization time-of-flight (MALDI-TOF) mass spectrometric data (relative intensity vs. m/z).

adjacent to the polymorphic site. Unlabeled deoxynucleotides are incorporated and terminated with a dideoxynucleotide, generating allele-specific diagnostic products of different mass. Salt is removed from the sample, and ≈10 nL of it is spotted onto an array coated with 3-hydroxypicolinic acid. This is placed into the MALDI-TOF, which measures the mass of the extension products. Once the mass is measured, the genotype is determined (Figure 17-19). Despite the complexity, automated systems processing 384 to 1536 samples at once are available.

High-Performance Liquid Chromatography (HPLC)

HPLC is commonly used for separating and purifying oligonucleotides. Separation usually is based on ion-pair, reversed-phase chromatography and is particularly useful for purifying fluorescently labeled probes guided by absorbance and fluorescent elution profiles.

A variant of this technology is denaturing HPLC (dHPLC). Denaturing HPLC is run at a single elevated temperature to partially denature double-stranded DNA. Similar to gel-based heteroduplex detection, dHPLC reveals the presence of heteroduplexes as additional peaks that are shifted in retention compared with homoduplexes.[130] Retention of double-stranded DNA is governed by electrostatic interactions and an acetonitrile gradient. DNA detection is most often performed by UV absorbance, although fluorescence or mass spectroscopy can also be used. Limitations of dHPLC include sequential (one at a time) analysis and the need to analyze some samples at multiple temperatures when more than one melting domain is present.

High-Throughput Sequencing

The need to understand the full extent of genome-wide human variation has led to the development of new high-throughput sequencing techniques.[111] Compared with dideoxy-termination sequencing (Sanger sequencing), these techniques generate between several hundred thousand and several hundred million times more sequence data in one operation, at fifty times to tens of thousands times lower cost per base. The techniques, none of which uses electrophoresis, are still evolving such that throughput and cost continue to improve. Much of the progress that has been made in this technology is dependent on progress in optical data processing, bioinformatics, and overall computer power. As the cost and turnaround time of these methods continues to decrease, they will be increasingly used in the clinical laboratory.

Most high-throughput sequencing techniques start by randomly fragmenting DNA into small pieces, usually less than 1 kb, and many between 100 and 500 bases. Short *adapter*

sequences are attached to each fragment by the use of ligase or other enzymes such as terminal transferase. The primary role of these adapters is to provide priming sites for each fragment to initiate massively parallel sequencing reactions. Adapters also facilitate initial capture of DNA fragments onto solid surfaces and spatially restrict clonal amplification products generated from the fragments onto beads or spots on an array surface. Clonal amplification is performed by one of several methods, including the following:

- *Emulsion PCR,* in which one strand of the template fragment is captured on one bead and is clonally amplified inside a water-in-oil droplet, generating a bead tethered by single-stranded amplicons (Figure 17-20). The beads are then deposited onto a glass slide[96] or into discrete wells on a fiberoptic slide.[62]
- *Bridge amplification,* which generates clusters of single-stranded amplicons tethered to the surface of a planar flowcell in which the clusters are spatially separated (Figure 17-21).[4]
- *Rolling circle amplification,* which generates concatemers of templates that self-assemble into DNA balls in solution and are deposited onto ordered spots on a silicon array.[21]

Sequence determination of nucleic acids is performed on these clonally amplified templates in a massively parallel fashion using sequencing by ligation or sequencing by synthesis, which includes *pyrosequencing* and iterative single-base extension using cleavable four-color nucleotide terminators that are removed each step after fluorescent interrogation.[4]

Sequencing by Ligation

Sequencing by ligation is used in a number of high-throughput sequencing techniques, as it is suited for parallel operations even though the read length produced by each reaction is very short. Instead of using dideoxy-termination or electrophoresis, sequencing by ligation uses an immobilized template to which two types of ligatable oligonucleotides (anchor and probe) are hybridized repetitively. First, an anchor oligonucleotide is hybridized to a known portion of the immobilized template. Then, a mixture of probes about eight bases long compete for ligation to the anchor. Each of the competing probes has one position with a defined base (A, T, G, or C) indicated by the color of a fluorescent label at the far end of the probe. The remaining bases of the probe may be degenerate (meaning that all four bases are used in the synthesis, creating a combination of 4^m different probes, where m is the number of degenerate base positions), or they may be universal bases (nucleotide analogs that pair with any of the four bases). The terminal fluorescent label blocks further concatenation of probes. At a stringent temperature, only the ligated anchor-probe complex remains hybridized to the template, and the defined base position is decoded by the color of the fluorescent label. The next cycle begins by stripping away the anchor-probe complex from the template and repeating the process, but offset by one base by using a different anchor. Eventually, a short string of bases immediately adjacent to the anchoring site is determined. A variant of the technique uses two defined bases on each labeled probe and extends the read

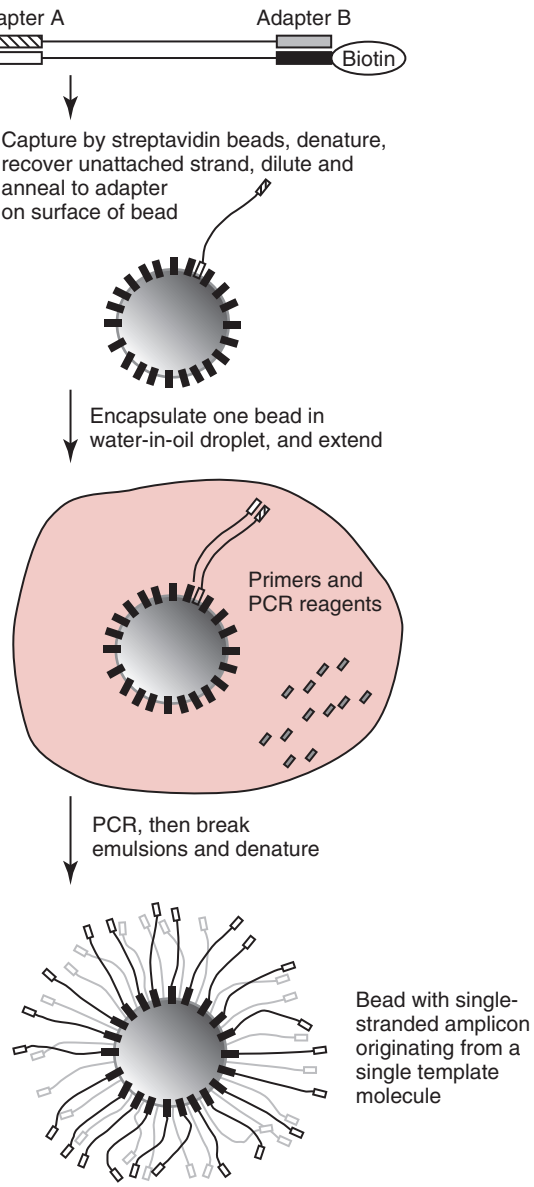

Figure 17-20 Emulsion polymerase chain reaction (PCR). Two adapters (*adapters A* and *B*) are randomly ligated to DNA fragments. *Adapter B* has a biotin on its 5′ end. Fragments with *adapter B* on one or both ends are captured by streptavidin beads, while fragments with only *adapter A* are washed away *(not shown)*. Then fragments are denatured, and the free strand with *adapter A* and *adapter B* at each end is collected (fragments with *adapter B* on both ends will not be released from the streptavidin bead). One molecule of the single-stranded template is then captured on a bead coated with adapter and is encapsulated inside a water-in-oil droplet that contains PCR reagents and primers. After PCR, the emulsion is broken and the DNA is denatured. This generates a bead with a large number of clonal single strands tethered to it. The bead is then deposited into one of many wells on a fiberoptic slide, or onto a glass slide for sequence analysis *(not shown)*.

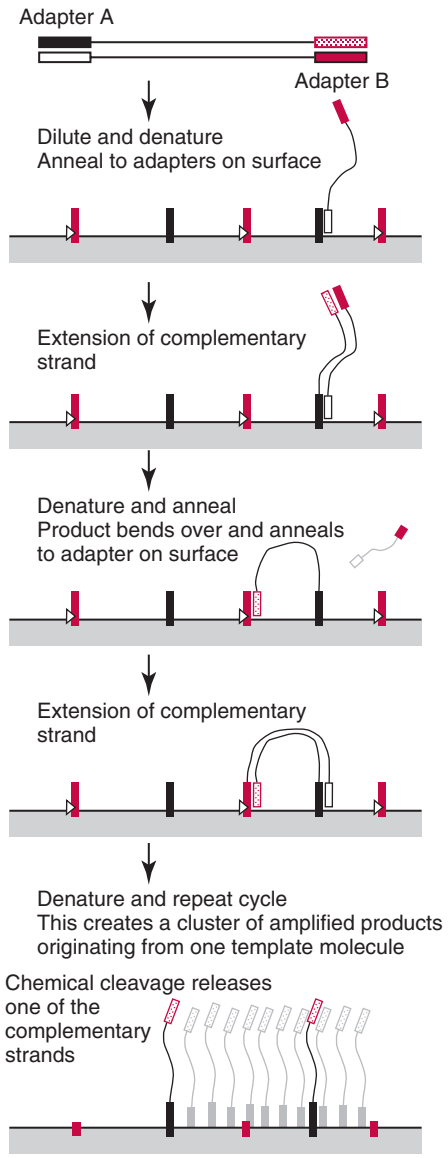

Figure 17-21 Bridge amplification. Two adapters (*A* and *B*) are ligated to a DNA template. Once diluted and denatured into single strands, the template is captured onto a flowcell surface by annealing to one of the two surface-bound primers that share sequences with *adapter A* or *B*. The polymerase reagent introduced into the flowcell extends the primer and generates the complementary strand of the template. The denaturant (usually sodium hydroxide) is introduced to the flowcell to release the original template strand. The free end of the newly synthesized strand anneals to a nearby primer by bending over, and a second round of reagent addition catalyzes the synthesis of another complementary strand. By repeating many of these cycles, a clonal cluster that consists of about 1000 copies of single-stranded template tethered to the surface is generated. This cluster is still a mixture of both complementary strands. One of the strands is selectively eliminated by treatment with periodic acid that cleaves the diol linkage present in one of the surface-bound primers *(open triangle on red primer)*. The cluster now contains only one of the template strands and is ready for sequence analysis.

length by cleaving part of the probe after recording the label (Figure 17-22).

High-Throughput Sequencing Without Amplification

Some high-throughput sequencing methods do not require template amplification. Sensitive optical techniques are used to observe incorporation of fluorescent nucleotides during strand synthesis on single template molecules. One such method observes real-time DNA synthesis by a single polymerase molecule immobilized inside a nanostructure array. The method uses four-color dNTPs whose label cleaves off as nucleotides are incorporated into the newly synthesized DNA strand. Each addition of a base is observed as a short pulse of one of the colors representing one of four bases. Long contiguous reads are possible.[23] If high accuracy can be achieved, this method has advantages for efficient sequence assembly, analyses of repetitive sequences and de novo sequencing. In contrast, many of the other high-throughput sequencing methods generate short sequence reads (30 to 70 bases long) that have to be aligned and analyzed to derive a consensus, then stitched together, and compared with reference genome sequences. Accurate assembly of sequence data relies on sufficient coverage or redundancy across the sequenced region (at least 15-fold redundancy is thought to be required for accurate resequencing[98]), and informatics tools for this process are still evolving.

Hybridization Assays: Principles

All hybridization assays are based on the ability of single-stranded nucleic acids to form specific double-stranded hybrids. The process requires (1) that probe and target nucleic acids are mixed under conditions that allow specific complementary base pairing, and (2) that a method is available to detect any resulting double-stranded nucleic acids. A *probe* indicates a nucleic acid whose identity is known, and the *target* or *sample* is a nucleic acid whose identity or abundance is revealed by hybridization. In some of the methods discussed here, hybridization occurs between a target in solution and a probe that is tethered to a solid surface. In *homogeneous* or *real-time* techniques, both the probes and the targets are in solution, and hybridization and detection occur without washing steps. Some of the homogeneous methods also monitor the dissociation of hybridized duplexes under controlled heating, revealing the identities of the hybridized duplexes by *melting curve* signatures.

As with any assay, both positive and negative controls are necessary. Positive controls contain sequences complementary to the probe, assess assay sensitivity, and ensure that the probe will hybridize to the target under the assay conditions. Negative controls without target sequence assess assay specificity and detect positive contamination if present.

Hybridization Thermodynamics

The favored structure of DNA under physiologic conditions is an ordered double-stranded helix held together by noncovalent interactions. The duplex structure is most stable when all opposing bases are complementary, allowing for maximal

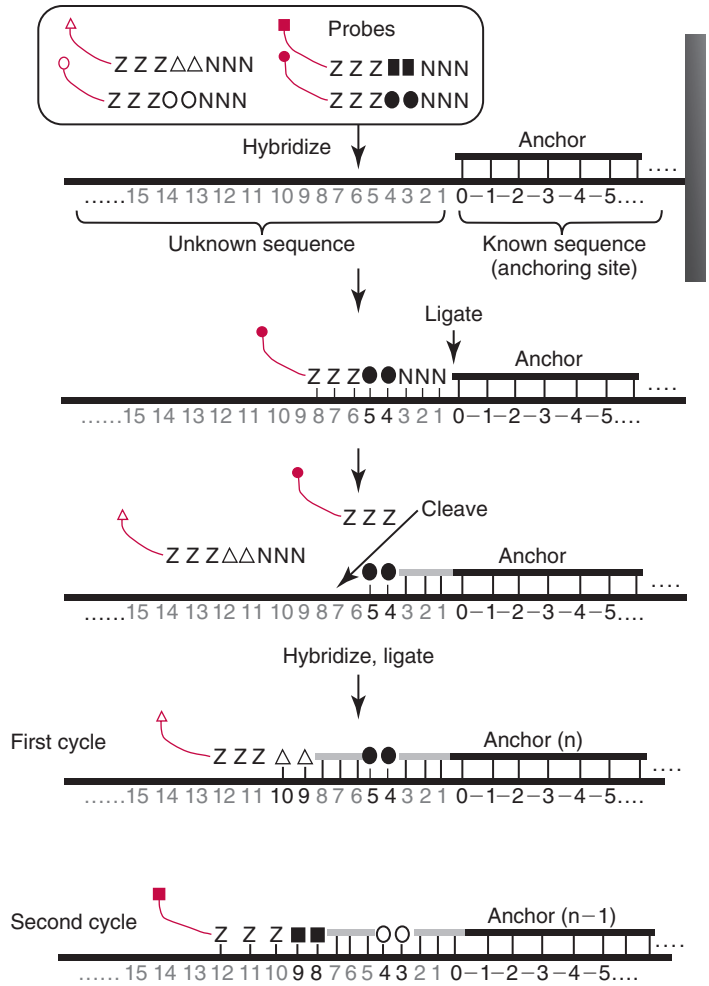

Figure 17-22 **Sequencing by ligation (two-base encoding method). An anchor oligonucleotide is hybridized to known sequences of the template (anchoring site). Structures of octamer (8-mer) probes are shown. *N* represents a degenerate base (A, T, C, or G), *Z* represents a universal base that pairs with any base, and the defined bases (, , ,) occupy the fourth and fifth base positions. The probes are color-coded by one of four labels *(shown in red),* with each color representing a set of four two-base combinations (e.g., color 1 is AT, TA, CG, or GC; color 2 is AC, CA, TG, or GT; color 3 is TC, CT, AG, or GA; and color 4 is AA, TT, GG, or CC). Once a probe hybridizes to the sequence adjacent to the anchoring site, ligase will connect the probe to the anchor. After the color is recorded, part of the probe is cleaved, and the label is removed together with some of the probe bases. This makes it possible for another probe to ligate to the extending complex. In fact, many rounds of ligation/cleavage can be performed, each time elongating the anchor-probe complex and providing additional two-base possibilities. After a few rounds of probe ligation/cleavage, the anchor-probe complex is stripped, and the next cycle, which is offset by one base, repeats the process. Cycles are repeated until one of the defined bases on the probe pairs with a known base on the anchoring site, allowing decoding of all of the two-base combinations. For example, in the first cycle, two-base possibilities for positions 4, 5, 9, and 10 are determined. In the second cycle, which is offset by one base (n-1), possibilities for positions 3, 4, 8, and 9 are determined. This process is repeated until the defined base on the probe pairs with the first base on the anchoring site (position 0). Because the identity of that base is known, the 0/1 base combination is decoded, which in turn decodes base position 2 and so on, until all of the two-base combinations are decoded.**

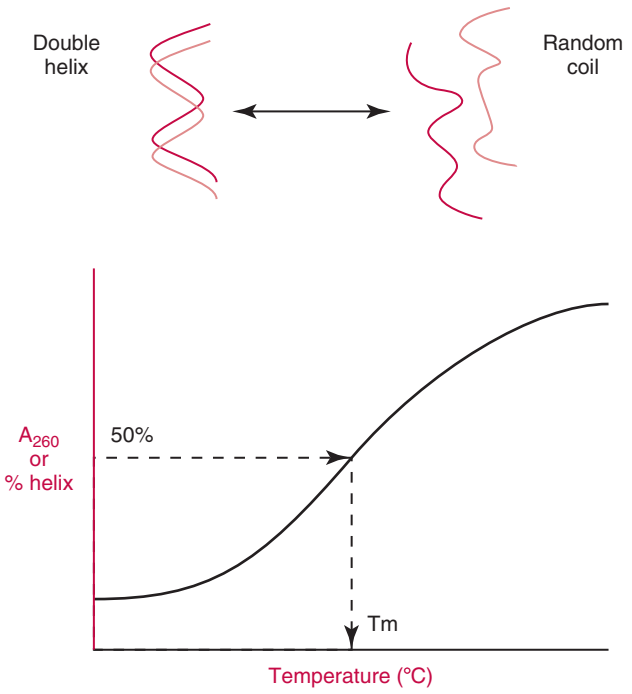

Figure 17-23 Absorbance melting curve of double-helical nucleic acid. *(Modified with permission from Piper MA, Unger ER. Nucleic acid probes: a primer for pathologists. Chicago: ASCP Press, 1989.)*

hydrogen bonding and base stacking. The noncovalent binding between two DNA strands is both specific (i.e., sequence dependent) and reversible. Denaturing agents (such as high temperature, formamide, or extremes of pH) favor dissociation of the double-stranded molecule into two separate random coils (Figure 17-23). On removal of the denaturant, single strands attempt to re-form duplexes, strongly favoring interactions that maximize complementary base pairing. Because temperature is the denaturant most easily manipulated, double- to single-strand transformation is referred to as *melting,* and the temperature at which one half of the DNA is melted is referred to as the *melting temperature,* or *Tm,* of the duplex. Duplexes with mismatched base pairs are less stable than those with a perfect sequence match and thus melt at a lower temperature. The reverse process, in which two complementary strands recombine to form a stable duplex molecule, is referred to as *annealing* or *hybridization.* Hybridization can occur between DNA strands, RNA strands, and strands of nucleic acid analogs (such as peptide nucleic acids[74]), in all combinations.

The hybridization environment defines the degree of base pair mismatch that can be tolerated in a duplex structure. Conditions of high *stringency* (low salt concentration, high formamide concentration, and high temperature) require exact base pairing. As the stringency is lowered by increasing the salt concentration, lowering the formamide concentration, or lowering temperature, more base pair mismatches can be tolerated in a duplex structure. The stringency of a hybridization reaction is determined by hybridization conditions and any washing steps designed to remove nonspecific nucleic acid. In real-time PCR and melting analysis, the hybridization solution is the buffer in which PCR occurs, and there are no washing steps.

Hybridization Kinetics

The kinetics of solution-phase hybridizations is second order, being proportional to the concentrations of both hybridizing strands.[118] The rate-limiting step is nucleation, where a small number of base pairs are formed in the correct orientation, followed by rapid "zippering" of complementary sequences. In the case of a probe present in great excess to the target, hybridization proceeds as a pseudo-first order reaction, depending only on the concentration of the target. However, the time required to hybridize the probe to a given fraction of the target remains proportional to the probe concentration. For example, during PCR, the concentration of primers is much greater than that of the target, and the reaction rate during each annealing step depends on the concentration of available single-stranded product, but the time required to anneal primers to a certain fraction of the target is proportional to the primer concentration.

The availability of nucleic acids for hybridization can also be an issue. In PCR, primer annealing competes with the formation of double-stranded product. As the concentration of product increases during PCR, some double-stranded product is formed before primer annealing can occur (see Figure 17-4). Similarly, when double-stranded probes are used at high concentrations, probe self-annealing interferes with probe-target hybridization. Available hybridization sites can also be limited by the intramolecular secondary structure of the probe or target (e.g., as seen in SSCP).

In addition to probe concentration and availability, the length of the probe and the nucleic acid complexity affect hybridization rates. Rates are directly proportional to the square root of the probe length and inversely proportional to complexity, defined as the total number of base pairs present in nonrepeating sequences. Mismatches up to about 10% have little effect on hybridization rates.

Hybridization rates are also influenced by many factors in the reaction environment, most notably temperature and ionic strength. Above the Tm, no stable hybrids are present, although transient complexes may form. As the temperature is lowered below the Tm, hybridization rates increase until a broad maximum occurs about 20 to 25 °C below the Tm. Hybridization rates also increase with ionic strength. Divalent cations such as Mg^{2+} have a much stronger effect than monovalent cations such as Na^{+} or K^{+}.

When the nucleic acid target or probe is immobilized on a solid support, the kinetics of hybridization is even more complex. Many of the preceding observations still hold true, but the rate and extent of solid-phase hybridization are lower than with solution-phase hybridization. Depending on the concentrations of the reactants, solid-phase hybridization can be nucleation limited or diffusion limited. Optimal efficiency of solid-phase hybridization is achieved under conditions that facilitate diffusion of the probe to the support and that favor hybridization over strand reassociation if double-stranded

probes are used. This usually means a small volume of hybridization solution and relatively low probe concentrations. In practice, solid-phase hybridization assays are empirically designed. Time of hybridization and probe concentration are the two variables most frequently adjusted in the assay. Conditions that tend to maximize the extent of hybridization and minimize the background or nonspecific attachment of the probe are selected.

Probes

Similar to antibodies in immunoassays, probes in nucleic acid hybridization assays can be unlabeled or labeled with one of a variety of reporter molecules, depending on the technique used to detect hybridization. Probes may be cloned (recombinant), generated by PCR, or synthesized (oligonucleotides). They may be DNA, RNA, or nucleic acid analogs, and single-stranded or double-stranded. Selection, purification, and labeling of probes are crucial to the success of hybridization assays.

Cloned Probes

Cloned probes consist of a known segment of DNA inserted into a plasmid vector that is propagated by growth in a bacterium. Many different plasmid vectors are now available; pBR322 was one of the first in common use.[7] Some plasmids, such as the F plasmid of *E. coli,* can be used to carry insert sizes that are very long (several hundred kb) and are called *bacterial artificial chromosomes,* or BACs. The entire plasmid DNA (insert plus vector sequences) may be used as a probe, or the insert may be purified first from the vector sequences. The latter method is obviously more cumbersome but may result in reduced background. The resulting probe is a double-stranded DNA probe, and it must be denatured before use.

Some vectors contain RNA promoter regions adjacent to the inserted DNA sequence. These regions permit generation of RNA transcripts from the DNA insert. Because only one strand is copied during RNA synthesis, single-stranded RNA probes are generated. Controlling the orientation of the insert in relation to the promoter region allows the production of transcripts in the "sense" direction (i.e., same as mRNA) or the "antisense" direction (i.e., complementary to mRNA).

PCR-Generated Probes

PCR-generated probes are simple to prepare.[45] During amplification, the PCR product typically is labeled with nucleotides that are radioactive or fluorescent, or have attached affinity labels. If desired, single-stranded probes can be obtained by amplifying with a biotin-labeled primer, followed by solid-phase separation with streptavidin.

Oligonucleotide Probes

Oligonucleotide probes are even easier to obtain than PCR-generated probes. These probes are usually 15 to 45 bases of single-stranded nucleic acid that are chemically synthesized to a specified base sequence. Most commonly, they are DNA, but RNA or nucleic acid analogs can be used. Automated, efficient, and accurate methods of synthesis continue to lower the cost of production. Sequence information is now routinely available in public databases [e.g., the National Institutes of Health (NIH) genetic sequence database, GenBank], and a similarity check for probe sequences can be performed using public algorithms (e.g., BLAST). Probe sequences must be carefully chosen to minimize cross-hybridization with pseudogenes (eukaryotes) or related species (bacteria and viruses). The melting temperature of the probe should allow both favorable hybrid stability and discrimination between related sequences under the stringency of the assay. Oligonucleotide probes are often prepared with covalent attachment of a reporter molecule (such as fluorescent dyes) or affinity labels that allow them to be attached to solid supports. Probes used in homogeneous (real-time) PCR are usually oligonucleotides with a fluorescent label.

Estimating Tms of Oligonucleotide Probes

Probe Tm prediction based on nearest neighbor thermodynamic parameters has improved with compilation of a unified database.[93] Consideration of all possible single-base mismatches and dangling ends further extends the usefulness of these estimates.[92] However, prediction parameters are typically determined using 1 M NaCl, far from typical assay conditions, so it is not surprising that predicted Tms are often at variance from observation. Empirical correction factors[77,112] that may include the concentrations of various cations, dNTPs, the target, and common additives may enhance prediction accuracy and are often used in software programs and Internet sites for in silico Tm estimation. Most fluorescent dyes also stabilize duplexes,[69,123] but this increase in Tm is seldom incorporated into predictions. For these reasons, absolute Tm predictions are seldom accurate in common laboratory and PCR buffers. However, relative Tms (i.e., the difference in Tm between two related probes, such as a probe that is matched and one that is mismatched to a single base variant) are considerably more accurate.[61]

Purity of Labeled Oligonucleotide Probes

The purity of labeled oligonucleotide probes is important for hybridization assays and critical in real-time PCR. Commercial oligonucleotides with a fluorescent label are of variable quality, and their concentration and purity should be assessed before use. Mass spectroscopy and/or coelution of absorbance (A_{260}) and fluorescence peaks on reversed-phase HPLC can indicate probe purity. Quantitative estimates of probe purity can also be obtained by simple absorbance measurements. The extinction coefficient of the oligonucleotide at 260 nm [$e_{260(oligo)}$] is first calculated from its sequence by tabulated values.[8] Some software programs and commercial suppliers provide the related value, nmol per absorbance unit at 260 nm, or nmol/$A_{260(oligo)}$, which is related to the extinction coefficient by the formula $e_{260(oligo)} = 10^6/[\text{nmol}/A_{260(oligo)}]$. Next the concentration of the fluorescent label (C_{fluor}) is calculated from its molar absorptivity[126]:

$$C_{fluor} = A_{\lambda max\ of\ fluor} / e_{\lambda max\ of\ fluor} \quad (1)$$

The concentration of the fluorescently labeled oligonucleotide is then calculated as

$$C_{oligo} = [A_{260} - (A_{\lambda max\ of\ fluor} \times e_{260(fluor)} / e_{\lambda max\ of\ fluor})] / e_{260(oligo)} \quad (2)$$

The equation takes into account the A_{260} contribution from the fluorophore. Similar equations for more than one label can be derived. The concentrations of fluorophore and oligonucleotide should be nearly equal (i.e., the ratio of fluorophore to oligonucleotide should be near 1). Acceptable ratios are between 0.8 and 1.2. Ratios less than 0.8 suggest incomplete labeling or destruction of the attached dye. Ratios greater than 1.2 suggest the presence of free dye or degraded labeled oligonucleotides. A ratio near 1 is a necessary but not a sufficient criterion of a pure probe.

Hybridization Assays: Examples

Hybridization reactions can be divided into two broad categories: *solid-phase,* in which either probe or target is tethered to a solid support while the other is in solution, and *solution-phase,* in which both are in solution (Table 17-3). It is somewhat surprising to note that nucleic acids bound on a solid matrix can still bind complementary nucleic acids. Solid-phase assays are useful because multiple samples can be processed together, facilitating control, washing, and separation procedures. However, hybridization on a solid support is less efficient than solution hybridization, and the kinetics is slower and more difficult to predict. Both solid-phase and liquid-phase assays are used routinely in the clinical laboratory. Solid-phase assays include dot blots, line probes, arrays, in situ hybridization, and Southern and Northern blotting.

Several classical methods first hybridize in solution and then separate the bound from the unbound labeled probe. Exclusion chromatography, and binding by hydroxyapatite, magnetic particles, or other affinity capture methods allow selective measurement of the labeled probe-target hybrid. For example, *hybrid capture* methods use an immobilized antibody that is specific for RNA-DNA hybrids that are formed during solution-phase hybridization of a DNA sample and an unlabeled RNA probe. The assay can be adapted to microtiter plate format for automation of washing and detection.

Solution hybridization has now been combined with amplification, detection, and quantification—all in the same tube. Such closed-tube, real-time assays do not require any addition, washing, or separation steps.

Dot-Blot and Line-Probe Assays

Conventional hybridization assays on membranes are known as dot blots or line probes, depending on the geometry of the individual spots. Nucleic acids are applied with suction, using a commercially available manifold that results in a shape that may be round (dot) or elongated (line or slot). After immobilization, the membrane is incubated with complementary nucleic acid at a constant temperature, followed by one or more washes to discriminate matched from mismatched nucleic acid. This method allows multiple probe-target hybridizations to be carried out simultaneously under identical conditions.

Two general formats are used for these assays: multiple samples may be affixed to the solid support and interrogated by a small number of probes ("sample-down"), or multiple probes may be attached to the support and a small number of samples used ("probe-down") (Figure 17-24). In the sample-down format, purified nucleic acid or amplified fragments from multiple samples are immobilized on the support.

In the probe-down format, unlabeled probes bound to the filter are allowed to interact directly with a specimen that carries the label (a technique also known as *reverse dot blot*). Alternatively, instead of having to label the sample, a set of secondary probes can be used for signal generation. Signal probes are attached to the filter only through sample-mediated hybridization; the sample nucleic acid forms a sandwich between the immobilized probe and the signal-generating probe. Results of a dot-blot or line-probe assay are usually qualitative: if hybridization has occurred, a signal is generated at the specified spot and a simple yes/no interpretation is given. Similar assays have been developed substituting microtiter plate wells for filters. This requires chemical modification of the plastic wells to bind short DNA probes at one end, allowing the bound probes to hybridize to sample, but this approach is more amenable to automation of washing and detection.

Medium-Density Arrays

Dot-blot and line-probe assays have largely been replaced by medium-density arrays that typically analyze 20 to 500 spots. Medium-density arrays are emerging in the clinical laboratory for testing multiple mutations in specimens for genetic disease, oncology, and pharmacogenetics. Many companies are involved in the supply of arrays, and the industry is moving swiftly.[37,44] These arrays do not need to be attached to a two-dimensional surface as long as their "address" can be decoded. For example, microspheres can be coded by fluorescence intensity in two different channels, while

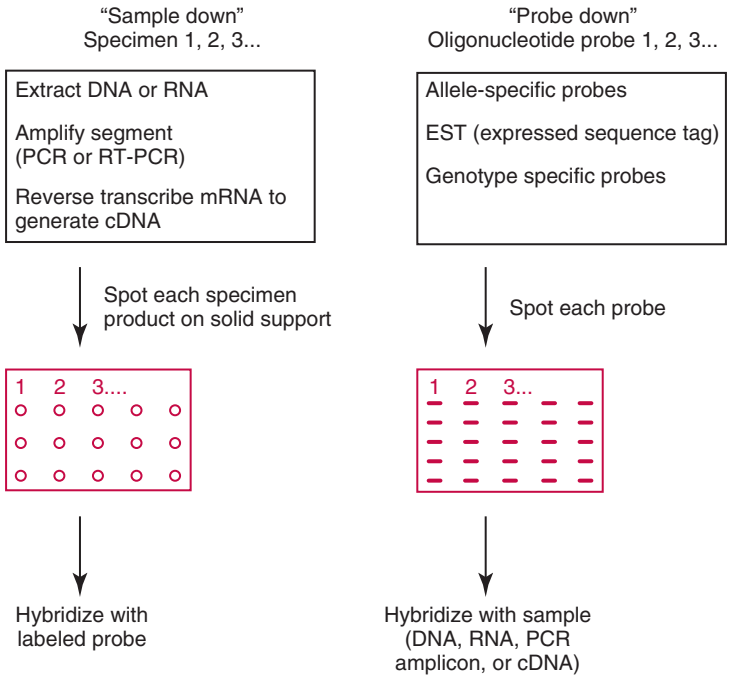

Figure 17-24 Two modes of dot-blot and line-probe assays. In the "sample-down" mode, DNA, cDNA, RNA, or amplified products are attached to the solid support and hybridized to labeled probes in solution. Alternatively, different probes are spotted onto the support ("probe-down"), and the sample is in solution.

fluorescence in a third channel monitors hybridization. All channels can be read simultaneously using a flow cytometer.[47] Some characteristics of arrays are listed in Table 17-4.

Microarrays

Extending further the density of hybridization assays, microarrays (also called *DNA arrays* or *DNA chips*) were introduced in the mid 1990s.[94] Compared with medium-density arrays, spot sizes in microarrays are decreased (typically to less than 200 microns in diameter) such that one array contains thousands to millions of spots. This dimensional change requires specialized detection equipment, software, and informatics to analyze the data. Microarrays are fabricated on solid surfaces (generally on glass, but sometimes on other supports, such as gel pads or coated gold surfaces) by synthesis of oligonucleotides on these surfaces or by physical spotting of probes with the aid of robotic arraying equipment or electronic addressing. The promise of microarrays is accompanied by challenges, including the need for strict requirements for controls and good experimental design. Because of their massively parallel capacity, microarrays have attracted tremendous interest among researchers who wish to monitor the whole genome for (1) single-nucleotide polymorphisms, (2) gene expression, and (3) copy number variants.

Single-Nucleotide Polymorphism (SNP) Arrays

Because SNPs represent the most common genetic difference between individuals, much effort has focused on correlating SNP alleles to phenotype and disease association. Microarrays that analyze human SNPs ("SNP chips") provide the technology to genotype most known human SNPs in one experiment. Nearby SNP alleles tend to cluster together as haplotypes, so disease association by haplotype simplifies the analysis. Although some valuable markers have been found by these genome-wide association studies,[31] the yield of useful disease markers obtained by these methods has been disappointing and many difficulties remain, such as identifying adequate control populations.[88] SNP arrays are also used to assess copy number variation and to genotype SNPs of known association with disease.

Gene Expression Arrays

Early gene expression arrays often used expressed-sequence-tag (EST) libraries. ESTs are short sequences that are expressed in certain cells, tissues, or organs at different developmental stages (Figure 17-25). An example of a two-color comparative EST microarray for gene expression studies is shown in Figure 17-26. Because the human genome is now completely sequenced, mRNA probes are usually directly synthesized on microarrays today. Modern gene expression arrays can measure the mRNA transcribed from all human genes in one experiment. They have been applied to almost every conceivable human condition, including neoplastic, inflammatory, and psychiatric. The promise consists of better diagnosis, molecular staging, prognosis, and therapy through understanding of disease pathogenesis. In oncology, arrays have led

TABLE 17-4 Microarrays and Medium-Density Arrays

Types of array surfaces	Glass (microscope slides, silicon wafers) Chemically coated transducers (gold electrodes, gold-coated piezoelectric crystals) Microelectrodes coated with gel pads Microsphere beads (4 μ diameter, incorporating fluorescent dyes)
What is tethered on the array surface	Oligonucleotide probes (20 to ≈80-mers) are synthesized in situ (on-chip) or by conventional synthesis followed by on-chip immobilization Expressed-sequence tags (200 to 500 bases long) Bacterial artificial chromosomes (BAC clones, typical insert size 100 to 200 kb) Sample DNA or cDNA
Hybridization	The array is exposed to labeled sample DNA or labeled sample cDNA (and less frequently to labeled probes) and is hybridized, and the identity/abundance of complementary sequences is determined.
Detection	Fluorescence detection: confocal or laser scanning devices, CCD cameras, near-infrared imaging, surface plasmon resonance imaging, flow cytometry (for microspheres) Other: electronic detection, mass spectrometry

CCD, Charge-coupled device.

to new diagnostic and prognostic markers in breast cancer,[109] bladder cancer,[110] leukemia,[34] and sarcoma,[17] among others. In the clinical laboratory, expression arrays are used directly in only a limited number of diagnostic or prognostic tests. Most arrays are used in marker discovery projects and for selection of a smaller panel of expression targets that are then analyzed by other quantitative methods such as real-time PCR that provide greater precision and dynamic range.

Copy Number Variant Arrays

One important clinical application of microarrays is the genome-wide analysis of deletions and duplications, also referred to as analysis of copy number variants, or CNVs. CNV analyses using microarrays are steadily augmenting, and in some cases replacing, traditional cytogenetic chromosome analysis (karyotyping) and fluorescence in situ hybridization (FISH) analysis (see next section) through higher resolution of microarray data. Similar to gene expression arrays, many of the CNV arrays use two-color comparative hybridization to determine the gene dosage in a specimen compared with a normal reference genome (comparative genomic hybridization, or CGH). Arrays for CGH may use BACs carrying large fragments of the genome as probes, or oligonucleotide probes for even higher resolution and data density. An example of CNV analysis using an oligonucleotide CGH array is shown in Figure 17-27. SNP arrays can also detect copy number changes by loss of heterozygosity (this method is sometimes referred to as *virtual karyotyping*). Unlike CGH, SNP arrays have the advantage of analyzing the specimen without the need to mix the reference genome with the specimen. SNP arrays can also detect copy number neutral changes caused by uniparental disomy that are not detected by CGH methods. Chromosomal abnormalities identified by CNV arrays in a clinical setting are usually confirmed by FISH or other methods.

In Situ Hybridization

In situ hybridization is a specialized type of solid support assay in which morphologically intact tissues, cells, or chromosomes affixed to a glass microscope slide provide the matrix for hybridization. The process is analogous to immunohistochemistry, except that nucleic acids instead of antibodies are used as probes. The strength of the method lies in linking morphologic evaluation with detection of specific nucleic acid sequences. When fluorescent probes are applied to metaphase chromosome spreads or interphase nuclei, the technique is referred to as fluorescent in situ hybridization, or *FISH*. Numeric aberrations or translocations of chromosomes can be detected rapidly. FISH can also be combined with immunohistochemistry so that information on both the amount of protein expression and the gene dosage can be found on the same slide. In situ hybridization is appropriate when localization of a target in tissue is important. However, experience in histology is necessary for accurate interpretation. In situ hybridization can provide information on the level of mRNA expression, but not on the size or structure of the mRNA. As might be expected, hybridization within a

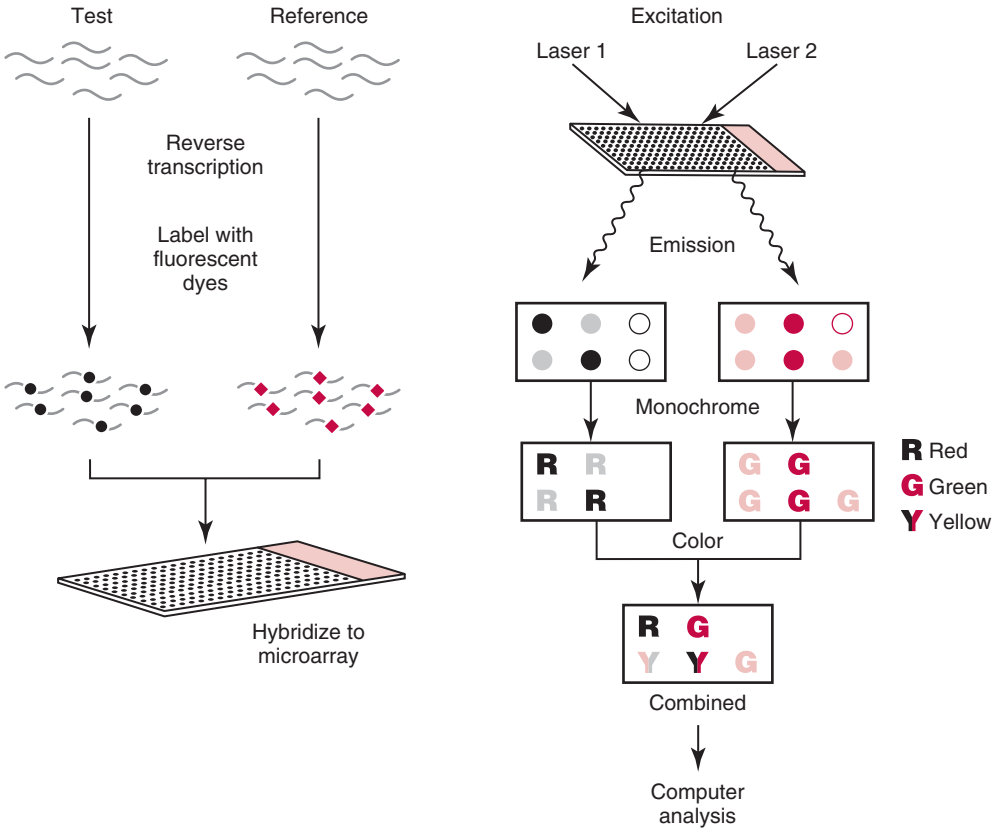

Figure 17-26 A two-color microarray experiment. An array of DNA clones representing expressed-sequence tags (ESTs) is affixed to a glass slide. Messenger RNAs in the test and reference specimen are converted into differentially labeled cDNA by reverse transcription and incorporation of two different fluorescent dyes. The two samples are hybridized together onto the array. The array is washed, and the image is captured twice, each time with a laser of a wavelength that excites one of the dyes but not the other. The monochromatic images are then converted to two colors [green for the test sample (G), and red for the reference (R)], and the images are combined. If the abundance of cDNA is the same in each of the two samples, then the composite spot will be shown as yellow (Y). If one is in greater abundance, then that color will be preserved. Upregulation and downregulation of gene expression are then analyzed by software.

tissue matrix is more variable than in solution or on well-characterized chemical surfaces.

Single-Copy Visualization

If a nucleic acid probe is labeled with many fluorescent molecules, it is possible to optically visualize a single copy of the nucleic acid target by fluorescent microscopy. One technique uses reporter probes that are labeled with a long string of multicolored fluorescent labels.[28] Several tandem color segments on the reporter probe each consist of about a hundred fluorophores, and the combination of different color segments uniquely identifies the target. The target nucleic acid is hybridized in solution with the reporter probe together with a capture probe and is washed, immobilized, stretched, and oriented on the surface of an optical slide. Each captured target is then identified by the color code of the reporter and is counted (Figure 17-28). Unfortunately, much of the target is lost during the washing step; therefore, the sensitivity of this technique is not as high as that of real-time PCR (see next section). A minimum of about 2000 target copies is currently required for quantification above background. However, the ability of the method to multiplex more than 150 reporter probes in one reaction tube and to count individual molecules is attractive. One application of this technique is direct measurement of mRNA expression in tissue specimens prepared from formalin-fixed paraffin blocks without the need for cDNA preparation or PCR.

Real-Time PCR

In real-time PCR, data are collected during nucleic acid amplification rather than at a single end point. The technique uses fluorescent reporter molecules and instrumentation that records fluorescence during thermal cycling. Data obtained provide information on the identity, quantity, and sequence

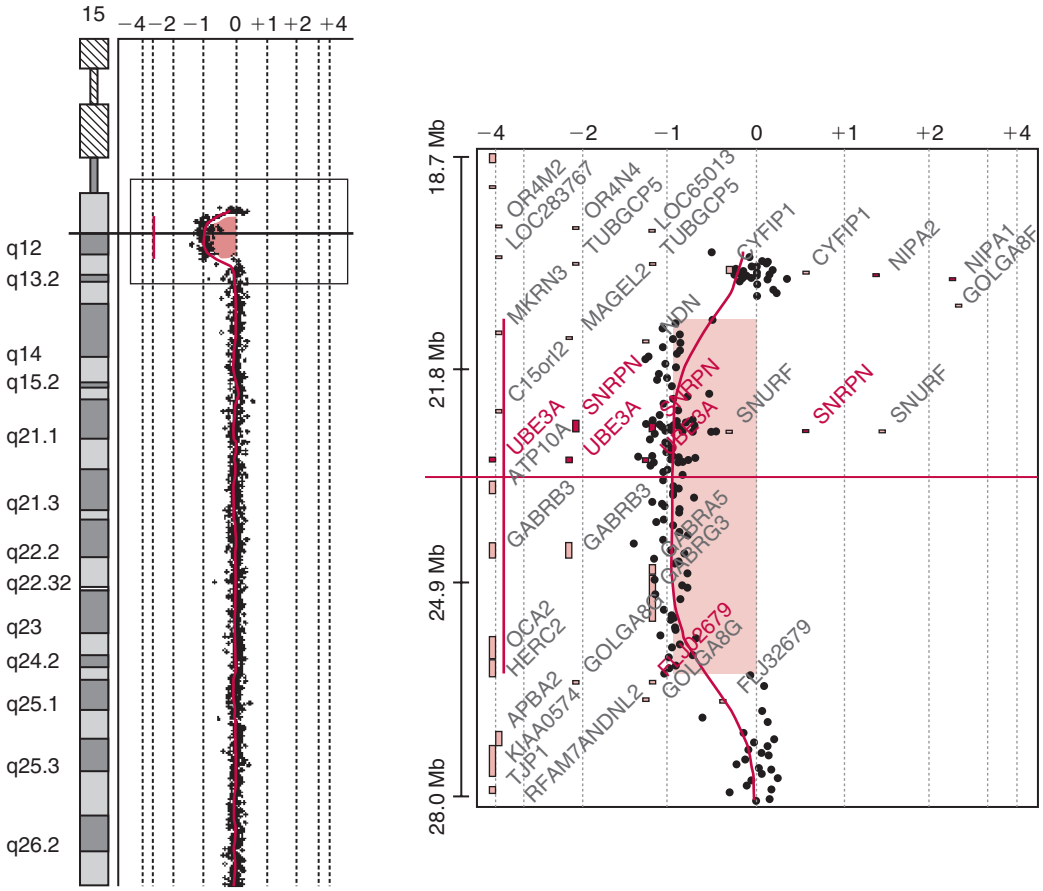

Figure 17-27 Copy number variation identified with a comparative genomic hybridization array made from oligonucleotides. DNA from a subject is fragmented, labeled with Cy5, and hybridized onto a microarray, together with Cy3-labeled reference DNA. On the array are nearly 44,000 oligonucleotide probes, each about 60 bases long and tiled across the whole genome at an average spacing of 75 kb. Shown on the left panel are results of probes on chromosome 15 (all other chromosomes are analyzed in this assay but are not shown). Each dot represents a specific probe to which the subject's DNA hybridizes. Their positions (0, −1, +1, etc.) reflect the dosage of the subject's DNA relative to the reference DNA. A majority of the probes line up on "0," indicating no quantitative difference compared with the reference DNA. Probes in the 15q11 to 15q13 region, however, are on the "−1" line, indicating that the subject has a deletion of that region in one of the chromosomes. A closer view of that region *(right panel)* shows that among the deleted genes are *UBE3A,* which causes Angelman syndrome, and *SNRPN,* which causes Prader-Willi syndrome. Because the method does not distinguish the methylation status of the deleted alleles, this result alone cannot determine which of the two disorders the subject has. *(Courtesy Sarah South, Ph.D., ARUP Laboratories.)*

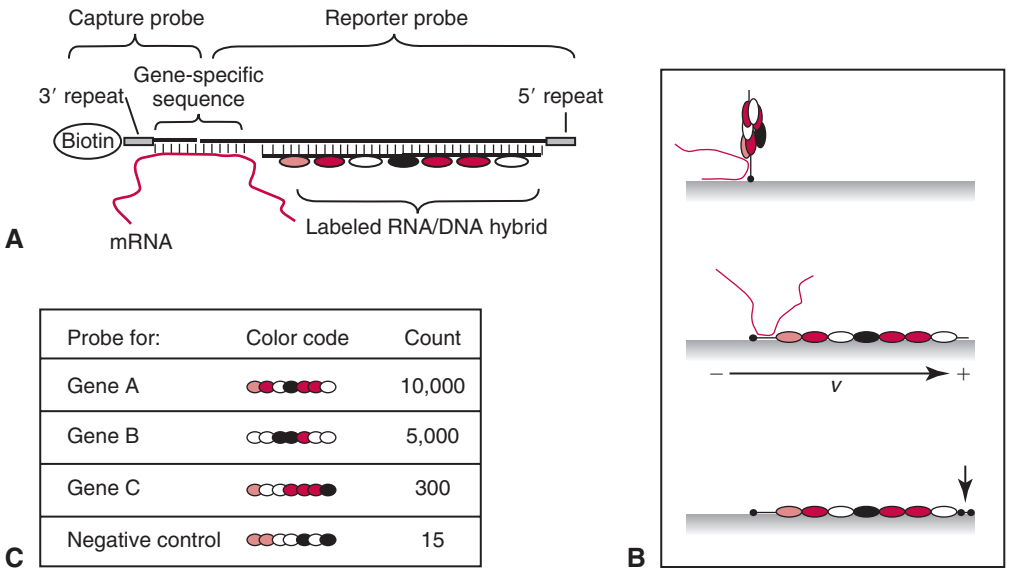
of the nucleic acid sample. Fluorescent dyes or probes capable of signaling the relative quantity of DNA are added to the PCR mixture before amplification. The same reaction tube is used for amplification and fluorescence monitoring, and there are no sample transfers, reagent additions, binding or washing steps, thereby eliminating the risk of product contamination in subsequent reactions. Because the process is simple and fast, real-time PCR is replacing many conventional techniques in the clinical laboratory.

Real-time PCR was first described using ethidium bromide to monitor the accumulation of a double-stranded PCR product with the fluorescence signal recorded once each cycle.[41,42] If target DNA is present, fluorescence increases. How early during PCR one begins to see a signal depends on the initial amount of target DNA, and this provides a systematic method of quantification. Further, when fluorescence is continuously monitored as the temperature is raised, a melting curve can be generated. Often the first derivative of this melting curve is plotted to visually aid a person in determining the position of the melting temperature. Melting analysis can be used to verify the identity of the amplified product and to detect sequence variants down to a single base



Probe for:	Color code	Count
Gene A		10,000
Gene B		5,000
Gene C		300
Negative control		15

Figure 17-28 Single-copy visualization. A pair of probes (capture probe and reporter probe) hybridize to the mRNA target in solution through gene-specific probe sequences (A). The reporter probe has seven color segments, each segment made of ≈900 RNA bases that are labeled with about a hundred fluorophores of one color. The labeled portion of the probe is a DNA/RNA hybrid that can be observed as a ≈3 nm fluorescent spot. Excess probes and unbound DNA are removed and the target complex is immobilized on a streptavidin-coated slide through the biotin on the capture probe (B, top). An electrical current is applied, and the complex is stretched (B, middle). The reporter probe is immobilized in extended form by biotin-labeled oligonucleotides complementary to its 5′ repeat sequence (B, bottom). The color code of the probe is read by an epi-fluorescent microscope, and each unique probe is counted (C). Normally, a number of negative control probes are present in the hybridization solution to establish nonspecific background counts.

(Figure 17-29). Real-time PCR and melting analysis can be considered as "dynamic" hybridization assays in which formation and dissociation of the probe-target duplex (or product duplex) are monitored in real time.

Dyes and Probe Formats for Real-Time PCR

Many different fluorescent reporter systems are used in real-time PCR, and some of the more common ones are shown in Figure 17-30. Many methods use probes with sequences complementary to the target. Others rely on double-stranded DNA binding dyes and the specificity afforded by PCR primers. Some have the additional option of melting analysis to verify the melting temperature of the probe or product.

Double-Stranded DNA Binding Dyes

Although ethidium bromide was the first dye used in real-time PCR, cyanine dyes are more widely used today. Several cyanine dyes have fluorescent properties similar to those of fluorescein, allowing the use of commonly available real-time optics.[22,127] The fluorescence increases as double-stranded DNA is produced during PCR (Figure 17-30, *row one*). Double-stranded DNA binding dyes are commonly used for real-time quantification, particularly in the research setting when the specificity of a probe is not needed and the cost of probes is prohibitive.

One disadvantage of some cyanine dyes is that they inhibit amplification at dye concentrations that are needed to saturate the amount of DNA produced by PCR. As a result, there is not enough dye to go around, and low Tm products are poorly detected in multiplex amplifications. However, alternative "saturating" DNA dyes that do not inhibit PCR have been developed. These dyes also detect heteroduplexes and enable very simple solutions for genotyping and mutation scanning.[84,123]

Fluorescently Labeled Primers

Labeled primers can also be used to monitor PCR. In one system, a primer with a 5′-hairpin is labeled with a fluorophore and a quencher so that fluorescence is quenched in the hairpin conformation. When the primer straightens out during PCR, fluorescence increases[73] (Figure 17-30, *row six*). If the sequence of the primer is carefully considered, the quencher moiety is not necessary.[72] Nonhairpin primers with a single label can also be used for detection and genotyping because of changes in fluorescence that occur with hybridization.[33]

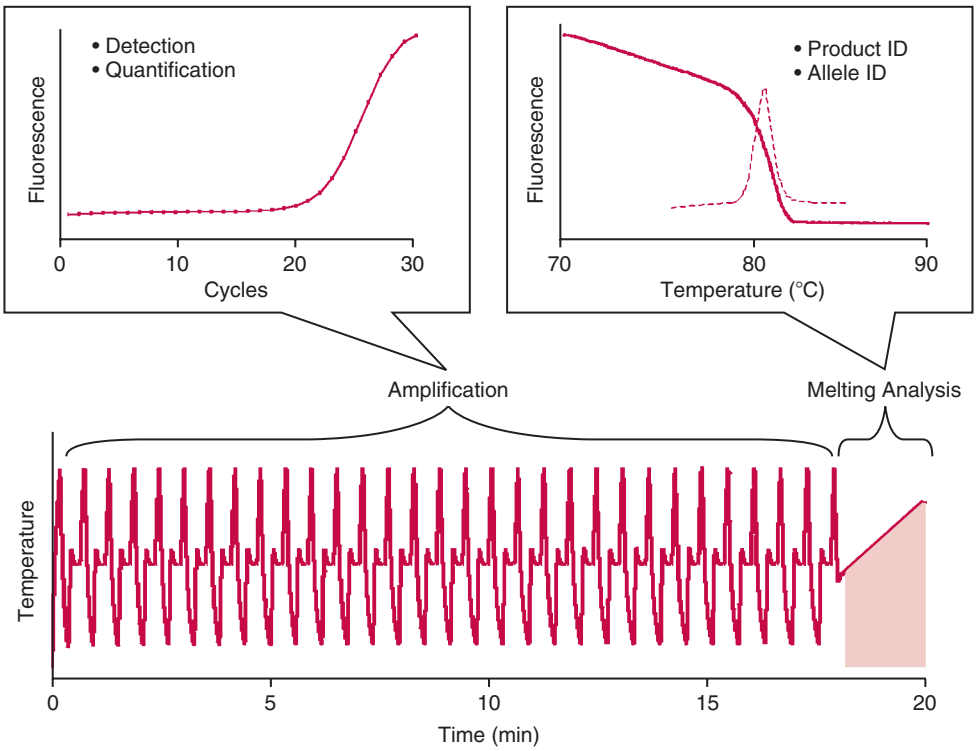


Figure 17-29 Real-time monitoring during amplification and melting analysis. The *bottom panel* shows a typical rapid-cycle temperature profile that is followed by a temperature ramp for melting analysis. When fluorescence is monitored during amplification once each cycle *(dotted lines)*, information is provided on the presence or absence of specific target sequences and allows quantification of the target. When fluorescence is monitored continuously through the melting phase *(shaded area)*, information can be provided that verifies target identification or establishes genotype. *(Modifed with permission of the publisher from Wittwer CT, Kusukawa N. Real-time PCR. In: Persing DH, Tenover FC, Versalovic J, et al, eds. Molecular microbiology: diagnostic principles and practice. Washington, DC: ASM Press, 2004:71-84.)*

One advantage of fluorescently labeled primers over dsDNA dyes is that multiplexing is possible. However, with both dsDNA dyes and labeled primers, reaction specificity depends on the primers. Any double-stranded product that is formed will be detected, including primer-dimers. Therefore, hot start techniques to increase specificity and melting curve analysis to confirm the desired product are useful.

Probe-Specific Detection

The use of fluorescent probes in PCR adds another level of specificity to the process. Fluorescent probes that hybridize to PCR products during amplification change fluorescence by two possible mechanisms: (1) a covalent bond between two dyes is broken by hydrolysis or is made through ligation, or (2) the fluorescence change follows reversible hybridization of the probe to the target. Following this distinction, when an irreversible covalent bond is involved, the probes are called *hydrolysis probes.* When probes reversibly change fluorescence on duplex formation, they are called *hybridization probes.* One major difference between the two probe types is that melting analysis is possible with hybridization probes, but not with probes that have been hydrolyzed.

Hybridization Probes. These probes change fluorescence upon hybridization, usually by fluorescence resonance energy transfer.[54,127] Two interacting fluorophores may be placed on adjacent probes (Figure 17-30, *row two*), or one may be placed on a primer and the other on a probe (Figure 17-30, *row three*). Only one probe with one fluorophore may be necessary if fluorescence is quenched by deoxyguanosine residues.[16] Another single-labeled probe design uses thiazole orange attached to a peptide nucleic acid.[101] In each of these designs, the fluorescence change that occurs with hybridization is reversible with melting.

Hydrolysis Probes. A fluorophore-labeled probe can be synthesized with a quencher located in a position that allows it to quench fluorescence from the fluorophore. If the probe is hydrolyzed between the fluorophore and the quencher during PCR, fluorescence will increase. The most common implementation uses the 5′-exonuclease activity of some DNA polymerases to hydrolyze the probe and dissociate the labels (Figure 17-30, *row four*). This method has been simplified by putting the fluorophores on opposite ends of the probe.[59] Hybrid-stabilizing agents, such as a minor groove binder, can be added to the probe to make the system more robust.[50]

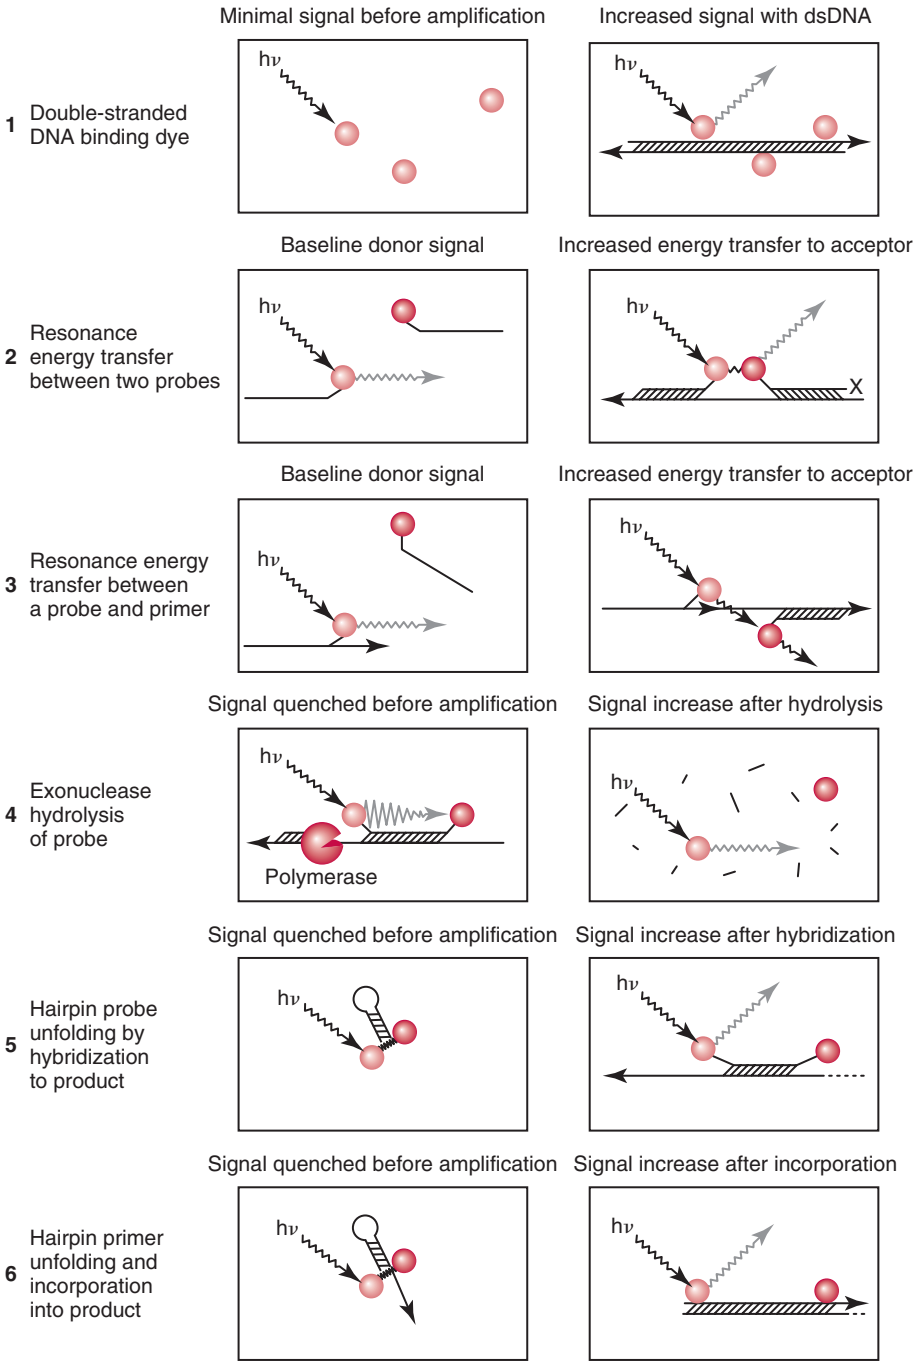

Figure 17-30 Common probes and dyes for real-time polymerase chain reaction (PCR). *(1)* Double-stranded DNA dyes show a significant increase in fluorescence when bound to DNA (*hv* = excitation light). *(2)* Adjacent hybridization probes. Fluorescence resonance energy transfer (FRET) is illustrated between a donor and acceptor fluorophore. The "x" indicates termination of the 3′-end of the probe to prevent polymerase extension. *(3)* FRET between a labeled primer and a single hybridization probe. *(4)* Hydrolysis probes are cleaved between a fluorescent reporter and a quencher, resulting in increased fluorescence. *(5)* Hairpin probes are quenched in the native conformation, but increase in fluorescence when hybridized. *(6)* Hairpin primers retain their native, quenched conformation until they are incorporated into a double-stranded product. *(Modified with permission of the publisher from Pritham GH, Wittwer CT. Continuous fluorescent monitoring of PCR. J Clin Lig Assay 1998;21:404-12. © 1998 Clinical Ligand Assay Society Inc.)*

Dual-labeled probes can also be cleaved using a DNAzyme (a DNA molecule that acts as a catalyst) generated during PCR.[104] Finally, irreversible ligation can be used for homogeneous genotyping with a fluorescent readout.[13] Hydrolysis probes generate fluorescence through changes in covalent bonds. The change in fluorescence signal is irreversible, and melting analysis of the hydrolyzed probe is not useful.

Mixed Mechanism Probes. Several probe systems appear to function by both hydrolysis and hybridization mechanisms. These include hairpin probes, self-probing amplicon primers, and displacement probes. A hairpin probe functions similarly to a hairpin primer in that it is designed to increase in fluorescence when the distance between the quencher and the reporter increases upon target hybridization (Figure 17-30, *row five*). Similarly, primers that result in self-probing amplicons have a hairpin that separates quencher from reporter when hybridized.[119] Competitive displacement probes separate quencher and reporter by competitive hybridization.[57] However, in all three cases, polymerases with exonuclease activity usually are used, and the labeled probes are potential substrates for exonuclease cleavage. Indeed, their amplification growth curves often resemble irreversible hydrolysis rather than reversible hybridization (Figure 17-31). Conversely, many exonuclease probes, especially probes labeled on each end, show significant hybridization signals.[59]

Detection and Quantification in Real-Time PCR

When fluorescence is monitored once each cycle in the presence of a dye, the data closely follow the expected logistic shape discussed earlier (see Figures 17-3 and 17-31, *top left*). However, with hydrolysis probes, fluorescence is cumulative and continues to increase even after the amount of product reaches a plateau (Figure 17-31, *top middle*). In contrast, reactions monitored with hybridization probes may show a decrease in fluorescence at high cycle number[124] (Figure 17-31, *top right*). Despite differences in the curve shape, all real-time systems follow the amount of product being produced during PCR, and this information is used for detection and quantification.

Detection

A fluorescent signal that increases during PCR and follows one of the expected curve shapes suggests that the specific target is present and was amplified. In contrast, a signal that stays at background even after 40 PCR cycles suggests that the target is absent and that no amplification occurred. Algorithms that analyze the entire curve may be more robust than simple threshold methods.[122] Positive controls (to rule out inhibitory factors) and negative controls (to rule out product contamination and nonspecific signal generation) are necessary. Melting analysis can be used to verify the expected Tm

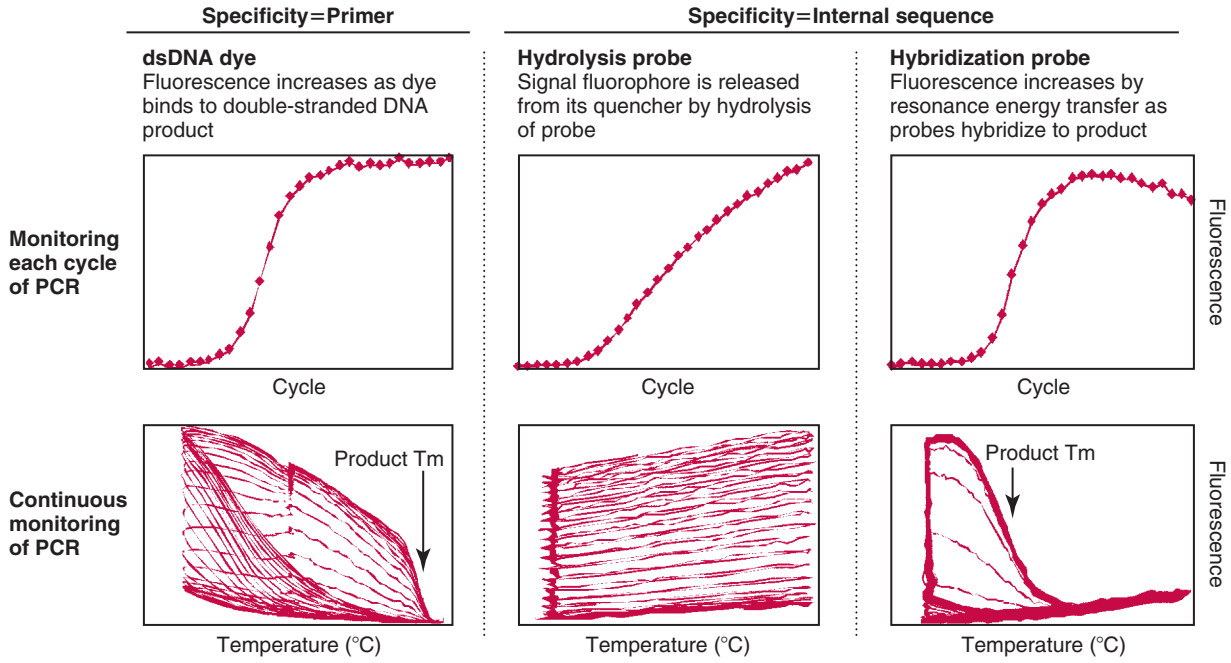

Figure 17-31 Monitoring in real time. The *top row* shows data collected once each polymerase chain reaction (PCR) cycle, and the *bottom row* shows data collected continuously (5 times per second) during all PCR cycles. Three different reporter systems are shown. *(Modified with permission of the publisher from Wittwer CT, Kusukawa N. Real-time PCR. In: Persing DH, Tenover FC, Versalovic J, et al, eds. Molecular microbiology: diagnostic principles and practice. Washington, DC: ASM Press, 2004:71-84.)*

of the probe or product if the fluorescence generated is reversible with hybridization.

When assay specificity depends on the primers (e.g., with DNA dyes or labeled primers), the possibility of amplifying undesired targets or primer-dimers is a concern. One way to eliminate or decrease the detection of unexpected targets is to acquire fluorescence during each cycle at a temperature just below the melting transition of the expected target. To illustrate the concept, Figure 17-32 shows a first-derivative melting curve of products at the end of a PCR that shows unexpected products along with the desired product. The signal was generated with a dye that detects all double-stranded DNA. The plot reveals both lower Tm species that are unexpected products and a single Gaussian-shaped peak that is centered on the target's predicted Tm. If fluorescence is acquired during each cycle at (in this case) 85 °C, the unexpected products will be denatured and will not contribute to the signal.[70]

Multiplex detection is possible with probes that are labeled with different colors or with probes or amplicons that have different melting temperatures. Examples in the clinical laboratory include probe multiplexing to detect the presence of more than one infectious organism, or to discriminate an internal control template from the target.

Quantification

Real-time PCR offers a convenient and systematic approach to quantification by monitoring the amount of product each cycle. Perhaps the most popular clinical use of real-time PCR is in the assessment of viral load, particularly for HIV and HCV. The clinical need for quantification is well established, and real-time methods give rapid and precise answers. However, other amplification systems, particularly transcription-based and branched DNA methods, are also used in this highly competitive field. Additional quantitative applications of real-time PCR include quantification of mRNAs (after reverse transcription) in gene expression studies and assessment of gene dosage in genetics and oncology.

One of the advantages of real-time PCR is its large dynamic range. Figure 17-33, *A*, shows an extended range of quantification standards in a typical real-time PCR. As the initial template concentration increases, the curves shift to earlier cycles. The extent of this shift depends on the PCR efficiency (Table 17-5). The cycle at which fluorescence rises correlates inversely with the log of the initial template concentration and is the quantification cycle or Cq (Figure 17-33, *B*). This "cycle" is actually a *virtual* cycle that includes a fractional component determined by interpolation, which can be calculated by several methods. One method uses the maximum of the *second derivative* of the curve to determine Cq (Figure 17-34). The second derivative of the amplification curve is estimated numerically with Savitzky-Golay polynomials.[81] The second derivative is derived from the shape of the curve,

TABLE 17-5 Slope of Real-Time Quantitative PCR Standard Curve, PCR Efficiency, and the Amount of PCR Product Produced After 30 Cycles Compared With the Amount Expected With PCR Efficiency of 100%

Slope of Calibration Curve*	PCR Efficiency, %	PCR Product After 30 Cycles, % Expected
−3.32	100	100
−3.35	99	86
−3.38	97.5	69
−3.45	95	47
−3.59	90	22
−3.74	85	10
−3.92	80	4
−4.34	70	1
−4.90	60	0.1
−5.68	50	0.02

*Assuming the log (initial template) is plotted on the *x*-axis as the independent variable, and the quantification cycle is plotted on the *y*-axis as the dependent variable, the slope of the calibration curve is as follows: Slope = ΔCycle/Δlog (initial template). Percent PCR efficiency is calculated as $(10^{-1/\text{Slope}} - 1) \times 100$.
PCR, Polymerase chain reaction.

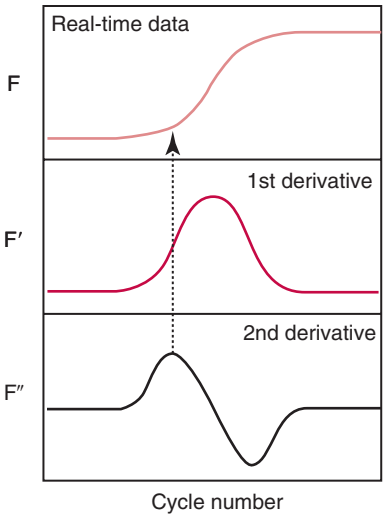

Figure 17-34 Finding the fraction cycle number for quantification. Real-time fluorescence data *(F)* from the amplification reaction are shown with the first *(F′)* and second *(F″)* derivatives. The maximum of the second derivative provides one way to determine the quantification cycle, Cq. *(Modified with permission of the publisher from Wittwer CT, Kusukawa N. Real-time PCR. In: Persing DH, Tenover FC, Versalovic J, et al, eds. Molecular microbiology: diagnostic principles and practice. Washington, DC: ASM Press, 2004:71-84.)*

and there is no need to adjust baselines or worry about normalizing the fluorescence values. Alternatively, in *threshold analysis,* a fluorescence level is selected that intersects with the amplification curves, and fractional cycle numbers are found by interpolation. However, when the sample fluorescence does not reach the threshold (as may happen with low copy samples), quantification is not possible.

Accuracy and Precision

The accuracy of real-time PCR quantification depends not only on the method chosen to analyze the curves, but also on the quality of the quantification standards used. Purified PCR products quantified by spectrophotometry are easily obtained. When serially diluted, these calibrators can accurately quantify the amount of target in human genomic DNA.[81] Synthesized oligonucleotides, purified plasmids, and genomic DNA can also be used as calibrators. *Limiting dilution* analysis can also be used to determine the amount of "amplifiable" DNA.[70] Sometimes absolute quantification is not needed, and quantification relative to one or more reference genes is performed. In this case, selection of the reference genes and PCR efficiency are critical. The precision of quantitative real-time PCR depends on the initial number of template copies in the reaction. When the initial target concentration is low, imprecision is high. Part of the variance comes from stochastic limitations as defined by the Poisson distribution described earlier. In addition, PCR efficiency is more variable at low copy numbers. Technical guidelines for performing quantitative PCR experiments have been published.[11]

Melting Analysis

Not only can amplification, detection, and quantification be performed by homogeneous hybridization, but detailed genotyping information can also be obtained. Genotyping is best performed in the same tube by monitoring the melting of hybridized duplexes during controlled heating, producing a melting curve signature for the duplex. Such a signature monitors melting over of a range of temperatures in contrast to the single-temperature analysis of conventional hybridization techniques, such as dot blots or microarrays. The advantages of complete melting curves also apply when different homogeneous techniques are compared. For example, methods that rely on hydrolysis for signal generation and/or those that acquire data only at one temperature are more susceptible to genotyping errors.[103] Real-time amplification and melting analysis make up a powerful combination of techniques that require only temperature control and sampling of fluorescence. Many other genotyping techniques require complex separation and/or detection equipment after PCR. Real-time PCR with melting curve analysis allows detection, quantification, and genotyping in less than 30 minutes (see Figure 17-29) without ancillary processing or additional equipment. A book series has been published on methods and applications of rapid-cycle, real-time PCR.[20,65,85,121]

When fluorescence is monitored continuously within each cycle of PCR, the hybridization characteristics of PCR products and probes can be observed.[128] Continuous spirals of fluorescence versus temperature are produced (see Figure

17-31, *bottom panels*).[127] With dyes, the melting characteristics of the amplified DNA identify the product.[87] No hybridization information is revealed with hydrolysis probes, whereas the melting of hybridization probes is readily apparent. Probe melting occurs at a characteristic temperature that can be exploited to confirm target identity and to analyze sequence alterations under the probe.

For routine testing in the clinical laboratory, a single melting curve is usually performed at the end of PCR instead of monitoring hybridization throughout the entire PCR process (see Figure 17-29). Immediately after the last PCR cycle, samples are momentarily denatured (94 °C), cooled to about 10 °C below the lowest temperature of interest, and heated at a rate of 0.1 to 0.3 °C/s, while fluorescence is continuously monitored. When hybridization probes are used, rapid cooling maximizes formation of probe-target duplexes while minimizing formation of the duplex PCR product. Primer asymmetry and use of 5′-exonuclease–deficient polymerases often augment the probe signal.

SNP Genotyping

A hybridization probe pair placed over a heterozygous polymorphism is shown in Figure 17-35. The reporter probe is complementary to the normal allele. As the temperature is increased, the mismatched mutant hybrid melts first, giving the first transition, followed by the matched normal hybrid. The melting temperatures of both hybrids are easily seen in the derivative plots.[81] A well-optimized probe design will provide a Tm difference of 4 to 10 °C for a single base mismatch under the probe.

SNP genotyping by melting curve analysis can be achieved with a variety of probe and dye methods. Figure 17-36, *A* shows the design of the traditional hybridization probe pair[5] and the results of homozygous wild-type, mutant, and heterozygous samples that are well discriminated from each other. Virtually the same result can be achieved by using a single hybridization probe in which the fluorescent signal is quenched on the free probe, but is dequenched as it forms a hybrid with the target (Fig. 17-36, *B*).[16] The third row shows genotyping with an *unlabeled probe* and a saturating DNA binding dye.[132] Both probe and amplicon melting transitions are present. The fourth row shows similar results using a *snapback primer*,[133] an unlabeled probe attached as a 5′-tail to one of the primers. The advantage of these last two methods is that they do not require fluorescently labeled probes. Finally, SNP genotyping is possible by amplicon melting alone if a saturating DNA binding dye is used (Fig. 17-36, *E*).[58] However, the temperature difference between genotypes is small, and high-resolution melting is required for accurate genotyping.

High-Resolution Melting Analysis

In earlier sections of this chapter, heteroduplex detection (by electrophoresis or by HPLC) was discussed as a means to scan stretches of DNA in which the presence of variation is suspected. Melting analysis with saturating dyes can detect heteroduplexes with better sensitivity than these methods and does not require any processing or separation.[84] Although conventional fluorescent melting analysis could distinguish PCR products that differed by only about 1 to 2 °C,[87] high-resolution melting instruments now provide precision and resolution improvement of at least 10-fold[123] and require only a few minutes.[38] Typically, melting data are normalized between 0% and 100% fluorescence, and different homozygotes are distinguished by Tm. Heterozygotes are best detected when comparing the melting curve shapes by shifting the curves along the temperature axis until they overlap. An example of heteroduplex detection and SNP genotyping by melting curve analysis is shown in Figure 17-37. Major applications of high-resolution melting include genotyping, mutation scanning, and sequence matching. High-resolution melting analysis has been reviewed.[24,25,113]

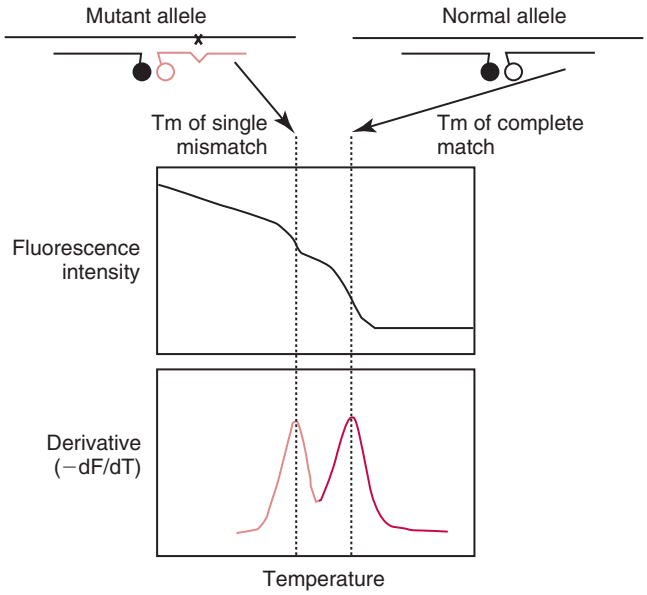

Figure 17-35 Melting curve single-nucleotide polymorphism (SNP) genotyping. A heterozygous specimen with an SNP under the probe is amplified and melted. Two temperature transitions are visible: one from the mutant allele that is mismatched with the probe and melts at a lower temperature, and one from the normal allele that is completely matched with the probe and melts at a higher temperature. The derivative plot shows the melting temperatures of both the mutant-probe and the normal-probe duplexes as peaks. *(Modified with permission of the publisher from Bernard PS, Pritham GH, Wittwer CT. Color multiplexing hybridization probes using the apolipoprotein E locus as a model system for genotyping. Anal Biochem 1999;273:221-228. © 1999 Academic Press.)*

Comparison of Closed-Tube SNP Genotyping Methods

Many methods are available for SNP genotyping, and the method of choice depends on several factors, including turnaround time, batch size, and throughput requirements. The necessities of high-volume genomic research are different

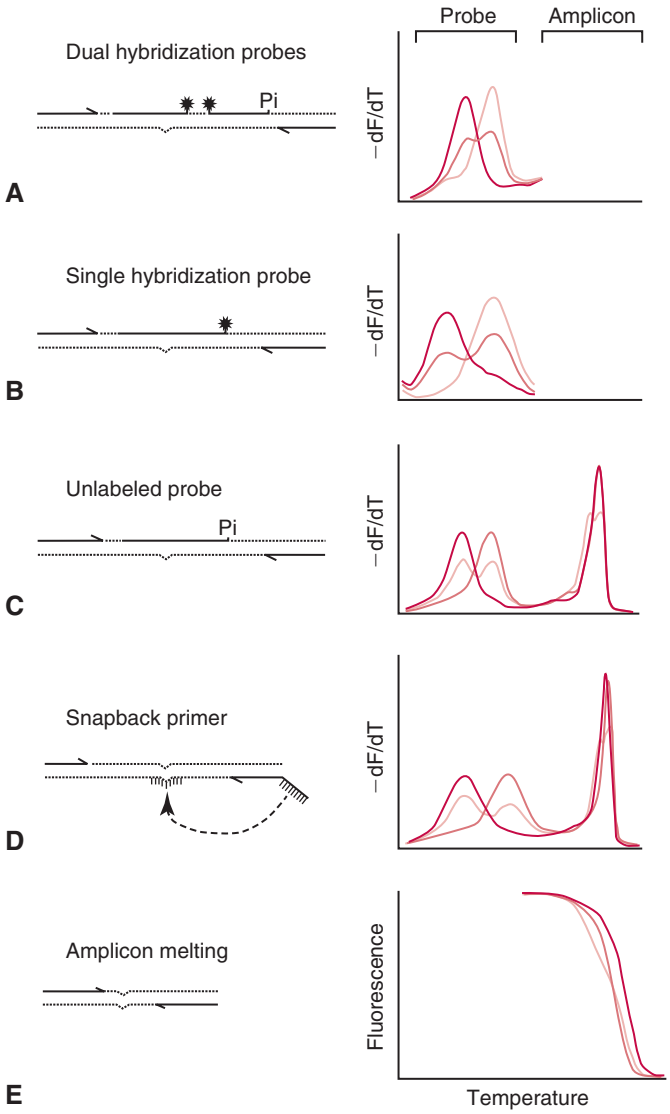

Figure 17-36 Five designs for single-nucleotide polymorphism (SNP) genotyping and corresponding melting curve results. The traditional dual hybridization probe design (A) uses a pair of probes: one labeled with an acceptor fluorophore and the other with a donor fluorophore. The single hybridization probe design (B) lacks the second probe. The unlabeled probe design (C) does not require a covalently attached fluorescent label, using instead a saturating DNA binding dye in solution. Snapback primers (D) are similar to unlabeled probes, with the probe attached to one primer as a 5′-tail. Finally, amplicon melting (E) uses only two regular polymerase chain reaction (PCR) primers, relying on high-resolution melting analysis to distinguish the small differences between genotypes. The two homozygotes are differentiated by melting temperature (Tm), and the heterozygote differs in shape from the contribution of heteroduplexes. Pi indicates a 3′-phosphate or other blocker that prevents polymerase extension.

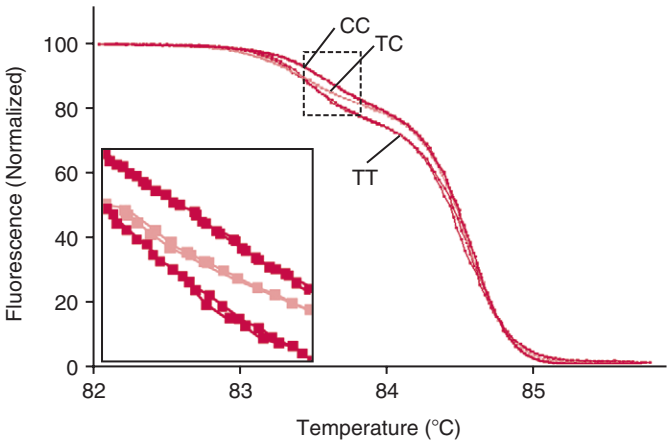

Figure 17-37 A single base change in a 544 bp fragment detected by melting analysis. Shown are high-resolution melting curves of polymerase chain reaction (PCR) amplicons from the gene *HTR2A* carrying a single-nucleotide polymorphism (SNP). Results are shown for six individuals, two different individuals for each of the three genotypes: wild-type homozygote (TT), mutant homozygote (CC), and heterozygote (TC). Two melting domains are present because of differing GC content. The SNP was present in the lower melting domain. The inset magnifies a portion of the data, showing that all three genotypes can be discriminated. *(Modified by permission of the publisher from Wittwer CT, Reed GH, Gundry CN, et al. High-resolution genotyping by amplicon melting analysis using LC Green. Clin Chem 2003;49:853-60. © AACC.)*

from those of a clinical reference laboratory, a medical clinic, or the STAT laboratories of the future.

Methods for homogeneous SNP analysis in a closed system differ greatly in their level of complexity (Table 17-6). The number of oligonucleotides required varies from 2 to 5. The simpler techniques do not require probes at all, although some of the more complex methods require up to three labels or modifications on each probe. All of these methods use fluorescence and solution hybridization. Some of the methods that use melting analysis will detect more than two alleles if present; those based on allele-specific amplification or end point analysis are limited to two.

The five simplest homogeneous SNP typing methods do not use fluorescently labeled probes. Amplicon melting requires only two primers and a heteroduplex-detecting DNA dye (see Figure 17-36, *E*).[58] The snapback primer system also requires only two primers—one with a self-probing 5′-tail (see Figure 17-36, *D*).[133] Unlabeled probe genotyping requires two primers and one 3′-blocked probe (see Figure 17-36, *C*).[132] Allele-specific PCR requires three primers and is based on a preference by the polymerase to extend only a perfectly matched primer. Genotyping can be obtained in two wells by monitoring fluorescence at each cycle,[29] or in one well by incorporating GC-clamp(s) so that alleles can be differentiated at the end of PCR by their melting temperatures.[116] Intermediate in complexity are hybridization probe

TABLE 17-6 Comparison of Homogeneous (Closed-Tube) SNP Genotyping Methods (In Order of Increasing Complexity)

Method	Oligonucleotides	Modifications	Comments
Amplicon melting[58]	2	0	Simplest and least expensive
Snapback primers[133]	2	1	Self-complementary 5′-tail
Allele-specific PCR (real-time)[29]	3	0	Requires one well for each allele
Unlabeled probes[132]	3	1	3′-phosphate on probe
Allele-specific PCR (melting)[116]	3	1-2	GC clamps
Single hybridization probe[16]	3	1-2	3′-phosphate if 5′-fluorophore
Dual hybridization probes[5]	4	2-3	3′-phosphate if 5′-fluorophore
Hydrolysis probes[55]	4	4	
Dual-labeled hairpin probes[105]	4	4	
Self-probing amplicon[119]	3-4	6	
Minor groove binder hydrolysis probe[18]	4	6	
Serial invasive signal amplification[35]	5	4	

GC, Short 5′-oligonucleotide tail of G and C bases used to modify allele Tm; *PCR*, polymerase chain reaction; *SNP*, single-nucleotide polymorphism.

melting assays. Designs with single[16] or dual hybridization[5] probes are shown in Figure 17-36, *A, B*.

The more complex closed-tube methods for SNP genotyping are end point assays. Allele-specific hydrolysis[55] and hairpin probes[105] are commonly used. Self-probing amplicons[119] and minor groove binder hydrolysis probes[18] both require three modifications on two probes for SNP typing. Finally, serial invasive signal amplification is a method of homogeneous genotyping that does not require PCR.[35]

CONCLUSION

Molecular diagnostics remains a developing field in laboratory medicine. Current progress in nucleic acid techniques is extraordinary, driven by the promise of great return. Can drug therapy be tailored to each individual by appropriate molecular tests? Can diagnostic biochips parallel the microelectronics revolution, continuing to provide more information at less expense? Will complete genome sequencing for individual predisposition testing become a reality? Although we are still years away from immediate, comprehensive testing, the time for personalized diagnostics will come. In the end, the rate-limiting factors seldom involve technology, but rather our ability to correlate test results with disease. Nevertheless, simple, powerful, and cost-effective techniques will aid this quest.

Molecular analysis often requires multiple steps, including sample preparation, amplification, and analysis. As a result, successful automation is critical for routine adoption in the clinical laboratory. However, to corruptly paraphrase Henry David Thoreau in Civil Disobedience: "I heartily adhere to the motto: The best automation is not needing to automate." The simplest techniques are often the best. As with immunoassays, methods that require separation and washing steps are being replaced by rapid, homogeneous methods. How to maintain this simplicity while handling the increased data density provided by current technology is a central challenge for molecular diagnostics today.

CHAPTER 18

Microfabrication and Microfluidics and Their Application to Clinical Diagnostics

Lindsay A. L. Bazydlo, Ph.D., and James P. Landers, Ph.D.

BACKGROUND

The first miniaturized analytical device with some degree of functionality was reported in 1979, when the separation of a simple mixture of low molecular weight compounds was achieved in only a few seconds in a microdevice fabricated in silicon.[156] The significance of this development can be appreciated only by a relativistic view of state of the art separation techniques common to the laboratories of that time. The 1970s saw most chemical separations carried out using open-column, paper, and thin-layer chromatographic processes, while gas chromatography (GC), having experienced several decades of development, was only beginning to mature into a bona fide technology for small molecule analysis. Pressure liquid chromatography began to evolve into a method that would bring faster analysis times with higher resolution, and the late 1970s saw new chemistries amenable to reverse-phase liquid chromatographic separations for improved resolution of similar compounds. Electrophoresis was the workhorse for large biomolecule separations, with Laemmli having established denaturing separations of proteins in acrylamide gels[81] and O'Farrell having just defined the power of two-dimensional (2D) gel separations for proteins[119]; the advent of sequencing gels[137] and the use of agarose gels for nucleic acid separations followed later that decade.

On that backdrop, envision the stark contrast of a paper that described a gas chromatographic analyzer fabricated out of silicon (Figure 18-1) using the tools under development for a microelectronics industry that was still in its infancy. The work of Terry and associates[156] provided the first evidence that microfabrication could be used to create miniaturized devices for analytical separations. Despite that, the scientific community did not immediately recognize the significance of this achievement nor see this as a glimpse into a future that would be seeded, in no uncertain terms, by Widmer's group at CIBA in Basel, Switzerland, roughly a decade later. Although several papers followed this initial work, it was not until the concept of a total analysis system (TAS), first proposed by Manz and colleagues in 1990,[104] that the idea of miniaturization had a significant impact. The TAS concept was originally motivated by a lack of adequate sensors for detection of specific species from a complex mixture. It was hypothesized in the seminal Manz paper[104] that, by improving the sample treatment steps and thereby increasing the selectivity of the sensor, an ultrasensitive sensor would not be required if interfering chemical compounds were removed. A TAS, as proposed, entailed initial sampling, transport of the sample, sample pretreatment steps, and final detection of the analyte. Miniaturization of all of the processes required for total analysis, a micro–total analysis system (μTAS), would allow development of a TAS that performs these functions at the site of measurement. Additional benefits are derived from decreasing the size of a TAS, such as decreased volumes of sample and reagent and the potential for drastically reduced analysis times.

MICRODEVICE FABRICATION

Since the inception of the μTAS concept, the field has expanded to exploit multiple different substrates for microchip fabrication. Initial work in this field involved silicon or glass as the microchip substrate and has been extended to polymers such as polydimethylsiloxane and polymethylmethacrylate. This section highlights the traditional processes used for fabricating glass and silicon devices, namely, photolithography and etching, and then discusses polymeric microchip fabrication broadly while highlighting two popular plastic substrate choices.

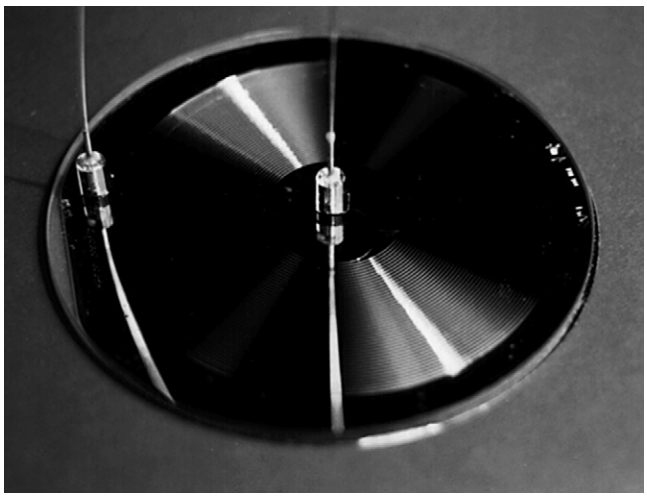

Figure 18-1 First microfabricated analytical device—integrated gas chromatograph (GC) microfabricated into silicon substrate.[118]

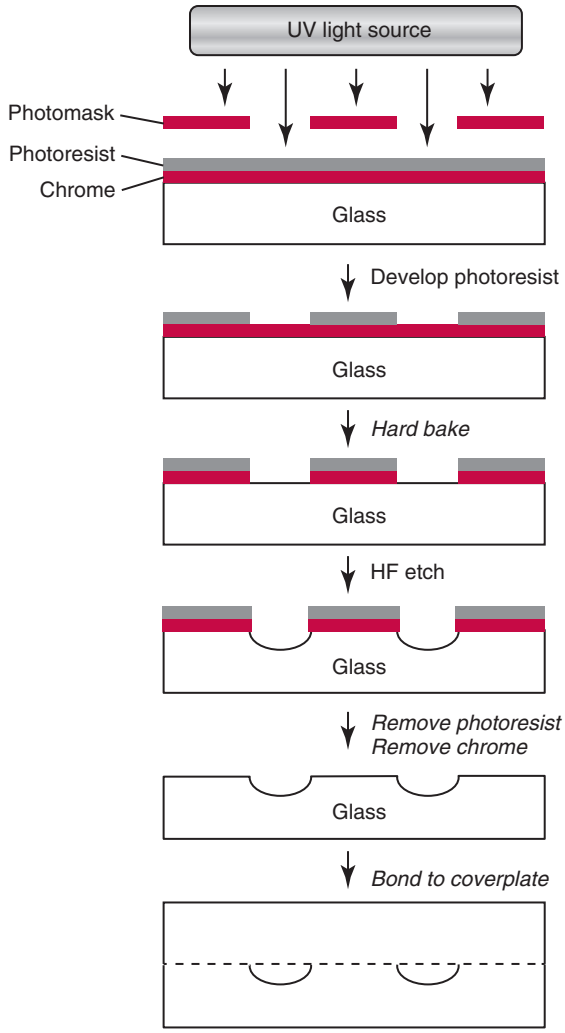

Figure 18-2 Glass microchip fabrication method. A diagram illustrating the processes involved in microchip fabrication using standard photolithography and wet chemical etching methods.

Photolithography and Glass Etching Techniques

In standard photolithography practices, glass is obtained with a photoresist and metal layer deposited onto the wafer (see Figure 18-2 for a schematic of the process). The function of these films is twofold: to allow for channel design and for glass protection during the chemical etching step. A chrome metal layer is first deposited onto the glass because of its tight bonding with both glass and silicon. This layer provides extra protection from hydrofluoric acid (HF) during wet chemical etching. On top of the metal is a layer of photoresist that allows for channel patterning. The traditional mode of application is to spin-coat the photoresist on top of the metal layer, although there are alternatives to this approach, such as the constant-volume injection method.[92] Because such fine precision can be attained using photolithography, application of the photoresist is performed under cleanroom conditions using specialized instrumentation. In most cases, glass can be purchased with both the photoresist and metals already applied.

Transfer of the channel pattern to the photoresist involves using a photomask containing the design. The photomask can be a film mask or a metal mask. For either mask, the microfluidic design is created using software (Adobe Illustrator, AutoCAD, etc). A film mask can be printed by a high-resolution printer, allowing for microfluidic channels on the order of 40 to 200 μm, while metal masks allow fabrication of structures of higher resolution (<20 μm). A photomask containing the pattern is placed on top of the photoresist, and the "sandwich" is exposed to ultraviolet (UV) light. The glass is then placed in a developer solution and the photoresist removed. The exposed chrome is then removed, exposing the glass only in the places where channels are to be etched.

Glass channels are achieved by wet chemical etching using a solution of HF. The etching rate of the solution depends on the concentration of HF in the etching solution—the higher the concentration of HF, the faster the etch rate. An etch rate of 10 μm/min can be achieved with a 49% HF etch solution[87] in borosilicate glass. The use of wet chemical etching results in an isotropically etched channel, where the glass is etched equally in all directions. This type of etching results in a channel architecture that has a semihemisphere shape (see Figure 18-2). Once the channels have been etched to their desired width/depth, access holes are drilled and the devices bonded. For glass-glass bonding, thermal bonding is widely used. With this technique, both glass wafers to be bonded are thoroughly cleaned, aligned, and brought into intimate contact. The bonding process takes place at a temperature of 620 to 690 °C over 6 to 8 hours and can be achieved using a programmable furnace. Multiple bonding cycles are typically required to get a fully bonded device, which is one of the biggest drawbacks to thermal bonding. Other approaches have been developed, such as room temperature bonding techniques,[17,57,67,128] UV-curable adhesives,[59,141] and silicate solutions.[63,78,139]

Alternatives to Traditional Photolithography and Wet Chemical Etching

Application of a photoresist requires a spin-coater and clean-room conditions, which can be fairly expensive. Alternatives to the use of a photoresist have been developed, where patterned polydimethylsiloxane (PDMS) was affixed to the glass wafer to be etched and HF flowed through the PDMS channels.[134] Enzyme nanolithography has achieved nanometer-sized depressions in a protein surface. Scanning probe microscopy was used to control a nanopipet, which delivered proteases to a dried bovine serum albumin film.[61,62] Although wet chemical etching does not require expensive instrumentation, the desire for high aspect ratio structures or for more control over the dimensions of the channel can lead to other types of etching techniques. For example, high aspect ratio structures were obtained in glass and fused silica wafers by using powder blasting,[7] fast atom beam etching[54] and deep reactive ion etching (DRIE).[16] All of these methods involve bombarding the wafer surface with particles; however, DRIE uses chemically reactive ions, typically fluoride, to collide and remove surface atoms while fast atom beam etching uses neutral particles.

POLYMERIC MATERIALS

Because of the expense involved in the fabrication of glass microchips, interest is increasing in the idea of using plastic materials as microfluidic substrates. Some of the key factors to consider when choosing a polymeric material for microchips include surface chemistry, optical clarity, chemical compatibility, temperature stability, and desired application. Glass microfluidic devices make an excellent platform for electrophoretic separations that utilize electro-osmotic flow (EOF), because of the abundance of silanol groups on the surface. This same surface can be difficult in applications such as polymerase chain reaction (PCR), because the glass surface can react with necessary components, thereby inhibiting the reaction. Polyimide is a thermoplastic polymer with a neutral surface charge that provides an excellent vessel for PCR,[37] yet it has less than optimal visible light transmittance, making optical detection difficult with this material. Another driving force for finding alternatives to glass for microfluidics involves generally easier fabrication methods.

As the list of possible substrates for microfluidic devices grows, ways of making fabrication easier and more streamlined with these materials are becoming more innovative. Polyester-toner microdevices have been made on overhead transparencies using laser printers.[20,21,26] The channel geometry is simply printed onto the transparency (where the absence of toner dictates the channels) and placed together with another piece of blank transparency containing only access holes. The sandwich is bonded by lamination, and the toner printing results in channels that are approximately 6 μm deep. These microchips have been used for electrophoretic separations using a number of different detection methods. SU-8 is a negative photoresist that has been used as a substrate for microfluidic devices. Fabrication of these devices takes advantage of the photoresist properties of SU-8 and allows the device to build in a number of layers.[162] The first layer is homogeneously spun onto silicon; this is followed by complete cross-linking with UV exposure. A second layer is spun onto the first layer and covered with a photomask during UV exposure, which allows the channel pattern transfer. The third layer is separately spun onto a piece of glass, completely cross-linked through UV exposure, and then placed onto the second layer. A low-temperature baking step, UV exposure of the whole device, and removal of the glass and silicon pieces complete the device. Thermoset polyester (TPE) is an unsaturated polyester in which cross-linking occurs upon addition of a catalyst; TPE can be fabricated using many of the same techniques as are used with PDMS (see section later).[166] Poly(cyclolefin), the same material used in making compact discs, has also been used in microfluidic devices.[73] Hot embossing is used to make these chips, and a silicon master allows for channel dictation. A cover plate is bonded to enclose the device, using heat and pressure to generate a complete seal.

Polydimethylsiloxane (PDMS)

Polydimethylsiloxane (PDMS) is one of the most popular polymeric materials used as substrates. Fabrication is fairly easy involving the combination of elastomeric base and curing agent. The PDMS surface has methyl groups on the surface, imparting a hydrophobic nature, and is flexible and optically transparent. The flexibility of PDMS allows it to be a highly chosen substrate for valving, and it can be both reversibly and irreversibly[5,6,73] sealed to a variety of surfaces. Several different PDMS fabrication methods have been reported (see Sun[151] for a review), with replica molding[73] and rapid prototyping being two processes that are readily used. Rapid prototyping involves the use of a master, which, once made, allows for fast and easy replication of that design. The master is made by using a negative photoresist, such as SU-8, spun onto a silicon or glass wafer. The microfluidic channel design is imparted onto the photoresist using photolithography and the wafer subsequently developed. Because SU-8 is a negative photoresist, only where the light is incident is where the photoresist is rendered insoluble, while the remaining photoresist remains soluble in the developer solution. This leaves photoresist only where the channels are, exposing the glass everywhere else. Etching of the glass results in the reverse architecture of the glass microfluidic layer, where the channels are raised instead of imprinted. The height of the photoresist over the glass dictates the depth of the PDMS channels. Although photolithography is still used in fabrication of the master, once made, multiple devices can be made easily.

PDMS is produced when an elastomeric base and a curing agent are mixed in the appropriate ratios. Once mixed, they are poured over the master and are allowed to cure; this can happen at room temperature overnight, although heating quickens the process. The cured PDMS can then be peeled from the master and bonded with the substrate of choice. The bonding method will depend on the substrate used for the

coverplate; PDMS/PDMS devices can be reversibly bonded by putting the two pieces into contact with one another. Irreversible bonding of PDMS/PDMS can be achieved through a number of different methods, one being activation of the surface by plasma oxidation.[6,73] Liu and coworkers reported another method, in which they altered the elastomer base to curing agent ratios, using 20:1 for the fluidic layer and 5:1 for the cover plate. The device was assembled and placed in an oven, at which point the two layers fused as the result of the distribution of excess reagents between the two layers.[5]

Plexiglas (PMMA)

Poly(methylmethacrylate) (PMMA) has become a popular substrate choice for microfluidic devices. PMMA is considered a thermoset polymer that softens into a viscous liquid when heated above its glass transition temperature. Multiple methods of fabrication are available, and the channel surface is easily modified to adapt to a particular application; see references 6 and 151 for reviews of polymer fabrication techniques. Hot embossing[80,131] is a technique that can be used with a variety of substrates; it consists of heating the polymer above the glass transition temperature and stamping the substrate with the desired microfluidic pattern. To make PMMA devices using this technique, a metal or silicon stamp is brought into contact with the PMMA and is embossed using a constant force and elevated temperatures to partially melt the substrate. The embossing process can be completed in less than 10 minutes, and once the apparatus has cooled, the stamp and the substrate can be carefully separated. This same process can also be done at room temperature using PMMA as a substrate; this yields channel dimensions that vary by less than 2%.[184] Injection molding, another fabrication technique used to make PMMA devices,[29] incorporates the use of a metal or silicon stamp. This involves heating the PMMA at high temperatures, which results in the formation of a viscous liquid. The PMMA is then pushed into the mold by applying high pressure and is allowed to cool; it is then removed from the mold. Both of these methods result in devices with micron-sized channels and are useful for mass production of devices with the same microfluidic pattern.

Certain applications require the use of sub–micron-sized features; x-ray lithography is capable of making these small channels and intricate structures. Figure 18-3 shows an example of post structures that can function as a solid phase for DNA chromatography. Solid phases for DNA extraction traditionally are created with silica beads, sol-gels, or silica bead/sol-gel hybrids (see section on DNA extraction). However, phases can also be microfabricated during the microchip fabrication process. This can be done by using a direct write process or a mask, typically fabricated in a thick gold layer because it can absorb the x-rays. Where the x-rays are incident upon the PMMA, the polymer degrades. The

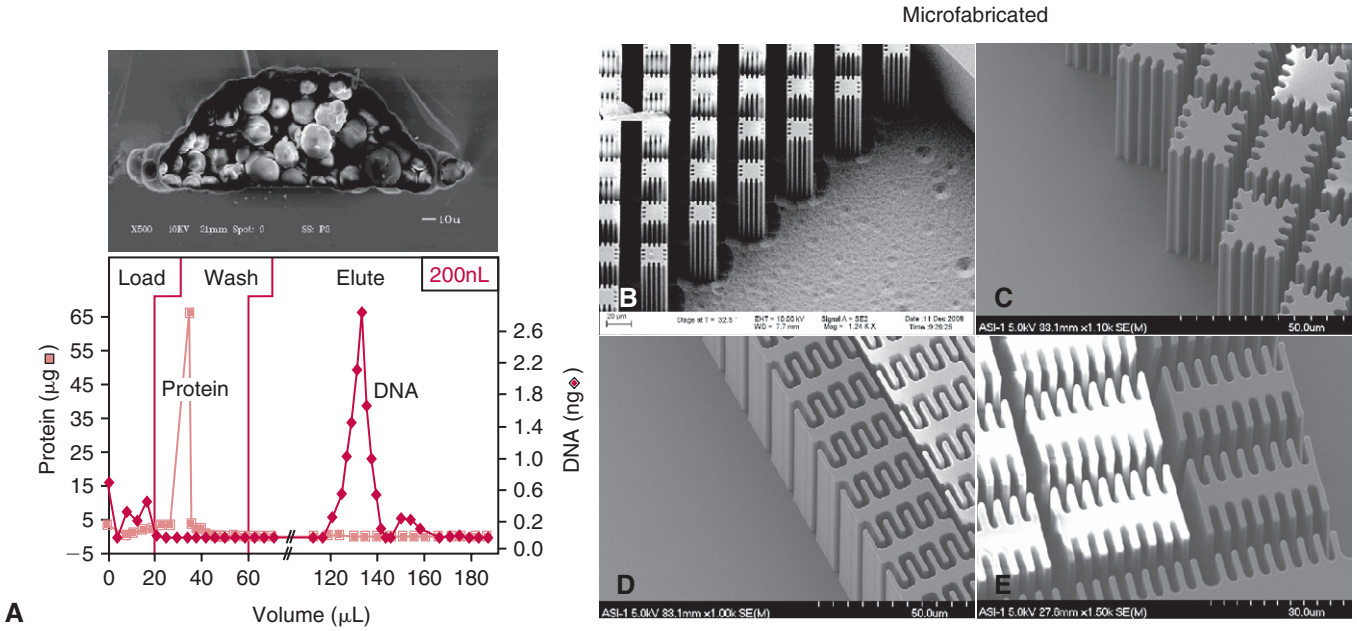

Figure 18-3 Solid phase for on-chip DNA purification/chromatography. **A, Microchromatogram *(lower)* showing the separation of protein and nucleic acid components from 200 nL of human whole blood on a sol gel–immobilized silica solid phase *(upper)*. B through E, Two designs for microfabricated solid phases use a LIGA process to generate polymethylmethacrylate (PMMA) (PlexiGlas) posts for the chromatographic process. The dimensions are as follows: B, 14 μm square posts with ≈3 μm extensions with 17 μm distance between posts. C, 14 μm square posts with ≈3 μm extensions with 4 μm distance between posts. D, 6 μm × 30 μm posts with 5 μm extensions. E, 6 μm × 30 μm posts with 8 μm extensions.**

device is placed into a developer solution which removes degradation products by solubilization. The length of exposure along with the energy used dictates the depth of the channels. Laser ablation is also used to make submicron features in PMMA devices. This involves bombarding the surface with a pulsed UV source to damage the polymer structure.[149] With both of these last two techniques, high aspect ratio features can be accomplished; however, neither of these methods is ideal for situations involving mass production of the same design.

SEPARATION AND DETECTION OF CLINICALLY RELEVANT ANALYTES

Miniaturized electrophoresis was the first and most dominant embodiment of a μTAS, with the driving force for the miniaturization related to an enhancement in its analytical performance, rather than a simple reduction in size.[104] Because separation efficiency is a function of the applied voltage, microfluidic devices use shorter separation lengths, along with application of high voltages typical of capillary separation, resulting in fast, efficient separations.

A core component in the development of microfluidic technology has been the use of microchips as an analytical platform for electrophoretic separation.[46] Components required for microchip-based electrophoresis (ME) include a detection system, a power supply, and a computer with programmable software for controlling application of voltage, for data collection, and for conditioning of raw data. A number of different detection systems can be used with microchips; however, a fluorescence detection system, essentially a homemade fluorescence microscope, is the most widely used.[46] In terms of selection of the components, power supply selection is critical, because a required number of voltage outputs are needed for electrokinetic injection of the sample and application of the desired electric field. For chip-based separations, the cross-t design originally proposed by Verheggen and associates[165] for electrokinetic injection of sample is the most popular. With this design, a minimum of four voltage outputs are required to control the sample injection and separation. As the complexity of the chip design increases, more outputs may be necessary, particularly if electrokinetic pumping of reagents and buffers is involved. The user is cautioned, however, that effective electrokinetic mobilization of solutions through the microchip architecture is limited to reagents that are low in conductivity and not high in organic solvent concentration; this results in obvious limitations with many clinical samples and, thus, may necessitate the implementation of pressure-driven fluidic control.

For injection, both pressure-driven and electric field–driven injection modes are used, as they are in capillary electrophoresis (CE). The pressure-driven injection mode commonly used in CE, which avoids bias associated with analytes that have a wide range of electrophoretic mobilities, is less popular with chip-based injection. That said, Karlinsey and colleagues[77] demonstrated that integrated diaphragm pumps on a hybrid PDMS-glass microchip could perform pressure sample injection for subsequent electrophoretic separations. The same type of electrokinetic bias associated with CE could be avoided on-chip with pressure injection, and pressure injection could be achieved with sample volumes as low as 500 nL while sample composition was maintained. This was later used by Easley and colleagues[32] for integrated microchip detection of infectious pathogens in blood. However, the injection mode that dominates for most applications in microchip electrophoresis is electrokinetic injection (driven by electrophoretic mobility and/or electroosmotic effects).

The more popular electrokinetic sample injection is dominated by two types—pinched and gated—that are used in standard cross-t design chips. With the pinched injection, a small sample plug is electrokinetically mobilized into the injection cross-t via a voltage applied between the sample and the sample waste reservoir and orthogonal to the separation channel.[65] Once the cross-t is adequately populated with sample, sample injection is accomplished by reconfiguring the primary electric field between the inlet buffer and the outlet buffer reservoirs. Injection "bleed" of sample into the separation channel is minimized by applying a small voltage to the sample and the sample waste. A gated injection allows the sample to electrokinetically migrate through the cross-t toward the sample waste reservoir and then is directed into the separation column by temporarily terminating the potential at the buffer reservoir via a high-voltage relay and allowing the sample to migrate into the separation channel electrokinetically.[66] Unlike a pinched injection, the injected plug volume is dependent on the amount of time the buffer reservoir potential is off. Additionally, this type of injection is susceptible to bias based on differences in analyte electrophoretic mobility.

Electrophoretic Separations

When chip-based separations are performed, the separation channel in a cross-t design provides the counterpart of the capillary in CE, although with a substantially truncated separation length (Figure 18-4). Many of the parameters governing electrophoretic separation in capillaries apply to chip-based separations. For example, like capillaries, one of the benefits of glass-based devices is their inherent ability to dissipate the Joule heat generated from use of the high electric fields needed to facilitate rapid separation. However, the same type of Ohm's law plot (applied voltage vs. current) that would be used to test buffer compatibility with high electric field application should be carried out here as well.[83] Using the appropriate buffer for the separation of interest, the channel surface must be conditioned in a manner not dissimilar to those processes used with capillary systems. If separations requiring EOF are performed, the rigorous cleaning method suggested for fused silica capillaries is required to ensure proper surface regeneration, but attention must be paid to hydration of the glass. The entire cross-t channel architecture of the device is filled, including the reservoirs, to ensure good electrical contact between the platinum electrodes and the solution. The holes drilled into the

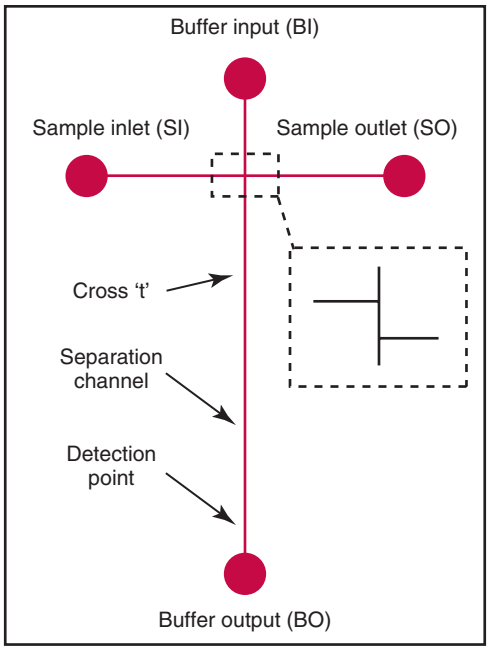

Figure 18-4 Schematic of microchip electrophoresis device design. The reservoirs are labeled as follows: *SI* is the sample inlet, *SO* is the sample outlet, *BI* is the buffer inlet, and *BO* is the buffer outlet. A closer view of the cross-t can be seen in the *dotted box*.

microfluidic device to function as reservoirs (i.e., buffer/sample microvials) may not be large enough to hold a sufficient volume of buffer to avoid buffer depletion. The user must remain cognizant of this and, even with expanded reservoirs generated by commercial "nanoports," or homemade trimmed pipette tips, replenishment of the buffer may be needed.

For sample injection, separation, and detection in a chip of simple design (see Figure 18-4), the sample is placed in the reservoir (SI) and a voltage is applied between SI to SO to inject the sample into the separation channel in a manner consistent with the injection mode chosen. Separation is initiated by application of voltage to BO and BI where electrophoresis of the sample analytes down the separation channel ensues. A point along the separation channel, most commonly at a location close to BO, is used for detection. The detection mode most commonly used is optical detection, and laser-induced fluorescence is popular because of its sensitivity. The detector system [e.g., a laser and photomultiplier tube (PMT)] is positioned at a point in the separation channel commensurate with providing the necessary effective separation length (L_{eff}) for the separation; sample analytes passing that detection point are excited, and the resultant fluorescence is collected. Although the electric fields (E; volts/cm) applied in microchip electrophoresis approach (but do not exceed) those used in capillaries, reduction of the L_{eff} is more easily achieved in microchips. The reservoirs and electrodes required to apply voltage to capillaries limit the minimal L_{eff} to tens of centimeters; microchips, in contrast, can easily allow for separation distances of a few centimeters. It is interesting to note that the U-shaped channel in microchips has little effect on the resolution of separations under high electric fields. The plug profile typically associated with capillaries and known to play a role in yielding high-efficiency (number of theoretical plates) separations does not seem to be adversely affected by the semihemispherically shaped channels.

Detection on Microchips

A detection system is required to measure the number and quantity of analytes electrophoretically separated in the channel as they pass the detection point. With increasing popularity of microchips for separation, a variety of different detection options have evolved that include optical detection methods that are, for the most part, similar to those employed in CE. However, electrochemical, conductivity, and mass spectrometric approaches have also been developed. For optical detection, the most prevalent method in CE and high-performance liquid chromatography (HPLC)—ultraviolet-visible spectroscopy (UV-VIS) detection—is not as common with chip-based electrophoresis, primarily because of challenges with the short optical path length (channel depth) in miniaturized systems and the difficulties involved in coupling light into and out of these channels.[167] That said, a number of reports have detailed progress with UV-VIS detection in analytical microsystems.[10,28,41,91,102,108,183] However, no universally successful method akin to that on CE has been devised. A number of other optical detection schemes for microchips have evolved with varied success and applicability, including infrared,[126] nuclear magnetic resonance (NMR),[175] surface plasmon resonance,[74] thermal lens microscopy,[161] and chemiluminescence/electrochemiluminescence.[55]

The most prevalent detection system used for chip-based separation is laser-induced fluorescence (LIF).[71] It not only is an extremely sensitive method for detection in chemical separations (subzeptomole detection limits), it also is well suited to detection in small volumes, hence, its widespread popularity in capillary electrophoresis separations. A number of reviews have detailed the components required for LIF, have provided a guide to alignment of the optical system, and have described the keystone elements (analyte velocity, probe volume, optimized signal-to-noise ratio as a function of excitation intensity) necessary to achieve sensitive detection.[71,75] Components of an LIF system consist of a light detection module, such as a photomultiplier tube or a charge-coupled detector (CCD) camera, a laser source, optics for alignment of the excitation/emission, an excitation source, and a computer for data collection. LabVIEW software (National Instruments, Austin, Tex), which is commonly used as the interface, allows easy application–specific computer programming to provide software interfaces that permit collection of data and control the detection system.[71,75] A typical method for performing LIF detection on a microchip is to bring the excitation light from a laser of light-emitting diode into the microchannel orthogonal to the device plane, which is relatively simple to align, and to then focus the beam into the channel using a microscope objective or some combination of achromatic lenses. LIF emission is collected

with a separate objective or lens combination, spatially and spectrally filtered, and recorded on a photodetector. Confocal detection systems were popular in the capillary electrophoresis literature early on,[51] when focusing and collection optics were one and the same, and the excitation and emission wavelengths were separated with a dichroic beam splitter. Variations in LIF detection setup exist, however, and He and colleagues presented a detailed illustration of their laser-induced detection system, in which excitation is brought into the microchannel from an angle.[50] Two relatively recent reviews provide detailed descriptions of the fundamentals and practice of LIF detection in microanalytical systems.[71,75]

Chip-based detection systems can involve multipoint detection in a single channel or the multichannel detection that is key to high-throughput analysis. For multipoint detection, waveguides can be incorporated into the microchip design for detection at multiple points along the same channel[109] and applied to microchip isoelectric focusing (IEF).[42] Yao and coworkers[186] carried out whole channel imaging during the IEF separation of proteins using a CCD array, ironically using organic LEDs as the excitation source. Alternatively, Raisi and coworkers used a scanning fluorescence detector and a single PMT to scan the entire separation channel.[132] In terms of multichannel scanning, Huang and associates used an acousto-optic deflector (AOD) to change the diffraction angle of an incident laser beam to address an eight-channel device designed for parallel DNA separations.[58] However, the most significant advances have involved the multichannel microdevices designed by Mathies and coworkers for high-throughput analysis. Paegal and colleagues multiplexed 96 channels on a radial capillary electrophoresis microchannel plate,[125] demonstrating that the microchip platform could compete with the 96 capillary arrays that had evolved for CE. Radial microdevices of this ilk for DNA analysis containing as many as 384 channels[34] have been demonstrated as possible.[143] More recently, this group reviewed the types of applications possible with these high-throughput chip-based systems.[95]

Multicolor LIF detection is not essential for all applications but certainly for some involving key genetic analysis techniques. Expanding the number of photodetectors needed to sample at multiple emission wavelengths is the simple approach that has been used for multicolor DNA sequencing[98] and genotyping[142] on microchips; however, Backhouse and associates used a diffraction grating to disperse the LIF emission onto a CCD array for four-color sequencing,[2] and Simpson and colleagues used a transmission imaging spectrograph with a wide imaging area to disperse LIF emission from a two-color genotyping experiment run in 48 parallel channels onto a CCD array.[144] More recently, a system was developed to complement the microchip platform by featuring a single acousto-optic tunable filter (AOTF) and a single PMT.[76] The filter behaves similarly to the previously described AOD, except that when an acoustic wave traveling through the crystal at a specific frequency interacts with the light, only select wavelength bands are diffracted by the crystal and collected by the PMT.[75]

Exemplary Separations

Separation of Nucleic Acids

Although small molecules were the target analytes in early chip-based separations (fluorescein and calcein),[47,105] the separation of amino acids[46] (Figure 18-5) changed the landscape to one that could involve biomolecules of interest and eventually led to a literature dominated by the separation of DNA fragments using laser-induced fluorescence as the detection method. The significance of the early studies showing electrophoretic separation of analytes in a planar glass system was less about faster analysis times and more about the drastic reduction in reagent consumption. It was this unprecedented analytical potential that paved the way for DNA separations in microdevices, shoring up the threat that CE was bringing to large, unwieldy slab gels that were slow to run, cumbersome to manipulate, and labor intensive to use in high-throughput mode. Early work from Mathies and coworkers laid the groundwork for successful separation in 120 seconds of ΦX174 Hae III restriction fragments ranging from 70 to 1000 bp.[180] This technology was advanced by this group, which accomplished high-resolution separations and DNA sequencing using multicolor fluorescence detection.[97,179]

Although Karlinsey and associates showed that using an AOTF for multicolor detection could be applied to short tandem repeat (STR) profiling for human identification, the microchip-based separation of amplified gene products for STRs of clinical significance has also been demonstrated. For example, fragile X syndrome has been correlated with a CGG repeat expansion seen in the 5′-untranslated region of the familial MR type I *(FMR1)* gene. Individuals with the

Micromachining a miniaturized capillary electrophoresis-based chemical-analysis system on a chip. Science 1993;261:895-7.)*

premutation show an unstable number of $(CGG)_n$ repeats and generally are asymptomatic; however, identifying the number of trinucleotide repeats is critical for genetic counseling. Sung and colleagues[152] used microchip separations that were completed in less than 1 minute to identify these trinucleotide repeats using a polymethyl(methacrylate) (Plexiglas) microchip; this represented a roughly 100-fold reduction in analysis time when compared with the 70 minutes consumed by the conventional slab gel approach. Similarly, Cantafora and colleagues[14] used microchip electrophoresis to detect the D19S394 tetranucleotide repeat $(AAAG)_n$. This repeat is highly polymorphic (with the number of repeats typically ranging from 1 to 17) and is a short recombination distance from the low-density lipoprotein (LDL) receptor gene, making it suitable for the study of familial hypercholesterolemia (FH). Analysis was performed using the commercial microchip electrophoresis system, with instrument control by dedicated software for completely automated sample injection, fluid manipulation, and data collection. This system is designed to analyze 25 to 500 base pair (bp) double-stranded (ds)DNA fragments with 5 bp resolution. Using this, 70 carriers of two LDL receptor mutations common in Northern Italy were compared with 100 healthy controls, and the microchip-based technique was successfully used for the sizing of D19S394 needed for a simple cosegregation analysis.

Nemoda and coworkers[117] used a microchip with 96 robotically loaded electrophoretic lanes for analysis of 20 bp repetitive sequence elements within the 5′-regulatory region of the serotonin transporter gene *(5-HTT)*. Two amplified products, one for each of two common alleles (a short 14-repeat and a long 16-repeat sequence), that were shown to have an impact on transcription of this key synaptic transporter, could be separated and detected in about 4 minutes. The reduction in analysis time for the 334 samples that were genotyped for variable repeats was dramatic in comparison with that required for conventional slab gel electrophoresis. This technology was applied in a similar way to the detection of variable repeat alleles of the dopamine receptor *(DR)* gene using PCR and microchip electrophoresis.[4] Following PCR amplification of a variable number of repeats of a 48 bp sequence, chip electrophoresis allowed separation and detection of the products in 90 seconds, highlighting the potential of pharmacogenetic analysis for mutations shown to correlate with effective doses of methylphenidate in school children.[43]

Mutation Detection via Microchip Analysis

An early diagnostic application of electrophoretic microchips involved the detection of T-cell receptor (TCR) gene rearrangement, where normal samples yield amplified PCR fragments representative of a polyclonal lymphocyte population, while lymphoma patients display a monoclonal population. Munro and coworkers[113] were able to separate B- and T-cell gene rearrangement PCR products on microchips, providing diagnostic information in an assay where the electrophoresis consumed only 160 seconds (Figure 18-6). This marked a 60-fold decrease in analysis time compared with conventional slab gel methods, with no loss in diagnostic capacity. More recently, Legendre and associates[85] demonstrated a microchip separation method for analyzing post-PCR products from patients' samples that were both positive and negative for T-cell lymphoma. They showed the resultant electropherograms, where negative samples show three broad peaks, characteristic of a range of different sized PCR products generated, and positive samples show the presence of one or two strong peaks, caused by the presence of a clonal cell population. These separations required less than 5 minutes on a microdevice—a more than 8-fold reduction in time when compared with commercial capillary electrophoresis.

With heteroduplex analysis (HDA), a common method for mutation detection, denaturation of the sample DNA followed by controlled re-annealing generates homoduplexes or heteroduplexes, depending on whether wild-type or mutant DNA is present. The relative presence of these can be parsed out via differences in the electrophoretic mobilities of the duplexes stemming from the degree of sequence mismatch. Tian and colleagues[158] used HDA-based electrophoresis to target *BRCA1* and *BRCA2* germline mutations. Using microchip HDA analysis, they demonstrated the detection of six different deletion, insertion, and point *BRCA* mutations in separations that were complete in 130 seconds, proving the microchip platform to be a powerful and efficient mutation screening. Similarly, Footz and coworkers[36] compared a microchip-based HDA technique versus denaturing HPLC (dHPLC) using glass microchips and a commercial self-coating sieving polymer. They showed that eight sequence variants of *BRCA1* and *BRCA2* genes could be detected, even without optimization of PCR amplification or of chip HDA conditions, demonstrating that the microfluidic technique could provide sensitivity similar to that of an extensively optimized dHPLC system.

An alternative mode of mutation detection, allele-specific PCR (AS-PCR), is commonly used for the rapid detection of known single-base DNA polymorphisms. AS-PCR was used by Medintz and associates[107] on a capillary array electrophoretic microplate for high-speed single-nucleotide polymorphism (SNP) analysis of the *HFE* gene, which is associated with hereditary hemochromatosis (HH). The HH disorder is an autosomal recessive disease of iron metabolism, affecting roughly 1 of every 300 people of Native American descent. The disease has been linked to an S65D (193A>T) substitution. In this analysis, two different fluorescently labeled primers were designed to detect the HH-associated substitution mutation [S65C (193 A>T)], with the A- and T-specific amplicons identified by both size and color. Using microchip electrophoresis on a radial 96-channel array, analysis of 96 samples could be completed in an unprecedented 10 minutes. This work was later extended by Emrich and colleagues[34] into a 384-lane microfabricated capillary array electrophoresis device for massively parallel genetic analysis, demonstrating the high-throughput SNP genotyping made possible by microchip-based microchannel arrays.

The AS-PCR was also exploited by Tian and coworkers,[157] in conjunction with HDA analysis of *BRCA* mutations. The wild-type homozygotes and heterozygotes were distinguished

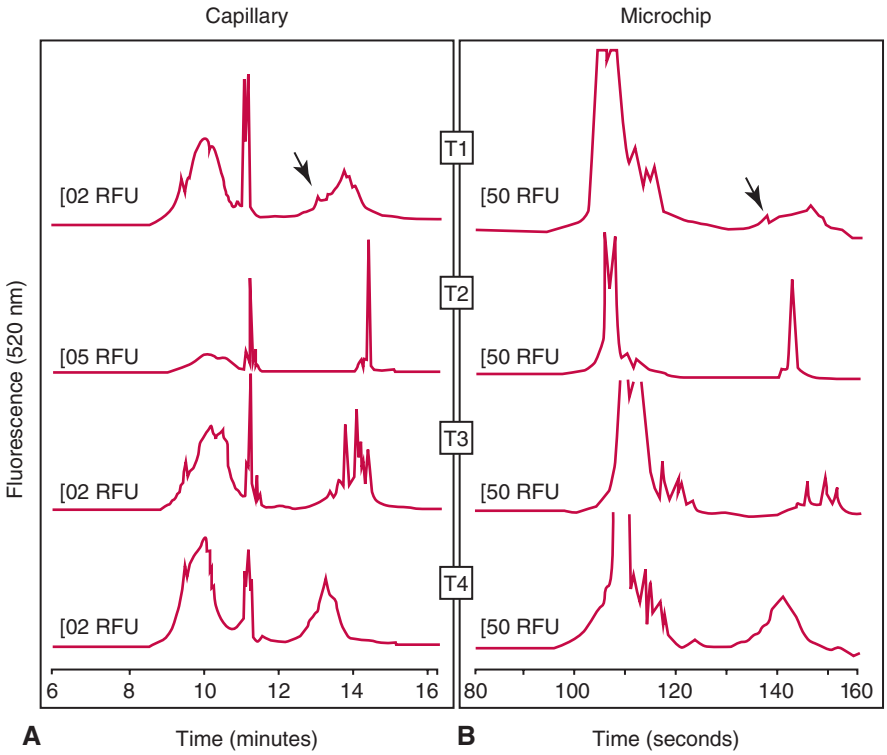

Figure 18-6 Microchip electrophoretic detection of T-cell receptor gene rearrangements. Electropherograms of T-cell receptor gene rearrangement products performed in (A) capillary or (B) microchip. Samples T2 and T3 are both positive samples, sample T4 is a negative sample, and sample T1 shows a sample interpreted as negative/equivocal. *(Modified from Munro NJ, Snow K, Kant JA, Landers JP. Molecular diagnostics on microfabricated electrophoretic devices: from slab gel- to capillary- to microchip-based assays for T- and B-cell lymphoproliferative disorders. Clin Chem 1999;45:1906-17.)*

on the basis of the number of peaks observed after chip-based electrophoretic separation (Figure 18-7). Alleles were identified in less than 180 seconds by microchip electrophoresis, for a total analysis time (including a 10-minute DNA purification and a 1.2- to 2-hour PCR amplification) of less than 2.5 hours. The method was simple and rapid, and because no enzymatic digestion was used, post-PCR processing was not required.

Chowdhury and associates[18] used microchip analysis to probe gene variants within the thiopurine-*S*-methyltransferase *(TPMT)* gene using AS-PCR and restriction fragment length polymorphism (RFLP)-PCR followed by chip-based electrophoresis with multicolor LIF. With both AS-PCR and microchip electrophoresis integrated into a single microchip that accepted off-chip purified DNA, this chip enabled PCR-RFLP-μCE analysis to be performed in 3 hours, compared with 9 hours for conventional methods,[18] and over 24 hours with an oligonucleotide array microdevice.[116] Excluding prepurification, the costs of the polymeric microchip and reagents used by these authors for a single analysis totaled only $10, demonstrating the potential of microfluidics to provide disposable chips for both reduced sample handling and contamination risk, as well as cost-effective decentralized point-of-care testing.

Single-stranded conformational polymorphism (SSCP), developed by Orita and colleagues[124] in the late 1980s, involves thermal denaturation of the sample post PCR amplification, followed by rapid cooling ("snap-cooling"), allowing single-stranded oligonucleotides to take on a self-annealed three-dimensional (3D) conformation. The discriminating aspect of this mutation detection method is the fact that the 3D conformation depends on the intrastrand base pair sequence, with different alleles forming differing conformations that can be resolved electrophoretically. For smaller PCR products (<200 bp), SSCP can resolve single base pair mutations with greater than 90% accuracy—this can approach 100% accuracy when coupled with heteroduplex analysis.[1,36] Following on their work with HDA, Tian and coworkers[160] were the first to implement SSCP on an electrophoretic microchip to detect mutations in two breast cancer genes, *BRCA1* and *BRCA2*. Following multiplex PCR amplification using fluorescently labeled primers and snap-cooling on ice to induce intrastrand secondary structures and separation of the products by microchip electrophoresis, resolution of the fluorescently tagged amplicons was possible in 130 seconds or less, representing analysis speed that was orders of magnitude faster than with slab gel analysis and even capillary electrophoresis.

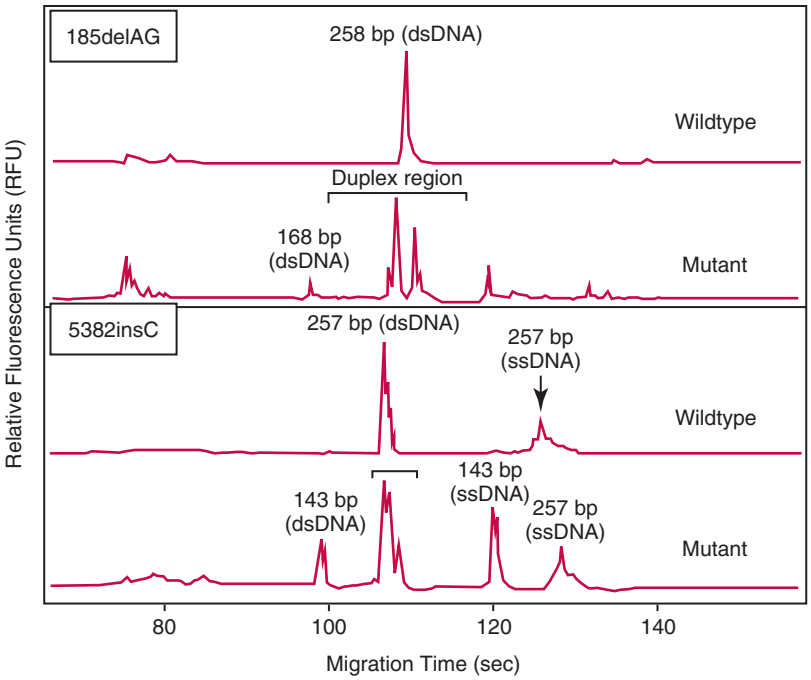

Figure 18-7 Fast mutation detection using allele-specific polymerase chain reaction (PCR) and heteroduplex analysis on a microfluidic electrophoretic chip. Panels show AS-PCR heteroduplex analysis results for wild-type and heterozygous mutants associated with a deletion (185delAG) and insertion (5382insC) mutation. The separation was in a chip containing a poly(vinylpyrrolidone) (PVP)-coated microchannel with an effective length of 55 mm filled with tris-borate-EDTA (TBE) buffer containing hydroxyethyl cellulose and glycerol; detection was laser-induced fluorescence. *(Modified from Tian H, Brody LC, Fan S, Huang Z, Landers JP. Capillary and microchip electrophoresis for rapid detection of known mutations by combining allele-specific DNA amplification with heteroduplex analysis. Clin Chem 2001;47:173-85.)*

Vahedi and associates[164] followed this work with fusion of HA and SSCP on a single electrophoretic microchip. Using the manual addition of formamide to the PCR amplicons from *BRCA1* exon 20, and *HFE* exon 2, they were able to electrokinetically inject into a traditional cross-t microchip, with subsequent separation yielding heteroduplex data. Although the ability to do sequential HA and SSCP on the same microchip with the same sample is advantageous, it is important to recognize that the manual addition of formamide to the sample reservoir removes the ability to repeat the HA analysis. An additional discriminator involves real-time labeling of the heteroduplex and SSCP products with intercalating dyes (as opposed to using fluorescently labeled primers). Shortly after, the same group[103] demonstrated that detection of all three major *HFE* mutations could be accomplished using similar HA/SSCP technology, but again, using the cumbersome manual addition of formamide. Barron's group addressed the issue of optimization of HA and SSCP on a microchip using PCR amplicons of p53 exons 5 through 9.[53] PCR-amplified products were subjected to HA and SSCP via heat denaturation followed by snap-cooling on ice. By evaluating a variety of sieving mediums and channel coatings synthesized and characterized by this group, and by using a high-pressure loading device to accommodate loading of the highly viscous polymers into microchip channels, they identified a polymer (600 kDa linear polyacrylamide) and a hydrophobic wall coating (poly-*N*-hydroxyethylacrylamide) that seemed to provide optimal resolution of DNA conformational variants by microchip electrophoresis.

Other Mutation Detection Schemes

Zhou and colleagues[191] exploited the fact that aberrant methylation of the *p16* suppressor gene is recognized as an early event in many forms of cancer, especially of the lungs, making methylation detection a potential biomarker for early detection. They compared a modified, seminested methylation-specific PCR on a plastic (PMMA) electrophoresis microchip versus conventional slab gel electrophoresis for the detection of tumor-associated *p16* gene hypermethylation in plasma and tissue DNA. In a blinded approach, they analyzed 153 specimens by microchip electrophoresis (94 cancer patients, 30 positive, and 30 negative controls). Not only were they able to identify all positive and negative controls, they also correctly identified the cancerous samples both faster and at a rate 26.6% higher than that attainable by conventional slab gel electrophoresis.

Jabasini and coworkers[64] presented a multiplexed PCR assay to probe nonobstructive spermatogenic failure based on interstitial deletions on the Y chromosome. Their method specifically targeted the amplification of three DNA

sequence-tagged sites on the human Y chromosome, which were subsequently separated on a 12-lane microchip electrophoresis system. With this separation system, 36 DNA markers (3 per separation × 12 lanes) were analyzed in less than 180 seconds, with acceptable resolution despite the only 11 bp difference between them. This type of rapid interrogation of specific deletion events commonly associated as a genetic cause of male infertility greatly enhances the potential for diagnostic testing for infertility, supplanting a conventional method that is cumbersome and time consuming. Yung and associates[188] sought a microfluidic solution for detecting two common epidermal growth factor receptor *(EGFR)* mutations in the plasma/tumor tissues of patients suffering from non–small cell lung cancers. Using a digital PCR-based approach, they were able to quantitatively probe mutations at two exons that account for more than 85% of clinically important *EGFR* mutations associated with responsiveness to tyrosine kinase inhibitors. The digital PCR system allowed 9180 PCR amplifications to be carried out simultaneously in nanoliter reaction volumes. With sensitivity at the single-molecule level, mutations in clinical specimens could be detected at low levels, and quantities of mutant and wild-type sequences were determined in a manner that predicted treatment response. Knowing that microsatellite instability (MSI) is associated with ≈15% of colorectal (as well as gastric and endometrial) carcinomas, and that this impacts clinical prognosis, Odenthal and colleagues[122] interrogated the five microsatellite loci (Bat25, Bat26, D2S123, D5S346, and D17S250) using an electrophoretic microchip with 40 patient samples having known MSI status (Figure 18-8). Results obtained from microfluidic chip analysis of the PCR products in all cases resulted in genetic profiles for the five microsatellite loci that correlated well with data derived from more conventional technology.

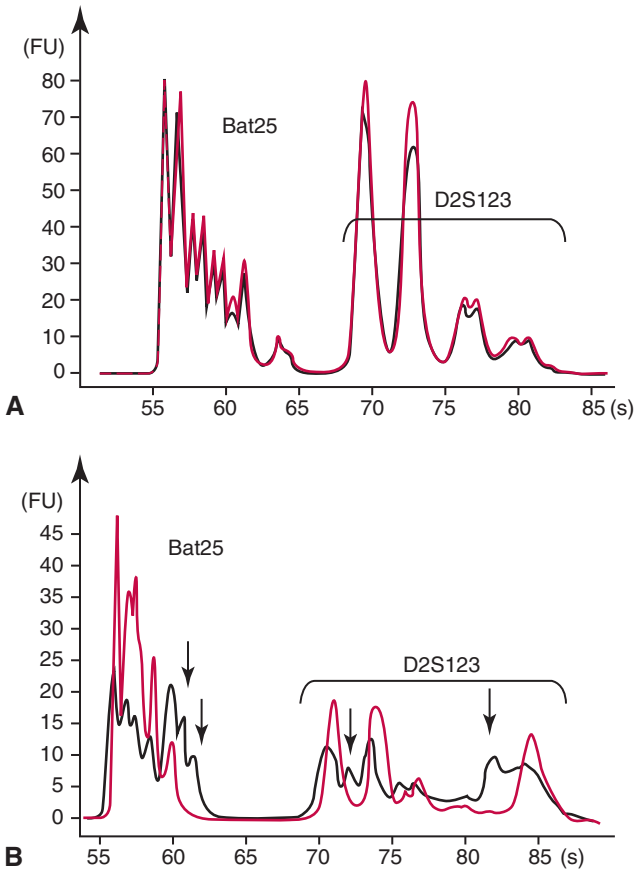

Figure 18-8 Microchip electropherograms of microsatellite markers in colorectal cancer. The separations are from polymerase chain reaction (PCR) products of both normal *(red)* and tumor *(blue)* tissue. A, The resultant electropherogram from stable microsatellites, as seen by the matching profiles from both samples. B, Indicative of instable microsatellites, as shown by deviations in the electrophoretic pattern. The tissues used were taken from cases with a known microsatellite instability status. *(Reprinted from Odenthal M, Barta N, Lohfink D, et al. Analysis of microsatellite instability in colorectal carcinoma by microfluidic-based chip electrophoresis. J Clin Pathol 2009;62:850-2.)*

Separation of Proteins

Although the literature is ripe with methods used for capillary electrophoretic separation of proteins, a vast majority of these involve nondenaturing separation in the absence of sodium dodecyl sulfate (SDS). Although this simple (no sieving matrix) and powerful (resolution) method can be used for protein analysis, sizing information is lost, and this is often an important component of protein-based clinical assays. In addition, the most common mode for the detection of proteins by CE is UV absorbance (200, 214, or 280 nm), and this has been difficult to translate to the microchip. Although LIF can easily be used (via massive development effort for DNA separations), it typically requires fluorescent labeling of the proteins, which has its own inherent limitations. Bousse and coworkers adapted SDS–polyacrylamide gel electrophoresis (PAGE) to a microdevice for the high-speed separation of proteins[11] with fluorescence detection that must use an on-chip, noncovalent labeling process; this technology has been commercialized in a glass microdevice with associated instrumentation (Agilent's Bioanalyzer, Agilent Technologies, Santa Clara, Calif). Giordano and associates[70] described a similar method for circumventing the covalent labeling of proteins with a "dynamic," on-chip approach that used commercially available fluorescent dyes in the separation medium to allow size-based protein analysis in a glass microchip. In a subsequent report,[38] they optimized conditions for dynamic interaction of the dye with protein, yielding a rapid, sensitive method for protein sizing and quantitation on microchips with a limit of detection (LoD) of 500 ng/mL for bovine serum albumin (BSA). On-chip analysis of patient serum samples allowed abnormalities in the levels of γ-globulins to be determined. Figure 18-9 shows partially purified human plasma separated on a glass microchip in comparison with that done in an 11% acrylamide SDS-PAGE gel, and clearly shows that the use of dynamic labeling enhances sensitivity without loss of resolution.

Nonglass substrates have been shown effective for protein separation as well. Liu and colleagues[94] showed that PMMA

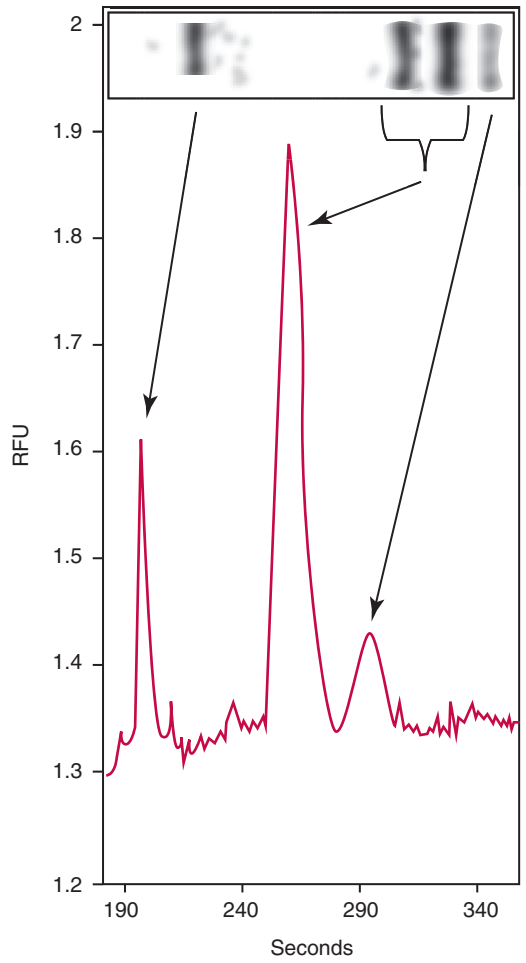

Figure 18-9 Comparison of 11% acrylamide sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) gel separation of partially purified human plasma versus microchip-based capillary electrophoresis-SDS (CE-SDS) analysis. Separation conditions include 25 mM/L Tris-CHES, 1 mM DTT, 0.1% SDS, 370 V/cm field strength, electrokinetic injection, and 0.2% (v/v) NanoOrange (excitation 488 nm, emission 590 nm). *(Reprinted from Giordano BC, Jin LJ, Couch AJ, Ferrance JP, Landers JP. Microchip laser-induced fluorescence detection of proteins at submicrogram per milliliter levels mediated by dynamic labeling under pseudonative conditions. Anal Chem 2004;76:4705-14.)*

microchips containing microchannels that had been passivated with polyethylene glycol could provide adequate resolution of the components of BSA; Roman and coworkers[135] used micellar-electrokinetic chromatography in a PDMS microdevice to perform high-resolution separations of standard protein using SDS-coated surfaces. The second most common mode of conventional protein separation in cross-linked gels, isoelectric focusing, has also been translated to the microchip platform using a variety of detection modes such as LIF, UV detection, and whole-column detection.[44,90,154] Guillo and coworkers circumvented the standard CE-type methods to mobilize focused zones past the detector (EOF or chemical mobilization) by using on-chip pumping generated by diaphragm pumps in a three-layer device containing deformable membranes. They illustrated success with this approach by defining the separation of L-lysine and L-histidine and by defining the dependence of resolution on mobilization flow rates.[42] Moreover, they analyzed low (<10 kDa) and high (>10 kDa) molecular weight fractions from patient urine when peaks in the former were assumed to represent a combination of metabolites and amino acids containing primary amino groups, such as creatine, methionine, phenyalanine, histidine, peptides, and small proteins, while the latter reflected larger proteins often present in urine at much lower concentrations. More recently, Xian and associates[182] used a microfluidic chip to evaluate the serum from 38 patients with type 2 diabetes, with focus on alterations in high-density lipoprotein (HDL) subfractions. Their results showed meaningful clinical correlations for total HDL and HDL2b and its ratio with triglycerides, suggesting that the microchip-based method may have predictive value when applied clinically.

Separation of Small Molecules and Ions

The vast majority of the microfluidic chip literature is focused on the separation of nucleic acids or proteins; however, other clinically relevant biological species have been shown to be measurable on microchips. Small molecule metabolites represent a significant portion of the assays carried out in clinical chemistry laboratories; therefore, development of microfluidic platforms that could address the detection and quantitation of metabolites, potentially in multiplexed form, would be powerful.

Wang and Chatrathi[171] showed that a glass microchip could be used to electrophoretically separate and detect glucose, uric acid, and ascorbic acid. These oxidizable species were detected by a downstream amperometric detector, with glucose detected in <100 seconds and all three detected within a few hundred seconds. Munro and colleagues[112] used glass microchips and indirect fluorescence detection (detection without fluorescent labeling) to separate 19 amino acids for urinanalysis (Figure 18-10, *A*). They reported on the detection of amino acids in a normal urine sample (Figure 18-10, *B*) and two abnormal urine specimens. The first abnormal urine sample was taken from a patient suspected of having nephropathic cystinosis with onset of Fanconi syndrome, for whom microchip analysis detected a generalized hyperaminoaciduria (Figure 18-10, *C*). The second abnormal sample was taken from a patient who exhibited symptomatic indicators for amino acid metabolic disorders in which glycine, serine, threonine, and histidine determined to be elevated via HPLC could be identified by microchip electrophoretic analysis (Figure 18-10, *D*). Deng and coworkers[23] used a microfluidic electrophoretic system interfaced with mass spectrometry as the detector to quantitate carnitine and select acylcarnitines in urine; Lunte and associates[127] used chip-based electrophoresis with electrochemical detection for the quantitation of homocysteine and glutathione in plasma samples at levels as high as 50 µmol/L, exceeding the reference interval (5 to 15 µmol/L) for healthy individuals. Henry and colleagues[35] measured uric acid concentrations in urine using a silicone (PDMS)/glass microchip with on-board

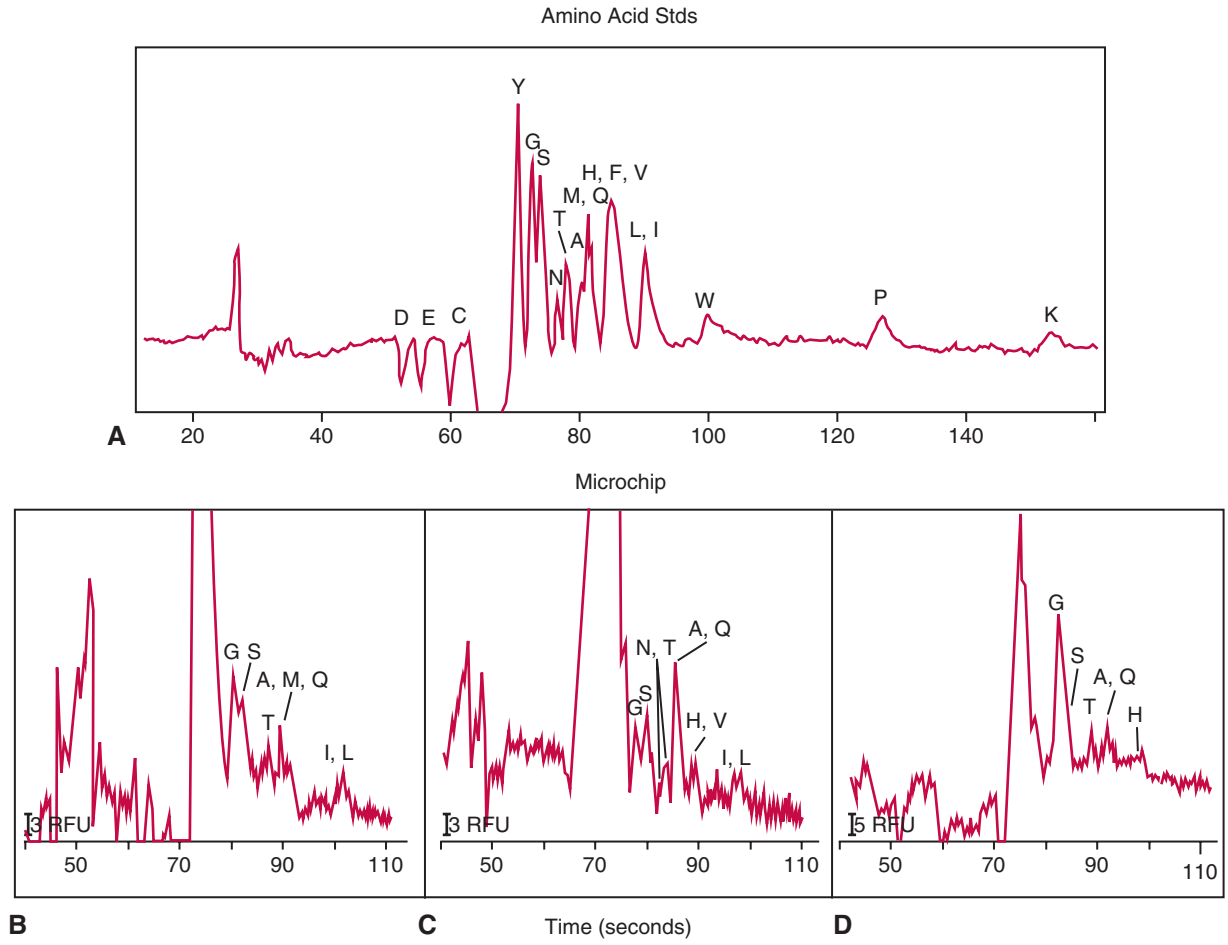

Figure 18-10 Indirect detection of the 19 amino acids by microchip electrophoresis. Electropherograms from (A) a sample containing amino acid standards, (B) a normal urine sample, (C) abnormal urine sample 1, and (D) abnormal urine sample 2. *A*, Alanine; *C*, cysteine; *D*, aspartic acid; *E*, glutamic acid; *F*, phenylalanine; *G*, glycine; *H*, histidine; *I*, isoleucine; *K*, lysine *L*, leucine; *M*, methionine; *N*, asparagine; *P*, proline; *Q*, glutamine; *S*, serine; *T*, threonine; *tau*, taurine; *V*, valine; *W*, tryptophan; *Y*, tyrosine. *(Modified from Munro NJ, Huang Z, Finegold DN, Landers JP. Indirect fluorescence detection of amino acids on electrophoretic microchips. Anal Chem 2000;72:2765-73.)*

amperometric detection. Similarly, Wang and Chatrathi[170] showed that markers of renal function—creatine, creatinine, *p*-aminohippuric acid, and uric acid—could be measured electrochemically in urine in roughly 5 minutes. Detector response was linear over the range of 15 to 110 µM, and analysis time was rapid (<30 seconds). Van den Berg and coworkers[169] developed an integrated glass microchip system that carried out sample cleanup followed by ion separation and detection for quantitation of lithium ion with conductivity detection. Using a simple sample collector requiring less than <10 µL of test fluid and an integrated filter membrane that prevented transport of blood cells into the microchip, they were able to separate sodium/calcium from lithium and magnesium within 20 seconds with a detection limit for lithium of 0.150 mmol/L (Figure 18-11). Investigators validated the device against routine lithium testing of five patients, demonstrating that the microchip-based system provided rapid analysis and comparable results and, hence, had the potential for point-of-care testing of electrolytes in serum and whole blood.

Using a simple, low-cost, PDMS-based microfluidic system, Songjaroen and associates[147] demonstrated that a chip-based two-point alkaline picrate kinetic reaction for determination of urinary creatinine was possible. Knowing that the reaction of creatinine with picric acid under alkaline conditions could be monitored photometrically using a miniature fiberoptic spectrometer (at 510 nm) interfaced with the PDMS chip, they showed linearity in detection from 0 to 40 mg/L creatinine, with a concentration detection limit of 3.3 mg/L (with a signal-to-noise ratio S/N = 3). Investigators concluded that the method was highly correlated with conventional spectrophotometric results obtained from urine samples.

Using a more generic metabolite detection approach, Do and colleagues[25] described a microfluidic chip system for the measurement of oxygen, glucose, and lactate in whole blood.

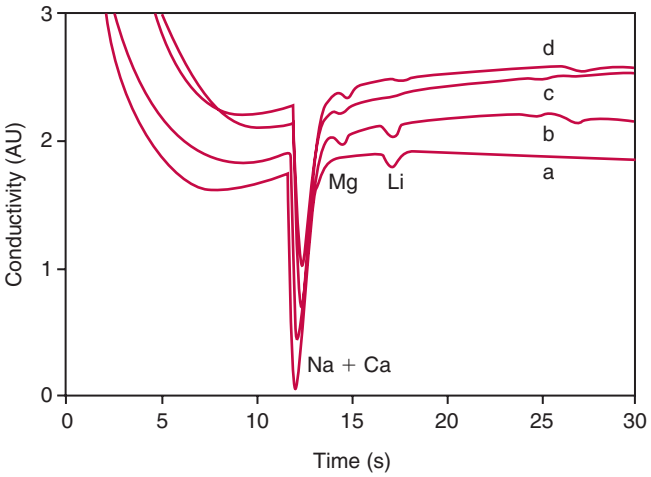

Figure 18-11 Microchip-based detection of lithium in blood samples. Electropherogram of *(a)* an aqueous calibration mixture containing 140 mmol/L sodium and 2 mmol/L lithium, *(b)* citrated whole blood enriched with 2 mmol/L lithium, *(c)* whole blood without anticoagulant, and *(d)* heparinized plasma from a patient on lithium therapy containing 0.62 mmol/L lithium. *(Reprinted from Vrouwe EX, Luttge R, Vermes I, van den Berg A. Microchip capillary electrophoresis for point-of-care analysis of lithium. Clin Chem 2007;53:117-23.)*

A reasonably compact portable analyzer was described that had multianalyte detection capabilities with a disposable microchip that accepted as little as 3.5 µL of blood. With total analysis times on the order of a few hundred seconds (sampling and sensing included), lactate and glucose could be detected in the ranges of 1 to 7 mmol/dL and 50 to 350 mg/dL, respectively, and dissolved oxygen in the range of 50 to 350 mg/dL could be measured.

MICROFLUIDIC VALVING

Volumes used in microfluidic devices can range from picoliters to microliters, with typical total solution volumes in the nanoliter range. A hurdle to the development of true "lab-on-a-chip" devices was absence of a method that could be used to reliably control these small volumes of fluid using practical fabrication methods. This capability was provided by the Quake[163] and Mathies groups,[40] which developed robust valves that were simple to fabricate. Key to these valving approaches was the use of a flexible PDMS membrane that could be pneumatically actuated to produce on-chip valves or fluidic switches. Although elastomeric membranes are not the only material amenable to such use, they represent the only substrate that has been used extensively thus far in the microfluidics field. Use of PDMS in microfluidics was, in fact, pioneered by Whiteside's group,[27,106] which developed the soft lithography techniques used by Quake and colleagues[163] to fabricate their valves.

The type of valve implemented in a microfluidic device typically can be categorized as "normally open" or "normally closed." Normally open, pressure-actuated valves are fabricated in the push-down[163] or push-up[150] configuration. A key feature of these types of valves is the essentially zero dead volume valving critical to effective fluid control on microdevices, but also having the inherent advantage that the valves can be arranged into high-density architectures (≥30 valves/mm^{-2}).[3] Moreover, with at least three valves coupled in series, peristaltic pumps can be created,[163] allowing precise metering of solutions within the device at flow rates up to 2.35 nL/s.

Normally closed, negative pressure–actuated valves developed by the Mathies group[40] are opened by vacuum, with the option of applying positive pressure to promote closing. Rather than patterning PDMS by soft lithography, these valves are defined by patterned glass layers (chemically etched) that sandwich a PDMS membrane. This provides a distinction from valves fashioned using soft lithography, in that most of the channel architecture can be made from glass; this can be advantageous when microchips are needed that are more rigid in structure (glass substrate) and that have enhanced chemical resistivity, while valving capabilities are maintained. The disadvantage of these valves is that the dead volume is not negligible; this is related to lower achievable valve density compared with the Quake valves, although the valves can be designed for <10 nL dead volume[40] and have been shown to be useful for injection of samples that are submicroliter in volume.[30,39] Either type of valve—normally closed or normally open—can be arranged into a diaphragm pumping configuration (at least three valves) with reported flow rates up to 25 µL/min.[40] It is notable that glass-based, normally closed valves are capable of pumping at rates approximately two orders of magnitude greater than their normally open counterparts. These types of devices have been used for amino acid detection,[145,146] DNA computing,[39] pressure injection for electrophoresis microchips,[32] and DNA sequencing,[9] and as fully integrated genetic analysis devices.[31]

Quake's group defined normally open valving systems on PDMS-glass hybrid chips.[150,163] These normally open, pressure-actuated valves are primarily fabricated as push-down valves and are typically restricted to a depth of less than ≈20 µm. A key feature of this type of valve is that it is essentially zero dead volume and can be arranged into high-density architectures (≥30 valves/mm^{-2}).[3] Valves coupled in series can perform as peristaltic pumps, thus providing on-board valving and pumping for precise metering of solutions within the device at flow rates up to 2.35 nL/s^{-1}. These valves have proved functional through implementation in a wide variety of applications such as protein crystallization,[45] nucleic acid processing,[56] multistep radiolabel synthesis,[84] and, more recently, sequencing of the human genome.[130]

APPLICATIONS

Nucleic Acids

DNA Extraction

Analytical techniques for nucleic acid (NA) extraction have been transferred in an effort to lessen sample handling,

reduce potential contamination, and expedite analysis time.[31,68,123] Several different approaches have been used for NA purification and preconcentration; the most widely used involves the use of silica-based solid supports. With the use of chemistries similar to commercially available silica-based NA extraction kits, the sample is lysed in a high–ionic strength, chaotropic-containing buffer. NA is loaded onto the silica support in this lysis buffer, and the high-salt environment drives NA onto the solid phase. An alcohol, typically ethanol or isopropanol, is rinsed over the phase to remove cellular debris, and the NA eluted from the phase using a low salt buffer, typically a Tris solution that is compatible with PCR. The silica solid support can exist in many different forms and has been demonstrated as a bead-packed column,[159] as micropillars fabricated into the channel,[19,176,177,185] as sol-gel,[140,173,174,181] and as immobilized silica particles.[8,12,86,178] Other methods used for microchip NA purification involve similar microfluidic strategies but with the use of different extraction chemistries. For example, pH-induced NA capture and release systems have been reported for NA extraction to avoid the harsh solutions used in silica-based extractions.[15,115] A microchannel was coated with a chitosan polymer, which has a pKa of 6.3, allowing for a loading step in pH 5 buffer and elution at pH 9 in a totally aqueous environment.[15,115] Even though the surface area-to-volume ratio of a microchannel is not optimal for performing NA extraction, Wu and associates were able to show 75% extraction efficiencies of DNA from 1.5 μL whole blood.

Polymerase Chain Reaction

Conventional means of performing PCR involve the reaction in a tube, placed in a stationary heating block that thermocycles through desired temperatures. Microfluidic PCR has greatly enhanced this process of conventional PCR by reducing volumes, introducing innovative thermocycling techniques, and allowing for amplification reactions that are limited only by the kinetics of the polymerase. One of the greatest advantages of microchip PCR is the decreased thermocycling times when compared with thermal block. Multiple different approaches have been developed, including infrared-mediated heating,[37,60,121,136] where a lamp is used to selectively heat the solution, and strategies by which thermocycling components are fabricated directly into the microchip, such as titanium/platinum heaters[82,93,190] and Peltier elements.[78] Another approach to thermocycling involves flow through a PCR device that exploits discrete temperature zones in the microdevice, when the PCR master mix solution is fluidically mobilized through different zones to change the temperature of the solution.[48,79,120] Using this strategy, Hashimoto and colleagues[48] were able to amplify 500-bp and 997-bp fragments in 1.7 and 3.2 minutes, respectively; investigators attribute this to the kinetic limit of nucleotide incorporation by *Taq* polymerase.

Integration

One of the long-standing goals in the microfluidic field has been to create a fully integrated device for which all components needed to perform an analysis are included in the microchip. The benefits of a device capable of this are many, ranging from faster analysis times to use of a completely closed system, leading to a decrease in potential sources of contamination. An example of this type of integrated device is the microgenetic analysis (MGA) device described by Easley and coworkers in 2006.[31] In this work, the authors were able to start with a sample—lysed blood or a human nasal aspirate—and perform DNA extraction, amplification, and electrophoretic separation for pathogen identification. Analysis time required for identification of *Bacillus anthracis* was just 24 minutes, and the sample remained completely enclosed in the microfluidic device throughout the entire process. Figure 18-12, *A*, illustrates all three processes: DNA extraction, PCR amplification, and three replicates of electrophoretic separation. Figure 18-12, *B*, shows a zoomed-in image of the electropherogram, illustrating reproducibility of the separation with the desired PCR product highlighted in red and surrounded by a DNA marker for sizing of the fragment. Figure 18-12, *C*, shows the glass microfluidic device encased in the PMMA macrointerface to microinterface; the actual size of the encompassed device is roughly equivalent to a deck of cards. In 2007, another report emerged that could identify bird flu (the H5N1 strain) in a droplet.[129] The authors were able to manipulate the 100-nL droplet through the use of magnetic beads and to isolate viral RNA, followed by ultrafast real-time RT-PCR, with the whole process requiring 28 minutes. This report states that compared with commercially available tests, their assay shows comparable sensitivity and is 440% faster and 2000 to 5000% cheaper.

Integrated microchips capable of genetic analysis have also been developed, with a focus on human genotyping and DNA sequencing. In 2006, Blazej and colleagues reported a bioprocessor microfabricated from glass and PDMS that integrates the three Sanger sequencing steps: amplification, post-PCR sample purification, and electrophoresis, all in one device.[9] They were able to read up to 556 continuous bases with 99% accuracy from only 1 fmol of DNA. The same group also developed a portable microsystem capable of rapid forensic short tandem repeat (STR) typing.[96] In this work, the authors designed both the microchip and a portable instrument capable of PCR thermal cycling, electrophoretic separation, four-color laser excited fluorescence, and fluidic control through the use of pneumatic valves. They showed STR typing of amelogenin (sex-determining marker) and 3 Y chromosome STR loci within 1.5 hours using their microsystem. They reported a limit of detection of 20 copies of male standard DNA in the reactor.

Hybridization Arrays

DNA hybridization arrays are powerful tools that allow for the interrogation of many genes in a single sample. Microarrays consist of slides, typically made from glass or plastic, that have multiple, different short DNA oligonucleotide probes affixed to the surface. The sample can be applied to the array, and through a predetermined detection scheme,

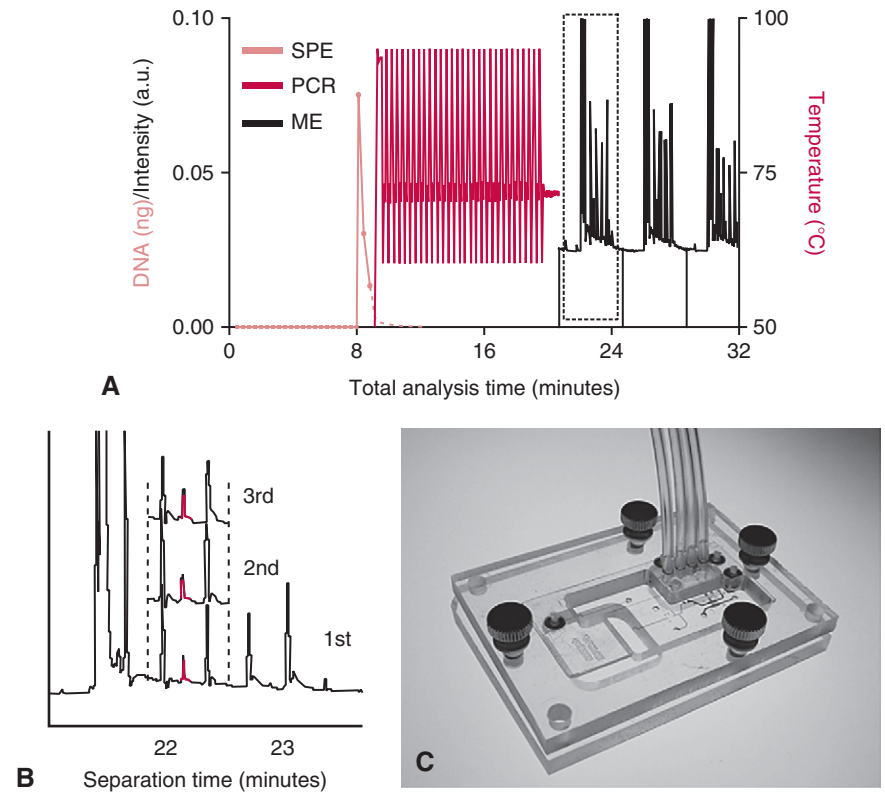

Figure 18-12 Integrated analysis for the detection of *Bacillus anthracis* from blood samples. A, A schematic representing DNA extraction [solid phase extraction (SPE)], polymerase chain reaction (PCR), and microchip electrophoresis (ME), all graphed with respect to time. ME shows three repetitive injections and separations. B, A magnified view of the ME from (A), where the PCR product is highlighted in red and is flanked by a DNA marker for sizing. All three injections and separations are shown. C, A photograph of the glass device enclosed in the polymethylmethacrylate (PMMA) manifold for microinterfacing to macrointerfacing. *(Modified from Easley CJ, Karlinsey JM, Bienvenue JM, Legendre LA, Roper MG, Feldman SH, et al. A fully integrated microfluidic genetic analysis system with sample-in-answer-out capability. Proc Natl Acad Sci U S A 2006;103:19272-7.)*

data can be obtained based on the hybridization of DNA sequences from the sample with those patterned on the slide. This is a very provocative technique that yields a lot of information from just a single sample. To fully understand the potential of this method, please see Chapter 17 by Wittwer for a more in-depth discussion.

PROTEINS

Immunoassays

Protein immunoassays are key to many biochemical analyses, in the clinical arena and in research, and these assays have also been adapted to a microfluidic format. The basic elements of a microfluidic-based immunoassay are the same when compared with a conventional assay, involving a mode for solution transport, a reaction solid phase, and a detection mechanism. One of the biggest differences between the two formats is the size, with conventional assays done in volumes on the order of 50 µL, where microfluidic assays are generally done in volumes less than 1 µL; this leads to a large difference in diffusion rates, which is one of the time-limiting factors in immunoassays. A comparison was performed to evaluate the effects of microtiter and microfluidic formats on diffusion.[138] Figure 18-13 shows a comparative schematic of the two different formats. The authors reported that it required nearly 15 hours for immunoreactions to occur in the microtiter format (Figure 18-13, *A*), while the signal intensity became constant after only 10 minutes in the 100 µm deep microchannel (Figure 18-13, *B*) packed with beads. They credit the decrease in reaction time to a reduction in diffusion distance due to the increased surface area-to-volume ratio. The longest distance that needs to be covered in a microtiter plate is 1.5 mm, whereas that distance is estimated to be less than 20 µm in a bead-packed microchannel. Because diffusion time is equal to the square of the diffusion distance, the time required for the same molecule to diffuse in the bead-packed microchannel is more than 5600 times shorter than in a microtiter plate.

Several microfluidic immunoassays have been used for clinical applications reported in the literature. Herr and

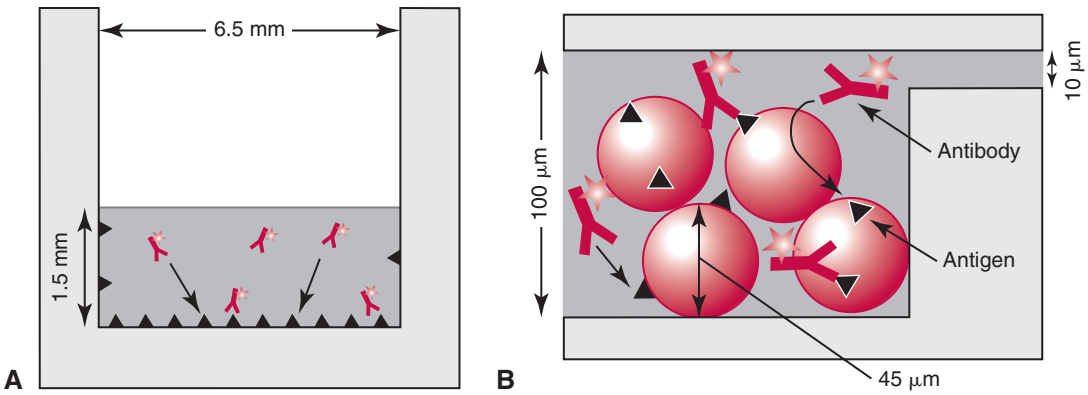

Figure 18-13 Illustration of antigen-antibody interactions in (A) microtiter and (B) microchip formats. *(Reprinted with permission from Sato K, Tokeshi M, Odake T, et al. Integration of an immunosorbent assay system: analysis of secretory human immunoglobulin A on polystyrene beads in a microchip. Anal Chem 2000;72:1144-7.)*

associates[52] demonstrated the use of a microchip-based point-of-care diagnostic immunoassay for the measurement of proteinaceous disease biomarkers in saliva. They evaluated saliva samples from both healthy subjects and those with moderate to severe periodontitis and looked for the detection of matrix metalloproteinase-8 (MMP-8). They performed sample loading, sample enrichment, and rapid diffusive mixing of sample and primary antibody, as well as electrophoretic separations of antibody-sample complexes from the unbound primary antibody—all integrated on the device; the electropherograms from these samples are shown in Figure 18-14, *A*. A linear regression analysis, shown in Figure 18-14, *B*, compares the microchip system versus the commercially available enzyme-linked immunosorbent assay (ELISA). Measurement of MMP-8 was accomplished within 10 minutes, requiring only 20 μL of saliva. Another group developed a microdevice for the immunofluorescent detection of viruses[99] using antibody-coated microbeads for analyte capture and quantum dots for detection. When they compared their device with a conventional ELISA method for detecting the presence of Singapore grouper iridovirus (SGIV), a marine iridovirus, the microfluidic format improved detection sensitivity from 360 ng/mL to 22 ng/mL, decreased detection time to less than 30 minutes, and reduced the quantity of antibodies required by a factor of 14.3. A PMMA device was developed for the detection of biomarkers in serum.[100] In this report, the authors demonstrated the detection of alpha fetoprotein (AFP) in healthy human serum. The microchip consisted of a channel coated with poly(ethyleneimine), containing abundant NH_2 groups to assist in capture of the monoclonal antibody to the channel surface. The sample was flowed through the channel, followed by a horseradish peroxidase–conjugated AFP antibody, and detection was achieved using a three-electrode electrochemical detection system. Investigators reported a detection limit of 1 pg/mL of AFP and a detectable linear concentration range of 1 to 500 pg/mL using their method.

Protein Microarrays

In their simplest form, protein microarrays consist of planar substrates affixed with proteins for sample interrogation. This rudimentary description has been expanded over the years, where the term "protein" encompasses antibodies, cytokines, tissue, and whole cell lysates, and "substrate" can include glass and microbeads. The proteins are attached through a number of different methods, with the four most widely used techniques involving adsorption, covalent binding, affinity interaction, and diffusion-based immobilizing techniques.[148] The most widely used protein chip is the planar antibody microarray, which has found use in both clinical and research applications. This involves the immobilization of a few hundred antibodies to capture proteins of interest from a more complex sample. In a report searching for alterations in cell signaling in colon cancer, the authors used a protein microarray with 224 antibodies affixed to the surface to identify altered proteins.[101] They screened soluble protein extracts from tumor biopsies of 11 different patients, all with varying stages of colorectal cancer. Using this experimental approach, the authors were able to identify new potential biomarkers that are preferentially expressed in this cancer. Another group enhanced the microarray by coupling it with microfluidics for immunoglobulin (Ig)E allergen testing.[22] They used glass slides coated with a novel copolymer that allows for immobilization of the allergens in their native conformation. Their fully automated assay is enhanced by using microfluidics to achieve mixing of the sample and serum with the surface of the microarray and can be performed in 25 minutes.

Microbeads provide another format that is used to probe protein and nucleic acid interactions. In this format, the protein is attached to microbeads, such as polystyrene microspheres, and detection can be accomplished through the use of laser-induced fluorescence or color coding of the beads, for example. Microbead-based arrays also allow for multiplexing, where one sample can be probed for multiple analytes, and this is followed by analysis via flow cytometry. When flow cytometry is used for detection, the beads can be discriminated by size using side scatter, or by fluorescence, where each capture protein has a different fluorochrome attached.[111] The ability to analyze multiple analytes from a single sample was demonstrated by Tarnok and colleagues, who evaluated the concentrations of cytokines that are elevated in infections in children.[155] They compared a commercially available fluorescent bead array assay versus traditional ELISA for detection of six different interleukins and tumor necrosis factor-α. Using flow cytometry for detection, the bead array had a calibration range that was 10 times wider when compared with ELISA results, and the authors were able to decrease the amount of blood used by more than 80% for three of the analytes. The authors showed that the bead array performed comparatively with ELISA and offered additional benefits, such as decreased operating time and the ability to multiplex the detection of multiple analytes in one sample. In another example of the usefulness of bead-based arrays, the authors analyzed up to 100 different serum cytokines in a single well in melanoma patients with interferon alpha2b treatment.[189] Using xMAP technology (Luminex Corp, Austin, Tex), they were able to compare cytokine expression in melanoma patients compared with healthy controls using fluorescence as the detection scheme to correlate treatment with altered serum levels of proinflammatory cytokines and growth factors.

Cells

The last decade has seen efforts to develop microchip-based cell culture platforms for performing multiplex culturing and combinatorial assay. Although numerous reports can be found in the literature,[33] the potential for culturing and assaying in the same microdevice offers numerous benefits. For example, Yu and coworkers[187] demonstrated the ability to culture NIH 3T3 fibroblast, B16 melanoma, and HeLa cells and, in a parallel manner, to assay for drug-induced apoptotic responses and demonstrate "on-chip" transfection of a reporter gene, followed by live-cell imaging of transcriptional activation of cyclooxygenase-2 expression. Perhaps more pertinent to this chapter is the ability to use microdevices for the capture of circulating tumor cells (CTCs).

Although this is still open to question, CTCs are emerging as a potential alternative to invasive biopsies as a source of tumor tissue for the detection, characterization, and monitoring of nonhematologic cancers.[110] The number of CTCs is a proven independent predictor of survival in patients with breast, prostate, lung, and colon cancers, and the importance of CTC analysis will continue to grow. The ability to identify, isolate, propagate, and molecularly characterize CTC subpopulations could further the discovery of cancer stem cell biomarkers and expand our understanding of the biology of metastasis. Although it is currently unclear how treatment decisions will be influenced by CTC analysis, or whether patient outcomes will be improved by decisions based on CTC data, the future of CTC analysis appears promising.

The only commercially available technique that is Food and Drug Administration (FDA) approved for CTC isolation is the CellSearch assay (Veridex LLC, Raritan, NJ). This automated, highly reproducible technique has been in use for several years. It utilizes ferrofluid nanoparticles coated with streptavidin and epithelial cell adhesion molecule (EpCAM) antibodies to isolate CTCs and can reliably detect CTCs in approximately 36% of patients with metastatic cancer.[1a] However, microfluidic assays for CTC isolation have begun to emerge from several research groups with the promise that this approach will be more sensitive. Nagrath and associates[114] showed that viable CTCs (i.e., tumor-derived epithelial cells) could be isolated from the whole blood of cancer patients. In this work, the authors flowed samples through an array of microposts coated with anti-EpCAM antibodies. Device characterization experiments determined a calculated capture efficiency of 65% using non–small cell lung carcinoma cells spiked into phosphate buffered saline (PBS). Peripheral blood samples from 116 patients with metastatic lung, prostate, pancreatic, breast, and colon cancers were analyzed, and CTCs were identified in 115 (99%) samples. More recently, Tan and colleagues[153] presented a label-free microdevice capable of

isolating cancer cells from whole blood based on physical properties (size and deformability) that are discriminators. The authors fabricated crescent-shaped isolation wells to act as a sieve, capturing the larger tumor cells (approximately 17 µm) in contrast to erythrocytes and leukocytes, whose cell diameters can range from 8 to 25 µm, yet their deformable nature lets them traverse capillaries that are 2 to 5 µm in diameter. Using breast and colon cancer cells, they showed an isolation efficiency of ≈80%. Soper and colleagues[1b] used plastic (PMMA) microdevices to isolate a small number of CTCs also using antibodies against EpCAM. They sampled milliliter input volumes of whole blood in less than 40 minutes and showed the capture of CTCs in small volumes (several hundred nanoliters) that could be detected with an integrated conductivity sensor following release from the capture surface. The highly quantitative (>97%) recovery of CTCs directly from whole blood by capture channels points to microfluidic devices as the next generation of devices to supplant CellSearch-type assays.

In a completely orthogonal approach with a different application, Lenshof and coworkers[88] reported the use of an acoustophoresis-based separation microchip to prepare plasma from whole blood for clinical applications. This work derived from earlier work from this group, in which they had used acoustic energy transduced to the microchannel from a piezo interfaced with the chip in a microfluidic system to cleanse blood of fat microglobules contaminating filtrate during open thorax surgery.[72] In that application, investigators exploited ultrasounds to set up standing acoustic waves (Figure 18-15, *B*) in the microfluidic channel, which augmented the

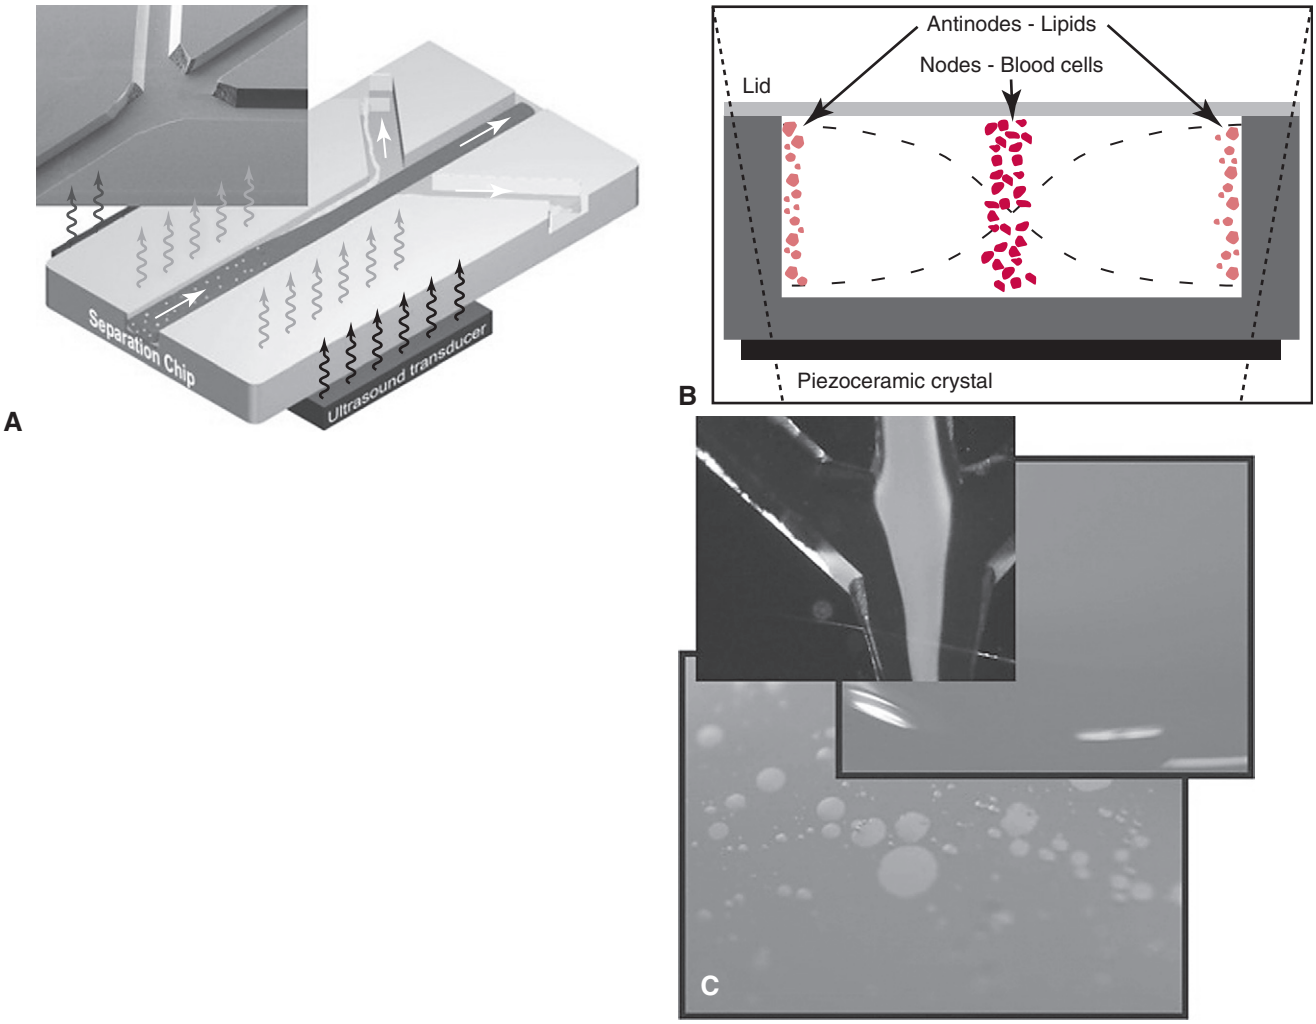

Figure 18-15 Cell-particle separation using standing acoustic waves. A, An illustration of the device, showing the flow of erythrocytes. B, A schematic of the acoustic standing wave, where the less compressible particles with higher density (erythrocytes) migrate to the nodes, and the lipid emboli move to the antinodes. C, The three panels show still images of the blood before *(bottom image)* and after *(middle image)* processing by the device. The lipid particles that are evident before *(bottom image)* are not visible after *(middle image)* the microfluidic separation. The *top image* shows an image of the chip during the separation, where the erythrocytes can be seen in the middle of the channel and the lipid particles are seen as white patch on the side of the channel. *(Reprinted from Jonsson H, Holm C, Nilsson A, Petersson F, Johnsson P, Laurell T. Particle separation using ultrasound can radically reduce embolic load to brain after cardiac surgery. Ann Thorac Surg 2004;78:1572-7.)*

flow of particles in a size-dependent way (also affected by density and compressibility). In a manner amenable to handling hundreds of milliliters per hour of pericardial blood during surgery, they showed that lipid particles purported to be associated with microembolisms could be cleansed from the blood (Figure 18-15, *C*). The Lenshof group[88] sought to remove cells in a single flow-through step process to yield high-quality plasma of low cellular content, in contrast to purifying them through a multistep process. They not only demonstrated that the plasma generated by the method meets European standard requirements for plasma in terms of the number of erythrocytes per liter ($<6.0 \times 10^{-9}$), they also successfully linked the plasmapheresis microchip to an antibody microarray chip for prostate-specific antigen (PSA) detection.

Wang and coworkers[172] used a PDMS chip to count CD4+ T lymphocytes in a microchannel. Using fluorescence detection combined with resistive pulse sensing mediated by a metal oxide semiconductor field effect transistor (MOSFET) signal, they were able to define the total number of cells passing through the channel, while fluorescence was used to detect cells tagged with a specific fluorophore. The CD4+ T cells counted and the percentage of total lymphocytes determined by the chip-based method showed comparable accuracy with data obtained with a commercial flow cytometer. The authors comment that this technique could be applied to the diagnosis of human immunodeficiency virus (HIV) and could greatly reduce the cost, making it more accessible to resource-poor developing countries.

Detection of Drugs and Drug Metabolites

The advent of rapid and simple analytical systems in the early 1990s set the stage for what point-of-care-testing platforms would bring to clinical diagnostics. In 1992, Biosite Inc (San Diego, Calif) released the Triage Drugs of Abuse Panel for the rapid detection of amphetamines/methamphetamines, cocaine, opiates, phencyclidine, and tetrahydrocannabinol.[13] This event preceded release of a similar kit in which acetaminophen, barbiturates, benzodiazepines, methadone, propoxyphene, and tricyclic antidepressants were detected via the Triage TOX Drug Screen (Biosite Inc). Assays for therapeutic drugs or drugs of abuse that employ chemistries that are deployable on-site are simple to use from raw sample (e.g., urine), are single-use and disposable, and highlight the need for microfluidic systems capable of rapid, information-rich analysis.

Thormann and coworkers[168] were the first to demonstrate the use of electrophoretic microdevices for drug analysis, showing that serum theophylline could be measured using micellar electrokinetic chromatography to carry out an immunoassay on microchip. Henion's group,[24] having pioneered effective microfabricated interfaces between microchip and mass spectrometer, demonstrated that imipramine and desipramine could be quantitated in human plasma. Similarly, Locascio and associates[69] used plastic microdevices (both copolyester and PDMS) for drug screening and residue analysis of barbiturates and phenobarbital, exploiting an on-board affinity preconcentration step. The problem with these assays is that no device has yet been produced that meets the requirements of "user friendliness" for the busy clinical laboratory or the rigid specifications demanded for recording quality assurance data.

LIMITATIONS OF MICROFLUIDIC SYSTEMS

Challenges in developing mass-producible microfluidic devices that can enhance productivity in the clinical chemistry laboratory are ongoing. First and foremost, integrated microfluidic systems with *sample-in-answer-out* capabilities are required to avoid generating devices that only incrementally improve part of the overall analytical process; these devices need to be not only robust in performance but turnkey in operation. Second, small volumes that lie at the heart of microfluidics offer a reduction in the cost of testing over more conventional analyses that use larger reagent volumes. For example, the reduction in master mix volume needed for PCR in an integrated microfluidic system (reduced from 25 µL down to 500 nL) represents a 50-fold reduction in reagent costs.[31] A report from the Yager Laboratory demonstrated a microfluidic T-mixer capable of measuring phenytoin concentrations in blood samples using less than 1 µL within 1 minute.[49] However, the microscale also extends to small sample volume capabilities, typically in the tens of microliters. Although this may be fine for some clinical applications, others require the microdevices to handle volumes ranging from hundreds of microliters to as much as several milliliters (testing for minimal residual disease), while forensic applications may require the concentration and detection of hundreds of milliliters of sample (e.g., food safety). It is in this respect that *large-volume reduction strategies* will be needed to concentrate the analytes of interest from large-volume samples into volumes that can be processed by the chip. The acoustic-based approaches described are ideal for cell and particle concentrations from larger volumes,[72] and chip-based methods for extracting nucleic acids from milliliter volume samples are being developed.[133] Third, new approaches to *fluidic control* on microdevices need to be devised. Although developments since 2000 have revolutionized microfluidic systems, allowing very different chemistries on the device to be chemically isolated yet fluidically connected via mechanical valves,[40,163] novel, compact valving strategies that minimize external hardware are needed. Leslie and associates[89] have shown that passive fluidic control elements may present the possibility of flow control without valve actuation, relying solely on frequency-specific pumping for control of flow. Fourth, although microfabrication of devices in glass once dominated the analytical microchip landscape, other chip substrates need to be explored. Polymeric substrates (e.g., PDMS, PMMA) are becoming increasingly popular and likely represent the future. The ability to hot emboss microfluidic structures in plastic substrates presents a direct path to the inexpensive, single-use, disposable microdevices that will be a must for adoption in clinical testing. Fifth, and finally, engineering of the hardware, firmware, and

software needs serious engagement in a collaborative effort with analytical chemists (who develop the "chemware") to define benchtop instrumentation amenable to turn-key operation by unskilled operators. Only then will rugged and "portable" instrumentation be developed with robust performance capabilities, and this will lay the groundwork for miniaturization of the instrument to hand-held, personal digital assistant (PDA)-like devices that will perform total biochemical analysis.

FUTURE OF MICROFLUIDICS IN CLINICAL DIAGNOSTICS

The barrier to implementing new technology in the clinical diagnostics sector is palpable, not because of lack of "need," but because competition is fierce, the sector is dominated by a handful of behemoth multinationals, and the profit margins are small. Although "need" should drive the development of new technologies, such as microfluidics, other driving forces often factor in. It is interesting when one views this retrospectively and outside the realm of "sector needs." A precedent has been established for national security applications to provide a large, powerful driving force for technology development. This is supported by historical recapitulation of the development of microelectronics, which was driven largely by the race-to-space and by military/civil needs. World War II drove the development of electronic circuits that were substantially smaller in size, weight, and power consumption, especially for implementation in aircraft. Layered on top of this was the need for NASA to have smaller, lightweight, more powerful circuits for the space-limited spacecraft that were evolving. Similarly, computer science and computer engineering were shaped by military funding of the early stages of digital computing, during which most of the basic technologies for digital computing were developed through a program focused on the development of an automated radar shield. It is not beyond the realm of possibility that the clinical sector will be the recipient of analytical microfluidic technology as a result of the development of *biowarfare detection* systems. This area saw serious capital investment come into play with the advent of 9/11 and can experience a fast track to market because it circumnavigates the FDA 510(k) approval process.

In addition, the focus on *personalized medicine* appears to be ever increasing—something that may be inevitable as we witness the aging of an educated population (i.e., baby boomers). The shift away from the passive role that the patient has traditionally played in the management of his or her health care to one that is more preemptive or active, even proactive, at some point will present new markets of opportunity to the diagnostic testing community. Microfluidic platforms may well play a significant role in making clinical testing more personalized. It is not unreasonable to envision the availability of self-test molecular diagnostic kits that allow a patient to do a rapid (and affordable) screen for the current flu season virus before incurring the costs associated with a weekend visit to the Emergency Room. Certainly, multiple technical challenges will have to be addressed before such visions can ever become a reality. Thorough validation and FDA approval will be required; although lengthy and arduous, these processes should not be insurmountable. A number of major bona fide issues are tethered to the technology, but the demonstrated advantages made possible by the field of microfluidics make it one likely vehicle to take us into an era where the term *personalized medicine* is not nebulous but, in fact, is commonplace. All that remains to be seen is whether the ethical, personal, societal, and political issues are adequately addressed.

CHAPTER 19

Automation in the Clinical Laboratory

James C. Boyd, M.D., and Charles D. Hawker, Ph.D., M.B.A., F.A.C.B.

The term *automation* has been applied in clinical chemistry to describe the process whereby an analytical instrument performs many tests with only minimal involvement of an analyst. The availability of automated instruments enables laboratories to process much larger workloads without comparable increases in staff. The evolution of automation in the clinical laboratory has paralleled that in the manufacturing industry, progressing from fixed automation, whereby an instrument performs a repetitive task by itself, to programmable automation, which allows the instrument to perform a variety of different tasks. Intelligent automation also has been introduced into some individual instruments or systems to allow them to self-monitor and respond appropriately to changing conditions.

One benefit of automation is a reduction in the variability of results and errors of analysis through the elimination of tasks that are repetitive and monotonous for most individuals. The improved reproducibility gained by automation has led to a significant improvement in the quality of laboratory tests.

Many small laboratories now have consolidated into larger, more efficient entities in response to market trends involving cost reduction. The drive to automate these mega-laboratories has led to new avenues in laboratory automation. No longer is automation simply being used to assist the laboratory technologist in test performance; it now includes (1) processing and transport of specimens, (2) loading of specimens into automated analyzers, (3) assessment of the results of the tests performed, and (4) storage of specimens. We believe that automating these additional functions is crucial to the future prosperity of the clinical laboratory.[1,2]

This chapter discusses the principles that apply to automation of the individual steps of the analytical process—both in individual analyzers and in the integration of automation throughout the clinical laboratory.

BASIC CONCEPTS

Automated analyzers generally incorporate mechanized versions of basic manual laboratory techniques and procedures. However, modern instrumentation is packaged in a wide variety of configurations. The most common configuration is the random-access analyzer. In *random-access analysis*, analyses are performed sequentially on a collection of specimens, with each specimen analyzed for a different selection of tests. Tests performed in random-access analysis are selected through the use of different vials of reagents stored on board the analyzer. This approach permits measurement of a variable number and variety of analytes in each specimen. Profiles or groups of tests are defined for a specimen at the time the tests to be performed are entered into the analyzer (1) via a keyboard, (2) by instruction from a laboratory information system in conjunction with bar coding on the specimen tube, or (3) by operator selection of appropriate reagent packs.

Historically, other *analyzer configurations* used include continuous-flow and centrifugal analyzers. Continuous-flow analyzers were the first automated analyzers used in clinical laboratories. Initially, these analyzers were used in a *single-channel analysis* configuration and carried out a *sequential analysis* of each specimen. Subsequently, *multiple-channel analysis* versions were developed, in which analysis of each specimen was performed on every channel in parallel. Results from nonrequested tests in the test profile were discarded as necessary after the analysis was complete. Inflexibility in the menu of tests that could be performed on these analyzers eventually led to their replacement in the marketplace by more versatile configurations.

Centrifugal analyzers used discrete pipetting to load *aliquots* of specimens and reagents sequentially into the discrete chambers in a rotor, and the specimens subsequently were analyzed in parallel *(parallel analysis)* by spinning the rotor to exert centrifugal force to mix the specimens and reagent and to drive the mixtures into cuvettes located on the periphery of the rotor. Such analyzers could be operated in a multiple-specimen/single-chemistry or a single-specimen/multiple-chemistry mode. Although such technology was developed as part of the space program and is suitable for application in a zero gravity environment, it was not sufficiently versatile to compete with other random-access

analyzers and has largely been abandoned for use in the routine laboratory.

AUTOMATION OF THE ANALYTICAL PROCESSES

The following individual steps required to complete an analysis often are referred to collectively as *unit operations* (Box 19-1). These operations are described individually in this section, and examples demonstrate how they have been automated in terms of operational and analytical performance. In most automated systems, these steps usually are performed sequentially, but with some instruments, they may occur in parallel.

Specimen Identification

Typically, the identifying link (identifier) between patient and specimen is noted at the patient's bedside, and maintenance of this connection throughout (1) transport of the specimen to the laboratory, (2) subsequent specimen analysis, and (3) preparation of a report is essential. Several technologies are available for automatic identification and data collection purposes (Box 19-2). In practice, automatic identification includes only those technologies that electronically detect a unique characteristic or unique data string associated with a physical object. For example, identifiers such as (1) serial number, (2) part number, (3) color, (4) manufacturer, (5) patient name, and (6) medical record number have been used to identify an object or patient through the use of electronic data processing. In the clinical laboratory, labeling with a bar code has become the technology of choice for purposes of automatic identification.

Labeling

In many laboratory information systems, electronic entry of a test order in the laboratory or at a nursing station for a uniquely identified patient generates a specimen label bearing a unique laboratory accession number. A record is established that remains incomplete until a result (or a set of results) is entered into the computer against the accession number. The unique label is affixed to the specimen collection container when the specimen is obtained. Proper alignment of the label on a specimen tube is critical for subsequent specimen processing when bar-coded labels are used. Arrival of the specimen in the laboratory is recorded by a manual or computerized log-in procedure. In other systems, the specimen is labeled at the patient's bedside, and patient identification and collection information is provided; then the labeled specimen is submitted to the laboratory with a requisition form. There it is assigned an accession number as part of the log-in procedure, which is usually a computerized process.

After accessioning, specimens undergo the technical handling processes. For those processes requiring physical removal of serum or plasma from the original tube, secondary labels bearing essential information from the original label must be affixed to any secondary tubes created. Some automated analyzers sample directly from the original collection tube while simultaneously reading the accession number from the bar code label on the tube. Secondary bar code labels, if necessary, may be generated at the time of accessioning, or in some analyzers by a built-in printer that is activated when the analyzer is programmed.

Many methods are used to achieve secondary labeling when bar code labels are not available. A number may be handwritten on the specimen cup, or a coded label may be affixed to the original tube or to a specimen cup. The label numbers require correlation with a manual or computer-generated work or load list. The load list usually records accession numbers in sequence with the physical positions of cups or tubes in the loading zone of the analyzer. This loading zone may be (1) a revolving tray or turntable, (2) a mechanical belt, or (3) a rack or set of racks by which specimens are delivered in a predetermined order to the sample aspiration station of the analyzer.

In those analyzers that do not automatically link specimen identity and sample aspiration, the sequence of results produced must be linked manually with the sequence of entry of specimens. Some analyzers print out or transmit to a host computer each result or set of results from a specimen

through the position of the specimen in the loading zone or the accession number programmed to that position.

Bar Coding

A major advance in the automation of specimen identification in the clinical laboratory is the incorporation of bar coding technology into analytical systems. A bar coding system consists of a bar code printer and a bar code reader, or scanner. One- and two-dimensional bar coding systems are available. A one-dimensional bar code is an array of rectangular bars and spaces arranged in a predetermined pattern according to unambiguous rules to represent elements of data referred to as *characters*. A bar code is transferred and affixed to an object by a *bar code label* that carries the bar code and, optionally, other noncoded readable information. *Symbology* is the term used to describe the rules specifying the way data are encoded into the bars and spaces. The width of the bars and spaces, as well as the number of each, is determined by a specification for that symbology. Different combinations of bars and spaces represent different characters. When a bar code scanner is passed over the bar code, the light beam from the scanner is absorbed by the dark bars and is not reflected; the beam is reflected by the light spaces. A photocell detector in the scanner receives the reflected light and converts that light into an electrical signal that then is digitized. A one-dimensional bar code is "vertically redundant" in that the same information is repeated vertically—the heights of the bars can be truncated without any loss of information. In practice, vertical redundancy allows a symbol with printing defects, such as spots or voids, to be read.

In practice, a bar code label (often generated by the laboratory information system and bearing the sample accession number) is placed onto the specimen container and is subsequently "read" by one or more bar code readers placed at key positions in the analytical sequence. The resultant identifying and ancillary information then is transferred to and processed by the system software. Initiating bar code identification at a patient's bedside ensures greater integrity of the specimen's identity in an analyzer. Systems to transfer information concerning a patient's identity to blood tubes at the patient's bedside have been introduced in many hospitals, and several companies are now offering these systems.

Unequivocal positive identification of each specimen is achieved in analyzers with bar code readers. Advantages of the use of bar code labels include the following:

1. Elimination of work lists for the system
2. Avoidance of mistakes made in the placement of tubes in the analyzer or during sampling
3. Avoidance of the need for analysis of specimens in a defined sequence
4. Decrease in identification errors.

Examples of types of bar codes that are used in chemistry analyzers are illustrated in Figure 19-1.

Figure 19-1 Examples of bar codes used in chemistry analyzers containing the same information. A, Code 39. B, Code I 2/5. C, Code 128B. D, Codabar. *(Courtesy Computer Transceiver Systems, Inc.)*

Identification Errors

Many opportunities arise for the mismatch of specimens and results. The risks begin at the bedside and are compounded with each processing step a specimen undergoes between collection from the patient and analysis by the instrument. The risks are particularly great when hand transcription is invoked for accessioning, labeling and relabeling, and creation of load lists. An incorrect accession number, one in which the digits are transposed, or a load list with transposed accession numbers may cause test results to be attributed to the wrong patient. An additional hazard exists when specimens must be inserted into certain positions in the loading zone defined by a load list. Human misreading of the specimen label or the loading list may cause misplacement of specimens, calibrators, or controls. Automatic reading of bar code labels reduces the error rate from 1 in 300 characters (for human entry) to about 1 in 1 million characters barring (1) minor imperfections in printed bar codes, (2) improper bar code scanner resolution, or (3) skewed orientation of bar code labels on containers, all of which can result in read errors.

Specimen Preparation

The clotting of blood in specimen collection tubes, their subsequent centrifugation, and the transfer of serum to secondary tubes require a finite time to complete. If performed manually, the process results in a delay in the preparation of a specimen for analysis. To eliminate the problems associated with specimen preparation, systems are being developed to automate this process.

Use of Whole Blood for Analysis

When whole blood is used in an assay system, specimen preparation time is essentially eliminated. Automated or semiautomated ion-selective electrodes, which measure ion activity in whole blood rather than ion concentration, have been incorporated into automated systems to provide certain test results within minutes of the drawing of a specimen. This approach now is used commonly for assays of electrolytes and some other common analytes. Another approach involves

manual or automated application of whole blood to dry reagent films and visual or instrumental observation of a quantitative change (see Chapter 20).

Automation of Specimen Preparation

Several manufacturers have developed fully automated specimen preparation systems. (These systems will be described in later sections of this chapter.)

Specimen Delivery

Automated methods are often used to deliver specimens to the laboratory instead of the historic method (courier service). These include (1) pneumatic tube systems, (2) electric track vehicles, and (3) mobile robots.

Pneumatic Tube Systems

Pneumatic tube systems provide rapid specimen transportation and are reliable when installed as point-to-point services. However, when switching mechanisms are introduced to allow carriers (the bullet-shaped containers used to hold specimens) to be sent to various locations, mechanical problems may occur and may cause misrouting of carriers. In addition, close attention to the design of the pneumatic tube system is necessary to prevent hemolysis of the specimen. Avoidance of sudden accelerations and decelerations and the use of proper packing material inside the carriers will minimize hemolysis.

Electric Track Vehicles

Electric track vehicles have a larger carrying capacity than pneumatic tube systems and do not have problems with damaging specimens by acceleration and/or deceleration forces. Some systems maintain the carrier in an upright position with the use of a gimbal (a device that permits a body to incline freely in any direction or suspends it so it will remain level when its support is tipped), enabling the carrier to move both vertically and horizontally on an installed electric track. The containers can hold dry ice or refrigerated gel packs with specimens if desired. They are especially useful in quickly transporting specimens between floors or between laboratory locations that are some distance from each other, by making use of the space in the ceiling plenum above the laboratory. A primary disadvantage is the cost of moving the track and loading/unloading stations if the laboratory is expanding or moving; in addition, the stations may be larger than the pneumatic tube stations. If the station is not located directly in the central laboratory (centralized testing; core laboratory), additional staff may be necessary to unload the carts and transport the specimens to their final destination, and the electric track system may not achieve its desired goal of rapid specimen transport.

Mobile Robots

Automated guided vehicles (AGVs), also called mobile robots, have been used successfully to transport laboratory specimens both within the laboratory and outside the central laboratory.[13] They are easily adapted to carry various sizes and shapes of specimen containers and are reprogrammable with changes in laboratory geometry. In addition, in a busy laboratory setting, delivery of specimens to laboratory benches by a mobile robot can be more frequent than human pickup and has been shown to be cost-effective. Inexpensive models follow a line on the floor, whereas others have more sophisticated guidance systems. Their limitations include the need to batch specimens for greater efficiency and, in most cases, the requirement for laboratory personnel to place specimens onto or remove specimens from the mobile robot at each stopping place. Some mobile robots have been integrated with robotic systems that automate loading and unloading of specimens; others initiate an audible or visual signal of their arrival at a specified station so that employees are able to load or unload the specimens being transported. Box 19-3 lists several vendors that provide mobile robot systems for clinical laboratories.

Specimen Loading and Aspiration

In most situations, the specimen for automatic analysis is serum or plasma. Many analyzers directly sample serum from primary collection tubes of various sizes. With such analyzers, the collection tubes most frequently used contain separator material that forms a barrier between serum or plasma and cells (see Chapter 7).

Many analyzers also sample from cups or tubes filled with serum transferred from the original specimen tubes. Often the design of the sampling cup is unique for a particular analyzer. Each cup should be designed to minimize dead volume, that is, the excess serum that must be present in a cup to permit aspiration of the full volume required for testing. Cups must be made of inert material so they do not interact with the analytes being measured. Specimen cups also should be disposable to minimize cost and contamination, and their shape should, even without a cap, minimize evaporation by minimizing the surface area of sample exposed to the air.

Specimens may undergo other forms of degradation in addition to evaporation. For example, specimens that contain thermolabile constituents may undergo degradation of such analytes if held at ambient temperatures. Other constituents, such as bilirubin, are photolabile. Thermolability is minimized when both specimens and calibrators are held in a refrigerated loading zone. Photodegradation is reduced by the use of semiopaque cups and placement of smoke- or orange-colored plastic covers over the specimen cups.

The loading zone of an analyzer is the area in which specimens are held in the instrument before they are analyzed. The holding area may be a circular tray, a rack or series of racks built into a cassette, or a serpentine chain of containers into which individual tubes are inserted. When specimens are not identified automatically, they must be presented to the sampling device in the correct sequence, as specified by a loading list. The sampling mechanism determines the exact volume of sample removed from the specimen.

For most analyzers, specimens for a subsequent run may be prepared on a separate tray while one run is already in progress. This process permits machine operation and human actions to proceed in parallel for optimal efficiency. In some analyzers, specimens may be added continuously by the operator as they become available. A desirable feature of any automated analyzer is the ability to insert new specimens ahead of specimens already in place in the loading zone. This feature allows the timely analysis of a specimen with a high medical priority. When specimen identification is machine-read, it is possible for the operator to easily reposition specimens in the loading zone. When specimen identification is tied to a loading list, however, insertion or repositioning of specimens must be accompanied by revision of the loading list.

Transmission of infectious diseases by automated equipment is a concern in clinical laboratories. The method of transmission by equipment is primarily through splatter of serum or blood during the acquisition of samples from rapidly moving specimen probes. The use of level sensors, which restrict the penetration of sample probes into specimens, and provision of software for smoother motion control greatly reduce splatter.

Because the potential for contamination exists when the stoppers of primary containers are opened or "popped" to decant serum into specimen cups, several firms have developed closed-container sampling systems for use in their automated hematology and chemistry analyzers. In these systems, the specimen probe passes through a hollow needle that initially penetrates the primary container's rubber stopper. This configuration prevents damage or plugging of the specimen probe while allowing the level sensor (used to reduce carryover and to detect short samples) to remain active. After the specimen probe is withdrawn, the outer hollow needle also is withdrawn, so the stopper reseals and no specimen escapes. Closed-container sampling is used widely in hematology analyzers.

Sample Pretreatment

Automation of analytical procedures requires the capability to remove proteins and other interferents from some specimens to ensure the specificity of an analytical method. Dialysis, column chromatography, and filtration have been used for this purpose.

Sample Introduction and Internal Transport

The method used to introduce the sample into the analyzer and its subsequent transport within the analyzer is the major difference between continuous-flow and discrete systems. In continuous-flow systems, the sample is aspirated through the sample probe into a stream of flowing liquid, whereby it is transported to analytical stations in the instrument. In *discrete analysis*, the sample is aspirated into the sample probe and then is delivered, often with reagent, through the same orifice into a reaction cup or other container. Carryover is a potential problem with both types of systems.

Technicon Instruments Corporation pioneered the use of peristaltic pumps and plastic tubing to advance the sample and reagents in continuous-flow analysis. Peristaltic pumps trap a "slug" of fluid between two rollers that occlude the tubing. As the rollers travel over the tubing, the trapped fluid is pushed forward and, as the leading roller lifts from the tubing, is added to the fluid beyond it. The peristaltic pump still is used in some hematology analyzers and analyzers with ion-selective electrodes, as well as for wash systems.

Discrete Processing Systems

Positive–liquid displacement pipettes are used for sampling in most discrete automated systems in which specimens, calibrators, and controls are delivered by a single pipette to the next stage in the analytical process.

A positive-displacement pipette may be designed for one of two operational modes: (1) to dispense only aspirated sample into the reaction receptacle, or (2) to flush out sample together with diluent. Both systems use a plastic or glass syringe with a plunger, the tip of which usually is made of Teflon.

Pipettes may be categorized as (1) fixed-, (2) variable-, or (3) selectable-volume (see Chapter 9). Selectable-volume pipettes allow the selection of a limited number of predetermined volumes. Pipettes with unlimited or selectable volumes are used in systems that allow many different applications, whereas fixed-volume pipettes usually are used for samples and reagents in instruments dedicated to the performance of only a small variety of tests.

Carryover

Carryover is defined as the transfer of a quantity of analyte or reagent from one specimen reaction into a subsequent one. Because it erroneously affects analytical results from the subsequent reaction, carryover should be minimized or eliminated. In discrete systems with disposable reaction vessels and measuring cuvets, carryover is caused by the pipetting system. In instruments with reusable cuvets or flowcells,

carryover may also arise from incomplete cleaning of the cuvettes or flowcells between assays.

Most manufacturers of discrete systems reduce sample-to-sample carryover by using disposable pipette tips or by incorporating wash stations for the sample probe that flush the internal and external surfaces of the probe with copious amounts of diluent. An adequate ratio of flush and rinse to specimen volume controls carryover in many cases to acceptable values. Appropriate choice of sample probe material, geometry, and surface conditions also influences carryover. Some systems wipe the outside of the sample probe to prevent transfer of a portion of the previous specimen into the next specimen cup. Use of disposable sample probe tips allows complete elimination of contamination of one sample by another inside the probe, as well as the carryover of one specimen into the specimen in the next cup, because a new pipette tip is used for each pipetting.

In practice, the reduction of sample-to-sample carryover is a more stringent requirement for automated analyzers that perform immunoassays in which some analytes (e.g., human chorionic gonadotropin) have a wide range of concentrations. Some systems use extra steps, such as additional washes, or an additional washing device to reduce carryover for selected tests to acceptable limits. Because extra steps reduce overall throughput, additional rinsing functions are initiated (by computer operator selection) only for assays with a large analytical measurement range.

Sample-to-sample carryover can be detected by the preparation of two sample pools—one having a very high analyte concentration (H), the other having a low concentration (L). By running sequences of tests such as HHHLLLHHLLHHLL, if sample-to-sample carryover is present, higher results will be noted in the low-concentration sample analyses that immediately follow a high-concentration sample analysis.

Reagent-to-reagent carryover also can occur on discrete systems that use a common reagent probe for pipetting all reagents; its minimization or elimination requires use of the same approaches just described for sample-to-sample carryover. Detection of reagent-to-reagent carryover can be difficult for end-users and usually requires the involvement of the instrument vendor. Users should be aware that the introduction of third party reagents in "open" channels on otherwise closed systems may introduce problems with reagent-to-reagent carryover. Consultation with the system manufacturer is advised to determine how to test for and minimize such carryover.

Reagent Handling and Storage

Many automated systems use liquid reagents stored in plastic or glass containers. For those analyzers in which a working inventory is maintained in the system, the volumes of reagents stored depend on the number of tests to be performed without operator intervention.

For many analyzers in which specimens are not processed continuously, reagents are stored in laboratory refrigerators and are introduced into the instruments as required. In larger systems, sections of the reagent storage compartments are maintained at 4 to 10 °C.

Some systems use reagents or antibodies that have been immobilized in a reaction coil or chamber to allow their repetitive use in a chemical reaction. Other systems use enzymes immobilized on membranes coupled to sensing electrodes. The reaction products then are measured by the sensing device. Only a buffer is required as a diluent and a wash solution; thus the membrane has an extended life, which lowers the cost of each test.

Reagent Identification

Labels on reagent containers include information such as (1) reagent identification, (2) volume of the contents or the number of tests for which the contents of the containers are to be used, (3) expiration date, and (4) lot number. Many reagent containers now carry bar codes that contain some or all of this information, and the manufacturer is able to retrieve any pertinent information when necessary.

Other advantages of using reagent bar codes include (1) facilitation of inventory management, (2) ability to insert reagent containers in random sequence, and (3) ability to automatically dispense a particular volume of liquid reagent. Furthermore, when a bar code reader is coupled with a level-sensing system on the reagent probe, it alerts the operator as to whether a sufficient quantity of reagent exists to complete a workload.

A bar code on a reagent container may also contain information about (multiple) calibrators, such as the definition of a calibration curve algorithm and values of curve constants defined at the time of reagent manufacture. Accompanying calibrator materials provided in their own bar code tubes at the time of manufacture ensure that calibration functions are integrated properly into the analysis.

Open versus Closed Systems

Automated analyzers are classified as "open" or "closed." In an open analyzer, the operator is able to change the parameters related to an analysis and to prepare "in-house" reagents or use reagents from a variety of suppliers. Such analyzers usually have considerable flexibility and adapt readily to new methods and analytes.

A closed-system analyzer is one in which reagents and calibrators are provided only by the manufacturer and other reagents or methods cannot be used.

Reagent Delivery

Liquid reagents are acquired and delivered to mixing and reaction chambers by pumps (through tubes) or by positive-displacement syringe devices. In those analyzers in which more than one reagent is acquired and dispensed by the same syringe, washing or flushing of the probe is essential to prevent reagent carryover.

Chemical Reaction Phase

Sample and reagents react in the chemical reaction phase. Factors that are important in this phase include (1) vessel in

which the reaction occurs; (2) cuvet in which the reaction is monitored; (3) timing of the reaction(s); (4) mixing and transport of reactants; (5) thermal conditioning of fluids; and (6) for some immunoassay systems, separation of bound and unbound fractions.

Type of Reaction Vessel and Cuvet

In continuous-flow systems, each specimen passes through the same continuous stream and is subjected to the same analytical reactions as every other specimen and at the same rate. In such systems, the reaction occurs in the flow-through component.

In discrete systems, each specimen in a batch has its own physical and chemical space, separate from every other specimen. Discrete analyzers use individual (disposable or reusable) reaction vessels transported through the system after sample and reagent have been dispensed, or they use a stationary reaction chamber.

Reaction vessels are reused in many instruments. The time before reusable cuvet/reaction vessels must be replaced depends on their composition and the washing mechanisms used. Some manufacturers have computer algorithms that automatically control when individual cuvet/reaction vessels are discarded, depending on how many assays and what types of assays have been performed in a given cuvet.

Mixing of Reactants

Various techniques are used to mix reactants. In a discrete system, these include (1) forceful dispensing; (2) magnetic stirring; (3) vigorous lateral displacement; (4) physical stirring; and (5) vigorous lateral displacement. Dry reagent systems obviate the need for mixing because the serum completely interacts with the dry chemicals as it flows through the matrix of the reaction unit. However, regardless of the technique used, mixing is a difficult process to automate and one that can contribute to reaction-to-reaction carryover among reused components.

Thermal Regulation

Thermal regulation requires the establishment of a controlled-temperature environment in close contact with the reaction container and efficient heat transfer from the environment to the reaction mixture. Various technologies have been used for temperature regulation, including air baths, water baths, and piezoelectric devices.

Separation in Immunoassay Systems

Automation of immunoassay procedures requires the separation of free and bound fractions of heterogeneous immunoassays. Several approaches have been used. For example, several automated immunoassay analyzers use bound antibodies or proteins in a solid-phase format. With this approach, the binding of antigens and antibodies occurs on a solid surface to which the antibodies or other reactive proteins have been adsorbed or chemically bonded. Different types of solid phases are used, including (1) beads, (2) coated tubes, (3) microtiter plates, (4) magnetic and nonmagnetic microparticles, and (5) fiber matrices. Additional details on automated systems that use various solid phases are found in books by Wild,[17] and Price and Newman.[12]

Measurement Approaches

Automated chemistry analyzers traditionally have relied on photometers and spectrophotometers to measure the absorbance of the reaction produced in the chemical reaction phase. Alternative approaches now being incorporated into analyzers include reflectance photometers, fluorometers, and luminometers. Immunoassay systems have used reaction schemes that produce fluorescence, chemiluminescence, and electrochemiluminescence to enhance sensitivity. Ion-selective electrodes and other electrochemical techniques also are used widely.

Photometry/Spectrophotometry

Measurement of absorbance requires the following three basic components (see Chapter 10): (1); an optical source; (2) a means of spectral isolation; and (3) a detector.

Optical Source

Radiant energy sources used in automated systems include (1) tungsten, (2) quartz-halogen, (3) deuterium, (4) mercury, (5) xenon lamps, and (6) lasers. In the quartz-halogen lamp, low-pressure halogen vapor (e.g., iodine, bromine) is enclosed in a fused silica envelope in which a tungsten filament serves as an incandescent light source. The spectrum produced includes wavelengths from approximately 300 to 700 nm.

Spectral Isolation

In automated systems, spectral isolation commonly is achieved with interference filters. Typical interference filters have peak transmissions of 30% to 80% and bandwidths of 5 to 15 nm (see Chapter 10). In several multitest analyzers, filters are mounted in a filter wheel, and the appropriate filter is moved into place under command of the system's computer. Monochromators with movable gratings and slits provide a continuous choice of wavelengths. They offer great flexibility and are suited especially for the development of new assays. However, because relatively few wavelengths are required for analyses in routine analyzers, many manufacturers use a stationary, holographically ruled grating, coupled with a stationary photodiode array, to isolate the spectrum. These two elements also are coupled with fiber optic light guides to transfer the passage of light energy through cuvets at locations convenient for mechanization. Use of these passive elements enhances the reliability of a system because no moving parts are required for spectral isolation (Figure 19-2).

Photometric Detectors

Photodiodes are used as detectors in many automated systems, either as individual components or in multiples as an array. Photomultiplier tubes are required in many immunoassay systems to provide a high signal-to-noise ratio and fast detector response times for fluorescent and chemiluminescent measurements.

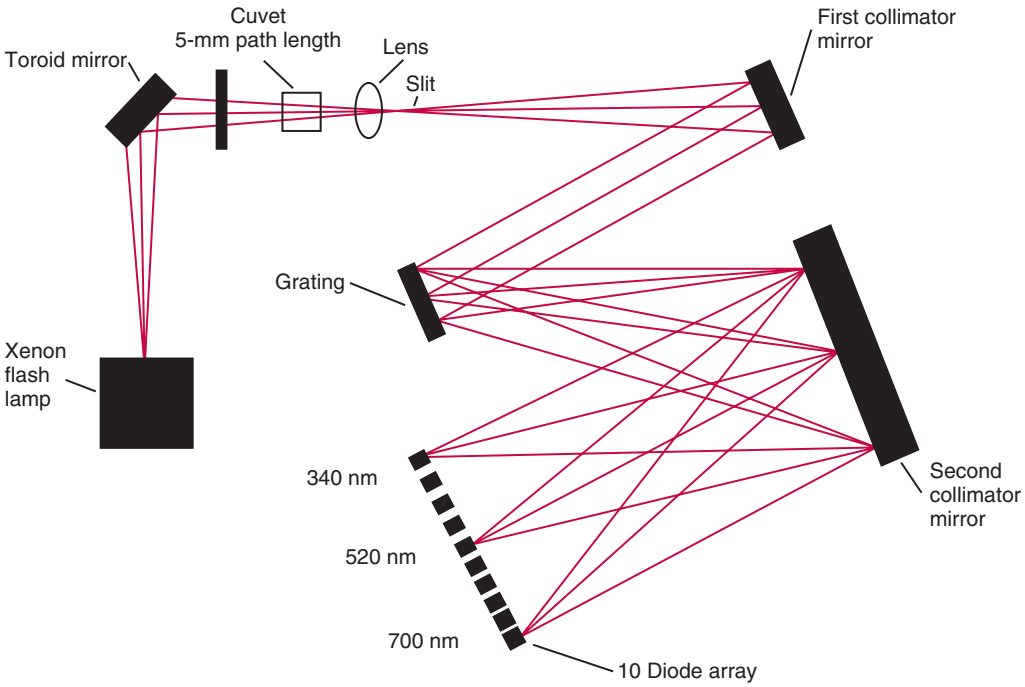

Figure 19-2 Use of a diode array in the SYNCHRON CX7 monochromator reduces requirements for moving parts. For simplicity, ray traces for only three wavelengths are shown. *(Courtesy Beckman Coulter, Inc.; www.beckmancoulter.com.)*

Proper alignment of cuvets with the light path(s) is important in both automated and manual analyzers. In addition, stray energy and internal reflections must be kept to acceptable levels. If the light path is not perpendicular to the cuvet, inaccuracy and imprecision may occur, particularly in rate analyses.

Reflectance Photometry

In reflectance photometry, diffuse reflected light is measured. The reflected light results from illumination, with diffused light, of a reaction mixture in a carrier or from the diffusion of light by a reaction mixture in an illuminated carrier. The intensity of the reflected light from the reagent carrier is compared with that reflected from a reference surface. Because the intensity of reflected light is nonlinear with concentration of the analyte, mathematical algorithms commonly are used to linearize the relation of reflectance to concentration.[16]

Fluorometry

Fluorescence is the emission of electromagnetic radiation by a species that has absorbed exciting radiation from an outside source. Intensity of emitted (fluorescent) light is directly proportional to concentration of the excited species (see Chapter 10).

Fluorometry is used widely for automated immunoassay. It is approximately 1000 times more sensitive than comparable absorbance spectrophotometry, but background interference due to fluorescence of native serum is a major problem. This interference is minimized by (1) careful design of the filters used for spectral isolation, (2) selection of a fluorophor with an emission spectrum distinct from those of interfering compounds, or (3) use of time- or phase-resolved fluorometry (see Chapter 10).

Different optical configurations are represented in different manufacturers' equipment. Right-angle fluorescence measurement is one of the common approaches used, with emitted light passing through the emission interference filter to a photomultiplier tube. In fluorescence polarization, the light source is in the form of polarized light. Measurement then is made of the change in the degree of polarized light emitted by a fluorescent molecule (see Chapters 10 and 16).

Turbidimetry and Nephelometry

Turbidimetry and nephelometry are optical techniques that are applicable particularly to methods measuring precipitate formation in antigen-antibody reactions (see Chapter 16). These techniques are used to measure plasma proteins and for therapeutic drug monitoring.

Chemiluminescence and Bioluminescence

Chemiluminescence and bioluminescence differ from fluorometry in that the excitation event is caused by a chemical or electrochemical reaction and not by photoluminescence (see Chapter 10). The applications of chemiluminescence and bioluminescence have increased significantly with the development of automated instrumentation and new reagent systems. Because of their attamole-to-zeptomole detection limits, chemiluminescence and bioluminescence reactions have been used widely as direct and indicator labels in the development of immunoassays.

Electrochemical

A variety of electrochemical methods have been incorporated into automated systems. The most widely used electrochemical approach involves ion-selective electrodes. These electrodes have replaced flame photometry in the determination of sodium and potassium. Electrochemical detectors also have been used for the measurement of other electrolytes and for indirect application in the analysis of several other serum constituents (see Chapter 11). The relationship between ion activity and the concentrations of ions in the specimens must be established with calibrating solutions, and such electrodes need to be recalibrated frequently to compensate for alterations in electrode response.

Peristaltic pumps are used to move the sample into chambers containing fixed sample and reference electrodes. The electrodes must remain in contact with the specimen from 7 to 45 seconds to reach steady-state conditions. The most common arrangement is to provide electrodes to assay three analytes, typically, sodium, potassium, and chloride. Because specimens and calibrators usually flow past a group of electrodes, results for all analytes are reported for most systems. Ion-selective electrode capability also has been incorporated into medium-sized and large automated analyzers as integrated three- and four-parameter modules; this incorporation has increased significantly these systems' throughputs because several results are produced in parallel.

Signal Processing, Data Handling, and Process Control

The interfacing and integration of computers into automated analyzers and analytical systems has had a major impact on the acquisition and processing of analytical data. Analog signals from detectors are converted to digital signals. Computer software then processes the digital data into useful and meaningful output. Data processing has allowed automation of complex calibration relationships. Computer workstations provide a central point of communication with the user regarding (1) instrument status, (2) order entry, (3) result display, (4) quality control functions, (5) instrument troubleshooting, and (6) autoverification of results. Several functions performed by computers in automated analyzers are listed in Box 19-4.

Test Autoverification

Autoverification is the process whereby patient results generated from interfaced instruments are compared by computer software against laboratory-defined acceptance parameters. If results fall within these defined parameters, the results are automatically released for reporting with no additional laboratory staff intervention. Any data that fall outside the defined parameters are reviewed by laboratory staff prior to reporting. Autoverification has been implemented in various ways, such as by using the laboratory information system to compare results against acceptance parameters, or, alternatively, by performing this function in separate computers that are interposed between the laboratory analyzer and the laboratory information system (termed *middleware* by some

BOX 19-4 Signal and Data Processing Functions Performed by Computers of Automated Analyzers

Data Acquisition and Calculation

Acquisition of response signal and signal averaging
Subtraction of blank response
Correction of response of sample for interferences (e.g., multiwavelength spectrophotometric corrections)
Linear regression for determining slope ($\Delta A/\Delta t$) of rate reactions; ($\Delta A/\Delta C$) of absorbance/concentration relation; ($\Delta R/\Delta C$) of any response parameter to concentration
Statistics (mean, Standard Deviation, Coefficient of Variation) on patient or control values
Mathematical transformation of nonlinear relations to linear counterpart
Mathematical transformation of results to alternative reporting units

Monitoring

Test for fit of data to criteria for calibration or rate reactions
Test of patient result against reference interval criteria
Test of control result against criteria of a quality control standard of performance
Test of moving average of patient results against quality criteria for detecting assay drift

Display

Display of specimens currently being analyzed, tests ordered on each specimen, and expected times of completion
Accumulation of sets of patient results
Collation of results for patient-oriented printout
Warning messages provided to alert operator to instrument malfunction, need for maintenance, or unusual clinical situation
Quality control charts provided for operator review
Troubleshooting flowcharts provided to assist operator

Control, Data Storage, Communications

Control of electromechanical operation of the analyzer
Ensurance that all functions are performed uniformly in the correct sequence
Acquisition, assessment, processing, and storage of operational data from the analyzers
Serial RS-232c or Ethernet interfaces provided with laboratory information systems

Workstation Functions

Point of interaction with the instrument operator provided
Test orders accepted
Monitoring of the testing process
Assistance with analysis of process quality
Facilities for review and verification of test results provided
Assistance with the review of completed test results
Assistance with rule-based autoverification

observers). Most autoverification systems use rule-based decision logic. The rules applied in such systems require careful development and validation by laboratories before and after they are implemented. Guidance for implementation, validation, and monitoring of autoverification systems is provided in a recent document from the Clinical and Laboratory Standards Institute.[6]

INTEGRATED AUTOMATION FOR THE CLINICAL LABORATORY

Significant progress has been made in automating preanalytical and postanalytical activities and integrating these operations with analytical systems. Several versions of stand-alone pre-analytical or "front-end" automation systems, which have largely automated various specimen processing steps, have become available. More options are also available as modules for total laboratory automation systems, and many vendors have increased the number of different analyzers that can be interfaced to their automation.

Large-scale automation of the laboratory usually includes an automated specimen processing area where specimens are (1) identified, (2) labeled, (3) scheduled for analysis, (4) centrifuged, and (5) sorted. After specimens are processed, automated specimen conveyor devices transport specimens to appropriate workstations in the laboratory, where they are analyzed without human intervention. Rules-based expert system software (1) assists with the review of laboratory results by automatically releasing results that have no associated problems, and (2) identifies any problematic results to bring to the attention of trained medical technologists. All specimens are catalogued after analysis and stored in a central storage facility, which may include automated storage and retrieval functions. As previously discussed, particularly important aspects of large-scale automation projects are the approaches used to process and transport specimens and the overall integration of automated components into a smoothly functioning whole.

Workstations

The task of integrating laboratory automation begins with the laboratory workstation. In general, a clinical laboratory workstation is usually dedicated to a defined task and contains appropriate laboratory instrumentation to carry out that task. Frequently, the workstation in the modern laboratory is defined in terms of the automated analyzer that is being used. Current laboratory instruments and systems are highly developed for stand-alone operation and fit into the workstation concept. Movement of specimens into and out of the workstation is accomplished by manual transport, and instrument operator activities are largely independent of those at other workstations. On a typical instrument, the operator follows a manufacturer-recommended sequence of calibration, quality control, and daily maintenance activities, and uses the instrument's front-panel functions to introduce specimens for analysis. If the analyzer has a bidirectional interface with a laboratory information system (LIS) and bar code reading capabilities, information regarding what assays to run on each specimen is downloaded from the LIS, and the operator simply loads bar code–labeled specimens into the specimen input area. The built-in diagnostics supplied in most modern analyzers provide sufficient "intelligence" in the analyzer that the operator is able to "walk away" from the instrument for short periods, confident of its reliable operation. Nevertheless, the operator needs to attend periodically to (1) instrument operation, (2) replenishing of reagents or other disposables, (3) evaluation of instrument diagnostic messages, and (4) introduction of new specimens into the specimen input tray.

Instrument Clusters

To reduce labor costs, instrument manufacturers are developing approaches that will allow a single technologist to simultaneously control and monitor the functions of several instruments. Initially, such workstations were configured with *clusters* of identical instruments, such as chemistry, immunochemistry, or hematology analyzers. More advanced instrument clusters may incorporate both chemistry and immunoassay analyzers from the same vendor; a possible extension of this concept is the development of clusters of unlike instruments that cross traditional laboratory disciplines. An example might be a cluster of chemistry and hematology analyzers.

A cluster of analyzers has its own central computer control module with software designed to assist the operator in monitoring the functions of each analyzer and to aid in the review of laboratory results generated by the cluster. Access to the many front-panel functions of each analyzer is provided by the interface between the analyzer and the central control module. Thus, the technologist loads specimens onto each instrument in the cluster and then monitors subsequent instrument operation and reviews the results at the central workstation. By incorporating the activities of what would be *several* workstations in most current laboratories into a *single* integrated workstation, this approach shows promise in saving laboratory manpower.

Work Cells

Another extension of the instrument cluster concept is the addition of robotic specimen handling and preparation. A robotic system is used to carry out various specimen preparation steps, such as checks of specimen adequacy, centrifugation, aliquot preparation and labeling, transport, and storage of specimens. The robotic system is then responsible for introducing specimens into the appropriate analyzer, allowing the technologist to assume a primarily monitoring role that also includes reagent replenishment, calibration, control operations, and instrument maintenance. An interface between the central control module and the robot controller (or combining these functions on a single computer) allows the activities of the robotic cluster to be fully coordinated.

Automated Specimen Processing

Although the manual operations carried out in a specimen processing area look simple, considerable complexity underlies them. Consequently, specimen processing has been one of the most difficult areas of the clinical laboratory to automate. This has been approached in various ways using both integrated and modular approaches, which are discussed in the following sections. Each specimen passing through a specimen processing area has to undergo a series of operations, including (1) receiving the specimen, (2) inspecting it for appropriateness (labeling, container type, temperature, and quantity of specimen), (3) logging onto the LIS, (4) labeling the specimen with an accession number, and (5) separating urgent and stat specimens from routine specimens. Also, specimens have to be sorted for centrifugation and aliquoted or otherwise prepared for the appropriate laboratory station.

Stand-Alone Specimen Processing Systems

An example of a stand-alone specimen processing system is shown in Figure 19-3. Similar systems place processed specimens into racks that must be transported manually to the testing areas, with some exceptions. Some of these are about the size of a large automated analyzer, and others may be a little larger. They may be a good choice for laboratories (1) with daily workloads of 500 to 2000 specimens, (2) with space limitations, or (3) that desire an upgrade path and ease of use with different analyzers from different vendors. Some laboratories may choose to use multiples of a stand-alone specimen processing system to automate archiving and preanalytical specimen processing.

These systems will (1) receive incoming specimens, (2) sort, (3) decap, (4) aliquot, and (5) label aliquot specimen containers with bar codes. All are interfaced to the laboratory's LIS. Some systems include automated centrifugation. Several of the systems sort into instrument-specific racks for analyzers from a number of different vendors. In addition, some users apply these systems to aliquot and sort reference or "send-out" testing, saving considerable time in locating the original specimens after testing in their own laboratory.

Figure 19-3 The Beckman Coulter Auto-Mate 2500 Lab Automation System is a work cell that performs presorting, specimen volume inspection, decapping, aliquoting, and destination sorting into racks specific to different analyzers with a throughput of up to 650 tubes per hour aliquoted and 800 per hour sorted. *(Courtesy Beckman Coulter, www.beckmancoulter.com.)*

Integrated and Modular Automation Systems

Several manufacturers offer integrated or modular automation systems for specimen processing that include additional functionality. A listing of automation vendors and their Websites can be found in Box 19-5. In addition to the functions described in the preceding section, these systems typically add (1) conveyor transport, (2) interfacing to automated analyzers, (3) more sophisticated process control, and, in some cases, (4) a specimen storage and retrieval system. All systems are of modular design, allowing the customer to choose the modules/features that should be included. Some systems use an open design, which permits interfaces to analyzers from a variety of vendors, whereas other systems are of a closed design and are interfaced only to the vendor's own or a limited number of analyzers. It should be noted that closed systems typically do not have process control software that is independent of the instruments or system, but rather the automation process control is integrated to work with the vendor's analyzers.

To achieve maximum effectiveness of an automation system, process control software should be able to read the specimen's identification (ID) bar code and obtain information from the laboratory's LIS about specimen type and ordered tests. This process control software is usually referred to as the Laboratory Automation System (LAS), not to be confused with the actual hardware of a laboratory automation system. The reader is referred to the Clinical Laboratory and Standards Institute (CLSI) standard on automation communications[5] for further information on LAS. It should then determine the processes the specimen requires and the exact route or course of action for each specimen. It should be able to (1) calculate the number of aliquots and the proper volume for each depending on the tests requested, (2) route the specimens to analyzers, (3) recap the specimens, and (4) retain the specimens for automatic recall. The software should be able to monitor analyzers for in-control production status and automatically make decisions if a test is not available. Specimen integrity checking should be automatic; rules-based decisions should monitor specimen quality and make these decisions. Finally, most process control software should include (1) "autoverification," which is validation of analyzer results by making rules-based decisions that flag exceptions for technologist review, and (2) "autoretrieval" of specimens for repeat, reflex, and dilution testing.

Although most of these systems are restricted to handling specific types of specimen containers, they are capable of processing much of the daily workload of a large clinical laboratory. A few laboratories with daily workloads as low as 600 to 800 specimen tubes have justified these systems because of a shortage of technical help, but typically these systems are designed for laboratories with workloads of 1000 to 10,000 specimens per day. In addition to process control software and the ability to be interfaced to the laboratory's LIS, each of these systems incorporates some or all of the following components:

1. *Specimen input area:* A holding area where bar code–labeled specimens are introduced into the system.
2. *Bar code reading stations:* Multiple bar code readers are placed at critical locations in the processing system to track specimens and provide information for their proper routing to various stations in the processing system.
3. *Transport system:* Segments of a conveyor belt line that move specimens to the appropriate location.
4. A *high-level device to sort or route specimens:* A device that separates specimens by type (such as by tube height) or by order code and passes them to the transport system or to a system using racks. A high-level sorter is often used to separate specimens that require centrifugation, or other processing steps, from specimens that do not, or to route specimens into completely different pathways within the total automation system.[8]
5. *Automated centrifuge:* An area of the specimen processor in which specimens requiring centrifugation are removed from the conveyor belt, introduced into a centrifuge that is automatically balanced, centrifuged (refrigerated or at room temperature), and then removed from the centrifuge and placed back on the transport system.
6. *Level detection and evaluation of specimen adequacy (specimen integrity):* An area in which sensors are used to evaluate the volume of specimen in each specimen container and to look for the presence of hemolysis, lipemia, or icterus.
7. *Decapper station:* An area or device in the automated system in which specimen caps or stoppers are automatically removed and discarded into a waste container.
8. *Recapper station:* An area or device in the automated system in which specimen tubes are automatically recapped with new stoppers or covered with an air-tight closure.
9. *Aliquoter:* A machine that aspirates appropriately sized aliquots from each original specimen container and places them into bar coded secondary specimen containers for sorting and transport to multiple analytical workstations. The LAS generally instructs the aliquoter as to how many aliquots of what volumes are required, based on the bar code ID of the specimen.
10. *Interface to automated analyzer:* A direct physical connection to an automated analyzer that permits the analyzer's sampling probe to aspirate directly from an open specimen container while the container is still on the conveyor, or that may robotically lift the container from the conveyor and place it in the analyzer. Some automation systems interface only to their own brand of analyzers or to a limited number of systems, whereas other automation systems use a so-called open design that complies with CLSI standards and permits interfaces to a variety of automated analyzers.
11. *Sorter:* An automated sorter to sort specimens not going to a conveyor-interfaced analyzer or workstation. Such a sorter typically sorts into 30 to 100 different sort groups in racks or carriers. In some systems, the racks are specific to certain analyzers for convenience.
12. *Take-out stations:* Temporary storage areas for specimens before or after analysis. The take-out station may be the same as the sorter described earlier, where specimens are sorted for manual delivery. However, it may also serve as a holding area (stockyard) for specimens awaiting autoverification of results in case a repeat test is required.
13. *Storage and retrieval system:* This unit may serve the same function as the take-out station or stockyard—that of holding specimens after analysis in case a specimen is necessary for a repeat test—but it has one major difference. These units are typically refrigerated and hold many more specimens (3 to 15,000) than the typical take-out station or stockyard. Depending on daily workloads, the laboratory may be able to retain up to 1 week's worth of specimens for possible repeat or additional tests. Specimen containers are loaded and retrieved with a robot.

Conveyor Belts

The main feature of integrated or so-called total laboratory automation systems is the use of conveyor belts. Ordinary

industrial conveyor belts have been used successfully when only transportation is required. However, in the past, when conveyors were integrated with other robotic systems to automate preanalytical and/or postanalytical functions, this technology had difficulty in handling the large variety of specimen containers found in the clinical laboratory. To increase the variety of types of specimen containers that are carried on a conveyor belt system, specimens are placed into specially designed carriers that fit on the conveyor belt line. Sometimes known as "pucks" or "racks" (depending on whether they carry individual specimens or groups of specimens), the carriers have receptacles for variously sized tubes, generally ranging from 13 × 75 mm to 16 × 100 mm—sizes that are consistent with the CLSI Standard AUTO01-A.[3] The industrial, motor-driven conveyor belts used in typical laboratory automation systems have transport rates of a few hundred pucks per hour up to 2000 per hour. In addition, linear synchronous motors (LSMs) and magnetic pucks are now being used for clinical laboratory automation (www.magnemotion.com/accessed April 18, 2011). This technology, which is an order of magnitude faster than present conveyors and has virtually no moving parts, may become the next generation of specimen transport for clinical laboratory automation systems.

Two types of conveyor belt systems are typically used as illustrated in Figure 19-4. Figure 19-4, *A*, depicts a loop conveyor that has a single module for both input of new specimens and removal of completed specimens, and the flow around the loop goes past the processing and analytical modules. Specimens may be sampled directly by the analytical instrument while on the conveyor, or a robot attached to the workstation may remove selected specimens from the conveyor for analysis. Figure 19-4, *B*, depicts a unidirectional conveyor in which specimens are input at one end of the belt, flow past various processing and analytical modules, and arrive at the opposite end, where they are removed. Analyzers access specimens in the same way as the loop conveyor. Depending on the vendor, both of these conveyor types can have bypass lanes that enable specimens not stopping at some modules to bypass them and proceed to other modules. This approach has the advantage that it does not require that specimens be aliquoted because specimens pass by all workstations at which tests are performed. It should also be noted that if specimens are robotically removed from their carriers on the

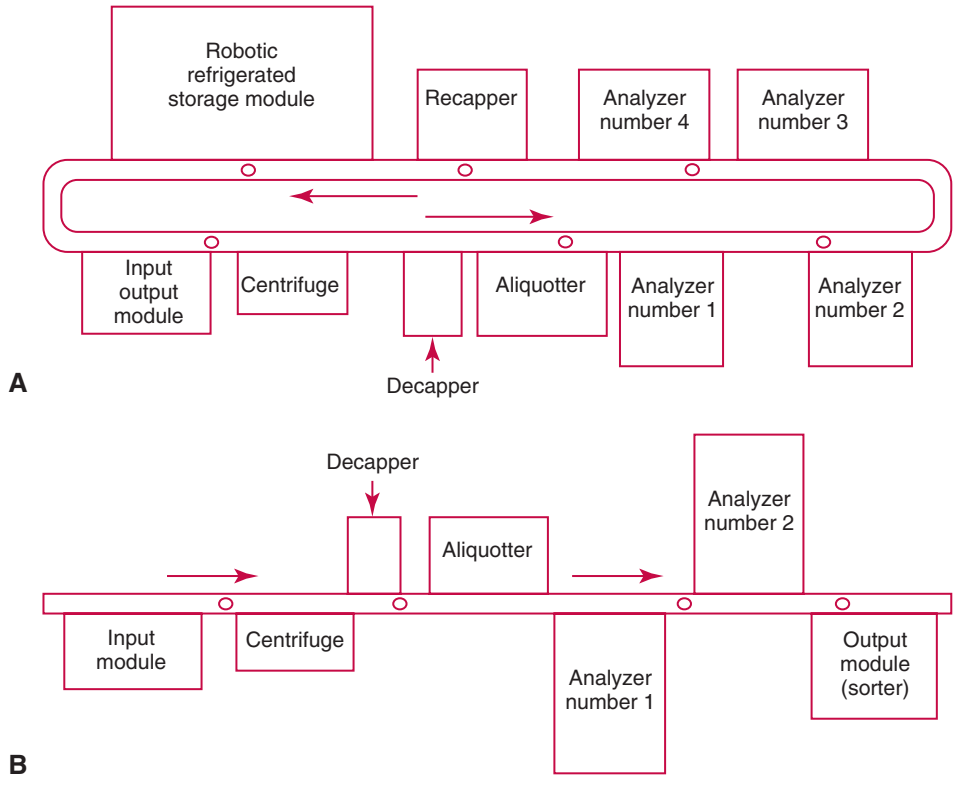

Figure 19-4 A, A depiction of a laboratory automation system employing a continuous loop–type conveyor. In this concept, a single module is used for loading of new specimens and unloading of completed specimens. Depending on the needs of the laboratory, all other modules illustrated are options that can be included or not. B, A depiction of a laboratory automation system employing a unidirectional conveyor. In this concept, separate modules are required for loading of new specimens and unloading of completed specimens. The output module may also perform sorting of specimens for other testing. Other modules can be included, depending on the laboratory's needs.

line for testing, systems for queuing empty carriers to return the tubes to the conveyor and to identify which specimen is in each carrier would be required.

Transfer of specimens from the conveyor belt to the laboratory workstation has been implemented in various ways. For example, some manufacturers have equipped their laboratory instruments with devices to move specimen containers from conveyor belt systems onto the analyzers, while others have installed the ability for the analyzer to sample directly from specimen containers remaining on the conveyor. In practice, the automation system requires a device that stops the tube in the exact location required by the analyzer for sample transfer and verifies and transfers the tube's bar code identification to the analyzer. The CLSI Standard AUTO05-A[4] specifies a common "point in space" that is this exact location for all analyzers and automation conveyor systems.

Depending on the particular automation system, specimens for "stat" testing may or may not be processed and analyzed at speeds that are faster than if manually handled. Laboratories that are purchasing laboratory automation systems are advised to learn how each system handles stat specimens.

Automated Specimen Sorting

In addition to the sorting described previously for stand-alone specimen processing systems and integrated automation systems, stand-alone sorting systems are available, most of which sort into racks for transfer to particular laboratory sections or analyzers. In some cases, the racks may be specific for a specific analyzer, eliminating additional handling of tubes.

Automated Specimen Storage and Retrieval

Automated capability to store and retrieve specimens on demand and with readily known exact storage locations is an important aspect of automated specimen delivery systems. In addition to those automated storage and retrieval options in some of the integrated systems described earlier, several automated or semiautomated options for storage and retrieval, as well as LIS modules and PC-based software systems, permit laboratories to track trays or racks of specimens in their own freezers or refrigerators. Some large reference laboratories have adapted large storage systems commonly used in other industries into their laboratory settings.

PRACTICAL CONSIDERATIONS

In this section, the practical considerations that influence a laboratory's decision to automate part or all of its operations are discussed. A 2007 review[9] outlined how a large hospital laboratory evaluated its needs for automation; the selection and decision processes used by that hospital may provide a useful supplement to this discussion.

Evaluation of Requirements

Any consideration of total or modular laboratory automation should start with an evaluation of requirements.[7] Such an evaluation begins with mapping of the current laboratory work-flow from the arrival of patient specimens through completion of testing and reporting of results. Box 19-6 lists potential work-flow steps that should be mapped. Mapping of material (specimen) flows and data flows is directly related to process flow and will assist the laboratory in determining process steps that (1) are bottlenecks, (2) waste labor, and (3) are prone to error.[10] Work flow mapping thus enables the laboratory to better identify what steps should be considered for automation.

BOX 19-6 Clinical Laboratory Steps for Work Flow Mapping

Unpacking from transport containers
Presorting
Temperature preservation
Order entry
Document management (requisitions, etc.)
Labeling
Sorting
Centrifugation
Labeling of aliquot tubes
Decapping
Pouring of aliquots
More sorting
Delivery to laboratory sections
More sorting
Preparing work lists
Labeling analyzer-specific tubes for specimens
Pouring or pipetting analyzer-specific specimens
Loading tubes on analyzers
Performing tests (steps such as extraction, centrifugation, precipitation, dilution, etc., are not specifically listed)
Unloading analyzers
Recapping
Data manipulations (calculations)
Results review and verification
Reporting of results
Delivery of specimens to archival storage system
Archival storage of specimens
Reflexive testing
Repeat testing, diluting, if necessary
Additional physician-ordered testing
Specimen retrieval for additional or repeat testing
Disposal of expired specimens

Some laboratorians use 80% as a "rule of thumb" in guiding decisions about automation. Clinical laboratories have many exceptional tests, specimen containers, and handling situations. Nevertheless, if 80% of specimen containers and handling situations can be standardized and automated, the laboratory will achieve a dramatic reduction in its labor usage and costs, which should be sufficient to justify the investment in automation and the planning and evaluation time involved.

Once the laboratory's work-flow has been mapped and its requirements have been identified, alternative solutions are considered. Vendors are invited to make presentations and to host visits of the laboratory management team to other

laboratories where vendors have successful installations. It is important at this stage to focus on the requirements identified by work flow mapping and to not allow the vendor to try to sell equipment that may not be necessary.

Problems of Integration

Building a highly integrated laboratory generates many potential problems. Most vendors of clinical laboratory automation systems prefer customer settings in which the integrated analyzers are their own brand. However, many laboratories may prefer to use analyzers from a vendor that is different from their automation system vendor, making integration of instruments and robotic devices from different manufacturers necessary. Decisions must be made concerning which device will be the master controller and which vendor will develop the software that provides overall control of the automation scheme. In addition, individuals or firms that will be responsible for configuration of the automation to the geometry and production schedule of the laboratory must be recruited and trained. Over the past decade, automation vendors have gained considerable experience implementing integrated systems. Although some clinical laboratories have had unsatisfactory experiences, integrated systems are becoming more commonplace.

The reader is referred to the CLSI standard AUTO03-A2 and, in particular, to the Functional Control Model (Section 4.2), which describes the relationships between the LIS, LAS, and various devices.[5] In this model, and throughout the series of CLSI automation standards, the term *LAS* represents the computer system that controls the automation system, not the actual automation hardware. Most often, it is the LAS that has the requisite process control software to support automation. The functional control model, which is depicted in Figure 19-5, supports analytical instruments that may be physically attached to the automation system and analyzers that may not be attached but are still interfaced to the LIS. The model does not give dominance to the LIS or the LAS, but rather allows for essential information flow in either direction to make the most efficient use of the strengths of each system. Although not specified in the AUTO03-A2 standard, some vendors have implemented redundant clustered computers as their LAS to protect customers from downtime associated with failure of a single computer.

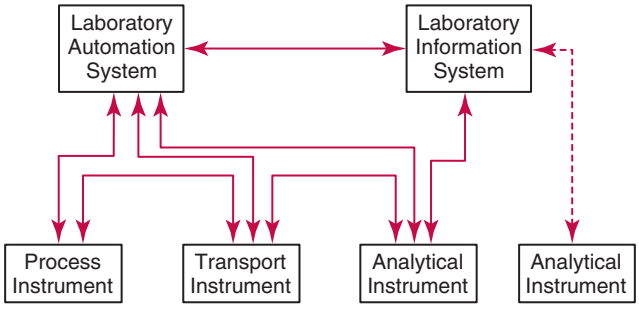

Figure 19-5 Functional control model of the CLSI AUTO3-A2 standard. The *solid lines and arrows* depict logical information flows supported by the standard. The *dotted line and arrows* show logical information flows permitted, but not supported, by the standard. *(Clinical and Laboratory Standards Institute. Laboratory automation: communications with automated clinical laboratory systems, instruments, devices, and information systems. CLSI Approved Standard AUTO3-A2. Wayne, Pa: Clinical and Laboratory Standards Institute, 2009. Figure reproduced with permission of CLSI.)*

Device Integration

One objective in developing an integrated laboratory is to link laboratory instruments and devices into an automated system to maximize the number of functions automated. Automatic specimen introduction requires the development of mechanical interfaces between each laboratory analyzer and devices such as conveyor belts, mobile robots, or robot arms. Some systems have added enhancements such as electronic interfaces for laboratory instruments to allow remote computer control of front-panel functions, notification of instrument status information, and coordination of the distribution of specimens between instruments. In the ideal integrated clinical laboratory automation system, the LAS may be a process controller that would integrate, automate, and monitor many of the decision-making tasks that occur in the daily activity of a laboratory. For example, the LAS would notify an operator that a particular analyzer (even if it is from a different vendor) may be running low on a reagent or may have a fault condition. The LAS (process controller) would control and schedule nonanalytical modules such as automated centrifuges, aliquoters, decappers, and so forth. Most existing LIS systems have no process control capability, and their interfaces with laboratory analyzers provide only the ability to download accession numbers and the tests requested on each specimen, and to upload results generated by the analyzer. The distribution of tasks must be carefully specified in developing such a communications network.

OTHER AREAS OF AUTOMATION

In addition to the automated devices described previously, a variety of other instruments and processes have been automated and used in the clinical laboratory. They include (1) urine analyzers, (2) cell counters, (3) nucleic acid analyzers, (4) microtiter plate systems, (5) automated pipetting stations, and (6) point-of-care testing analyzers.

Urine Analyzers

Many of the same analytical principles are used for the quantification of serum and urine constituents. It is more difficult, however, to automate testing of urine than serum because of the broad range of concentrations of many urine constituents. This requires a low limit of detection to measure low concentrations and expanded linearity to permit measurements of high concentrations without dilution. This requirement, together with the relatively low demand for urine tests compared with that for serum tests, slowed the development of analyzers designed specifically for urine constituents. However, with the deployment of new-generation analyzers,

automation of urinalysis is gaining acceptance in many laboratories.[14]

Cell Counters

Analyzers that perform a complete blood count (CBC) have been automated through the use of (1) the "Coulter principle," which is based on cell conductivity, (2) light scatter, and (3) flow cytometry. Individual blood cells are analyzed by application of one or more of these techniques. The Coulter principle is based on changes in electrical impedance produced by nonconductive particles suspended in an electrolyte as they pass through a small aperture between electrodes. In the sensing zone of the aperture, the volume of electrolyte displaced by the particle (cell) is measured as a change in voltage that is proportional to the volume of the particle. By carefully controlling the quantity of electrolyte drawn through the aperture, several thousand particles per second are counted and sized individually. Red blood cells, white blood cells, and platelets are identified by their sizes. Alternating current in the radiofrequency range short-circuits the bipolar lipid layer of the cell membrane, allowing energy to penetrate the cell. Information about intracellular structure, including chemical composition and nuclear volume, is collected with this technique.

Flow cytometry typically uses cells stained with a supravital or fluorescent dye that travel in suspension one by one past a laser light source. (Unstained cells also are measured.) Scattered light and emitted light are collected in front of the light source and at right angles, respectively. Information derived through measurement of light scatter when a cell is struck by the laser beam is then used to estimate (1) cell shape, (2) cell size, (3) cellular granularity, (4) nuclear lobularity, and (5) cell surface structure. Some cell counters classify white cells using the Coulter principle, cell conductivity, and light scattering of unstained cells to differentiate cell types, whereas other cell counters use multiple flow cytometry channels or a combination of flow cytometry, cell conductivity, and light scattering.

Nucleic Acid Analyzers

Automation of the analysis of nucleic acids developed rapidly as an outgrowth of the Human Genome Project.[18] Several manufacturers have developed automation to assist with the isolation of nucleic acids and with analysis of nucleic acids using several amplification schemes and nucleic acid sequencing. Many of these techniques have been miniaturized using chip technology (see Chapter 18).[11,15] Microfluidic chip-based approaches hold promise for reducing analysis time and reagent consumption, and for reducing the costs associated with robotics and laboratory apparatus needed for the macroscale approaches.

Microtiter Plate Systems

Microtiter plate systems are commonly used in immunoassays and nucleic acid analyses. As used for enzyme-linked immunosorbent assays (ELISAs), microtiter plates usually are made of polystyrene and have 48 or 96 wells coated with antibody specific for the antigen of interest. After incubation of serum in the microtiter plate well, the well is washed to remove unbound antigen, and a second antibody with conjugated indicator enzyme is added. After a second incubation period, the well is washed to remove the unbound conjugate. A color-producing product is developed by the addition of enzyme substrate, and the reaction is terminated at a specific time. With the development of automated pipetting stations, the liquid handling steps required for microtiter plate assays have been fully automated to make microtiter plate assays a viable technology for carrying out large numbers of immunoassays. Automated pipetting stations have a cartesian robot with a pipette fixed to the end of a probe that moves about a rectangular space. The probe is capable of moving in the *x*-, *y*-, and *z*-axes. Liquids may be aspirated and dispensed in any location within the rectangular space. Measurement of absorbance and data processing are also automated in such automated instruments.

Automated Pipetting Stations

Pipetting stations may be used to automate an analytical procedure for which an automated analyzer does not exist or cannot be cost justified. Most pipetting robots (1) are relatively easy to program, (2) rarely malfunction, and (3) are capable of delivering aliquots of liquids with extreme precision and accuracy. Multiple-channel pipetting robots allow parallel processing of specimens with 8- or 12-channel probes to handle microtiter plates.

CHAPTER 20

Point-of-Care Testing

Christopher P. Price, Ph.D., F.R.S.C., F.R.C.Path., and Andrew St. John, Ph.D., M.A.A.C.B.

Advances in a range of analytical and fabrication technologies, such as (1) thin film sensors, (2) semiconductor engineering, (3) plastic molding, (4) microfluidics, (5) nanotechnology, and (6) consumer electronics, have made it possible to adapt most of the methods used in the laboratory to the point-of-care setting.[78] This prompts the question as to whether there is the beginning of a general movement of testing away from the central laboratory to the point of care.[112,113,120] Christensen and associates believe that point-of-care testing (POCT) is one of the key enablers required to deliver changes in healthcare provision through disruptive innovation, namely, radically changing the way that healthcare is delivered.[23]

Although early POCT technologies were very much associated with acute clinical needs (e.g., medical emergencies), it is more appropriate to define POCT as "when a test is performed at the time at which the test result enables a decision to be made and an action taken that leads to an improved health outcome." Other terms used to describe POCT have included (1) "bed side,"[97] (2) "near patient,"[32] (3) "physician's office,"[87] (4) "extralaboratory,"[108] (5) "decentralized,"[6] (6) "off site," (7) "satellite," (8) "kiosk," (9) "ancillary," and (10) "alternative site" testing[50]; many of the latter descriptors identify a specific location where the test is intended to be performed, while others clearly describe the adjunctive nature of the testing site to the central laboratory. "Self-testing" should be added to these descriptions to reflect that there is an increasing repertoire of tests that are, performed by patients themselves.

In the hospital setting, POCT has been described in (1) coronary care units,[31] (2) intensive care units,[46] (3) surgical wards,[36] (4) emergency rooms,[41,81] and (5) pediatric units,[42,119] and for monitoring patients with acute[49,54] and chronic conditions.[1] More testing is now being performed using POCT in primary care, both to help in rapid diagnosis and to determine the appropriateness of triage to secondary care, as well as to manage patients with chronic conditions. The "wish list" for the capability to perform POCT in primary care is extensive![92] However a systematic review conducted in 1997 provided little high quality evidence to support this utility.[57]

Although POCT can be viewed as a means to deliver results rapidly to where they are needed (clinical need), it can also be seen as a means of reducing the complexity of the process associated with obtaining a test result (process need). Clinical needs met by POCT can include clinical urgency and improving the interaction between the patient and the clinician/carer to achieve greater patient empowerment and the potential to improve the clinical outcome. Similarly, process needs met by POCT can improve the immediate patient/clinician/carer interaction as alluded to previously, as well as the longer process of the whole patient journey and the patient experience.

Improving clinical and process outcomes has the potential to reduce errors and wastage of resources while also reducing the cost of care and increasing societal gain. This argument can be applied simply to the testing process (Figure 20-1) or to the wider aspects of the whole patient journey. Thus, such a radical change in the provision of healthcare can be seen to have several potential advantages, while exposing stakeholders to different risks, and hence disadvantages (Box 20-1).

Thus an important feature of POCT is identification of healthcare needs and performance requirements associated with meeting those needs, which must be complemented by the quality management and reimbursement strategies required to ensure "fitness for purpose."

The following sections of this chapter describes the technology available for POCT and the organizational factors that are important when POCT is implemented in a healthcare setting. The chapter concludes with a short discussion of the future of POCT.

ANALYTICAL AND TECHNOLOGICAL SOLUTIONS

The commercial POCT market is reported to make up nearly 30% of the total in vitro diagnostics (IVD) market and is worth in excess of $13 billion (U.S.).[68] Within this market are a wide variety of devices that are difficult to classify succinctly but that can be divided into smaller, single-use, hand-held devices and larger benchtop devices that may be single- or multiple-use items (Table 20-1). An additional group, is the wearable devices, an example of which was the GlucoWatch G2 Biographer.[124]

Although all manufacturers of diagnostic medical devices aim to make their devices simple to use and to reduce the risk of error, these goals assume a greater imperative for POCT

devices because they are likely to be used by personnel who have not received laboratory training and who lack the skills required to detect when devices may not be working correctly and are giving incorrect results. Thus much of the ingenuity and engineering that have gone into producing the myriad of POCT devices that exist today have been directed toward achieving these goals. The novel mechanical design and engineering solutions are matched in importance by software that makes the device operate in a way that minimizes the risks of mechanical failure and operator error.

This section focuses on some of the key technologies that are used in hand-held and benchtop devices, including specific design features that are aimed at preventing misuse or errors, and refers to some commercial examples. Box 20-2 provides a summary of the ideal requirements for a POCT device against which new technologies and devices are assessed. Readers requiring additional information are referred to more comprehensive texts[75,109] or to vendors of POCT devices.

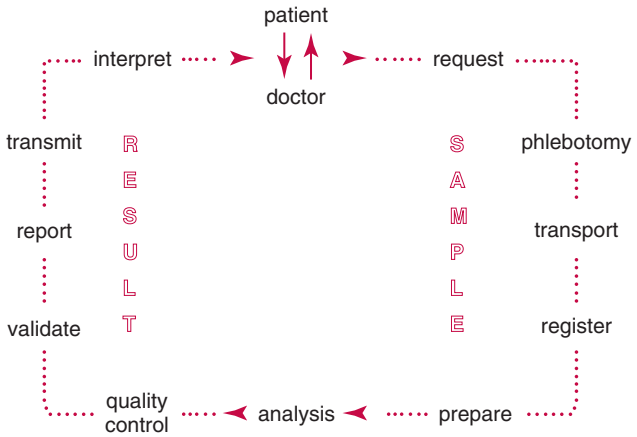

Figure 20-1 Schematic representation of the key steps in requesting, delivering, and using a diagnostic test result.

Hand-Held, Single-Use Devices

No hard and fast definition of a hand-held device as compared with a benchtop instrument is available, but one typical definition used by Kricka and Thorpe is that hand-held

BOX 20-1 Potential Advantages and Disadvantages of Point-of-Care Testing

Advantages
Reduced turnaround time for test results
Improved patient management; improved interaction between patient and carer
Improved patient morbidity and mortality
Reduction in the administrative work associated with test requesting and reporting
Reduced risk of errors
Reduction in clinic visits
Reduction in hospital admissions
Improved cost of care

Disadvantages
Increase in administrative work associated with training and certification of operators
Caregiver required to perform test
Increased risk of error if tests are performed by untrained operators

TABLE 20-1 Classification of Types of Point-of-Care Testing Instruments or Devices

Type of Technology	Analytical Principle	Analytes
Single-use, qualitative or semiquantitative cartridge/strip tests	Reflectance	Urine and blood chemistry
	Lateral flow or flow-through immunoassays	Infectious disease agents, cardiac markers, hCG
Single-use quantitative cartridge/strip tests with a reader device	Reflectance	Glucose
	Electrochemistry	Glucose
	Reflectance	Blood chemistry
	Light scattering/optical motion	Coagulation
	Lateral flow, flow-through, or solid phase immunoassays	Cardiac markers, drugs, CRP, allergy, fertility tests
	Microfluidics, PCR	*Chlamydia*
	Immunoturbidimetry	HbA_{1c}, urine albumin
	Spectrophotometry	Blood chemistry
	Electrochemistry	pH, blood gases, electrolytes, metabolites
Multiple-use quantitative cartridge/benchtop devices	Electrochemistry	pH, blood gases, electrolytes, metabolites
	Fluorescence	pH, blood gases, electrolytes, metabolites
	Multiwavelength spectrophotometry	Hemoglobin species, bilirubin
	Time-resolved fluorescence	Cardiac markers, drugs, CRP
	Electrical impedance	Complete blood count

PCR, Polymerase chain reaction.

BOX 20-2 Ideal Requirements for a Point-of-Care Testing System

First results in a minute or less
Portable instruments with consumable reagent cartridges
Single-step operating protocol
Capability of performing direct specimen analysis on whole blood, CSF, urine, and stool specimens (nonprocessed samples)
Simple operating procedures that do not require a laboratory-trained operator
Flexible test menus
Results that meet the analytical specifications that are "fit-for-purpose," and with accuracy and precision comparable with those of the central laboratory, if necessary
Built-in/integrated calibration and quality control
Ambient temperature storage for reagents
Results provided as hard copy, stored, and available for transmission
Low instrument cost
Service by exchange
Built-in regulatory record keeping

devices are up to about the size of the electronic book readers that are now gaining popularity.[79] Hand-held devices first appeared in the form of paper strips many centuries ago for the testing of urine. Test strips as we know them today were introduced in the 1940s and 1950s through companies such as Ames and Roche, while the first disposable immunochemical test could be deemed to be the relatively rapid (2 hours) pregnancy test presented by Wampole in 1970.

To provide some insight into the wealth of different designs that make up disposable hand-held devices, four categories of devices will be reviewed in some detail (1) urine or blood dipsticks; (2) glucose and coagulation strips together with accompanying meters; (3) lateral flow devices including immunosensors; and (4) cartridge or cassette devices. A key attribute of all these devices is that they are used only once and therefore are referred to as single-use devices. Test strips were originally designed to be read by the operator, and with some devices this is still the case, but many strips are now used in conjunction with meters or reading devices. Advances in meter design have been greatly influenced by advances in consumer electronics, and the ability of POCT devices to meet the goals mentioned previously is a consequence of both the design of the strip or analytical system and the meter with which the strip or device is used. Control and communication systems are a major component of all POCT devices other than qualitative or semiquantitative strip tests that do not require a reader or measurement device. In even the smallest device, a control subsystem coordinates all the other systems and ensures that all required processes for an analysis take place in the correct order. Operations that require control include (1) insertion or removal of the strip, cartridge, or cassette; (2) temperature control; (3) sample injection or aspiration; (4) sample detection; (5) mixing; timing of incubation and detection processes (such as absorbance measurement); and (6) waste removal. Fluid movement often is accomplished by mechanical means through pumps or centrifugation, and by fluidic properties, such as surface tension; the latter can be a critical element in the design of simple strip tests and in microfabricated systems.[72]

Urine and Blood Dipsticks

Dipsticks are relatively simple in construction and are composed of a pad of porous material, such as cellulose, that is impregnated with reagent and then dried.[134] The reaction is indicated by a visible color reaction that is compared with a chart. More complex pads are composed of several layers, the uppermost of which is a semipermeable membrane that prevents red cells from entering the matrix. Despite their simplicity, critical operator factors can affect the result, and manufacturers have tried to overcome some of these problems through innovative designs. Thus not all strips now require that the whole pad be covered with the sample to obtain a reliable result. Although reactions in dipsticks do not always proceed to completion, the time between placement of the sample on the pad and comparison of the resulting color with a color chart is less critical for some strips than for others.

However, the need for reproducible timing has driven the need to use small meters to complete the measurement process. This also has the added benefit of reducing operator variability in assessing the color change. For blood tests, it may be necessary to remove all blood before placing the sample in the reflectance meter, but some manufacturers have overcome this problem by reading the color from the underside of the strip.

Further progress with these single-stick devices has included the use of multiple pads for measurement of (1) different concentrations of the same analyte, such as hemoglobin and glucose[134]; (2) both albumin and creatinine (semiquantitative) to obtain an albumin-to-creatinine ratio[114]; and (3) up to 10 different urine analytes; as well as the use of a reflectance meter to quantitate the color change.[85] Table 20-2 lists some of the tests performed by single or multipad dipsticks and the chemistry used for analysis.

Glucose Strips and Meters

Point-of-care glucose testing using disposable strips represents a market that was worth nearly $10 billion (U.S.) in 2008.[68] The size of the market has driven considerable innovation in strip and meter design in an effort to produce devices produce results comparable with those obtained through laboratory methods. Significant improvement has been noted in attributes such as ease of use; however, limitations of this technology are particularly important when testing is conducted in hospitals.

Glucose strips are biosensors in that they all use an enzyme as the recognition agent; glucose oxidase (GO), hexokinase (HK), or glucose dehydrogenase (GDH) with photometric (reflectance) or, more commonly, electrochemical detection may be used.[98] Each strip comprises several layers, each having a specific function. When blood is added, both water

TABLE 20-2 Examples of Single or Multipad Stick Tests

Test	Sample	Chemistry
Acetaminophen	Whole blood	Acyl dehydrogenase
Alanine aminotransferase	Whole blood	Alanine/glutamate
Albumin	Whole blood, urine	Dye binding
Cholesterol	Whole blood	Cholesterol oxidase
Creatinine	Whole blood, urine	Copper complexation
Glucose	Whole blood	Glucose oxidase
Lactate	Whole blood	Lactate dehydrogenase
Uric acid	Whole blood	Uricase
Alcohol	Urine	Alcohol dehydrogenase
Bilirubin	Urine	2,4-Dichloroaniline
Hemoglobin	Urine	Peroxidase activity
Leukocyte esterase	Urine	Pyrrole amino ester hydrolysis
Ketones	Urine	Sodium nitroprusside reaction
Nitrite	Urine	*p*-Arsanilic acid reaction
pH	Urine	Double indicator principle
Protein	Urine	Protein error of indicators
Specific gravity	Urine	Polyacid pH change
Urobilinogen	Urine	Ehrlich's reaction

and glucose must pass into the film or analytical layer; for photometric systems, erythrocytes must be excluded. These processes are achieved by what is called the separating layer that contains various components, including glass fiber fleeces, membranes, and special latex formulations. In photometric systems, a spreading layer is important for fast homogeneous distribution of the sample, whereas electrochemical strips use capillary fill systems. The support layer is usually a thin plastic material that in the case of reflectance-based strips may have reflective properties. Additional reflectance properties have been achieved through the inclusion of substances such as titanium oxide, barium sulfate, and zinc oxide.

The use of different chemistries and detection systems is driven by a number of requirements, including (1) accurate and precise results with freedom from common interferences, (2) rapid response of detection, (3) ease of use, and (4) low cost. The relative importance of these goals differs somewhat

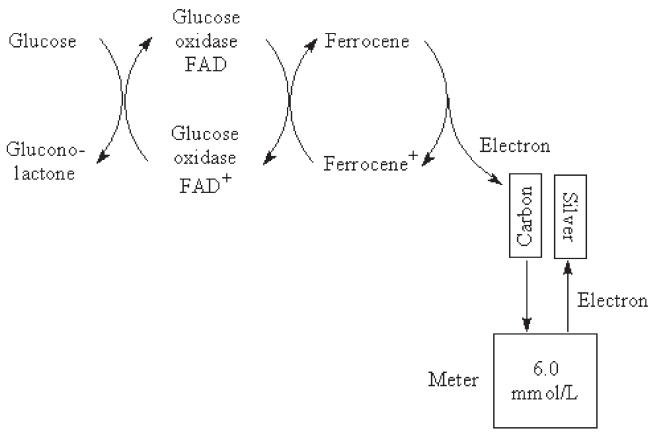

Figure 20-2 Schematic diagram of the reactions taking place in a MediSense electrochemical glucose strip. *(Modified from Henning TP, Cunningham TP. Biosensors for personal diabetes management. In: Ramsay G, ed. Commercial biosensors. New York: John Wiley & Sons, 1998:3-46.)*

between meters used in the hospital, where there can be significant problems due to interferences, and those used by patients for self-monitoring, when ease of use and low cost are priorities.

A major advance in the development process was the use of ferrocene and its derivatives as immobilized mediators in the construction of electrochemical glucose strips.[33] The strip is composed of an Ag-AgCl reference electrode and a carbon-based active electrode, both manufactured using screen printing technology with the ferrocene or its derivatives contained in the printing ink. The sample is placed in the sample observation window, and the hydrophilic layer serves to direct the sample over the reagent layer. Conversion of glucose is accompanied by the reduction of ferrocene and the release of electrons (Figure 20-2).[33] Another significant advance has been the use of techniques such as capillary filling to ensure that the right amount of sample is in place.

In practice, glucose strips are produced in large batches; after extensive quality assurance procedures, each batch is given a code that is stored in a magnetic strip on the underside of each test strip. This code describes the performance of the batch, including the calibrating relationship between the photometric or electrochemical signal and the concentration of glucose. For many years, it was necessary to provide a means for recalibrating a meter (e.g., providing the algorithm on a bar coded strip that could be read by the meter) when a new batch of strips was employed, which led to errors when patients forgot to perform the recalibration.[115] However, strips now can be manufactured with sufficient consistency such that recalibration between different lots is no longer required.[8]

Parallel with advances in strip technology has been the evolution of the consumer electronics industry, in particular the miniaturization of electronics.[95] The latter, together with the use of amperometric methods, has enabled the production of smaller meters, nonwipe strips, sample volumes

<1 µL, less need to clean instrument optics, and results obtained within 5 seconds. Some meters also include substantial information technology (IT) capability, including the ability to lock users out if they have not completed required procedures such as quality control (QC) and the capacity to store and download patient results. In conjunction with docking stations and data managers is the capability to institute the type of informatics procedures that are required of central laboratory testing, such as identification and possible lockout of operators, together with transmission of results to the laboratory information system (LIS), along with accompanying patient information.

Thus the capability of glucose meters has advanced significantly over the years and is such that appropriately trained and motivated patients with diabetes can monitor their own glucose with a reasonable degree of assurance and tailor their insulin therapy accordingly. The use of glucose meters in sick or hospitalized patients has been more problematic. For example, a major problem with glucose oxidase methods was their susceptibility to the ambient tension of oxygen in blood, which may vary substantially in critically ill patients. This interference was essentially removed by using glucose dehydrogenase as the enzyme, but several reports and at least one death have been the result of maltose interference in glucose dehydrogenase strips that use the pyrroloquinolinequenone form of the enzyme (GDH-PQQ), the maltose being given as part of the patient's therapy.[43] Subsequently, improved strips such as the StatStrip by Nova BioMedical (Waltham, Mass) appear to overcome this problem.[58]

In addition, evaluation reports indicate that this newer design is not affected by hematocrit, unlike most other glucose strips. Hematocrit can vary substantially in young infants and in critically ill adults with the glucose concentration being inversely related to the hematocrit; those who look after the critically ill need to be aware of this phenomenon. Many interferent issues and the resulting performance gap between glucose meters and laboratory results have been brought into sharp focus with the adoption of procedures such as tight glycemic control (TGC) in intensive care unit (ICU) patients.[132] Although meter performance has undoubtedly improved over the years, reports show that the analytical performance of most current meters is not good enough for them to be used in TGC protocols.[14] An International Organization for Standardization (ISO) document reviews the performance goals required for meters in hospitals, in physician and practitioner offices, and for patients performing self-monitoring.[62]

Coagulation Strips and Meters

The clinical need to monitor anticoagulant therapy in both acute and chronic medical settings has been well defined, and the value of POCT devices has been demonstrated in several studies.[36,53] The number of patients requiring long-term anticoagulant therapy is growing, and coagulation monitoring is one of the largest sectors of the POCT market after glucose monitoring and pregnancy testing. General features of a typical coagulation meter include a design that utilizes fingerstick samples in the case of home or clinic monitoring, with minimal demands on the user in terms of sample application. The reaction usually takes place in a cassette or test strip that is maintained at a temperature above 37 °C to maximize reaction kinetics and minimize changes in outside temperature. The latest generation of portable meters generally used in hospital locations is much easier to use, compared with earlier systems, and requires smaller specimen volumes.

Manufacturers have used a variety of systems to detect the clotting event in coagulation meters, but newer detection technologies that are classified broadly as electrochemical are used in HemoSense and Roche CoaguChek XS instruments. With the HemoSense InRatio2 coagulation meter (HemoSense Inc., Inverness Medical Innovations, Waltham, Mass) for measurement of prothrombin time (PT), clotting is detected by impedance rather than by current.[64] Because this device is likely to be used by patients, it has various features designed to make QC automatic or to require minimal involvement of the patient. These include a test strip that has three channels—one for the patient test and two for different concentrations of internal QC reference materials; all three channels operate simultaneously when a patient sample is applied to the strip (Figure 20-3). Similar features of integrated on-board QC operate in other smaller meters or devices likely to be used by patients, such as the ITC ProTime Microcoagulation System (ITC, Edison, NJ). Several studies have shown that the ProTime device can be used satisfactorily by patients for self-testing purposes.[99,100] Many meters have QC lockout features that prevent operation of the device when QC results are not within prescribed limits, as well as software to detect common errors such as expired reagents

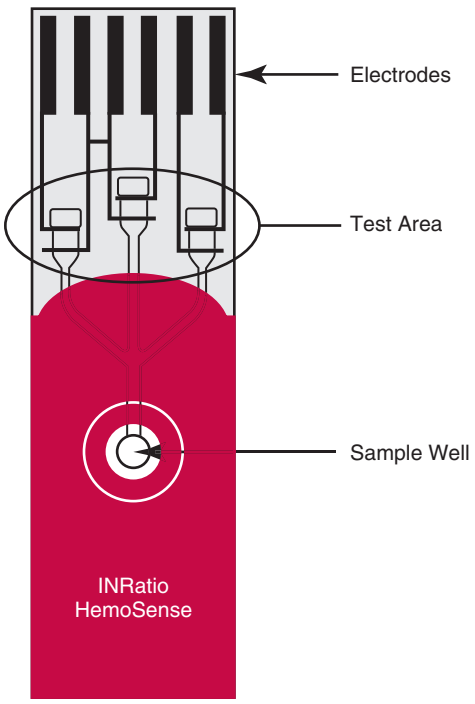

Figure 20-3 Schematic diagram of the HemoSense PT strip. *(Courtesy Hemesense.)*

and incorrect specimen placement or volume. The Roche CoaguChek XS (Roche Diagnostics, Mannheim, Germany) uses a similar amperometric detection principle. Thrombin-activated cleavage of thromboplastin in the strip leads to generation of electrochemically active phenylenediamine, and when the current generated by this species reaches a certain value, the PT can be determined.[105] Environmental changes in the strip that might occur as the result of incorrect handling are detected by an integrated QC system in the strip, which, under the Clinical Laboratory Improvement Amendments (CLIA) of the United States, means there is no need to run liquid quality controls on the strip.

One persistent problem that remains for point-of-care coagulation testing is the poor correlation between POCT devices and coagulation analyzers in the central laboratory. This is a particular problem for activated clotting time (ACT), for which a so-called gold standard for comparison does not exist.[106] Reports in the literature indicate that despite improvements and progress with standardization, lack of agreement can still be a problem.[69,125]

Lateral Flow Strips

Many POC tests use lateral flow strips, usually for immunoassays; the original application that was filed as a patent in 1979 was called an *immunochromatograph.*[48,111] These devices are biological sensors in which the recognition troponin binds to the two antibodies. The antibody-troponin complex flows along the cellulose nitrate strip and reaches the capture zone, which contains streptavidin. The latter binds to the biotin in the troponin complex, immobilizing it and appearing as a purple band due to the presence of gold particles on one of the antibodies. Unreacted gold-labeled antibody is able to move down the strip, where it is captured by a synthetic peptide that contains the epitope of human cardiac troponin T, which is visualized as a separate second band. This band indicates that the sample has flowed along the strip and the device has worked correctly, which represents a form of built-in control.

A growing application of lateral flow strip immunoassay is for infectious disease testing and the rapid detection of various infectious antigens and antibodies, including (1) *Chlamydia trachomatis,*[65] (2) group A streptococci,[21] (3) *Helicobacter pylori,*[51] (4) infectious mononucleosis,[40] and (5) human immunodeficiency virus.[67]

Although many lateral flow strips rely on visual reading by the operator, an increasing number are used in conjunction with meters or reading devices. An integral part of many of these instruments is a charge-coupled device (CCD) camera that is a multichannel light detector, similar to a photomultiplier tube in a spectrophotometer, but with a higher signal-to-noise ratio so it detects much lower signals at low quantities of light. For example, the Roche Cardiac Reader contains a CCD that will quantitate separate lateral flow immunoassay strips for measurement of troponin T, myoglobin, and D-dimer.

Several immunosensor-based devices have been developed that are capable of measuring a panel of analytes, such as cardiac markers,[4] drugs of abuse tests,[17] and fertility tests.[12] With these devices, a mixture of antibodies is placed at the origin, and complementary antibodies for various analytes are located at varying positions along the porous strip. In the

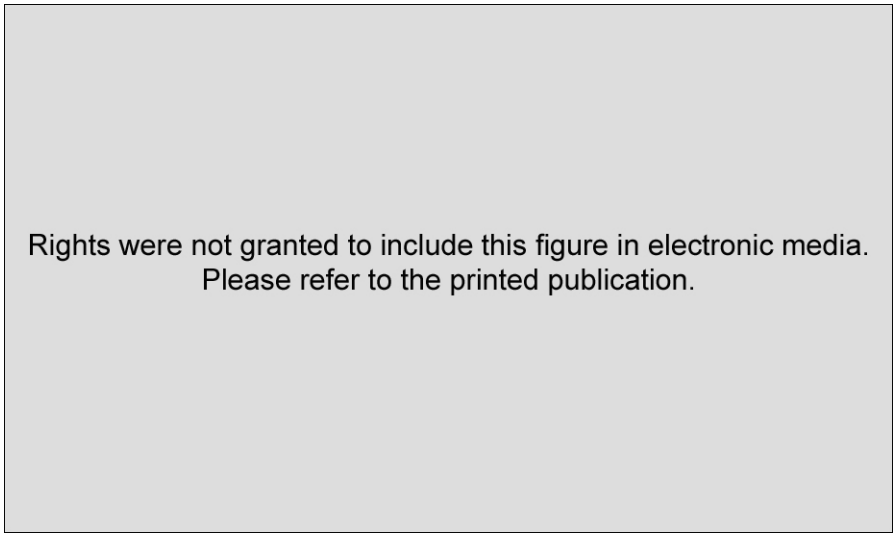

Figure 20-4 Schematic diagram of a lateral flow immunoassay strip for troponin T. *(Courtesy Roche Diagnostics.)*

case of drugs of abuse, devices are designed such that positive responses are obtained only if the concentration is above a precalibrated cutoff value.[17]

Although lateral flow devices are the most common form of POCT immunosensor, other formats include a flow-through design.[130] Alternative detection mechanisms to reflectance or absorbance are also being investigated; these include (1) surface plasmon resonance, (2) evanescent wave, (3) fixed-polarized ellipsometry, and (4) diffraction.

Cartridge or Cassette Devices

Another major category of single-use devices consists of integrated cartridges or cassettes that operate in conjunction with a hand-held meter. The most common example is the i-Stat Analyzer (Abbott Laboratories, Chicago, Ill), which when introduced some 2 decades ago, measured only blood gases, electrolytes, and glucose but now has a menu that includes creatinine, certain coagulation parameters, and troponin.[11,39] To achieve the full menu requires different combinations of cartridges. Each of these contains sensors or electrodes as wafer structures constructed with thin metal oxide films using microfabrication techniques directly comparable with those used in the computer industry.[35] Another important component of the cartridge is the microfluidic network, which directs and controls the movement of calibration liquids and blood sample to each of the sensors.[72] This device was one of the first to introduce the concept of electronic QC, a procedure that checks the status of the cartridge prior to analysis of a patient sample. Although this is a valuable procedure, it is agreed by most laboratory professionals that it cannot substitute for conventional QC procedures.[135] The size of the device allows it to be used directly at the bedside and via the use of a docking station or cradle connected to the LIS or hospital information system (HIS); patient results can be captured and retained in the patient record. Some hospitals use these systems for all critical care testing; others retain them as a backup or use them in locations where testing is done relatively infrequently.

The need for clean air fabrication means that the cost of I-stat–type devices is relatively high, which has driven research into alternative and less costly ways to manufacture such complex cartridges. One example is the Epoc system (Epocal Inc., Ottawa, Ontario, Canada), which uses technology from the smart-card industry by manufacturing blood gas, electrolyte, and immunoassay devices as credit card–sized items on 35-mm tape-on-reel format.[80] Similar to the I-Stat system, the cards are used in conjunction with a hand-held meter, but this type of technology has significant advantages in terms of manufacturing cost.

In a similar vein, microfluidic cards are now being developed as an alternative to more conventional cassettes for a number of applications, including polymerase chain reaction (PCR)-based tests for infectious agents. In one approach under development by Atlas Genetics (Bristol, United Kingdom; www.atlasgenetics.com/accessed April 14, 2011), the disposable card (Figure 20-5) has many functions, which use a common architecture to ensure a simple, low-cost

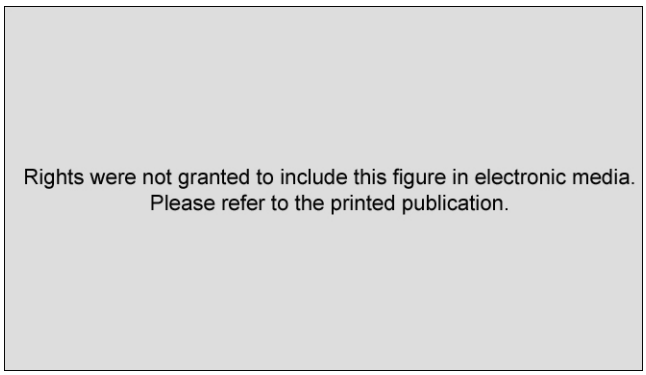

Figure 20-5 Schematic diagram of a microfluidic card employing a molecular test for *Chlamydia trachomatis*. *(Courtesy Atlas Genetics, Bristol, United Kingdom.)*

device that combines sample preparation, PCR amplification, and electrochemical detection. The lower molding contains fluidic channels through which reagents are moved using a series of bellows and valves created by the flexible rubber layer. This enables an instrument to remain isolated from the fluids in the card by simply applying pressure to the card to run the assay. The foil on the bottom of the card has excellent barrier properties for long-term storage of wet reagents, while providing a low-resistance path for rapid thermocycling.[55]

Multiple-Use Cartridges and Benchtop Systems

A significant proportion of multiple-use systems are used for critical care testing in locations such as the ICU, the surgical suite, and the emergency room. The technology for measuring blood gases and associated parameters has existed for many years, but the menus of so-called blood gas instruments have recently been extended to include biosensors for parameters such as glucose, lactate, and urea. Although they use similar technology to that described previously, they differ in that the sensors are designed to be reusable.[34] To improve convenience for non–laboratory trained users such as nurses and doctors, the sensors have been incorporated with reagents and calibrators into a single cartridge or pack that is placed in the body of a small to medium-sized, portable critical care analyzer (Figure 20-6). Each pack will measure a certain number of samples during a particular time period, after which replacement is a relatively simple procedure. This type of technology is available as the (1) Instrumentation Laboratory GEM Premier 3000 and 4000 (Instrumentation Laboratory GEM, Bedford, Mass),[9,10] (2) Radiometer ABL800 (Radiometer ApS, Copenhagen, Denmark),[84] and (3) Siemens Healthcare Diagnostics Rapidpoint 400 (Deerfield, Ill).[86]

Other key developments for critical care devices include liquid calibration systems that use a combination of aqueous base solutions and conductance measurements to calibrate the pH and PCO_2 electrodes, with oxygen being calibrated with an oxygen-free solution and room air.[90] This dispenses with the need for gas bottles. Another important innovation is the integration of automated QC packages into these analyzers, which ensure that QC samples are analyzed at regular

intervals. These comprise packs or bottles of QC material that are contained within the instrument and are sampled at predetermined intervals with onboard software interpreting the results and generating alerts, if necessary. Such devices can even be remotely monitored and programmed to respond to problems with instruments located long distances from the central laboratory.[56]

Critical care POCT instruments are also available for measuring various hemoglobin species and performing CO-oximetry determinations. The latter relies upon multiwavelength spectrophotometry where light absorption by hemolyzed blood is measured at up to 60 or more wavelengths to determine the concentration of the five hemoglobin species.[16] Manufacturers have extended the capability of multiwavelength spectrophotometry to measure bilirubin directly in whole blood.[13,117]

The menu of critical care tests is also being extended to parameters that can be measured only by immunoassay. Two particularly important parameters required for acute care are troponin and beta–**chorionic gonadotropin** (CG). As has been described, both can be measured using hand-held devices, usually using lateral flow or similar technology, but the precision and accuracy of such techniques are occasionally not fit for the purpose for which they are intended. Thus manufacturers have devised larger instruments for immunoassay measurement that are capable of comparable analytical quality to laboratory instruments, but they use whole blood, thus facilitating their use close to patient care. The Radiometer AQT90 Flex uses an all-in-one dry-reagent concept and the well-established technique of time-resolved fluorescence used in laboratory-based instruments. Whole blood or plasma samples are used, and the instrument includes an automated sample aspiration module, thus minimizing the time that operators have to interact with the instrument and reducing the risk of preanalytical error (Figure 20-7). The sample is added automatically to the cup containing assay-specific reagents, and in the case of troponin, the assay is a one-step immunofluorometric assay using two biotinylated antibodies for capture and one europium-labeled antibody for detection. Whole blood results are corrected for hematocrit using conductance measurement and are available in less than 20 minutes.[52]

The case for performing acute care testing close to the patient is obvious and well established. In recent years, healthcare providers have seen the need to improve the process for managing patients with chronic conditions such as diabetes. Part of this improvement includes the provision of laboratory testing at the time of the actual consultation; in the case of diabetes care, this has created the need for point-of-care devices that can measure key analytes such as glycated hemoglobin ($HbA1_C$), lipids, and urinary albumin.

Several small devices exist for measurement of HbA_{1c}, but as indicated in a study performed with nurses in a diabetes clinic, only one was considered capable of meeting the required analytical specifications for the monitoring of HbA_{1c}.[121] The DCA 2000 uses an established analytical method of light scattering immunoassay for glycated hemoglobin, but the measurement has been incorporated into a single-use cartridge (Figure 20-8) that is placed in a small benchtop instrument and requires minimal interaction with the operator.[102,107] The Axis-Shield Affionion AS100 (Axis-Shield plc, Dundee, Scotland) is a newer, not dissimilar, cartridge-based analyzer that measures C-Reactive Protein (CRP) as well as HbA_{1c} with analytical performance adequate for the monitoring of HbA_{1c} in patients with diabetes.[5]

Other developments in POCT benchtop technologies have included small instruments for measuring cellular components of blood. Thus the Chempaq analyzer and associated cassettes (Figure 20-9) employ an impedance sensor to count blood cells, which can differentiate between cell types and subgroups by measuring their size, expressed as a change in electrical impedance, when the cells pass the sensor. The

disposable unit (termed the PAQ) contains two chemical reagents. The first reagent is an isotonic solution, which dilutes the blood and enables quantitation of red blood cells (Mean Cell Volume) and platelets (PLT). The second reagent is used to lyse the red blood cells (RBC)s, thereby enabling quantitation of white blood cells, a three-part differential, and hemoglobin.The reagent used to measure hemoglobin lyses the red blood cell membrane, releasing hemoglobin and further causing chemical reformulation of released hemoglobin to form a stable methemoglobin complex. The amount of hemoglobin is measured using spectrophotometry at two different wavelengths.[116] A white cell counter (HemoCue WBC Analyzer, HemoCue, Cypress, Calif) has been described that uses a digital photomicroscope and specially designed software with image analysis algorithms to detect white cells following staining of the nuclei with methylene blue dye.[101]

INFORMATICS AND POCT

POCT devices require the same variety of informatic functions required by conventional laboratory analyzers. Primarily, these functions are associated with electronic transfer of data from analyzers to the LIS and ultimately into a patient's electronic medical record. This provides healthcare professionals with quick, accurate, and appropriate access to the patient's medical history and information. In reality, it is rare for POCT devices to be directly connected to the LIS, and they are usually connected via some sort of docking station and/or data management system (DM), which, in turn, is connected to the LIS (Figure 20-10).

Informatic Requirements in POCT Devices

With advances in software and hardware capabilities, it is possible to considerably enhance the value and quality of the

patient result with additional accompanying information. In the course of selecting a POCT device and its associated informatics, consideration should be given to devices that ensures that certain information items always accompany the patient result across the two interfaces.[26] These obligatory information items include the following:

- Patient identifiers: medical record number (MRN) or similar number and name
- Sample identifiers or accession number (AN)
- Date and time of specimen collection
- Type of specimen
- Test requested
- Test result
- Units to be attributed to the result if applicable
- Date and time of analysis
- Operator identifier
- Device identifier
- Error messages and action messages

Other optional information items that operators may wish to transfer from the device to the DM and possibly to the LIS include (1) reference interval, if not generated by the LIS; (2) specific comments (e.g., error messages); (3) consumable material details (e.g., lot number and expiry date); (4) calibration information, including expiration date; (5) QC parameters; and (6) date and time of system alerts, such as "low battery" and "calibration due."

Development of POCT Connectivity Standards

Although the importance of linking POCT devices to information systems and enhancing the value of the patient result is clear, problems have been associated with achieving this goal, primarily because of interfacing difficulties. These difficulties arose because specific vendor instruments and accompanying DM systems came with proprietary interfaces that rarely allowed devices from other vendors to be linked without significant cost. Because it is common for laboratories to use POCT devices from multiple vendors, this lack of ability to connect different devices through a single DM led to many devices not being linked to any sort of information system. Consequently, patient results often did not get entered into the patient record, thus running the risk of duplicate testing, or they were entered manually with risk of transcription error.[66,122]

At the time, it was thought that the development of a set of common universal "plug and play" interfacing standards for incorporation into all POCT devices would address this problem. Such standards would ensure that POCT devices meet critical user requirements, such as (1) bidirectionality; (2) device connection commonality; (3) commercial software intraoperability, security; and (4) QC and/or regulatory compliance. Accordingly, the Connectivity Industry Consortium (CIC) of more than 30 companies involved in the POCT industry designed a set of connectivity standards that incorporated the following features: (1) use of a proven architecture and notation, (2) use of existing standards and architectural patterns wherever possible, (3) focus on services that would enable software intraoperability and add value to overall functionality, and (4) reduction in the complexity of device communications.

CIC connectivity standards are represented simply as the two interfaces between POCT devices and information systems (see Figure 20-10). The device interface passes patient results and QC information between the POCT instrument and devices, such as docking stations, concentrators, terminal servers, and point-of-care data managers. The latter have to be linked to a variety of information systems via the observation reporting interface or electronic data interface, for transmission of ordering information and patient results.

The initial connectivity standard was approved by the National Committee for Clinical Laboratory Standards [now the Clinical and Laboratory Standards Institute (CLSI)] in 2001, and a revised second edition (designated POCT01-A2)[25] was published in 2006. A POCT device that conforms to this standard should be able to communicate with DM and LIS systems, allowing exchange of data and information in a standardized format, irrespective of vendor or location.

Unfortunately, the uptake of POCT01-A2 has not been as rapid as was anticipated, and not all POCT device companies have adopted the standard. To promote awareness of the potential benefits that could be gained from a universal connectivity standard, CLSI published POCT02-A, "An Implementation Guide of POCT01 for Healthcare Providers," a document that provides in relatively nontechnical terms an explanation of connectivity and what users should look for in POCT01-compliant devices.[26]

Benefits of Connectivity and Future Developments

One of the most important benefits of connectivity is to facilitate the transfer and capture of patient POCT and quality-related data into permanent medical records.[22] Other destinations for point-of-care data include the bedside monitors and clinical information systems that reside in critical care units. These systems integrate data from various sources, including vital signs and diagnostic results. In conjunction with clinical guidelines and expert systems, they can produce critical care maps used in the management of the critically ill patient.[49] Integration of POCT data with other laboratory and clinical information is now commonly seen in disease management systems supporting the care of patients with chronic diseases, such as diabetes mellitus and hyperlipidemia. In the case of diabetes mellitus, the DM serves to maintain a record of blood glucose results and any other observations that the patient wishes to record, to bring to the attention of the clinician at the next clinic visit. This record is then used to help patients in the management of their own disease. In the case of hyperlipidemia, data may be fed into an algorithm together with other observations to calculate a risk score that is used by the patient and his or her clinician to identify life-style, dietary, and therapy changes, together with expected outcomes (e.g., reduced risk of cardiovascular disease). Linking POCT with decision support tools and associated treatment algorithms is seen as the future in a number of situations, including glycemic control in intensive care,[132] management

of diabetes,[47] management of heart failure,[82] and assistance with self-dosing for patients on anticoagulants.[53]

Improvements in the quality management of POCT are also assisted by an ability to easily link devices to networks and to those who are ultimately responsible for the device. Most manufacturers of POCT devices now provide software to allow central laboratories to monitor their instruments in remote locations. In conjunction with network technology, remote control software not only allows monitoring of the performance of the device, it also enables those responsible for the instrument to carry out some service procedures or even to shut the instrument down completely if required. Such software can manage a large number of devices that may be geographically dispersed, and, by reducing the necessity to physically visit each device, its use can result in significant staff savings.[56]

Informatic-related features for the future include greater adoption of the POCT01-A2 standard. Although one can appreciate that some device vendors may prefer to always retain their proprietary interfaces rather than open their systems to competitor devices, there remains a call by users for more universal connectivity.[83] A randomized controlled trial of POCT in general practice in Australia was groundbreaking in many respects, but it did not include the use of any form of comprehensive data management or informatics, partly because the devices used were obtained from multiple vendors, and it was impossible to easily interface them to a single data management system.[15] A second important demand for the future is wireless connectivity, which would provide many management benefits, particularly for those devices used in conjunction with docking stations.[93]

IMPLEMENTATION AND MANAGEMENT CONSIDERATIONS

Implementation, management, and maintenance of a high-quality POCT service require proper organization, training, and management. Consequently, several factors must be considered, including (1) establishing need, performance specifications, risks, and change management challenges; (2) organizing and implementing a POCT Coordinating Committee; (3) establishing a POCT testing policy and accountability; (4) procuring equipment and its evaluation; (5) training and certification of operators, and establishing a QC, quality assurance, and audit policy; (6) ensuring documentation; (7) establishing a policy for accreditation and regulation of POCT, which, in certain situations (e.g., a hospital setting), may require conformance to accreditation and regulatory requirements applicable to the local laboratory.

Several published guidelines on POCT are based on the ISO standard 22870 ["Point-of-Care Testing (POCT): Requirements for Quality and Competence"].[59] Separate ISO standards have been put forth for self-testing of blood glucose[60] and for monitoring for oral anticoagulation therapy.[61] The CLSI has published a second edition of its guidelines for POCT,[27] as have a number of organizations in other countries.[2,7,89] The following paragraphs summarize some of the main features of these guidelines.

ESTABLISHMENT OF NEED, RISKS, AND CHANGE MANAGEMENT CHALLENGES

As with laboratory testing in general, the decision to implement a POCT service requires definition of (1) the healthcare need; (2) the clinical, operational, and economic benefits; (3) the performance requirements; (4) the clinical risks; and (5) the costs involved.

Box 20-3 lists typical questions that should be asked when one is establishing the requirement for a POCT service. Analytical performance specifications are an important part of these considerations. Reference has already been made to the fact that the performance should be "fit for purpose," and although this is often considered equivalent to laboratory performance, in many cases, little formal evidence is available to support this conjecture. Thus one situation where laboratory quality method precision has been shown to be important is in the measurement of blood glucose to support tight glycemic control of patients in the intensive care unit. On the other hand, a semiquantitative POCT method for measurement of the urine albumin-to-creatinine ratio may be acceptable for the rule-out of albuminuria in a primary care setting. Fitness for purpose therefore is based on the combination of need, performance, and outcome.

Responses to the questions should help the clinician to identify what benefits are likely to accrue to the patient, the caregiver and/or the healthcare provider organization by introducing a more rapid service. An economic assessment of the costs of delivering the current service and the costs associated with the POCT service should be conducted. The

BOX 20-3 Assessing the Need for a Point-of-Care Testing Service

Which tests are required?
What is the turnaround time required?
What clinical question is being asked when requesting this test?
What clinical decision is likely to be made upon receipt of the result?
What action is likely to be taken upon receipt of the result?
What outcome should be expected from the action taken?
Why isn't the laboratory able to deliver the required service?
Will POCT provide the required accuracy and precision of the result?
Is staff available to perform the test?
Are facilities adequate to perform the test and store the equipment and reagents?
Will you abide by the organization's POCT policy?
Are there operational benefits to this POCT strategy?
Are there economic benefits to this POCT strategy?
Will a change in practice be required to deliver these benefits?
Is it feasible to make the changes in practice that might be required?

benefits must be identified and accounted for in a way similar to that involved in identifying the cost of other elements of the health service. The total cost of the current service and that of a revised service based on POCT should be determined. Total cost will include all resources used to deliver the service, including personnel and process management functions. In addition, potential cost savings due to decreased length of stay or substitution of physician time for another care provider's time must be considered, as reducing costs may be the key objective in using POCT.

A risk assessment should also be conducted that will focus primarily on procedures and processes that have to be put in place to ensure the maintenance of a high quality of service.[74] Issues of concern include (1) robustness of the POCT device; (2) quality of the results produced, including changes in accuracy and/or precision and/or specificity of POCT results compared with central laboratory results, and how such changes will influence interpretation of results and clinical action based on those results; (3) competence of the operator of the device; (4) effectiveness of the process for transmission of results to the caregiver; (5) competence of the caregiver to interpret the results provided; (6) procedures in place to ensure that an accurate record of the results is kept; (7) identification of what practice changes may have to be made to deliver the benefits that have been identified; (8) how the staff will be retrained if appropriate; and (9) how changes in practice will be implemented.[70,94,110,118]

ORGANIZATION AND IMPLEMENTATION OF A COORDINATING COMMITTEE

It is important to consult with all parties involved in delivering, and receiving, a POCT service. This is best achieved by establishing a POCT Coordinating Committee. Such a committee is charged with managing the whole process of delivering a high-quality POCT service. Committee members should include representatives of those who use the service and those who deliver the service, together with a representative of the organization's management team. The users will include physicians, nurses, other healthcare providers, and maybe even a patient. The providers should include at least one representative from the laboratory and of those involved in the use of other diagnostic and therapy equipment close to the patient (e.g., respiratory measurement technologists, nurses). Typically, a laboratory professional will chair such a committee because it is the laboratory that will provide the necessary backup if a service failure occurs; furthermore, the laboratory professional will have had training and will have gained expertise regarding the analytical issues that are likely to arise. For many reasons, the committee should report to the medical director of the provider organization. The committee should then designate members who will take responsibility for overseeing the training and certification of all POCT operators, and also for QC and quality assurance. The work of the committee should be governed by the organization's policy on POCT.

POCT POLICY AND ACCOUNTABILITY

Implementation of a POCT service requires a POCT policy that establishes all of the procedures required to ensure delivery of high-quality service, together with the responsibility and accountability of all staff associated with the POCT. This may be (1) part of the organization's total quality management system,[63] (2) part of its clinical governance policy,[44] and (3) required for accreditation purposes.[19,20] The elements of a POCT policy are listed in Box 20-4.

EQUIPMENT PROCUREMENT AND EVALUATION

Equipment procurement and evaluation involve first identifying candidate POCT equipment having the prerequisite analytical and operational capabilities to meet the clinical requirements of a POCT service. Performance requirements should then be established and compared with the performance characteristics of these devices (obtained from the manufacturer or assessed as part of the procurement exercise). These characteristics include parameters such as

accuracy, precision, specificity for the analyte, turnaround time (TAT), calibration frequency, potential interferents, calibrator and reagent stability, lot-to-lot variation for reagents and calibrators, and QC requirements. In addition, operational requirements have to be identified, and the potential for operator error (e.g., effects of delayed addition of the sample and use of an incorrect sample volume) determined. Independent validation of these analytical and operational characteristics can be obtained from (1) published evaluations performed by agencies such as the Medicine and Healthcare Products Regulatory Agency (MHRA) in the United Kingdom; (2) Norwegian Quality Improvement of Primary Care Laboratories[96]; and (3) reports in the peer-reviewed literature. When performance data are reviewed, particular attention should be paid to the precision and accuracy of measurement, including concordance between results from the POCT device and the routine laboratory method, because patients are likely to be managed using both analytical systems. Evaluation of analytical performance is discussed in a CLSI guideline on selection criteria for POCT equipment.[28]

An economic assessment of the equipment, including the costs of consumables and servicing, should also be completed. Any comparison of costs with the laboratory service will highlight only the cost per test, which, as stated earlier, will not give an accurate assessment of the cost-effectiveness of using the system. However, it is helpful at this point to obtain a good assessment of the relative staff costs associated with different systems, because these are likely to be key features in the decision-making process.

After comparison data have been obtained, tabulated, and interpreted, a POCT device is selected if the assessment has indicated value in using such an approach. It is recommended that the laboratory professional should then conduct a short evaluation of the equipment to gain familiarization with the system. This evaluation will help to determine the content of the training program that will be used, as well as a troubleshooting protocol. Such an evaluation should document the concordance between results generated with the device and those provided by the laboratory. All of this information should then be recorded in a logbook associated with the equipment. In addition, the organization may wish to undertake some form of safety check, give the device some form of local code, and enter the code into the local equipment register.

TRAINING AND CERTIFICATION OF OPERATORS

The confidence of the clinician, the healthcare provider, and the patient in results generated by a POCT device depends heavily on the robustness of the instrument and the competence of the operator, assuming that it has already been shown to meet the analytical requirements of the clinical setting. Many of the agencies involved in the regulation of healthcare delivery now require that all personnel associated with the delivery of diagnostic results demonstrate their competence through a process of regulation, and this applies equally to POCT personnel.

BOX 20-5 Main Elements of a Point-of-Care Testing Training Program

Understanding the context of the test—pathophysiologic context
- Clinical requirement for the test
- Action taken on basis of result
- Nature of test and method used

Patient preparation required—relevance of diurnal variation
- Relevance of drug therapy

Sample requirement and specimen collection
Preparation of analytical device—machine and/or consumables
Performance of test
Performance of quality control
Documentation of test result and quality control result
Reporting of test result to appropriate personnel
Interpretation of result and sources of advice
Health and safety issues (e.g., disposal of sample and test device, cleaning of machine and test area)

The elements of a training program are listed in Box 20-5. In practice, such a program is tailored to suit the needs of the individual and the organization.[123] These may include formal presentation to groups, or on a one-to-one basis, self-directed learning using agreed documentation, or computer-aided learning. For example, several of the current models of blood gas and electrolyte analyzers have onboard computer-aided training modules. Whatever the training strategy employed, it is important to document satisfactory completion of training, and that the individual has been tested and found competent with a combination of questions concerned with understanding and practical demonstration of the skills gained. The latter can be achieved by performing tests on a series of QC materials and repeat testing of samples that have been analyzed recently (parallel testing). Finally, the operator should be observed on a minimum of three occasions throughout the procedure involved in the POCT.

Competence on a long-term basis is maintained through regular practice of skills and continuing education; it is important to build these features into any education and training program. Regular review of performance in QC and quality assurance programs will provide a means of overseeing the competence of operators. However, this is not always sufficient, particularly when operators are employed on irregular shifts or may not always be called upon to perform POCT. In this latter situation, it may be necessary to create specific arrangements for individuals to undertake tests on QC material. The error log may highlight when problems are arising. However, the most important thing is to encourage an open approach to the assessment of competence, so that operators themselves can seek help if they believe that problems are occurring. Such an open approach should

be supported with audit and performance review meetings where problems are aired and developments discussed. Regular assessment of competence should be built into a formal program for recertification that will be a requirement of most accreditation programs.

QUALITY CONTROL, QUALITY ASSURANCE, AND AUDIT

Quality control and quality assurance programs provide a formal means of monitoring the quality of a service (see Chapter 8). The within-organization QC program offers a relatively short-term view of performance and typically compares current performance with acceptance criteria for the measurement device. External quality assurance (proficiency testing) on the other hand takes a longer-term view and in some respects addresses other issues surrounding the quality of the result. Thus external quality assurance method compares the testing performance at different sites and/or with different pieces of equipment or methods.[18,131] An audit is a more retrospective form of analysis of performance and, furthermore, it can provide a more holistic view of the whole process. However, the foundation to ensuring good quality remains a successful training and certification scheme.

Classically, quantitative within-laboratory (or within-organization) QC involves analysis of a sample for which the analyte concentration is known, either because the material has been analyzed on many occasions and the distribution of results documented, or because it has been analyzed independently and the mean and interval range of results have been quoted for the method used. The essence of using within-laboratory QC material is to establish the interval of results that is acceptable; the current analytical result is compared with the interval of results deemed acceptable (see Chapter 8). The QC result must then be documented, usually graphically, because it shows the conformity of results to preestablished acceptance criteria and any trends in results that may be occurring. The major aim is to use a means of documentation that ensures that comparative performance is assessed.

Several challenges have been put forth regarding the classical approach with POCT. The first concerns the frequency of testing—should a QC sample be analyzed every time that (1) a sample is analyzed, (2) a new operator uses the system, (3) a new lot number of reagents is used, or (4) the system is recalibrated? No consistent agreement on the correct approach has been reached, and one probably has to be guided by the reproducibility and overall analytical performance of the system and local circumstances, such as the (1) number and competence of the operators, (2) frequency with which the system is used, and (3) risk to the patient of an erroneous result not being detected. For a benchtop and/or multitest analyzer, the frequency of measuring QC samples conforms to regulatory requirements applicable to the measurement setting. It can be argued that with the frequent turnover of staff in larger institutions, frequency should be a minimum of once per shift—three times a day. Many critical care analyzers can be programmed to perform a QC check at intervals set by those responsible for the device.

For single-use POCT disposable devices, the previous strategy does not completely monitor the quality of the test system.[103,135] For example, when conventional QC material is analyzed on a unit-use or single-test POCT system, only that testing unit is monitored. Thus it is impossible to test every unit with control material because by definition they are single-test systems. Under these circumstances, greater dependence is placed on the manufacturing reproducibility of devices, to ensure a good quality service.[24]

Some users may wish to continue with a QC testing strategy that is similar to that applied for multiuse devices. If testing is infrequent, another approach that can be used would be to analyze a QC sample whenever a change to the testing system occurs, such as with a different batch of testing materials or a different operator.[27] However, it is important to follow the manufacturer's recommendations. Other QC approaches may be used, but many do not test the whole process. For example, the use of a plastic surrogate reflectance pad as a QC sample will test only the performance of the reflectance meter and not processes such as sample addition, reagent stability, reagent calibration, or performance of the test. Similarly, other forms of electronic QC checks only verify the functionality of the electronic systems.[135]

External quality assurance or proficiency testing is a systematic approach to QC monitoring in which standardized samples are analyzed by one or more laboratories to determine the capability of each participant. With this approach, the operator has no knowledge of the analyte concentration. Results are transmitted to a central authority, which then prepares a report and returns a copy to each participating laboratory. The report will identify the results obtained for the complete group of participants and may be classified according to the different methods used by participants in the scheme. The scheme may encompass both laboratory and POCT users, which gives an opportunity to compare results with laboratory-based methods. In practice, external quality assurance or proficiency testing is used in POCT to determine and document long-term performance and concordance of results among users of the same POCT devices, and, when commutable samples are used, between the POCT service and an organization's central laboratory. It is also possible to operate an external quality assurance scheme within a hospital or organizational setting; such a scheme typically would be run by qualified laboratory personnel. If authentic patient samples are used for a scheme within a hospital or organizational setting, the results reported by the laboratory and by other POCT sites within the same organization can be compared. This can be important when patients are managed in several departments, or when devices are not available and samples are taken to other sites for testing. When deteriorating or poor performance is identified in one of these schemes, it is important to document the problem and then to provide and document a solution. It may be necessary as part of this exercise to review some of the patient's notes to ensure that incorrect results have not been

tahir99-VRG & vip.persianss.ir

reported and inappropriate clinical actions taken. In addition, if the solution highlights a vulnerable feature of the process overall or for one particular operator, process improvement or retraining must be instituted.

An example of data from an external quality assurance scheme for POCT is shown in Figure 20-11. Such schemes are run on national and international bases, and some Website schemes are listed in the references.[29,126,133]

MAINTENANCE AND INVENTORY CONTROL

Implementation and maintenance of a POCT service require that a supply of devices (both instrumentation and consumables) be maintained at all times, and that this is supported by a formal program. This approach may be taken for larger benchtop systems within a large organization; however, similar arrangements (e.g., rapid replacement of faulty units) can be achieved for smaller organizations (e.g., a physician's office laboratory) through an appropriate arrangement with the supplier. In the case of consumables, the key points in this process are to (1) adhere to recommended storage conditions for reagents, calibrators, and controls, (2) be aware of the stated shelf life of consumables, and (3) ensure that stocks are released in time for any preanalytical preparation to be accommodated (e.g., thawing). When multiple sites are using the same materials, a central purchasing, supply, and inventory control system should be put in place—not only to gain benefit from bulk purchasing, but also to ensure that individual systems are not supplied unknowingly with different batches of consumables.

Complexity in the maintenance of reusable devices will vary from system to system, but clear guidelines will be available from the manufacturer and should be adhered to rigorously. Issues that usually require particular vigilance include expiration dates, biocontamination, electrical safety, maintenance of optics, and inadvertent use of inappropriate consumables.

DOCUMENTATION

Documentation of all aspects of a POCT service has been a major issue for many years, compounded by the fact that the storage of data in laboratory and hospital information systems has often been limited and inconsistent. Thus it is critically important to keep an accurate record of the test request, the result, and the action taken—as an absolute minimum. Although the last point may be seen as beyond the scope of the laboratory, the incidence of errors in laboratory medicine that have been attributed to preanalytical and postanalytical phases suggests that the laboratory should play a more integrated role in the whole care process. Some of the issues concerning documentation are now being resolved with the advent of the electronic patient record, electronic requesting, and better connectivity of POCT instrumentation to information systems (see earlier discussion). Documentation should extend from the standard operating procedure(s) for the POCT systems to records of training and certification of

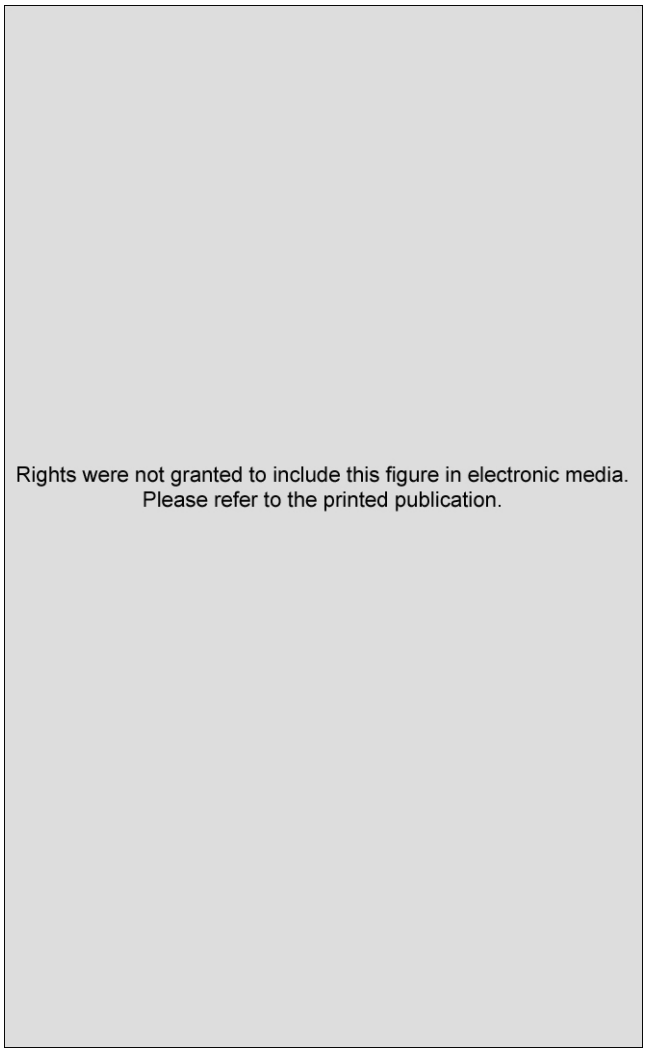

Figure 20-11 Extract of data from a recent distribution of the U.K. NEQAS Glycated Hemoglobin scheme. The "*B score*" is the average of % biases of all samples distributed within the six-distribution rolling time window. In the HbA_{1c} scheme, three samples are sent out per month, so this will be 18 samples. Data are trimmed by 10% at either end of the ranked data set, so that the middle 14 results are used to calculate average % bias and hence the *B score*. The "*C score*" is the standard deviation of the *B score*, adjusted by the method of Healy to correct for the amount of trimming performed. The *B score* therefore is a smoothed, robust indicator of average bias, and the *C score* is an estimator of the variability of this bias for different samples with different analyte concentrations in the scoring time window. A high *C score* may have components of within-run imprecision, between-run reproducibility, batch-to batch reagent variability, and concentration-dependent bias. The limits of B and *C scores* shown by *dotted lines* on the plots are those agreed to by the National Quality Assurance Advisory Panel for Chemical Pathology, outside of which laboratories are deemed to have unacceptable performance. Laboratories with scores persistently outside these limits may be contacted by the Panel, and ultimately intervention may be required. *(Courtesy Dr. J. Middle, U.K. NEQAS.)*

operators, reagents, calibrator and control inventory, verification of performance of devices and shipments of consumables, and QC and external quality assurance, together with error logs and any corrective action taken.

ACCREDITATION AND REGULATION OF POCT

The features of the organization and management of POCT described previously should be the same as those for accreditation of any diagnostic services.[19,20] Accreditation of POCT should be part of the overall accreditation of laboratory medicine services, or indeed should be part of the accreditation of the full clinical service, as has been the case for several years in many countries, including the United States and the United Kingdom. Thus the Clinical Laboratory Improvement Amendments of 1988 (CLIA) and the final rule on quality systems requirements as specified in 2003 legislation in the United States stipulate that all POCT must meet certain minimum standards.[127-129] In the United States, the Centers for Medicare and Medicaid Services, the Joint Commission on Accreditation of Healthcare Organizations, and the College of American Pathologists are responsible for inspecting sites, and each is committed to ensuring compliance with testing regulations for POCT.[38]

FUTURE OF POCT

In the previous edition of this chapter, we suggested that the three key drivers for expansion of POCT services in the future will be (1) changes in the way healthcare is provided, (2) patients' needs and expectations, and (3) technological innovations. We also observed that trends in the way that clinical care is being delivered are completely opposite to those in which diagnostic testing services are moving. Observations on healthcare provision in the United States as put forth by the Institute of Medicine[73] have been reiterated in many other countries,[113] with similar conclusions such as recommending more patient-centered care, improved access, and better choices for patients. Christensen and coworkers[23] suggested that POCT and information technologies (namely, connectivity, the electronic patient record, and decision support systems) provide some of the key technologies to enable a disruptive solution to the provision of healthcare, namely, offering solutions to the problems that many health systems face today by radically changing the way that care is organized and delivered.

Patient expectations are increasing and will drive the trend toward a more patient-focused style of care, with fewer clinic visits, shorter waiting times, and an expectation of better care. POCT has been shown to be capable of shorter "lengths of stay" and, in many cases, improved health outcomes. As health service decision makers (both purchasers and providers) realize that it is possible to achieve lower "costs per patient episode" with the use of POCT, more effort will be put into this testing modality. So what will facilitate this revolution? The answer lies in new technology—in terms of the development of new delivery platforms and the discovery of new markers—with the use of new business models and value networks.[23,109]

Considerable efforts are being made to develop and manufacture miniaturized analytical devices (see Chapter 18) that will enable faster analytical times to be achieved, with smaller sample requirements. Several examples in the field of microfabricated devices have been shown to meet these aspirations.[76-78,109] In the future, continued technological advances will result in even smaller devices that can be tailored for a large number of analytes and that are very simple to operate.

Noninvasive testing remains the "holy grail" for POCT, and over the past two decades, evidence has suggested some success in this area. Most work has been performed on a range of imaging techniques that seek a signature of the molecule of interest (e.g., glucose) from among the many signatures of the extracellular and tissue matrices.[71,88,91,104] Alternative approaches have sought to access the extracellular fluid space or to sample extracellular fluid directly, as with the Glucowatch[124] and other developments.[109]

Areas of testing that are showing significant progress include (1) testing for infectious agents using molecular-based techniques, (2) testing for predisposition to disease, and (3) assessing an individual's response profile toward a new drug. In all three scenarios, the key to having a POCT is the need for early decision making to implement therapy (or life-style change), together with the need for patient counseling. The technology is clearly available to detect any form of biological entity at the point-of-care, including very rapid analysis of deoxyribonucleic acid (DNA) from saliva samples.[45,109] However, many ethical issues surround analysis for genetic predisposition and tests for certain infectious diseases (see Chapter 1). These developments notwithstanding, evidence also indicates that POCT is being used increasingly in the management of long-term conditions—probably the area where the greatest volume of testing is focused.

If one accepts that patient empowerment is a key development in healthcare for the future, self-testing is likely to increase. This is an area that is well established for blood glucose and is increasingly used in the management of oral anticoagulation therapy. As emphasis slowly moves toward health promotion and wellness monitoring, issues of access to testing will become significant drivers of the use of diagnostic tests. Perhaps the most interesting aspect of patient empowerment, however, is the fact that it changes the relationship between the patient and the health professional. It could be argued that in the not too distant future, the patient will not be expected to make an appointment or to travel to see the health professional, but rather will expect better access and convenience. This vision requires a totally new way of assessing "clinical need" and a better understanding of all of the processes of care, as well as stakeholder needs, as advocated by Donabedian,[37] who investigated system redesign in search of improved quality of care.[109] This may lead to a totally different perspective on the repertoire (and combinations) of tests required for POCT, as well as on the way in which care is delivered.

Amino Acids, Peptides, and Proteins

*Glen L. Hortin, M.D., Ph.D**

Amino acids, peptides, and proteins are crucial for virtually all biological processes. Amino acids have diverse roles in metabolism, neurotransmission, and intercellular signaling, as well as serving as structural subunits of peptides and proteins. Peptides include many hormones, signaling molecules, and protein fragments that are of physiologic and diagnostic significance. Nucleic acids provide the information or software program, and proteins serve as the hardware that performs most cellular functions. Proteins are multifunctional and constitute the machinery of life. Biologically, they (1) form many important intracellular and extracellular structures; (2) generate energy through catalysis and electron transfer; (3) produce motility through contractile elements; (4) assemble molecules; (5) serve as ion channels and pumps; (6) act as carriers; (7) perform immune defense; (8) serve as receptors, hormones, and cytokines for intercellular regulation; and (9) constitute signaling networks for intracellular regulation.

In humans, more than 20,000 genes encode proteins. Completion of the sequence of the human genome defines much of the sequence information for proteins and facilitates the identification of protein and peptide sequences. The number of proteins is greater than the number of genes, however, because of variable splicing of messenger RNA (mRNA), somatic recombination and mutation, proteolytic processing, and numerous post-translational modifications of proteins. The Human Antibody Initiative has developed specific antibodies for thousands of human proteins, and these antibodies have been used to assemble a Human Protein Atlas that uses immunohistochemistry to define the expression of more than 5000 proteins in different tissues of the body (http://www.proteinatlas.org/accessed April 19, 2011).[124] These efforts serve as major resources for identification of tissue sources of proteins and potential assay reagents. Many proteins are secreted or leak out of cells in response to cellular injury or turnover, allowing their analysis in biological fluids such as blood and urine. The *proteome* represents the complete set of proteins in an organism or subcompartment of an organism such as the plasma space.[3] Initial efforts of the Human Proteome Organization's (HUPO's) Plasma Proteome Project tentatively identified sequences of about 3000 gene products in plasma, and many structural variants of these gene products may exist.[114,117] Several databases include extensive information about the sequence and post-translational modification of proteins. The U.S. National Library of Medicine and the Swiss Institute of Bioinformatics maintain gene and protein databases and sequence analysis tools that are available via the Internet [http://www.ncbi.nlm.nih.gov/accessed April 19, 2011 and http://ca.expasy.org/accessed April 19, 2011; The HIP2 Database (Healthy Human Individual's Integrated Plasma Proteome); http://bio.informatics.iupui.edu/HIP2/accessed April 19, 2011/] and include data on more than 12,000 protein entries].[134] The Human Protein Reference Database and Human Proteinpedia are additional resource (http://www.hprd.org/accessed April 19, 2011).[101] Most databases are designed mainly to assist with peptide and protein identification, and more data are needed related to the abundance of components in healthy and diseased populations, which is the usual basis for diagnostic applications.[2,3,60]

This chapter begins with a discussion of the properties and metabolism of amino acids. Inherited disorders of amino acid metabolism are discussed in Chapter 58. A general description of protein structure is followed by information on several high-abundance proteins in plasma and several other fluids including cerebrospinal fluid. This chapter provides limited discussion of urinary proteins, which are covered in Chapters 25 and 48. Virtually all tissues contribute proteins to plasma via secretion or cell injury. The resulting diversity of plasma proteins leads to high informational content and broad clinical utility of the analysis of proteins in plasma or serum. Other proteins are discussed in the chapters on enzymes (see Chapter

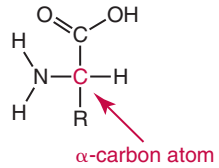
22), tumor markers (see Chapter 24), lipoproteins (see Chapter 27), hormones (see Chapter 29), and specific disease processes. Chapter 32 describes analysis of hemoglobins, which are the major protein component of whole blood and are major plasma components when red blood cell lysis occurs.

AMINO ACIDS

Amino acids are major metabolic intermediates and the basic structural units of proteins. Their measurement in physiological fluids assists with fundamental studies of metabolism and the diagnosis of pathologic processes and inherited conditions.

Basic Biochemistry

Amino acids are organic compounds containing both an amino group (—NH_2) and a carboxyl group (—COOH) or another acidic group such as sulfonic acid (—SO_3). Technically, proline, hydroxyproline, and sarcosine are imino acids (—NH—), but they usually are grouped together with amino acids. Those occurring in proteins are α-amino acids, with amino groups linked to the α-carbon, as diagrammed here:

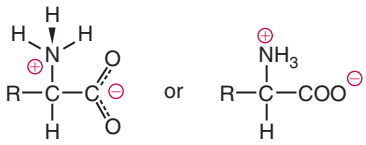


R represents a variety of different sidechains as listed in Table 21-1. Amino acids in physiologic fluids also include β-amino acids such as β-alanine and taurine, and γ-amino acids such as γ-aminobutyric acid (GABA).

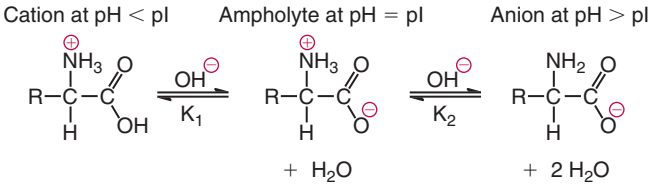
With the exception of glycine, all α-amino acids are asymmetric about the α-carbon, with four different groups linked to this carbon. Most α-amino acids in humans, including all of the amino acids incorporated into protein, have the L-configuration. Small quantities of D-amino acids occur in physiological fluids. In most cases, these are not known to have specific functions. An exception is D-serine, which represents 5 to 20% of total serine in cerebrospinal fluid; D-serine may serve as a neurotransmitter.[41] Amino acids with the D-configuration occur in some bacterial products, foods, and pharmaceuticals. D-Amino acid oxidases in liver and kidney convert D-amino acids to ketoacids, which can be metabolized. L-Amino acids in proteins undergo slow racemization to a mixture of L- and D-amino acids over many years. Aspartic acid undergoes the most rapid racemization and can be used to estimate the time of synthesis of proteins undergoing very slow turnover, such as lens proteins in the eye or collagens in intervertebral disks, where half-lives may exceed 50 years.[145] Two amino acids—threonine and isoleucine—have a second asymmetric carbon, and the stereoisomers are referred to as *allothreonine* and *alloisoleucine*. Table 21-1 diagrams the structures of the 21 amino acids that are encoded by codons in messenger RNA and incorporated into proteins. Twenty amino acids are incorporated into most proteins. Selenocysteine is a special case of an amino acid synthesized on a specific transfer RNA and incorporated into a few sites in only about 25 proteins.[92] Many additional amino acids are generated by post-translational modification of proteins or by metabolism.

Acid-Base Properties of Amino Acids

Acid-base properties of amino acids depend on the amino and carboxyl groups attached to the α-carbon and on the basic or acidic groups occurring on some sidechains (R). In the physiologic pH range of plasma near pH 7.4, the carboxyl group is dissociated, and the amino group is protonated to give the following structure:



Thus, at neutral pH, amino acids have both positively and negatively charged groups and occur as zwitterions.



The pH at which an ionizable group, such as an amino or carboxyl group, occurs equally in charged and uncharged forms is referred to as the pK for that group. Amino acids have two or more pKs, including one for the carboxyl, one for the amino group, and an additional pK if an ionizable sidechain is present. The isoelectric point (pI) is the pH where an amino acid or other molecule has a net charge of 0. For a typical neutral amino acid such as glycine, the pI of 5.97 is midway between the pK_1 of 2.34 for the carboxylic acid and the pK_2 of 9.60 for the amino group. Ionization constants for amino acids are given in Table 21-2. The pKs of amino acid sidechains in proteins vary somewhat because of the influence of neighboring amino acids.

The buffering capacity of ionizable groups is primarily in a pH range within ±1 of the pK for the respective groups. Amino acids and proteins therefore have a limited buffering capacity near physiologic pH, mainly caused by the contribution of imidazole sidechains of histidine. Amino acids serve as buffers at pHs near the pKs of their ionizable groups; glycine, for example, sometimes is used as a buffer near pH 2.5 or 9.5.

Hydrophobicity, Solubility, and Stability of Amino Acids

Sidechains produce variation in the properties of different amino acids. Table 21-1 shows the structures of amino acids, molecular weights, and the Kyte and Doolittle index of the hydrophobicity of their sidechains.[83] Amino acids with longer

TABLE 21-1 Amino Acids Incorporated into Protein, Their Properties and Structures

Name and Abbreviation	HI	MW*	Structure at pH 6-7	Comments
I. Neutral Amino Acids				
Alanine Ala, A	1.8	89.09		Important metabolic substrate in alanine cycle; substrate for ALT
Leucine Leu, L	3.8	131.17		Essential; branched-chain R group; ketogenic; metabolism is faulty in maple syrup urine disease
Isoleucine Ile, I	4.5	131.17		Essential; partly ketogenic; see leucine above
Valine Val, V	4.2	117.17		Essential; partly ketogenic; see leucine above
Proline Pro, P	1.6	115.13		Has α-imino rather than α-amino; high content in collagens and can be hydroxylated to hydroxyproline; destabilizes α-helical structures
Methionine Met, M	1.9	149.21		Essential; important as donor of methyl groups; provides sulfur for other sulfur-containing compounds
Phenylalanine Phe, F	2.8	165.19		Essential; elevated concentrations in phenylketonuria as conversion to Tyr is impaired.
Tryptophan Trp, W	–0.9	204.22		Essential; metabolites in carcinoid disease; contains indole ring; precursor of serotonin, melatonin
Glycine Gly, G	–0.4	75.07		No stereoisomer; used in biosynthesis of purines and porphyrins; transfer to bile acids, hippurates, and other conjugates
Serine Ser, S	–0.8	105.09		Source of one-carbon groups for folates; can undergo post-translational addition of phosphate, sugars
Threonine Thr, T	–0.7	119.12		Essential; can undergo post-translational addition of phosphate or sugars
Cysteine Cys, C	2.5	121.16		Sulfhydryl group in active sites of some enzymes; forms disulfides; homocysteine is homolog with sidechain one carbon longer
Selenocysteine Sec, U		168.05		Active form of selenium; found in some enzymes involved in oxidation-reduction reactions; formed on a specific transfer RNA

Continued

TABLE 21-1 Amino Acids Incorporated into Protein, Their Properties and Structures—cont'd

Name and Abbreviation	HI	MW*	Structure at pH 6-7	Comments
Tyrosine Tyr, Y	−1.3	181.19		Usually nonessential; intermediate in synthesis of catecholamines, thyroxine, and melanin; functional phenolic group
Glutamine Gln, Q	−3.5	146.15		Transport form of ammonia; supplies nitrogen atoms used in purine and pyrimidine biosynthesis
Asparagine Asn, N	−3.5	132.12		Attachment site of oligosaccharides in Asn-Xxx-(Ser or Thr) sequences
Acidic Amino Acids				
Aspartic acid Asp, D	−3.5	133.10		Precursor for pyrimidine and purine biosynthesis; a substrate in urea cycle
Glutamic acid Glu, E	−3.5	147.13		Transport form of ammonia γ-glutamyl transfer from glutathione; a neurotransmitter
Basic Amino Acids				
Lysine Lys, K	−3.9	146.19		Essential; sidechain has an additional amino group
Arginine Arg, R	−4.5	174.20		Involved in urea synthesis; sidechain has a guanidinium group
Histidine His, H	−3.2	155.16		The imidazole group has a pK near physiologic pH, so charge can vary with physiologic pH change

*A higher value for hydropathy index (HI)[83] indicates greater hydrophobicity of amino acid sidechains.

aliphatic or aromatic sidechains such as isoleucine, leucine, and phenylalanine have greater hydrophobicity than shorter sidechains such as alanine, indicating lower water solubility. Neutral amino acids having polar groups such as hydroxyl or amide groups in their sidechains are more hydrophilic. Acidic amino acids have sidechains with carboxylic acids, and basic amino acids have sidechains with amino, guanidine, or imidazole groups. Acidic and basic sidechains generally represent highly polar and water-soluble sidechains. The structural diversity of sidechains contributes to the participation of amino acids in many metabolic pathways and the ability to form proteins with wide variation in structure and physical properties. The occurrence of an imino rather than an amino group in proline results in some differences in physical properties and reactivity of proline and in the geometry of peptides containing proline.

Amino acids generally occur freely in solution in plasma and other physiologic fluids, with a few exceptions. The thiol group of cysteine and homocysteine and small peptides such as cysteinylglycine and glutathione oxidize easily and become linked to other molecules via disulfides in the extracellular space, which is an oxidizing environment. This contrasts with the cytoplasm, which is predominantly a reducing environment maintained by a high concentration of glutathione in reduced form.[127] In plasma, cysteine occurs as cystine (dimeric cysteine linked via a disulfide) or as a mixed disulfide with

TABLE 21-2 Ionization Constants of Ionizable Groups in Free Amino Acids and in Proteins*

Ionizing Group		Range of pK Values: Free Amino Acids	Range of pK Values: Proteins
Principal carboxyl = pK_1		1.7-2.6	3.0-3.2
α-Amino = pK_2		9.0-10.8	7.6-8.4
Second carboxyls of Glu and Asp		3.8-4.3	3.0-4.5
Imidazole nitrogen of His		6.0	6.0-7.0
Sulfhydryl of Cys		8.3	9.1-10.8
Phenolic hydroxyl of Tyr		10.1	9.2-9.8
ε-Amino of Lys		10.5	9.4-10.6
Guanidinium group of Arg		12.5	11.5-12.6

*The pK value for the primary carboxyl varies from 1.71 for Cys to 2.63 for Thr. The pK for the α-amino group varies from 8.95 for Lys to 10.78 for Cys. In protein chains, the local environment modifies the pK for any given ionizable group. The amino acid symbols are listed in Table 21-1.

albumin or other proteins. About half of cysteine is covalently bound to protein and can be released by the addition of reducing agents. Analysis of amino acids without reduction detects only the cystine component. Homocysteine, cysteinylglycine, and glutathione are similarly distributed as mixed disulfides with cysteine or protein.[157] During storage of plasma specimens, some change in the distribution of homocysteine occurs, and the proportion bound to protein increases.[59,157] Tryptophan is another amino acid that occurs approximately 50% bound to albumin, although in this case the binding is noncovalent.

Most amino acids are water soluble and stable in plasma specimens, again with a few exceptions. Solubility of cystine and a few of the more hydrophobic amino acids can be limiting in some disorders of transport or metabolism. Crystals of cystine, leucine, or tyrosine may deposit when concentrations become elevated in urine in cystinuria or tyrosinemia or within intracellular compartments in cystinosis. Glutamine degrades in solution as the result of intramolecular cyclization to pyroglutamic acid (also termed *5-oxoproline*) with release of ammonia. Quantification of glutamine therefore requires rapid processing of specimens and frozen storage, similar to requirements for ammonia analysis. Homocysteine (usually measured as total homocysteine after reduction) is stable in plasma but requires rapid processing of blood specimens to avoid elevation resulting from continuing release from cells.[128] Arginine can be degraded in specimens with increased arginase concentrations; some arginase is present in erythrocytes and may be increased by hemolysis.[112]

Amino Acid Metabolism

Amino acids participate in many metabolic pathways, in addition to serving as a substrate for protein synthesis.[31] In the healthy state, women require ≈46 g/d and men ≈56 g/d of dietary protein (0.8 g/kg body weight), and substantial increases in demand occur during growth and in many disease states.[118] Dietary protein is digested by proteases in the stomach and small intestine to yield amino acids. Endogenous protein turnover serves as another source of free amino acids. Dietary sources and endogenous turnover, therefore, serve as dual sources of amino acids for protein synthesis. Eight amino acids used for protein synthesis—(1) isoleucine, (2) leucine, (3) lysine, (4) methionine, (5) phenylalanine, (6) threonine, (7) tryptophan, and (8) valine—are not synthesized by humans and therefore are considered "essential" constituents of the diet. Meat, milk, eggs, and fish contain a full range of essential amino acids. Gelatin is deficient in tryptophan, and individual plant sources of protein may be deficient in lysine, methionine, or tryptophan. Diets based on a single source of plant protein may be deficient in some amino acids. When liver function is compromised,[162] cysteine and tyrosine become essential because they are not converted from their usual precursors methionine and phenylalanine. Arginine may be conditionally essential.[112] Essential amino acids usually have been defined for the entire body, but additional amino acids may be essential for specific tissues or for some human cells in culture. As an example, administration of asparaginase to deplete asparagine is useful therapy for acute

lymphoblastic leukemia, because the lymphoblasts are not able to synthesize asparagine. Glutamine is considered to be an important metabolic substrate for immune cells and enterocytes.[132] Supplementation of glutamine and arginine may be beneficial in critically ill patients.[162]

Requirements for dietary protein to maintain nitrogen balance increase per unit body weight during infancy and childhood when there are demands for protein for growth, and in pregnancy, lactation, and states of protein loss or catabolic states.[24,80] Daily requirements increase by up to 3.5 to 4 g protein/kg body weight for premature infants.[50] A diet severely deficient in protein and consisting primarily of high-starch foods can lead to kwashiorkor, with decreased serum albumin, immune deficiency, edema, ascites, growth failure, apathy, and many other symptoms.[67] Marasmus results when protein and energy sources such as carbohydrates are deficient; protein-calorie starvation causes generalized wasting of muscles and subcutaneous tissues and lesser edema. Inadequate nutrition is frequently a problem in surgical, burn, or trauma patients in a catabolic state and with decreased food intake.[69] Negative nitrogen balance can contribute to delayed wound healing and impaired immunity. Measurements of plasma markers such as albumin or prealbumin are indicators of adequacy of the amino acid supply. Protein intake is related to urinary urea and acid excretion in the form of sulfate. A high-protein diet promotes excretion of acidic urine, and a vegetarian diet of a neutral urine. In kidney disease, high protein intake appears to be harmful, and protein restriction has been used as a therapeutic intervention to slow the progress of kidney disease.[89]

Amino acids normally are released from dietary protein by degradation with pepsin in the acidic environment of the stomach and with pancreatic hydrolases added in the duodenum.[31] Digestion of protein may be impaired by gastric or pancreatic disorders. Uptake by intestinal and other cells occurs by active transport with several separate transport systems that handle neutral amino acids, acidic amino acids, basic amino acids, and cystine, glycine, and proline. Amino acids are actively transported by γ-glutamyltransferases that transport amino acids by linking them to glutamic acid transferred from glutathione. Active transport maintains higher concentrations of amino acids inside cells than outside in the extracellular space and, in renal tubules, reclaims most amino acids that undergo glomerular filtration.[70]

Amino acids are critical intermediates in many metabolic pathways, including the urea cycle for converting ammonia to urea and the alanine cycle for transferring nitrogen and fuel sources from muscle to liver, both described later. Other major pathways include ammonia generation in the kidney from glutamine and glutamic acid, glutathione formation and reduction to maintain a reducing environment intracellularly, and the glutathione cycle for cellular uptake of molecules.[127] Amino acids are precursors for many hormones and signaling molecules such as thyroid hormones, catecholamines, serotonin, melatonin, nitric oxide, and hydrogen sulfide. Activated pathways for metabolism of tryptophan and cysteine are effector pathways for interferon action.[139] Serine is a major source of one-carbon units transferred by tetrahydrofolic acid for purine synthesis, methylation of deoxyuridylic acid to thymidylic acid, and conversion of homocysteine to methionine. Glycine, aspartic acid, glutamine, and serine contribute atoms to purine and pyrimidine synthesis. Glycine and arginine are precursors for creatine synthesis. Methionine serves as a methyl donor after activation as S-adenosylmethione for a wide range of methylation reactions, including creatine synthesis, protein methylation, and choline synthesis, and yields homocysteine as a byproduct. Several amino acids participate in conjugation reactions that serve as excretory pathways and generate products such as glycine or taurine conjugates with bile acids. Cysteine and glutathione form mercapturates with reactive compounds as a protective mechanism. Metabolism of the sulfur-containing amino acids generates sulfate, which is excreted in urine in increased amounts with consumption of high-protein diets.

The alanine cycle is a metabolic pathway that allows muscle cells to use amino acids as a fuel source and to export excess nitrogen in the form of alanine, which then is metabolized in the liver as diagrammed in Figure 21-1. In muscle cells, ammonia is transferred from amino acids to pyruvate by aminotransferases to form alanine. Alanine is excreted from muscle cells and is taken up by the liver, where aminotransferases transfer ammonia from alanine to 2-oxoglutarate, forming pyruvate and glutamic acid. Pyruvate can serve as a substrate for gluconeogenesis or for energy, and glutamate serves as a donor for urea synthesis. This pathway explains the need for high aminotransferase catalytic amounts in liver and muscle.

The urea cycle converts ammonia to urea in the liver (see Chapter 50). Ammonia, bicarbonate, and ATP join in formation of carbamoylphosphate, which is transferred to ornithine to form citrulline. Aspartic acid and citrulline are condensed to form arginosuccinic acid, which, in turn, is cleaved to arginine and fumaric acid. Arginase hydrolyzes arginine to urea and ornithine to allow the cycle to repeat. Net changes from the cycle include input of ammonia, bicarbonate, aspartic acid, and energy in the form of ATP and output of urea and fumaric acid. Urea usually is viewed simply as a waste product, with urea production related to protein intake. However, one beneficial action of urea is its contribution to the ability of kidneys to concentrate urine. Urea is the main component accounting for high osmolality in the renal medulla, and maximal urinary concentrating ability decreases when protein intake is low and urea production is decreased.

Amino Acid Concentrations

Plasma amino acid concentrations are high during the first days of life, especially in premature neonates, but they tend to be low in infants with low birth weight for gestational age because of placental insufficiency. *Plasma* amino acid concentrations vary by about 30% during the day; therefore, blood specimens should be collected at the same time each day. Values are highest in midafternoon and lowest in early morning. This diurnal variation affects detection of heterozygous defects in metabolism.[70]

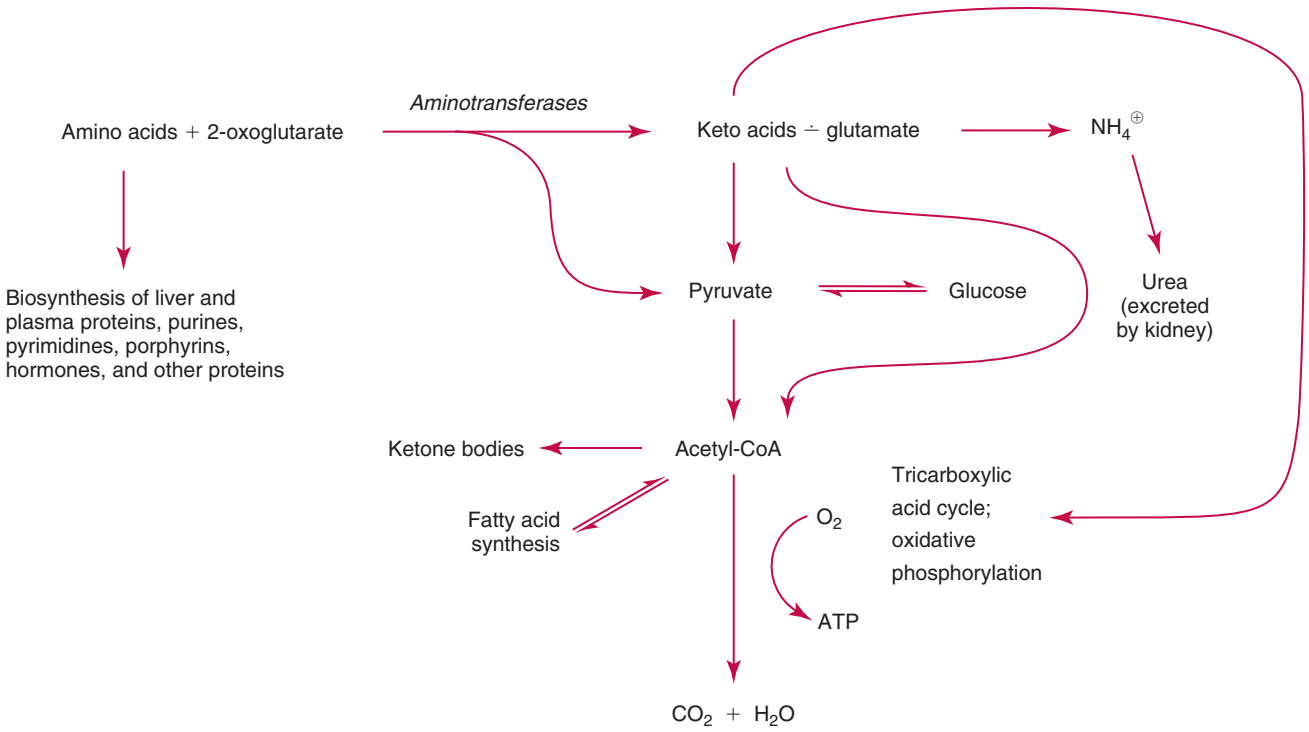

Figure 21-1 A generalized scheme of amino acid metabolism in the liver. Alanine represents one of the major metabolic substrates.

Most amino acids in blood undergo efficient glomerular filtration but are reabsorbed in proximal renal tubules by saturable transport systems (see Chapter 48). Increased renal excretion of amino acids *(aminoaciduria)* results from overload from increased plasma concentrations or from tubular impairment related to hereditary disorders or tubular injury. Amino acid excretion in urine varies with renal tubular maturation. Premature infants, especially during the first week, have a generalized aminoaciduria; even at full term, amino acid excretion is greater than in normal adults. In the urine of normal adults, glycine is the most abundant amino acid, followed by histidine, taurine, glutamine, serine, and alanine. Amounts of 1-methylhistidine may be high, depending on meat intake.

For adults, CSF concentrations of most amino acids, except for glutamine, are several-fold lower than in plasma. Glutamine is the main component, with usual concentrations of 0.4 to 1.0 mmol/L that are slightly higher than in plasma. Most amino acids other than alanine, serine, and threonine have CSF concentrations <0.03 mmol/L. Newborns have a smaller gradient of amino acid concentrations versus plasma than do adults.

Cells generally have intracellular amino acid concentrations higher than plasma concentrations. Intracellular concentrations of glutathione are in the mmol/L range. Many cells maintain high concentrations of taurine, which may serve as an antioxidant and as a component for regulation of intracellular osmolality. Regulation of intracellular amino acid concentrations may be one mechanism for controlling intracellular osmolality, particularly in tissues such as the renal medulla and brain.[5]

Clinical Implications of Amino Acid Concentrations

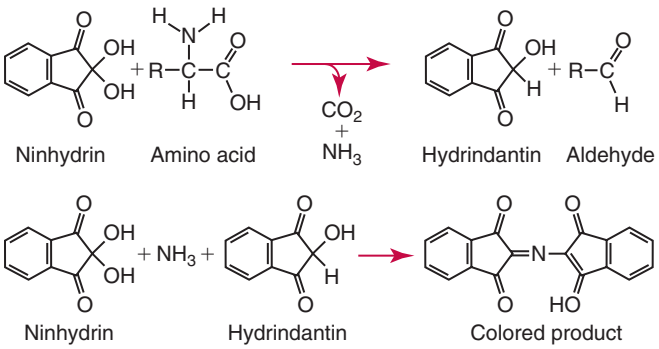
Historically, clinical laboratory assessments of plasma and urinary amino acids have been used primarily to detect or monitor inborn errors of metabolism, as detailed in Chapter 58. Measurement of plasma homocysteine is of clinical interest, as increased homocysteine is an indicator of deficiency of folic acid or vitamin B_{12} and is correlated with risk of cardiovascular disease.[71,128] Fasting concentrations of plasma homocysteine are relatively constant within individuals and are correlated with risk for cardiovascular disease and thrombosis. Many hypotheses have been advanced for how homocysteine might be a cause of cardiovascular disease or thrombosis, but these hypotheses have been undermined by some recent intervention trials that have not observed decreased cardiovascular disease in response to lowering of homocysteine by increased intake of folic acid and vitamin B_{12}.[71] However, even if homocysteine does not cause cardiovascular disease, it could still serve as a measurable risk factor.

Measurement of amino acids has not been extensively used in clinical practice for monitoring of patients with nutritional, metabolic, infectious, or psychiatric disorders. In part, this is because plasma amino acid concentrations do not always reflect severe deficiencies in malnutrition states; most amino acid metabolism and function are intracellular. Also

amino acid analysis has been expensive, with limited availability and slow turnaround time. Metabolomic studies may provide increased insight into metabolic pathways and potential clinical applications of measurement of amino acids. Several amino acid concentrations are of potential clinical interest. Drops in tryptophan concentration are associated with depression and other psychiatric disease.[107] Tryptophan degradation along the kynurenine pathway and cysteine metabolism by cysteine dioxygenase are stimulated by interferon, so that quantification of tryptophan, cysteine, and their metabolites is an indicator of immune activation.[139] Concentrations of arginine and citrulline are indicators of activation of the nitric oxide synthase pathway and adequacy of the substrate arginine for nitric oxide synthesis. This pathway may be important for pathogenesis of vascular disorders in sickle cell disease, asthma, and other disorders and may be a pharmacologic target.[43,111] Increased concentrations of asymmetric dimethylarginine, which inhibits nitric oxide synthase, may be physiologically significant in the development of cardiovascular and kidney disease.[75] Glutamine concentration may be monitored to assess the nutritional adequacy of postsurgical patients and those with other conditions.[132,162] Measurements of intracellular concentrations of glutathione or ratios of reduced and oxidized glutathione may serve as measures of oxidative stress, nutritional depletion in cancer or other states, or overdose with toxic compounds such as acetaminophen. Advances in the ability to measure amino acids rapidly and efficiently may expand clinical application of amino acid measurements.

Analysis of Amino Acids

Methods used to measure amino acids in biological samples are detailed in Chapter 58. The standard method for many years was the cation-exchange chromatography with spectrophotometric detection after postcolumn reaction with ninhydrin, as developed by Stein and Moore in the 1950s. This method quantifies 30 to 40 components in plasma and urine. However, newborn screening programs usually apply tandem mass spectrometry, and an increasing range of chromatographic and mass spectrometric methods are being applied to amino acid analysis. Analytical procedures usually involve deproteinization prior to analysis by precipitation with acids or organic acid or by ultrafiltration. This yields good recovery of most amino acids, except recovery of tryptophan may vary as the result of protein binding; substantial amounts of cysteine, homocysteine, and thiol-containing peptides such as cysteinylglycine and glutathione are linked via disulfide bonds to proteins.[157] Recovery of total cysteine and homocysteine requires reduction of specimens before precipitation steps. Most amino acids are stable in blood specimens, except for glutamine, which undergoes intramolecular cyclization to form pyroglutamic acid (5-oxoproline) with the release of ammonia. Specimens should be processed rapidly and stored frozen to preserve glutamine. Rapid processing of specimens is needed for accurate determination of homocysteine to avoid effects of homocysteine excretion from blood cells.[128]



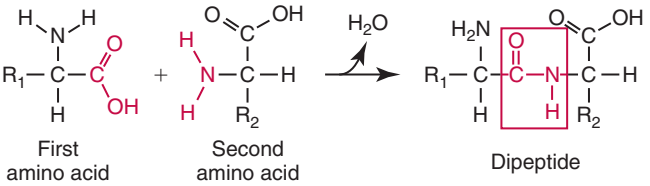
Several methods are available for measurement of total homocysteine, including immunoassay after enzymatic conversion to S-adenosylhomocysteine, enzyme cycling reactions, chromatographic or electrophoretic methods after derivatization, chromatographic analysis with electrochemical detection, and tandem mass spectrometry.

PEPTIDES AND PROTEINS

This section describes the basic biochemistry of peptides and proteins, and provides details on several high-abundance plasma proteins and selected methods for protein analysis used in the clinical laboratory.

Peptide and Protein Structure

A *peptide bond* is the amide bond formed between the amino group of one amino acid and the carboxyl group of a second amino acid. An example of a peptide bond joining two amino acids is diagrammed with the peptide bond enclosed by a box:



Isopeptide bonds refer to amide bonds linking amino acids via amino acid sidechains; an example is glutathione, in which the γ-carboxyl of glutamic acid is linked to the amino group of cysteine. Polymers of several amino acids are termed *peptides,* and amino acid sequences are described from the amino- or N-terminus, the amino acid with a free α-amino group. The final amino acid in the chain is the carboxy- or C-terminus. Peptide bonds, similar to all amide bonds, are planar structures that fix the geometry about the bonds, so that the major conformational flexibility of the peptide backbone results from rotation about the axes of the two bonds to the α-carbon. Short peptides are identified by the number of constituent amino acids, such as dipeptide, tripeptide, tetrapeptide, or pentapeptide. When peptides reach sufficient length to have a defined globular structure—about 50 or more residues—polypeptides begin to be referred to as *proteins.*

The terms *proteose* and *peptone* refer to partial digestion products of proteins, sometimes used as a source of amino acids for bacterial culture or other purposes.

The structures of peptides and proteins consist of five elements:

1. *Primary structure* is the sequence of amino acids in a peptide or protein. Post-translational modifications of amino acids contribute to increased diversity.
2. *Secondary structure* is the restriction of the peptide backbone by hydrogen bonds between different peptide bonds. Elements of secondary structure include α-helix, β-sheet, and β-turn. An α-helix has about 3.6 residues per turn, and hydrogen bonds are between amide oxygens and amide hydrogens 4 residues later. A β-sheet involves hydrogen bonds between the peptide bonds of adjacent peptide chains arranged in parallel or antiparallel configurations. *Random coils* refer to segments of peptide that lack defined secondary structure. Turns are commonly located on the surface of proteins and represent frequent sites of mutation because fewer constraints are imposed on sidechain packing than on interior regions of a protein.
3. *Tertiary structure* refers to folding of the polypeptide chain and elements of secondary structure into a compact three-dimensional shape. Folding is a complex process driven by energy minimization of intramolecular and solvent interactions. Hydrophobic groups tend to fold into the interior with less exposure to solvent, and charged and polar sidechains tend to be located on the surface, where sidechains are exposed to solvent. The three-dimensional structure is stabilized by intramolecular hydrogen bonds, van der Waals forces, and hydrophobic interactions. Disulfide bonds between cysteine residues stabilize three-dimensional structure. High stability of a structure is reflected by maintenance of structures up to high temperatures. *Denaturation of protein* refers to unfolding that occurs with temperature change or in the presence of organic solvents, detergents, or reagents that disrupt hydrogen bonds. Limited denaturation can be reversible, but extensive unfolding and denaturation of proteins often lead to aggregation and precipitation, which is difficult to reverse.
4. *Quaternary structure* refers to the incorporation of two or more polypeptide chains or subunits into a larger unit. Examples are creatine kinase with two subunits and lactate dehydrogenase and hemoglobin with four subunits.
5. Ligands and prosthetic groups provide additional functional and structural elements, such as metals in metalloenzymes, heme in hemoglobin and cytochromes, and lipids in lipoproteins. Proteins without their associated ligands are often referred to as apoproteins (e.g., apotransferrin without iron, apolipoproteins without lipid).

Many proteins are organized with subassemblies of smaller structural units or domains somewhat analogous to a string of beads. Similar domains may occur in different proteins, but diversity in structure is possible through assembly of domains in different combinations and three-dimensional configurations. This is exemplified by a number of proteins of the coagulation and complement systems that are formed from different combinations of small globular domains. Many gene products have arisen from duplication of common ancestral genes. Homologous genes not only commonly have sequence homology but fold into similar three-dimensional structures. The serpin (originally from serine proteinase inhibitor) superfamily consists of more than 1000 related proteins in different organisms that have been subdivided into 16 clades (lettered A through P).[88] Humans have 36 serpins, of which 29 are protease inhibitors and 7 lack protease inhibitor function.[88] Serpins that act as protease inhibitors in plasma include α_1-antitrypsin, α_1-antichymotrypsin, α_2-antiplasmin, antithrombin III, C1 inhibitor, heparin cofactor II, protein C inhibitor, and plasminogen activator inhibitor-1. Some serpins without known protease inhibitor function are cortisol-binding globulin, thyroxine-binding globulin, angiotensinogen, intracellular proteins, heat shock protein 47, and the tumor suppressor maspin. Serpins illustrate how a common structure is adapted to multiple functions. Extensive information about structures of serpins provides insight into disorders of protein conformation and folding discussed later. Other examples of families of plasma proteins are the albumin and lipocalin families. The albumin family includes albumin, α-fetoprotein, and afamin.[121] The lipocalin family includes several plasma proteins such as α_1-acid glycoprotein, retinol-binding protein, apolipoprotein D, α_1-microglobulin, prostaglandin D synthase (β-trace), β-lactoglobulin, neutrophil gelatinase-associated lipocalin (NGAL), inter-α-trypsin inhibitor, and C8 γ-chain.[171] Lipocalins generally have a barrel-shaped structure that is well suited to serve as a carrier for small molecules.

Disorders of Protein Folding

Protein folding is an error-prone process, and many molecular chaperones work to refold, prevent aggregation of misfolded proteins, or degrade misfolded proteins.[28,44] Several heat shock proteins that increase in response to a variety of stresses are molecular chaperones. When cells detect increased accumulation of misfolded proteins, an adaptive mechanism—the unfolded protein response—is activated.[135] This response increases production of chaperones and slows general protein synthesis to allow more time to fold new proteins. Despite these protective mechanisms, several families of age-related, genetic, and infectious diseases appear connected to disorders of protein folding and protein aggregation. Prion diseases are infectious diseases in which the transmissible agent may be protein that catalyzes misfolding of endogenous proteins. In Alzheimer's disease, accumulation of deposits of amyloid may contribute to pathogenesis. Polyglutamine diseases result from genetic expansion of repeat units encoding glutamine and are associated with Huntington's disease or other neurodegenerative disorders; polyglutamine sequences aggregate as β-sheets.[169] TDP-43 proteinopathies are neurodegenerative disorders, including amyotrophic lateral sclerosis, resulting from aggregation of transactive response DNA-binding protein.[81] Several inherited disorders related to mutations in specific proteins probably result from problems in protein folding. In α_1-antitrypsin

deficiency, hepatic injury results from aggregation and accumulation of misfolded protein.[14,144] In cystic fibrosis, the cystic fibrosis transmembrane conductance regulator (CFTR) protein has a one–amino acid deletion that may influence interactions with chaperones and the stability of the protein. Accumulation of misfolded proteins has been suggested as a pathogenic mechanism contributing to vascular, cardiac, and beta cell failure in diabetes.[44,135]

Protein Synthesis and Processing

Proteins are synthesized by ribosomes reading from the 5′-end of mRNA. Triplet codons in mRNA are matched with complementary sequence in transfer RNA carrying specific amino acids. Protein synthesis begins with an AUG codon encoding methionine, and the polypeptide chain is synthesized from the N-terminus. As originally outlined by Blobel in the signal hypothesis, proteins that are secreted, located in vesicular compartments, or oriented on the external surface of cell membranes usually contain an N-terminal signal peptide about 15 to 30 amino acids in length. Signal peptides interact with signal recognition particles and attach ribosomes to the endoplasmic reticulum (ER). Nascent peptide chains are inserted through the membrane of the ER as the protein is synthesized. Signal peptides of most secretory proteins are removed even before synthesis of the entire protein chain is completed. Some post-translational modifications such as asparagine-linked, also termed N-linked, glycosylation occur in the ER.[100] This modification entails assembly on a dolichol carrier of a branched oligosaccharide ending with multiple mannose subunits, and the oligosaccharide is transferred en bloc to asparagine residues that are in the sequence Asn-Xxx-(Ser or Thr), where Xxx can be any amino acid but proline. Within the cisternal compartments of the ER and Golgi apparatus, many biosynthetic processing steps occur. The structures of N-linked oligosaccharides are modified into a complex set of structures that usually end in sialic acids; a variety of O-linked oligosaccharides are attached, primarily to Ser and Thr, and many modifications of sidechains occur, such as phosphorylation, sulfation, hydroxylation of Pro, Lys and Asp, and carboxylation of Glu at selected sites in proteins. Oligosaccharide processing may change in different physiologic states and may serve as a marker for disease.[45] Numerous molecular chaperones assist with folding and disulfide bond formation of proteins, including peptidylprolyl isomerases and disulfide isomerases.[28]

Many proteins and peptides are synthesized as larger precursors. Proinsulin, discovered as the precursor for insulin by Steiner in the 1960s, served as the prototype of a peptide precursor. Proinsulin is a single polypeptide chain that sequentially contains the B-chain of insulin, connecting or C-peptide, and the A-chain of insulin. The C-peptide is excised by proteases and insulin is produced, with A- and B-chains linked by two disulfides. Synthesis of insulin as a precursor assists in appropriate formation of disulfide bonds. Most small bioactive peptides (e.g., gastrin, ACTH, angiotensin, bradykinin, vasopressin, thyrotropin-releasing hormone) are synthesized as precursors, and peptides are released by proteolysis prior to release or extracellularly. Many larger proteins are synthesized as precursors as well, including albumin, haptoglobin, and C3 and C4. Synthesis as precursors aids in appropriate folding and assembly of disulfides for proteins such as haptoglobin, C3, and C4, which are cleaved into multiple peptide chains.

Different sets of post-translational modifications occur on intracellular proteins. N- and O-linked glycosylation typical of extracellular proteins does not occur; instead, reversible addition of N-acetylglucosamine to Ser and Thr is noted.[49] Reversible phosphorylation of proteins by signaling cascades of kinases and phosphatase serve as important regulatory systems. Many other biosynthetic modifications influence protein function and intracellular localization. Modification of histones and nuclear proteins by acetylation and methylation affects transcription. Coupling of the small protein ubiquitin is a mechanism for targeting proteins for degradation into peptides by proteasomes. This is an important process for degrading misfolded or damaged proteins, for protein turnover, and for generating peptides that are presented for immune surveillance and activation.[53]

In addition to biosynthetic modifications, proteins undergo chemical modification by free radicals and other reactants. As an example, glucose reacts with amine groups to generate reversible Schiff's bases; some of the reaction products rearrange to more stable glucose conjugates, and the products are referred to as glycated proteins. Amounts of hemoglobin A_{1c} and glycated plasma protein measured as fructosamine serve as measures of exposure to glucose. Sidechain carbonyls serve as an indicator of free radical generation. Nitrotyrosine can be assessed as a measure of exposure to reactants. Oxidants can modify a number of amino acid sidechains, including oxidation of methionine to methionine sulfoxide and sulfone and cysteine to cysteic acid. Albumin serves as a model for many chemical modifications of plasma proteins.[105,121]

Physical Properties of Proteins

Variable amino acid sequences and three-dimensional structures of different proteins result in variation in physical properties. Tyrosine and tryptophan residues absorb light at 280 nm, and the abundance of these amino acids determines the strength of absorbance of a peptide or protein. Absorption at 280 nm, therefore, is used to quantify a purified protein. Tryptophan residues are intrinsic fluorescent groups with variable fluorescence efficiency and lifetimes, depending on their local environment. Some proteins, such as hemoglobin, contain heme or other chromophores that can be assessed at visible wavelengths. Peptide bonds have strong absorbance at wavelengths below 220 nm, so that spectrophotometric detection in this range detects all peptides and proteins, and absorbance is much greater than at 280 nm. Ionizable groups in proteins exert a strong effect on physical properties and changes in structure that occur in response to changes in pH. Common ranges of pKs are shown in Table 21-2, although the ionization of individual amino acids may be influenced

strongly by neighboring amino acids. Differing physical properties serve as the basis of methods to separate proteins (see also Chapter 12). Some important characteristics include the following:

1. *Differential solubility.* The solubility of proteins is affected by pH, ionic strength, temperature, and the dielectric constant (addition of solvents such as ethanol). Changing solvent pH affects the net charges of a protein; at its pI (net charge zero), a protein in polar solvent usually has its lowest solubility. Changing ionic strength affects the hydration and solubility of proteins. "Salting-in" and "salting-out" procedures were early methods for separating and characterizing proteins. Serum was originally divided into albumin, which is soluble in water, and globulins, which require salt to remain in solution. Albumin also stays in solution at high concentrations of salts such as ammonium sulfate that precipitate globulins. Addition of organic solvents and polyethylene glycol has been used for differential precipitation. Fractional precipitation of plasma with ethanol, using protocols developed by Cohn and coworkers, leads to several Cohn fractions that are enriched in immunoglobulins, α- and β-globulins, or albumin (fraction V). Polyethylene glycols induce precipitation by steric exclusion and, therefore, preferentially precipitate large proteins or complexes.
2. *Molecular size.* Separation of small and large molecules can be achieved by dialysis or ultrafiltration. Size exclusion chromatography, ultracentrifugation, and electrophoresis perform size separations under native conditions where proteins and peptides are in native globular states or under denaturing conditions. Addition of reducing agents allows separation of disulfide-linked components. Polyacrylamide gel electrophoresis in the presence of the denaturing detergent sodium dodecylsulfate is a method for estimating the molecular weight of polypeptide chains in proteins.
3. *Molecular mass.* Advances in mass spectrometry allow the determination of masses of peptides and proteins with increasing accuracy. Peptides and proteins can be ionized by matrix-assisted laser desorption/ionization (MALDI) or by electrospray ionization. Highest detection sensitivity and mass accuracy are for peptides, and tandem mass spectrometry can be applied for sequence analysis of peptides. Large proteins with extensive mass heterogeneity due to variable modifications pose challenges related to their high mass and the formation of multiple peaks.
4. *Electrical charge.* Ion-exchange chromatography, isoelectric focusing, and electrophoresis separate peptides and proteins based on charge.
5. *Surface adsorption.* Adsorption of peptides and proteins to particles have been used as the basis for separations. Hydrophobic interaction chromatography and reverse-phase chromatography rely on differential hydrophobic interactions of peptides or proteins.
6. *Affinity chromatography.* Specific ligands, antibodies, or other recognition molecules have been used to separate peptides or proteins selectively.

Plasma Proteins

Plasma is a complex mixture of proteins representing thousands of gene products.[2,57,117] The most abundant products are proteins secreted directly into the circulation primarily by the liver, and immunoglobulins contributed by lymphatic tissue. Classical methods for protein fractionation and purification over several decades led to isolation and characterization of about 100 of the most abundant plasma proteins.[3] The 12 most abundant proteins represent more than 95% of total protein mass, and a progressive decline in abundance of other components has been noted.[2,60] Albumin alone represents more than 50% of the total mass of protein and an even higher proportion of the number of molecules, so that albumin is the main factor in colloid osmotic pressure (oncotic pressure). For some purposes, such as evaluation of contributions to oncotic pressure, inhibitory capacity of proteases, and binding capacity for ions, drugs, or small molecules, it is useful to express abundance of proteins on a molar basis rather than as mass abundance, and a slightly different set of proteins is identified that includes some lower molecular weight proteins that do not represent major components by mass. Lists of the 30 most abundant proteins by mass and molecular abundance are provided in Table 21-3.

It is apparent, for example, that although α_2-macroglobulin (AMG) is the most abundant protease inhibitor by mass abundance, α_1-antitrypsin and several other protease inhibitors have a higher molar concentration and capacity for protease inhibition.

The most appropriate way to express protein abundance depends on the method of analysis. Signal intensities of stained bands in gels and chromatographic separations with photometric detection usually relate to protein mass. Signal responses in immunoassays and mass spectrometry usually correspond to numbers of particles (i.e., the molar abundance of proteins). Components with highest molar abundance in Table 21-3 are easiest to detect by immunoassay (allowing use of less sensitive methods such as immunoturbidimetry and immunonephelometry) and generally will yield tryptic peptides with the highest abundance for mass spectrometric detection.[60] Use of molar abundance allows better comparison of the stoichiometry of molecular forms of proteins and different proteins that differ substantially in molecular weight. Currently, concentration of proteins s are typically expressed in units of mass or molarity. High-abundance proteins most often are reported in units of mass per volume by clinical laboratories in the United States.

The Plasma Proteome and Peptidome

Plasma contains a complex mixture of thousands of proteins and peptides. The complete set of proteins is referred to as the *proteome.* Current efforts to compile a database of components found in plasma include more than 12,000 protein entries.[134] Considerable variation among proteins is related to post-translational and genetic variation.[114] In addition to the diversity of proteins, plasma contains complex mixtures of peptide components—the peptidome—which only recently has been fully appreciated.[122] Although many peptides are

TABLE 21-3 High-Abundance Plasma Proteins Ranked According to Reference Intervals by Mass or Molar Abundance

	Ranked by Mass Abundance (mg/L)		Ranked by Molar Abundance (μmol/L)	
Rank	**Protein**	**Concentration**	**Protein**	**Concentration**
1	Albumin	35,000-52,000	Albumin	500-800
2	Immunoglobulin G	7000-16,000	Immunoglobulin G	40-120
3	Transferrin	2000-3600	Apolipoprotein A-I	30-70
4	Immunoglobulin A	700-4000	Apolipoprotein A-II	30-60
5	α_2-Macroglobulin	1300-3000	Transferrin	25-45
6	Fibrinogen	2000-4000	α_1-Antitrypsin	18-40
7	α_1-Antitrypsin	900-2000	Haptoglobin	6-40
8	Apolipoprotein A-I	910-1940	α_1-Acid glycoprotein	15-30
9	C3	900-1800	α_2HS-glycoprotein	9-30
10	IgM	400-2300	Immunoglobulin A	5-30
11	Haptoglobin	300-2000	Hemopexin	9-20
12	Apolipoprotein B	600-1550	Apolipoprotein C-III	6-20
13	α_1-Acid glycoprotein	500-1200	Fibrinogen	5-18
14	α_2HS-glycoprotein	400-1300	Gc-Globulin	8-14
15	Hemopexin	500-1150	Apolipoprotein C-I	6-12
16	Gc-Globulin (vitamin D-BP)	400-700	C3	5-10
17	Factor H	240-740	α_1-Antichymotrypsin	4-9
18	α_1-Antichymotrypsin	300-600	Apolipoprotein D	2-10
19	Inter-α-trypsin inhibitor	200-700	Prealbumin	4-8
20	Apolipoprotein A-II	260-510	β_2-Glycoprotein I	3-6
21	C4b-binding protein	200-530	Apolipoprotein A-IV	3-6
22	Ceruloplasmin	200-500	Apolipoprotein C-II	2-7
23	Factor B	180-460	Serum amyloid A4	3-6
24	Prealbumin	200-400	Inter-α-trypsin inhibitor	3-5
25	Gelsolin	200-400	Antithrombin III	3-5
26	Fibronectin	300	α_1B-glycoprotein	3-5
27	C1 inhibitor	190-370	Gelsolin	3-5
28	C4	100-400	Ceruloplasmin	2-5
29	Plasminogen	150-350	Factor H	2-5
30	Antithrombin III	170-300	Factor B	2-5

Based on values in Hortin GL, Sviridov D, Anderson L. High-abundance polypeptides of the human plasma proteome comprising the top 4 logs of polypeptide abundance. Clin Chem 2008;54:1608-16.

cleared rapidly by renal clearance and peptidolysis, some peptides accumulate bound to albumin or other carrier proteins.[122] The peptidome is of potential diagnostic interest because of its large diversity and information content, reflection of activity of physiologic proteases, and suitability for direct analysis by mass spectrometry. Many approaches for proteome analysis are known, including (1) two-dimensional electrophoresis and chromatography, (2) microarrays of antibodies or other proteins, and (3) mass spectrometry with electrospray ionization or matrix-assisted laser desorption/ionization.[2,29,56,117,134,149] Analysis of multiple components expands the ability to examine changes in patterns of protein concentration versus traditional analysis of one protein at a time, and high-resolution separation techniques offer the opportunity to identify many structural changes, as well as quantitative changes, in proteins. Sequence analysis can be performed rapidly on small peptides, allowing identification of components. Simultaneous analysis of many peptides or proteins offers opportunities to empirically identify protein markers for disease without knowing beforehand which protein to test for. It has been suggested that mass spectrometric patterns of peptides might serve as signatures of disease that could be interpreted by complex pattern recognition by computers.[122] However, it is not clear how usual standards of laboratory practice, such as calibration, quality control, and verification of accuracy, would be assessed.[55] The U.S. Food and Drug Administration has proposed guidelines for in vitro *diagnostic multivariate index assays* to address special issues raised by this approach. Although untargeted empirical analysis may be a useful discovery approach, most methods for multiplex analysis of peptides and proteins for clinical use are likely to rely on targeted analysis. Substantial advances have been made in the quantitative analysis of proteins by digesting proteins into peptides with the protease trypsin and then

quantitating released tryptic peptides by tandem mass spectrometry using isotopically labeled internal standard peptides. It has been proposed that *proteotypic peptides* (peptides that are unique to a single protein) for more than 20,000 proteins should be identified to provide a means of quantifying virtually any human protein.[2] Peptide quantification via tandem mass spectrometry is being applied to measurement even of relatively low-abundance proteins such as thyroglobulin and troponins,[54,79] and it may serve as a valuable method for measuring bioactive peptides. Multiplex immunoassays are coming into routine clinical laboratory use as the result of microparticle or planar arrays.[78,90] Products currently available for clinical use measure several components; highly multiplexed assays still present some challenges with respect to reproducibility and quality control.[32]

Plasma Protein Concentrations

The characteristic of proteins that has been applied most frequently is their plasma concentration, and the range of plasma concentrations of different proteins measured in clinical assays extends well over 10 logs of concentration.[3,60] Relative to the highest abundance protein, albumin, concentrations of plasma proteins decrease progressively over several logs of concentration for proteins released from tissues of smaller cell mass, and the ability of endogenous proteins to enter the circulation generally decreases hierarchically: (1) proteins secreted directly into plasma, (2) cell membrane proteins shed into the circulation, (3) secretory proteins in exocrine secretions, (4) high-abundance cytoplasmic proteins, (5) low-abundance cytoplasmic proteins, (6) transmembrane proteins, and (7) organellar proteins that must traverse more than one membrane to exit cells. Many proteins serve as useful markers of physiology and disease, as these processes alter the production or release of proteins into plasma. Changes in plasma concentrations of secretory proteins usually reflect changes in synthetic rates, secretion, or clearance, and plasma concentrations of cytoplasmic and organellar proteins tend to reflect cellular injury and rates of leakage into plasma. In addition to endogenous sources of proteins, multiple exogenous sources of proteins include infectious organisms, dietary sources, and therapeutic interventions. For diagnostic purposes, clinical laboratories currently assess only a small proportion of the thousands of gene products in the circulation and identify only a small proportion of diversity of post-translational processing. Antibodies and T-cell receptors represent special cases wherein somatic recombination and mutation result in repertoires of millions of sequences and binding specificities. A small portion of this diversity is assessed by serological or functional assay.

Plasma concentrations of proteins depend not only on rates of production and efficiency of entry to the circulation, but also on rates of clearance. Proteins and peptides substantially smaller than albumin are cleared from the circulation by glomerular filtration unless they are bound to larger carriers, such as small apolipoproteins bound to lipoprotein particles or retinol-binding protein bound to prealbumin.[116] Peptides and small proteins not bound to carriers are cleared with half-lives of about 2 hours under conditions of normal kidney function and accumulate to higher concentrations in kidney failure. Examples of proteins and peptides that increase dramatically in renal failure include β_2-microglobulin, cystatin C, immunoglobulin light chains, parathyroid hormone fragments, complement factor D, Clara cell protein (CC16), atrial natriuretic peptide, interleukins, and, to a lesser extent, retinol-binding protein. Accumulation of components in renal failure identifies components with renal clearance[161] as a primary clearance mechanism; hundreds of increased plasma peptide components can be detected by mass spectrometry.[136] Many bioactive peptides in plasma, such as insulin, intact parathyroid hormone, and kinins, have much shorter circulating half-lives of only a few minutes, indicating receptor-mediated uptake or degradation by exopeptidases or endopeptidases.[56] Proteins the size of albumin or larger generally have an upper limit of about 7 days for their circulating half-lives because of pinocytosis and degradation by cells. Two exceptions to this are albumin and immunoglobulin G, which have a receptor-mediated process to recycle these proteins from pinocytotic vesicles. The recycling mechanism extends the half-life of albumin and immunoglobulin several-fold.[131,165] Many proteins are subject to uptake by specific receptors or degradation by proteolysis. Half-lives <7 days suggest clearance mechanisms other than bulk pinocytosis.

Major Plasma Proteins

Protein abundance of major components, as listed in Table 21-3, probably reflects the concentrations of proteins needed for major physiologic processes. Transport proteins, protease inhibitors, antibodies, complement factors, and coagulation components are well represented. Many of the proteins in Table 21-3 have been measured for diagnostic purposes. Only a few of the high-abundance proteins represent diagnostic orphans. Clinical laboratory analysis of α_2HS-glycoprotein (fetuin-A) has been limited, and its physiologic significance, possibly related to regulation of mineral deposition in bone, has been unclear.[102] Gelsolin has not been measured frequently, although it may have an important function, together with Gc-globulin (also known as vitamin D–binding protein), in clearing actin and preventing actin filament formation in the circulation.

Historically, major plasma proteins were classified according to electrophoretic mobilities in agarose gels at pH 8.6. Table 21-4 lists several major plasma proteins of diagnostic interest in order of electrophoretic mobility, together with other characteristics. Only about 10 of the most abundant plasma proteins by mass are prominently observed by staining of agarose gels; other, more selective procedures are needed to analyze lesser plasma protein components. Detailed descriptions of several high-abundance proteins are provided in this chapter; other chapters describe other plasma proteins, including enzymes (see Chapter 22), lipoproteins (see Chapter 27), hormones (see Chapter 29), and hemoglobin, fibrinogen, and other coagulation proteins (see Chapters 32 and 59).

Plasma concentrations and molecular forms of major secretory proteins vary in response to nutritional, physiologic,

TABLE 21-4 Properties of Selected Plasma Proteins

Electrophoretic Region	Protein	Half-Life	pI	MW, daltons	Function, Comments
Prealbumin	Retinol-binding protein (RBP)	12 h		21,000	Carrier of retinol (vitamin A) Complexed to prealbumin
Prealbumin	Prealbumin (transthyretin)	48 h	4.7	54,980 (tetramer)	Transports thyroid hormone Binds RBP
Albumin	Albumin	15-19 d	4-5.8	66,438	Maintains oncotic pressure Transports fatty acids, bilirubin, and other organic molecules; binds calcium, drugs
α_1	α_1-Antitrypsin (AAT)	4 d	4.8	51,000	A serine protease inhibitor (serpin); inhibits neutrophil elastase
	α_1-Acid glycoprotein (AAG, orosomucoid)	5 d	2.7-4	40,000	Carrier for steroid hormones Binds cationic drugs, a lipocalin
α_2	Haptoglobin (Hp, HAP)	2 d	≈4.1 (type 1-1)	85,000-840,000	Binds hemoglobin; molecular weight depends on phenotype (1-1, 2-1, or 2-2)
	α_2-Macroglobulin (AMG)	5 d	5.4	720,000 (tetramer)	General proteolytic inhibitor Homologous to C3 and C4
	Ceruloplasmin (CER)	4.5 d	4.4	132,000	Oxidizes iron to Fe^{+3} Blue color from copper ligand
β_1	Transferrin (Tf, siderophilin)	7 d	5.7	79,600	Transports iron, two Fe^{+3} binding sites
	C4, fourth component of complement	X		206,000	Covalently binds to target molecules, releases C4a peptide
β_2	C3, third component of complement	2-3 d		180,000	Covalently binds to target molecules, releases C3a peptide
	β_2-Microglobulin	X		11,800	Component of HLA on cell surfaces
γ	IgG	24 d	6-7.3	150,000	Antibody from secondary responses Four subclasses: IgG1, IgG2, IgG3, IgG4
	IgA	6 d		≈160,000	Major secretory antibody; two subclasses
	IgM	5 d		900,000	Antibody from primary responses

and genetic factors. Development of reference materials and value transfer to routine clinical assays represent a challenge for each protein.[11] The interim consensus reference intervals for 14 plasma proteins are listed in Table 21-5.[22] Molecular forms, in some cases such as haptoglobin and apolipoprotein(a), differ substantially with genetic variation. Many factors affect the concentrations of specific plasma proteins, including age, gender, genetic variation, diet, hormonal variation, inflammatory processes, and many other factors. The example of changes in several proteins in response to

TABLE 21-5 Interim Consensus Reference Intervals for 14 Plasma Proteins in Human Serum Referenced to CRM 470[72]*

Protein	g/L	mg/dL
α_1-Acid glycoprotein	0.5-1.2	50-120
Albumin	35-52	3500-5200
α_1-Antitrypsin	0.9-2.0	90-200
C3*	0.9-1.8*	90-180†
C4	0.1-0.4	10-40
Ceruloplasmin	0.2-0.6	20-60
C-reactive protein	<5	<0.5
Haptoglobin	0.3-2.0	30-200
IgA	0.7-4.0	70-400
IgG	7-16	700-1600
IgM	0.4-2.3	40-230
Prealbumin	0.2-0.4	20-40
α_2-Macroglobulin	1.3-3.0	130-300
Transferrin	2.0-3.6	200-360

*Values are applicable only to adults between 20 and 60 years of age.
†Values are slightly lower in samples assayed <8 hours after draw.

steroid hormones shown in Table 21-6 illustrates how physiologic and pharmacologic factors can strongly influence plasma protein concentrations.

The Acute-Phase Response

Systemic inflammation in response to infection, tissue injury, or inflammatory disease triggers changes in hepatic production of multiple plasma proteins, as indicated in Table 21-7.

TABLE 21-7 The Acute Phase Response (APR): Changes in Plasma Protein Concentrations

Positive APR	C-reactive protein (extreme)
	Serum amyloid A (extreme)
	α_1-Acid glycoprotein
	α_1-Antitrypsin
	α_1-Antichymotrypsin
	Antithrombin III
	C3, C4, and C9
	C1 inhibitor
	C4b-binding protein
	Ceruloplasmin
	Factor B

Data from Craig WY, Ledue TB, Ritchie RF. Plasma proteins: clinical utility and interpretation. Scarborough, Maine: Foundation for Blood Research, 2001; Gabay C, Kushner I. Acute-phase proteins and other systemic responses to inflammation. N Engl J Med 1999;340:448-54; and Vollmer T, Piper C, Kleesiek K, Dreier J. Lipopolysaccharide-binding protein: a new biomarker for infectious endocarditis? Clin Chem 2009;55:295-302.

This process, mediated by the action of interleukin-6 (IL-6) and other cytokines has been termed the *acute-phase response (APR).*[42] It is a nonspecific reaction to inflammation, comparable with the increase in temperature or leukocyte count. Studies have suggested that it is possible to therapeutically block the APR with inhibitors of tumor necrosis factor α (TNF-α), which may be beneficial in some cases where products of the APR contribute to inflammation or deposit in tissues as amyloid.[74] In the APR, synthesis of a few proteins, including albumin, transferrin, and prealbumin, is downregulated; such proteins are termed *negative acute-phase reactants.* Albumin concentrations fall faster than expected from decreased synthesis; acute response might also reflect increased capillary permeability and redistribution of albumin to extracellular fluids. Production of a number of proteins, including α_1-antitrypsin (AAT), α_1-acid glycoprotein (AAG), haptoglobin (Hp), ceruloplasmin, C4, C3, and fibrinogen increases several-fold. Production of C-reactive protein (CRP) and serum amyloid A (SAA) increase greatly, and

plasma concentrations can increase up to 1000-fold or more in extreme cases. The decrease in apolipoprotein A-I, coupled with increases in serum amyloid A, results in remodeling of high-density lipoproteins (HDLs) from forms with apolipoprotein A-I as the major component to forms with increased amounts of serum amyloid A. These changes in composition of HDL have been related to decreased capacity for reverse cholesterol transport and antioxidant activity, and a general change in function of HDL from anti-inflammatory to proinflammatory.[47]

Procalcitonin is another component measured to assess APRs. Procalcitonin is a polypeptide of 116 amino acids that serves as the precursor for calcitonin in C cells of the thyroid. In response to inflammation, procalcitonin begins to be synthesized by other tissues, such as liver, kidney, and pancreas, where it is not cleaved into smaller peptide components,[137] and plasma concentrations increase more rapidly than other acute-phase reactants from a very low baseline concentration. Plasma concentrations of individual acute-phase proteins rise at different rates—first, procalcitonin, CRP, SAA, and α_1-antichymotrypsin; after the first 12 hours, AAG; after 24 to 48 hours, AAT, Hp, C4, and fibrinogen; and finally, C3 and Cp. All reach maxima within 2 to 5 days following an acute insult and then decrease in the same order as their increase. Measurement of CRP and SAA, which have the greatest change in concentration, can be used to monitor the progress of an inflammatory reaction or its response to treatment. Increased erythrocyte sedimentation rate (ESR) is another indicator of inflammation. Fibrinogen concentrations are considered a major determinant of ESR, so that ESR probably relates to changes in fibrinogen in the acute-phase response. APRs to bacterial infection usually are stronger than those to viral infection, and procalcitonin or other acute-phase reactants sometimes are measured in newborns or in complex adult patients to try to rapidly identify patients with bacterial infection before results from bacterial culture can be obtained.[7,84] Procalcitonin measurements therefore assist in determining whether antibiotic therapy should be used. Concentrations of procalcitonin are low in infants, and a cutoff of 0.12 ng/mL has been recommended to detect bacterial infection in infants presenting with fever.[98] Concentrations below a higher cutoff of 0.5 ng/mL indicate low risk of sepsis in adult patients in intensive care units. Lipopolysaccharide-binding protein is another acute-phase reactant that has been suggested as a useful marker for detecting infection; concentrations of lipopolysaccharide-binding protein are markedly increased in most patients with infectious endocarditis in comparison with noninfectious valvular disease.[163] Qualitative changes in proteins also are seen with the APR, such as altered changes in glycosylation of proteins.[45] Changes in glycosylation of immunoglobulins may have an immunomodulatory effect.[72]

Chronic infection, such as viral hepatitis, yields different changes in the composition of plasma proteins compared with acute infection. Stimulation of lymphocytes to produce antibodies leads initially to increased amounts of IgM and later to increased IgG and IgA antibodies to the infectious agent. Many plasma proteins have been used as indicators of impaired liver function in cirrhotic liver disease, including α_2-macroglobulin, apolipoprotein A-I, haptoglobin, vitronectin, and fibronectin, and measures of some of these components have been included in several different multiparameter indices of hepatic fibrosis.[46]

Differences Between Plasma and Serum Proteins

Plasma refers to the fluid portion of blood after cells are removed by centrifugation. Some type of anticoagulant needs to be added to prevent coagulation of blood due to contact with foreign surfaces in blood collection devices (see Chapter 7). Common anticoagulants include dry heparin or EDTA or solutions containing citrate. Dry additives produce only slight osmotic effects on plasma volume, and citrate solutions introduce some specimen dilution. Variation in platelet concentration is noted, depending on the time of centrifugation and the force applied. Preparation of platelet-poor plasma commonly requires spinning specimens twice to ensure platelet removal and remove their contribution to plasma proteins. Platelets undergo some activation and release of their granules during routine blood collection, and specialized blood collection tubes with additives such as theophylline, adenosine, and dipyridamole that suppress platelet activation are needed to assess plasma concentrations of some components contained in platelets.[66]

Serum is the fluid component of blood after blood is allowed to clot. It differs from plasma in several respects.[56,93,126] An approximate 4% decrease in total protein content is related mainly to removal of fibrinogen during coagulation. This results in serum having a lower viscosity than plasma, because fibrinogen contributes to plasma viscosity. Besides fibrinogen, several other clotting factors are removed in the clot and activation peptides released into serum. An increase in complexes of proteases is seen with inhibitors. Platelets are trapped in the clot, but during coagulation, platelets release their granules, which contain hundreds of proteins, including platelet factor 4 and thromboglobulins.[18,66] Activation of coagulation proteases during clotting may modify a variety of other proteins, and substantial amounts of exopeptidase activity in serum degrade small peptides. Given the complex processes that occur in the conversion of plasma to serum, many protein and peptide components differ substantially in plasma and serum. For proteomic analysis, plasma (usually EDTA) rather than serum generally is recommended, because plasma represents a protein and peptide composition more similar to that seen in in vivo conditions. Serum offers a slight advantage for analysis of some abundant components such as immunoglobulins because the reduced specimen viscosity improves specimen delivery, decreases precipitates formed during freezing and thawing, and decreases the opportunity for fibrin formation in specimens. Most of the high-abundance components described in this chapter are relatively stable globular proteins that are not degraded substantially during clotting of plasma and can be analyzed on serum or plasma specimens. For traditional agarose protein electrophoresis, serum is the preferred specimen, because

fibrinogen yields a prominent band near the β-λ border that can be mistaken for or can obscure a paraprotein.

Determination of Total Protein

Plasma normally contains about 6.5 to 8.5 g/dL protein, and serum about 4% less. Determination of total protein in biological fluids in some respects represents a greater challenge than analysis of a specific protein, because variable protein composition of biological fluids leads to variable carbohydrate composition, charge, and physical characteristics of proteins in the mixture. Many methods of protein analysis respond differentially to different proteins and present problems when applied to specimens of varying protein composition. Most methods other than the biuret method have not been thoroughly examined for interactions with small peptide components as well as intact proteins, and this may become a significant issue in renal failure with increased accumulation of peptides and small proteins.[161]

Specific Methods. Many methods have been developed to measure the total protein content of biological fluids. Several are reviewed here.

Kjeldahl Method. This method is rarely used in clinical laboratories but is of historical importance and is sometimes used as a reference method. Protein nitrogen is converted to ammonium ion by heating with sulfuric acid in the presence of a catalyst. Ammonium ion is measured by alkalinization, distillation, and acid titration, or by Nessler's reagent. Protein is estimated to contain 16% nitrogen (multiply N by 6.25). Errors in protein estimation occur if the amino acid composition is unusual, and if nitrogen content differs from 16%. Nonprotein N, such as from urea and amino acids, also is measured, so a protein precipitation step may be required. The Kjeldahl method was one of the first methods used for reproducible total protein measurement, but it is time-consuming and impractical for routine use. This method has been used to assign values to reference materials for the biuret method.[70]

Biuret Method. Under strongly alkaline conditions, Cu^{2+} ions form multivalent complexes with peptide bonds in proteins. Binding shifts the absorption spectrum of Cu^{2+} ions to shorter wavelengths, leading to a color change from blue to violet that has been termed the *biuret reaction*. Binding of Cu^{2+} ions to the organic compound biuret yields a similar color change, hence the name. Absorbance change from protein addition is measured spectrophotometrically at ≈540 nm, and this serves as a relatively simple method for quantifying protein. Absorbance changes at 540 nm also result from binding of Cu^{2+} ions by many compounds that can form chelates with five- or six-member rings, where amino, amide, or hydroxyl groups bind to Cu^{2+} ions.[58] Such compounds include (1) serine, (2) asparagine, (3) ethanolamine, (4) tris(hydroxymethyl)aminomethane, and (5) many others. Small compounds lead to a smaller spectral shift than proteins. Historically, the biuret method was not considered to react with amino acids and dipeptides, but absorbance changes occur with some amino acids, with amino acid amides, and with dipeptides.[58] The biuret action also was considered to react equally according to peptide content with all proteins and peptides longer than two amino acids, but subsequently, peptides containing proline were noted to have reduced reactivity, and some sidechains may contribute.[58] As long as proteins are not extremely proline-rich or do not have a very unusual composition, different proteins probably have similar reactivities with respect to peptide content as long as the biuret reaction is performed in the typical end point manner. Bilirubin, lipemia, and other serum components can introduce slight interference with serum measurement by biuret assays, and calibration with albumin results in a slight bias relative to a Kjeldahl method.[17] Interference has also been noted for immunoglobulin lambda light chains.[155]

Biuret rate assays are also available but should be considered as a separate category from equilibrium assays. Cu^{2+} ions complex with small molecules and accessible sites in proteins almost instantaneously; additional absorbance change over time for the kinetic analysis probably depends on the rate of unfolding of a protein and exposure of additional binding sites for Cu^{2+} ions under strongly alkaline conditions. Different proteins are likely to unfold at different rates.[58] An advantage of the kinetic biuret assay is the decreased effect of low molecular weight compounds; they usually react before the measuring interval occurs.

Direct Optical Methods. Absorbance of UV light at 200 to 225 nm and 270 to 290 nm have been used to measure protein concentrations and is commonly applied to monitor chromatographic separations of peptides and proteins. Absorbance at 280 nm depends primarily on the tryptophan and tyrosine content of a protein. This technique works best for purified proteins with known absorptivity. For complex mixtures, accuracy and specificity suffer from variable content of tryptophan and tyrosine and from absorbance of low molecular weight compounds such as free amino acids, uric acid, and bilirubin. At 200 to 225 nm, peptide bonds are chiefly responsible for UV absorbance (70% at A_{205}); specific absorption by proteins at these shorter wavelengths is 10 to 30 times greater than at 280 nm.[70] Many low molecular weight compounds such as urea also have absorbance at *wavelengths* below 220 nm. Accurate measurement of proteins by this method may require removal of low molecular weight molecules before absorbance measurements are performed. Several other optical methods using infrared or Raman analysis of specimens offer methods for total protein determination based on complex spectral analysis.[63]

Dye-Binding Methods. Dye-binding methods depend on shifts in the absorbance spectra of dyes when they bind to proteins. Variable binding of dyes to different proteins is a limitation. Calibration with a protein mixture may be hard to define consistently. Calibration with a pure protein such as albumin may not simulate binding to the complex mixture of proteins in serum or plasma. Using the dye Coomassie brilliant blue, immunoglobulins often give only 60% of the response of an equivalent concentration of albumin or transferrin.[70] This dye binds to polypeptide chains under acidic conditions, resulting in decreased absorbance at 465 nm and

increased absorbance at 595 nm. Dye-binding methods offer good sensitivity, and pyrogallol red has become one of the most commonly used dyes for analysis of fluids with lower protein concentrations such as urine and CSF.

Lowry (Folin-Ciocalteu) Method. The detection limit of the Lowry method is about 100 times lower than that of the biuret method. Specimens are mixed with an alkaline copper solution followed by addition of the Folin-Ciocalteu reagent. Phosphotungstic acid and phosphomolybdic acid are reduced to tungsten blue and molybdenum blue by copper complexed with peptide and by tyrosine and tryptophan residues. Absorbance of products is measured at 650 to 750 nm. Reactivity of proteins varies with the content of tyrosine and tryptophan. Low molecular weight compounds including tryptophan and tyrosine and drugs such as salicylates, chlorpromazine, tetracyclines, and some sulfa drugs also give positive interference. Analysis of a fluid such as urine with high concentrations of phenolic compounds requires removal of low molecular weight substances before protein is measured.[70]

Refractometry. Refractometry is a method used to rapidly estimate protein at high concentrations. Accuracy decreases at protein concentrations <35 g/L, where salts, glucose, and other low molecular weight compounds have a larger proportional effect on refractive index.[70] Refractometry is used more often in clinical laboratories to assess the concentration of solutes in urine specimens than for determining total protein.

Turbidimetric and Nephelometric Methods. Many different reagents have been used to aggregate protein for turbidimetric or nephelometric assays, including (1) trichloroacetic acid, (2) sulfosalicylic acid, (3) sulfosalicylic acid combined with sodium sulfate, and (4) benzethonium chloride or (5) benzalkonium salts under alkaline conditions. Precipitation methods for total protein assay depend on forming a suspension of uniform, insoluble protein particles, which scatter incident light. Albumin and globulins often give different reactivities in precipitation methods.

Calibration of Total Protein Methods. Bovine or human albumin is commonly used to calibrate biuret methods, which react nearly equivalently with the peptide content of most proteins (see section on the biuret method). Protein mixtures with usual albumin-to-globulin ratios often have been recommended for calibration of other methods, with total protein content established by the biuret or Kjeldahl method.

Reference Intervals. The total protein concentration of serum obtained from healthy ambulatory adults is 6.3 to 8.3 g/dL and 6.0 to 7.8 g/dL for adults at bed rest. Plasma usually contains a protein concentration about 0.3 g/dL higher (unless diluted by a volume of anticoagulant such as citrate solution) because of the content of fibrinogen and other proteins removed during clotting to form serum. *Hemoconcentration* and relative *hyperproteinemia,* with increased concentrations of all plasma proteins, occur with inadequate water intake or excessive water loss as in severe vomiting, diarrhea, Addison's disease, or diabetic acidosis. Some hemoconcentration also occurs with standing (reduced intravascular volume) or prolonged tourniquet time during blood collection. *Hemodilution* and relative hypoproteinemia, with decreased concentrations of all plasma proteins, occur with water intoxication or salt retention syndromes, during massive intravenous infusions, and physiologically when a recumbent position is assumed. A recumbent position decreases total protein concentration by 0.3 to 0.5 g/dL and many individual proteins including albumin by up to 10%.[70] This reflects the redistribution of extracellular fluid from the extravascular space to the intravascular space and therefore dilution of a constant amount of plasma protein in a larger volume.

Of the individual serum proteins, albumin is present in such high concentrations that low concentrations of this protein alone may cause *hypoproteinemia.* Hypoalbuminemia is very common and has many causes. Mild *hyperproteinemia* may be caused by an increase in the concentration of specific proteins normally present in relatively low concentration as, for example, in dehydration, with increases in acute-phase reactants, or with increases in polyclonal immunoglobulins as a result of infection. Marked hyperproteinemia may be caused by high concentrations of the *monoclonal immunoglobulins* produced in paraproteinemias.

Prealbumin (Transthyretin) and Retinol-Binding Protein (RBP)

Prealbumin and RBP are nonglycosylated transport proteins. RBP is bound to prealbumin, which was named for its electrophoretic mobility. In 1981, the term *transthyretin* was proposed for prealbumin to reflect its binding and transport of both thyroid hormones and RBP. Both *prealbumin* and *transthyretin* are terms in common use.

Biochemistry and Function. Prealbumin (MW 35 kDa) is composed of four identical, noncovalently bound subunits, forming triiodothyronine (T_3)- and thyroxine (T_4)-binding sites. It binds and transports ≈10% of both hormones. (Thyroxine-binding globulin transports ≈70%, and albumin binds ≈20%.) Because of negative cooperativity of thyroid hormone binding, usually only one prealbumin-binding site is occupied. Prealbumin's synthesis is stimulated by glucocorticosteroid hormones, androgens, and many nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin. Prealbumin is synthesized in the liver and to a lesser extent in the choroid plexus of the brain.[138] Synthesis in the choroid plexus may account for relatively high concentrations of prealbumin in CSF.

RBP is a 21-kDa transport protein for all-*trans* retinol, the active form of vitamin A. RBP is synthesized in the liver and in adipose tissue.[16] Minor variants that lack one or two C-terminal residues are observed by mass spectrometry.[114] Studies in the metabolism literature sometimes refer to RBP as retinol-binding protein-4.[160] Zinc is required for synthesis, and retinol is required for its transportation by the Golgi apparatus.[70] In plasma, RBP occurs mainly as a 1:1 complex with prealbumin, slowing glomerular filtration of RBP. Prealbumin usually has twofold to threefold molar excess over RBP. Uptake of retinol by target cells is followed by

dissociation of the prealbumin-RBP complex and clearance of apoRBP (RBP without retinol) from the circulation by the kidneys. RBP has a half-life of only about 12 hours, but it is extended in renal failure.[161]

Clinical Significance of Prealbumin and RBP. If vitamin A intake is adequate and renal function is normal, concentrations of prealbumin and RBP often rise and fall in parallel. Adipocytes appear to be a significant site for synthesis of RBP, and its concentrations may increase with obesity or syndromes of insulin resistance.[160]

Increased Plasma Concentrations. Serum RBP increases in chronic renal disease, including diabetic nephropathy.[161] Concentrations are increased with corticosteroid or NSAID therapy and in Hodgkin's disease. Interest in RBP has been stimulated by recognition that it is synthesized in adipose tissues, and that excretion from adipose tissue may increase in syndromes of insulin resistance, together with other products of adipocytes such as leptin, adiponectin, and resistin.[16,160]

Decreased Plasma Concentrations. Decreased concentrations of prealbumin and RBP are seen primarily in liver disease, protein malnutrition, and the APR. Zinc deficiency results in low serum concentrations of both RBP and vitamin A. Prealbumin concentrations are often used as an indicator of adequacy of protein nutrition because of its relatively short half-life, high proportion of essential amino acids, and small pool size. However, it is a negative APR. Concentrations also fall in cirrhosis of the liver and protein-losing diseases of the gut or kidneys. An acute-phase reactant, such as CRP, should be assayed along with prealbumin if concentrations are to be used to estimate nutritional status. History and physical examination are also important aspects of nutritional assessment.[25]

Genetic Aspects. The gene coding for prealbumin is on chromosome 18q. More than 75 genetic variants have been described, a few affecting T_4 binding. Variants with increased affinity for T_4 are associated with euthyroid *hyper*thyroxinemia, similar to albumin variants with increased T_4 affinity. Changes in T_4 binding affect total T_4 measurements but not other assessments of thyroid function such as thyrotropin or free T_4.

Some prealbumin variants are associated with tissue deposition of amyloid fibrils. These autosomal dominant hereditary amyloidoses include amyloidotic cardiomyopathy, familial amyloidotic polyneuropathy, and senile systemic amyloidosis (see later section in this chapter on amyloidoses). Variants can be detected by mass spectrometry or by genetic analysis.[8,143] The *RBP* gene is on chromosome 10q, and clinically significant variants are not described.

Laboratory Considerations and Reference Intervals. Prealbumin migrates as a minor component anodal to albumin on routine serum electrophoresis and is not routinely observed by most methods. It is a proportionately greater component of CSF. Prealbumin and RBP usually are measured by immunonephelometric or immunoturbidimetric methods. The adult reference interval for RBP is 3.0 to 6.0 mg/dL. The RBP concentration at birth is 1.1 to 3.4 mg/dL and at 6 months increases to 1.8 to 5.0 mg/dL. The adult reference interval for prealbumin, based on the Certified Reference Material (CRM) 470, is 20 to 40 mg/dL (0.2 to 0.4 g/L).[22] Concentrations in healthy neonates are approximately half those found in adults; they increase into puberty, with a larger increase noted in boys than girls, and decrease in both sexes after age 50.[70]

Albumin

The name *albumin* (*L. albus* = white) originated from the white precipitate formed during the boiling of acidic urine from patients with proteinuria. Normally, albumin is the most abundant plasma protein from the fetal period onward, accounting for about half of the plasma protein mass. It is a major component of most body fluids, including interstitial fluid, CSF, urine, and amniotic fluid. More than half of the total pool of albumin is in the extravascular space. The monograph by Peters is a source of extensive information about albumin.[121]

Biochemistry of Albumin. Albumin has a nonglycosylated polypeptide chain of 585 amino acids and a calculated molecular weight of 66,438 Da. It has a heart-shaped three-dimensional structure stabilized by 17 intrachain S-S bonds.[121] It is a relatively stable protein, resisting denaturation up to higher temperatures than most plasma proteins. Albumin has a high abundance of charged amino acids that contribute to high solubility, and it has a net negative charge of about −12 at neutral pH.[37] Albumin therefore contributes about 6 to 10 mmol/L to the anion gap at normal albumin concentrations of 0.5 to 0.8 mmol/L, and lesser amounts at lower albumin concentrations. At a pH of 8.6 for alkaline electrophoresis, albumin has a net charge of about −25, resulting in high mobility toward the anode. One unpaired cysteine at position 34 occurs partially in reduced form and partially in exchangeable disulfide bonds with small compounds such as cysteine and homocysteine. The unpaired cysteine has an unusually low pK of <6 and high rates of disulfide exchange.[121] Consequently, it serves as a major plasma carrier of compounds with free sulfhydryls.

Albumin is synthesized by hepatocytes. The synthetic reserve of the liver is substantial; in nephrotic syndrome, albumin synthesis can increase threefold above normal. The synthetic rate is controlled primarily by colloidal osmotic pressure (COP) and secondarily by protein intake.[121] As noted previously, albumin is a negative acute-phase reactant.[42] Catabolism occurs mainly by pinocytosis by multiple tissues, with lysosomal degradation of protein to amino acids. Normally, only small amounts (10 to 20% of the total catabolized) are lost into the gastrointestinal tract and the glomerular filtrate.[121] Albumin losses by these routes may become substantial, however, in protein-losing enteropathies and glomerular disorders, resulting in nephrotic states. Burn injuries also result in major losses of albumin. The normal plasma half-life of albumin is 15 to 19 days. Albumin and IgG have several-fold longer plasma half-lives than most proteins because of the action of a recycling receptor, the neonatal IgG receptor, that recovers these two proteins from pinocytosed fluids.[131,165]

At high concentrations of albumin, the receptor may be saturated and the half-life of albumin decreased. At low concentrations of albumin, such as in analbuminemia (described later), the half-life of albumin is markedly extended.

Function of Albumin. Albumin is not essential for humans; rare individuals with analbuminemia have been found.[121] However, the large metabolic expenditure for abundant albumin formation, mechanisms of regulation, and specific recycling mechanisms argue for beneficial functions. Albumin may serve as a storage form of amino acids that can be delivered to tissues in catabolic states and as an antioxidant, particularly through the action of its free sulfhydryl group. The two most clearly defined functions of albumin are (1) serving as the major component of colloid osmotic pressure (patients in hypoalbuminemic states, such as nephrotic syndromes, are prone to develop edema; albumin solutions sometimes are administered as a replacement fluid to try to acutely maintain intravascular volume); and (2) serving as a transporter for a diverse range of substances, including fatty acids and other lipids, bilirubin, foreign substances such as drugs, thiol-containing amino acids, tryptophan, calcium, and metals.[121] Some of these substances, such as fatty acids and unconjugated bilirubin, have very low solubility in water in the absence of a carrier molecule; albumin therefore serves as an important carrier for a variety of hydrophobic metabolic substrates and drugs, assisting with transport to the liver or other sites of metabolism. Albumin has up to six binding sites for free fatty acids. The reference interval of 0.28 to 0.89 mmol/L[156] for free fatty acids corresponds to a stoichiometry of about one fatty acid per albumin molecule, and this ratio increases in obesity and other states with increased free fatty acids. Purified albumin usually contains bound fatty acids unless special stripping procedures are used.[121]

Clinical Significance of Albumin

Increased Plasma Concentrations. Increased concentrations of albumin occur with dehydration or artifactually from prolonged tourniquet time or specimen evaporation prior to analysis. High albumin concentrations therefore suggest problems with hydration or specimen handling.

Decreased Plasma Concentrations. Low concentrations of albumin are associated with decreased survival and poorer outcomes in kidney and cardiovascular disease.[1,62] Decreased albumin concentrations can result from decreased synthesis, increased metabolic turnover, increased distribution to extravascular fluids, or losses from glomerular and gastrointestinal disorders, burns, or other wounds. Decreased synthesis occurs with rare genetic variants, acute-phase responses, and liver dysfunction. Hypoalbuminemia leads to decreases in the anion gap. Albumin usually binds half the calcium in the circulation; therefore, decreased albumin concentrations need to be considered in interpretation of total calcium concentrations that may be expressed as values corrected for calcium concentration.[85]

Analbuminemia. Only about 20 families with inherited analbuminemia have been reported.[121] Although affected individuals have plasma albumin concentrations <0.5 g/L (≤1% of normal), symptoms often are absent or consist of mild edema, lipodystrophy, and dyslipidemia. No increased risk for atherosclerosis has been noted. The plasma half-life of infused albumin in affected individuals is prolonged to 50 to 60 days.

Inflammation. Inflammatory disorders lower albumin by (1) increasing capillary permeability, allowing increased distribution of albumin into the extravascular space; (2) decreasing synthesis in response to inflammatory cytokines such as IL-6; (3) responding to increased quantities of positive acute-phase reactants that contribute to oncotic pressure; and (4) increasing the catabolism of albumin by cells.[121]

Hepatic Disease. The liver has synthetic capacity to maintain albumin concentrations until parenchymal damage or loss is severe, with loss of more than 50% of function. Mechanisms other than direct loss of function may lead to lower albumin concentrations. Potential mechanisms include nutritional deficiencies, direct inhibition of synthesis by toxins such as alcohol, and increased distribution of albumin in extravascular spaces.[70]

Urinary Loss/Kidney Disease. Normally, the glomerular filtration barrier efficiently prevents entry into the urinary ultrafiltrate by proteins the size of albumin or larger.[116] Usually, only 1 to 2 g/d of albumin passes through the glomerular barrier, and 99.9% of albumin in the glomerular ultrafiltrate is taken up by proximal tubules of the kidney and degraded. Only about 10 mg/d of albumin is normally excreted in urine. Small increases and urine albumin excretion to >30 mg/d are indicators of early stages of glomerular or tubular injury.[105] This has been termed *microalbuminuria* ("micro" refers to excretion of small amounts, not a smaller form, of albumin). (See Chapter 25 on kidney function tests.) Nonpathologic increases in albumin excretion are observed in some individuals with postural changes, strenuous exercise, and fever. Therefore, urinary albumin should be collected under controlled conditions, and collection repeated if a question arises. First or second voided specimens in the morning may decrease postural effects. Severe glomerular injury and nephrotic syndromes are characterized by excretion of >3.5 g/d. In nephrotic syndrome, the glomerular leakage of proteins is increased but some size selectivity is retained; therefore, very large proteins are still retained. Even though the liver compensates through increased protein synthesis, concentrations of proteins up to about 200 kDa, including albumin, decrease substantially. Concentrations of very large proteins, such as α_2-macroglobulin (AMG), larger isotypes of Hp (genotypes 2-1 and 2-2), cholinesterase, and apolipoprotein B are increased.

Gastrointestinal Loss. Protein-losing enteropathy may result in losses as great as those seen in the nephrotic syndrome. If protein-losing enteropathy occurs secondary to lymphangiectasis, larger proteins—especially the immunoglobulins—may be lost in large quantities. Patients with Ménétrier's disease who have gastric protein losses or inflammatory bowel disease of the intestinal tract, such as Crohn's disease with intestinal losses, can develop hypoalbuminemia.[36]

Protein-Calorie Malnutrition. Albumin concentrations serve as a means of detecting and monitoring protein-calorie

malnutrition, because concentrations vary directly with adequacy of intake. However, the response of albumin to increased or decreased protein ingestion is relatively slow, in part because of its relatively long half-life. Also, effects of acute or chronic inflammation may decrease the correlation of albumin concentration with nutrition.[70]

Burn Injury. Patients with burn injury can experience severe losses of albumin from wounds. Severely decreased plasma albumin concentrations probably relate to combined effects of epithelial losses, accelerated catabolism, and stimulation of the acute-phase response.[69]

Edema and Ascites. Edema and ascites rarely are the result of decreased plasma albumin concentrations per se. Usually they occur secondary to increased vascular permeability, which permits the loss of albumin into these spaces. Albumin concentrations in these fluids vary from very low to higher than those in plasma, the latter in particular with certain forms of ascites.[52] Increased volumes of extravascular fluid may be large enough to contain a substantial portion of total body albumin. In patients with edema or ascites associated with low plasma albumin, effects of albumin infusion are transient because of rapid equilibration with extravascular fluid. In acute hypovolemic shock, albumin infusion may help to maintain vascular volume, but rapid infusion may result in symptoms of hypocalcemia due to calcium binding by albumin.

Genetic Aspects of Albumin. The albumin gene is on chromosome 4, linked to homologous genes for α-fetoprotein (AFP) and vitamin D–binding protein (Gc-globulin). Inherited analbuminemia has been reported in a few families. Inheritance is autosomal recessive, with heterozygotes having low normal to moderately reduced concentrations.[121] More than 80 different inherited structural variants of albumin have been described, most with normal concentrations of albumin. All variants have a population frequency of <1 : 1000. Variants may have altered electrophoretic migration, leading to two bands for albumin or *bisalbuminemia* for heterozygotes. Variants with abnormal intramolecular disulfide bonding, such as Alb Hawkes Bay, may form homodimers or heterodimers with other proteins such as α_1-antitrypsin AAT.[121] Electrophoretic variants of albumin and bisalbuminemia may be acquired as effects of bound drugs or metabolites. Most albumin isoforms have normal function; an exception consists of increased or decreased binding affinities for T_4 of certain albumin variants. Variants with increased affinity for T_4 yield familial dysalbuminemic hyperthyroxinemia, where total serum T_4 is elevated, although individuals are euthyroid and have normal thyrotropin concentrations.

Laboratory Considerations for Albumin

Plasma and Serum. Most clinical laboratories assay albumin in plasma or serum samples by dye-binding methods, which rely on a shift in the absorption spectrum of dyes such as bromcresol green (BCG) or purple (BCP) upon albumin binding. The affinity of these dyes is higher for albumin than for other proteins, providing some specificity for albumin. BCP generally is slightly more specific for albumin and yields lower values than BCG, particularly for patients with kidney failure.[85] Heparin in collection tubes is reported to affect some dye-binding methods.[104] Dye-binding assays also tend to be less accurate when the serum or plasma protein composition is abnormal. Dye-binding methods have decreased accuracy for patients with cirrhosis, possibly related to oxidized or other modified forms of albumin.[166] Unfortunately, disorders with abnormal plasma protein compositions, such as kidney and liver disease, often present situations in which accurate analysis is most desired. Albumin concentrations are considered an important indicator of adequate nutrition in patients with kidney failure, and guidelines for monitoring patients with kidney failure recommend correcting total calcium values for albumin concentration.[85] Guidelines also recommend nutritional supplementation of patients with kidney failure to maintain serum albumin concentrations of at least 40 g/L by the BCG method.[1] Low albumin concentrations are a strong predictor of unfavorable outcomes for many clinical disorders, including patients on chronic hemodialysis. Albumin concentrations increasingly are used as a measure of quality of care by physicians or patient care units, so that methods of analysis and accuracy of results are of increasing concern to many medical professionals. Serum albumin also is used as a criterion in the staging of patients with multiple myeloma, with albumin ≥3.5 g/dL necessary for patients to be in stage I with best prognosis.[82] Estimation of albumin concentration by serum protein electrophoresis yields discordant values with immunonephelometry and BCG methods for some patients with high paraprotein concentrations.[147]

Many ligands of albumin, including drugs and metabolites, bind to albumin but usually do not affect dye-binding assays of serum or plasma significantly unless their concentrations are very high. Because of their simplicity and low cost, dye-binding assays are likely to remain the predominant means for assaying albumin in serum and plasma. In assessment of albumin in ascitic fluid, dye-binding methods have been noted to give spuriously high results.[33]

Densitometric scans of electrophoretic patterns can determine the percentage of protein made up of albumin. Along with a measure of total protein concentration, albumin concentration can be calculated. Care is needed in calibrating assays and determining ranges of linear responses of staining or absorbance measurements in capillary electrophoresis. Scanning often offers low precision and linearity, and multiple measurements are combined, generally resulting in albumin measurement with lower accuracy, less precision, and greater potential for interference.[147] Immunoturbidimetry and immunonephelometry offer greater specificity and accuracy of albumin measurement than other methods, along with the higher sensitivity needed for specimens with low albumin concentrations such as urine and CSF.

Reference Intervals of Albumin. Based on the international protein reference CRM 470, the recommended interim reference interval for albumin in serum of adults 20 to 60 years of age is 35 to 52 g/L (3.5 to 5.2 g/dL).[22] Albumin concentrations reach adult concentrations around 20 to 30 weeks'

gestation and remain relatively constant until at least 20 years of age. Concentrations then slowly decrease with age in both sexes. Concentrations are lower in individuals living in the subtropics and tropics, probably because of higher immunoglobulin concentrations secondary to infection. Concentrations are posture dependent, increasing by up to 10 to 15% if an individual is standing versus recumbent. This reflects a shift of fluid between intravascular and extravascular spaces; albumin is preferentially retained in the intravascular space. A similar increase in albumin results from prolonged tourniquet time before blood collection.

α_1-Acid Glycoprotein (AAG)

AAG, also known as orosomucoid, was one of the first plasma glycoproteins to be isolated and extensively characterized. AAG is a major constituent of the seromucoid fraction of plasma, which consists of a group of proteins that are "slimy" ("mucoid" is from Greek *myxa* = slime) because of their high carbohydrate content.

Biochemistry of AAG. AAG actually consists of two proteins that are products of homologous genes on chromosome 9. Each of the two gene products has a polypeptide chain of 183 amino acids, but the two differ at about 21 positions. About two thirds of AAG is the product of the *AAG-1* (or *ORM1*) gene. Both have a molecular mass of 35 to 40 kDa, of which ≈45% is carbohydrate (CHO), including ≈12% sialic acid; 5-N-linked oligosaccharides include a variable mixture of biantennary, triantennary, and tetraantennary structures with terminal sialic acids, resulting in heterogeneity of AAG upon isoelectric focusing.[38] Oligosaccharide structures and charge of AAG change with inflammation, as do many proteins.[45,72]

AAG is synthesized mainly by hepatocytes, but granulocytes and monocytes may contribute to plasma concentrations in sepsis. Removal of desialylated AAG by hepatic asialoglycoprotein receptors contributes to catabolism. The plasma half-life of intact AAG is ≈3 days, whereas that of the desialylated protein is only a few minutes.[70]

Function of AAG. AAG is a *lipocalin,* a family of homologous proteins, including RBP, many of which bind lipophilic substances. AAG binds a large number of basic and lipophilic compounds, including progesterone and related steroid hormones. Binding of drugs to AAG increases the total plasma concentration while reducing the proportion of drug that is free and bioactive. Affected drugs include propranolol, quinidine, chlorpromazine, cocaine, imatinib, and benzodiazepines. Because AAG concentrations may change several-fold in acute-phase responses, interpretation of total drug concentrations for some drugs requires measurement of AAG or alternative measurements of free rather than total drug concentrations. Besides its carrier function, AAG has been proposed to serve a variety of functions, including down-regulation of the immune response, depression of phagocytosis by neutrophils, inhibition of platelet aggregation, inhibition of mitosis, inhibition of viruses and parasites, and action as a cofactor for lipoprotein lipase; it also acts as a contributor to capillary selectivity.[70]

Clinical Significance of AAG. Various pathologic conditions are associated with increased and decreased concentrations of AAG.

Increased Plasma Concentrations

Acute-Phase Response. Plasma AAG concentrations increase up to fourfold in response to inflammation or tissue necrosis, with peak concentrations noted around 3 to 5 days after the initial insult. As an example, AAG serves as an indicator of the clinical activity of ulcerative colitis.

Hormonal Effects. AAG concentrations are increased by glucocorticoid hormones, either endogenous (e.g., Cushing's syndrome) or exogenous, along with Hp and prealbumin concentrations.

Decreased Plasma Concentrations

Hormonal Effects. Synthesis and plasma AAG concentrations are decreased by estrogens.

Sieving Protein Loss. AAG is slightly smaller than albumin and therefore is lost in the urine in nephrotic syndrome and in gastrointestinal secretions in protein-losing enteropathy.

Laboratory Considerations for AAG. The major applications of AAG measurement are to monitor APRs and to assess effects on drug binding. Measurement of total drug concentrations may require correction for AAG concentration.[70] Hormonal effects and the APR are similar for AAG and haptoglobin, so that measurement of AAG may assist in interpreting whether changes in haptoglobin are due to in vivo hemolysis (which does not affect AAG concentrations). Although AAG is one of the proteins of highest concentration in the α_1-globulin region on routine serum electrophoresis, it does not stain well with protein stains because of its high carbohydrate content. It can be visualized by using periodic acid–Schiff or other carbohydrate stains. AAG usually is quantified by immunoturbidimetry, immunonephelometry, or radial immunodiffusion (RID).

Reference Intervals for AAG. The proposed interim reference interval for white adolescents and adults is 0.5 to 1.2 g/L (50 to 120 mg/dL), based on CRM 470.[22] Concentrations at birth are only 20 to 30% of this, but approximately adult concentrations are reached by 6 to 12 months of age.

α_1-Antitrypsin (AAT)

Schultze described AAT in 1955, recognizing inhibition of trypsin. However, AAT inhibits a variety of serine proteinases, leading to the term α_1-*proteinase inhibitor.* Both names are used currently. *AAT* is the term commonly used by clinicians and clinical laboratorians, but phenotypes are commonly abbreviated as Pi.

Biochemistry of AAT. AAT has a single polypeptide chain of 394 amino acid residues with 3 *N*-linked oligosaccharides, giving a total MW of ≈51 kDa. It is SerpinA1 of the serpin superfamily (where *A* refers to subgroup or clade). It has Met as a reactive site residue at residue 358, helping to define its specificity for inhibition of elastase and its susceptibility to inactivation by oxidation of the methionine sidechain.[14] Serpins are suicide inhibitors of serine proteases, which abortively try to cleave the inhibitor at the reactive site residue but remain covalently linked to the reactive site residue

because of a conformational shift of the inhibitor upon cleavage. Serpins usually occur in a "stressed" conformation, and cleavage leads to a dramatic conformational shift to a "relaxed" form. AAT and other serpins serve as important models for conformational change in protein function and aggregation.[14]

Most AAT in plasma is synthesized by the hepatocytes, and AAT genotype changes with liver transplantation. AAT is an acute-phase reactant, with hepatic synthesis and plasma concentrations rising up to several-fold. Catabolism occurs by several routes, in addition to usual bulk pinocytosis of plasma proteins: AAT-protease complexes are removed by serpin-enzyme complex receptors [low-density lipoprotein (LDL)-related receptor],[68] along with several other serpin-enzyme complexes. Proteases complexed with AAT also may be transferred to AMG; AMG-protease complexes are removed even faster by the liver than are AAT-protease complexes. AAT can also be removed by asialoglycoprotein receptors, which bind AAT that loses sialic acid. The normal plasma half-life is 6 to 7 days for the Pi M genotype; Pi S and perhaps other variants have a shorter half-life and secondarily lower plasma concentrations.

Function of AAT. AAT covalently binds to the active sites of serine proteases, thus blocking their enzymatic activity. Other members of the serpin superfamily include the proteinase inhibitors α_1-antichymotrypsin, α_2-antiplasmin, antithrombin III, heparin cofactor II, and C1 inhibitor, plus angiotensinogen, thyroxine-binding globulin, and other proteins with no apparent inhibitory activity.[88] AAT is one of the 10 most abundant plasma proteins and the most abundant protease inhibitor on a molar basis. AAT inhibits many proteases, but physiologically, one of its most critical actions is inhibiting elastase released from neutrophils. As first established by Laurell, deficiency of AAT is associated with emphysema related to elastin degradation in the lung by neutrophil elastase. Smoking serves as a cofactor in this process by stimulating chronic inflammation and neutrophil infiltration in the lungs, and by promoting inactivation of AAT through oxidation of its reactive site Met residue.[14]

Clinical Significance of AAT

Increased Plasma Concentrations. Plasma AAT concentrations are increased in the APR and with estrogens.

Acute-Phase Response. In acute inflammatory processes, serum AAT concentrations begin to rise after approximately 24 hours and peak at 3 to 4 days. Synthesis is stimulated by cytokines, particularly IL-6, and by AAT-elastase complexes taken up via the LDL-related receptor. Cytokines, including IL-6, induce a broader APR. Inflammation of hepatocytes may be associated with increased serum AAT without the other components of the APR.[70]

Estrogens. Synthesis of AAT is stimulated by estrogens; elevated concentrations are seen particularly during late pregnancy and during estrogen therapy.

Decreased Plasma Concentrations. Plasma AAT concentrations are decreased with genetic deficiency, increased turnover, and urinary or gastrointestinal loss.

Genetic Deficiency. More than 75 genetic variants of AAT have been noted, and prevalence of clinical AAT deficiency in the United States is estimated at 1:3000 to 1:5000.[144] About 10% of individuals express genetic variants of AAT, but clinical disorders usually occur only in individuals expressing variants at both alleles. Severe genetic deficiency of AAT (Pi ZZ or Pi Z null genotypes) increases risk for pulmonary emphysema, and onset of disease is relatively early, with changes beginning in the second to fourth decades of life in 90% of Pi ZZ individuals. Progression of emphysema is highly variable, but age at onset and median age at death are, on average, younger in smokers. Patients with Pi SZ genotype have less risk for lung disease than those with Pi ZZ genotype.[144]

AAT deficiency also is associated with liver disease, including neonatal cholestasis or hepatitis, cirrhosis, and hepatocellular carcinoma. About 10% of infants with Pi ZZ or Pi Znull genotype have prolonged obstructive jaundice; 2% progress to liver failure in childhood.[144] Early differentiation of cholestasis from AAT deficiency and biliary atresia can be challenging histologically.[70] Liver disease with AAT variants has a risk for progression to hepatocarcinoma. Hepatic injury in AAT deficiency probably is related to intracellular accumulation of AAT, but many factors may determine disease progression.[144]

Increased Utilization. Low concentrations of AAT are seen in neonatal respiratory distress syndrome, severe neonatal hepatitis, and severe preterminal pancreatic disease. In nonfatal pancreatitis, concentrations increase from the APR, and increased concentrations of complexes with trypsin may indicate diagnosis or prognosis in patients with possible pancreatitis.

Urinary or Gastrointestinal Loss. AAT is similar in size to albumin; therefore, urinary and gastrointestinal losses occur in parallel to those noted with albumin in nephrotic syndromes and protein-losing enteropathies. AAT is normally present in excreted stool, mostly complexed to pancreatic trypsin and elastase. Evaluation of AAT excretion in stool is used as a measure of protein-losing enteropathy (see section on stool protein).[6,152]

Genetic Aspects of AAT. The gene for AAT (*Pi,* for protease inhibitor) is found on chromosome 14. It is a polymorphic gene with more than 75 genetic isotypes of AAT, designated as Pi (pronounced *pee eye*) plus letters from B to Z in order of decreasing electrophoretic mobility, with B being the most anodal.[12] About 30 variants are associated with decreased AAT.[144] The usual or wild type is Pi M. In many populations, 10% or more of individuals are heterozygous for AAT variants. Most clinical disorders occur in individuals with two variant alleles. Numbers or subscripted place names indicate subtypes (e.g., Pi M1 and Pi M_{malton}); null is used for deleted or nonproducing alleles. Several variants are associated with reduced plasma concentrations, with an aggregate population frequency of about 1:3000. AAT concentrations are reduced to about Pi P 25%, Pi S 60%, Pi W 80%, Pi Z 15%, and Pi null 0%. Pi Z is most common among northern Europeans, and Pi S is most common in those in

southwestern Europe. Pi Z, clinically the most important deficiency variant, has a lys → glu substitution at position 342, whereas Pi S has a 264 glu → val substitution. Mutations resulting in Pi null are rare. The concentrations and the variants are codominant; therefore an individual with Pi MZ, for example, would have a concentration of ≈58% of the normal Pi MM concentration [(100 + 15)/2]. One variant, Pi $M_{pittsburgh}$, with a Met → Arg substitution at position 358 (the reactive site residue), inhibits elastase poorly but inhibits clotting enzymes, including thrombin and kallikrein. Heterozygotes for this variant have a bleeding disorder because of its anticoagulant effects.[140] This variant demonstrates the importance of reactive site residue in serpin specificity.

Laboratory Considerations for AAT. The Global Initiative for Chronic Obstructive Lung Disease recommends quantitative testing of AAT for patients with chronic obstructive pulmonary disease with family history or onset before age 45.[144] AAT usually is quantified by immunoturbidimetry or immunonephelometry. AAT represents the majority of serum inhibitory activity versus trypsin and elastase and could be assessed by inhibition assays of these enzymes. Leukocyte proteases may be released into serum stored on the clot after blood drawing, and the proteases may complex with AAT, altering both electrophoretic mobility and immunochemical quantification. Bacterial contamination and release of bacterial proteases can have a similar effect. Serum should be removed from the retracted clot and stored aseptically at 4 °C (for up to 3 to 4 days) or at −70 °C (for long-term storage). Phenotyping of AAT usually is performed by isoelectric focusing. For genotyping, the most important types to detect are Z and S, but a large number of other rare alleles are known, and it is important to consider what variants are detected.

AAT usually is the major serum component stained in the α_1-globulin band on agarose gel electrophoresis. Decreases in the α_1-band suggest a quantitative decrease in AAT or variants with altered mobility. Variants forming dimers with albumin have altered electrophoretic mobility but normal concentrations. The two other highest abundance α_1-globulins, AAG and α-lipoprotein, do not stain well with peptide stains because of their high contents of carbohydrate and lipid, respectively. Five to eight AAT bands are found on acid gel electrophoresis or isoelectric focusing (pIs approximately 4.2 to 4.9, depending on the genetic phenotype), as shown in Figure 21-2.

Microheterogeneity within a single genetic variant results primarily from variation in oligosaccharides and, in the case of the two most cathodal bands, absence of the first 5 amino acids of the peptide chain.[70]

Reference Intervals for AAT. For adults, the recommended consensus reference interval, based on CRM 470, is 0.9 to 2.0 g/L (90 to 200 mg/dL) for individuals with the Pi MM phenotype,[22] with a median of approximately 1.3 g/L. Concentrations are slightly higher in women in childbearing years and in elderly individuals. Concentrations are also higher in patients with inflammatory disorders, malignancy, or trauma, and in women who are pregnant, on estrogen therapy, or taking oral contraceptives. Neonates have higher concentrations, possibly because of maternal estrogen. Individuals with concentrations below 70 mg/dL should be phenotyped or genotyped, especially if they or family members have diseases that may be associated with AAT deficiency. AAT concentrations in Pi ZZ genotypes usually are 0.1 to 0.5 g/L (10 to 50 mg/dL). AAT replacement therapy, with weekly infusions, has been approved by the U.S. Food and Drug Administration for patients with AAT <56 mg/dL (<11 μmol/L).[144]

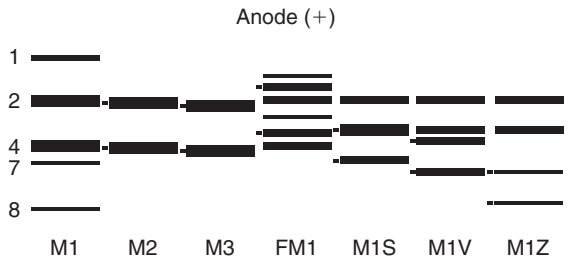

Figure 21-2 Diagram of common variants of α_1-antitrypsin, as demonstrated by isoelectric focusing. The five major bands are shown for M1, but only the 2 and 4 bands are shown for the other variants *(with dots to the left of each)*. Variants F, S, V, and Z are shown in combination with M1 for the sake of clarity. If cysteine is added to the samples before focusing, the F-2 and F-4 bands shift to the locations of the faint bands.

α_2-Macroglobulin (AMG)

AMG is a large protein with Mr of ≈720 kDa. It is a versatile protease inhibitor with a different mechanism than serpins. AMG is homologous to complement components C3 and C4 and, like those proteins, contains an internal thioester that is activated by proteolytic cleavage and reacts to bind covalently to neighboring molecules.

Biochemistry of AMG. AMG has four identical subunits with MW of 180 kDa, occurring as a pair of dimers. The dimers are disulfide-linked, whereas the pairs are held together by noncovalent bonds. The dimer is the active unit; one molecule of AMG binds up to two protease molecules. Each monomer contains a reactive thioester, which is formed internally between cysteine and glutamine sidechains at positions 949 and 952 in the peptide chain. The thioester is exposed when a "bait" region is cleaved by a protease. The thioester reacts to form covalent bonds with the protease, thus immobilizing it, but the active site of proteases is not blocked and retains activity versus low molecular weight substrates.[61,77] AMG is synthesized primarily by hepatocytes and has a half-life of several days. However, once AMG's thioester is cleaved clearance occurs within minutes via a hepatic receptor. Also, desialylated AMG is removed rapidly by asialoglycoprotein receptors.

Function of AMG. AMG is a versatile inhibitor of many proteases, including enzymes in the kinin, complement, coagulation, and fibrinolytic pathways and classes of proteases not inhibited by serpins. In addition, AMG accepts

transfer of proteases complexed to serpins (e.g., elastase-AAT), and AMG-protease complexes are then rapidly removed by receptors. Because of its large size, AMG is restricted primarily to the vascular space. In addition to serving as a protease inhibitor, AMG may serve as a transport molecule for cytokines, growth factors, and zinc. Transport functions may contribute to apparent activity of AMG in modulating immunologic and inflammatory reactions. Oxidation dissociates AMG tetramers into dysfunctional dimers. Thus as is the case for AAT and other serpins, inhibitory activity is reduced or eradicated by increased concentrations of oxidants (such as those from cigarette smoke or from neutrophils).[70]

Clinical Significance of AMG

Increased Plasma Concentrations. Increased plasma concentrations of AMG relate to hormonal effects, age, and the nephrotic syndrome.

Hormonal Effects. Synthesis and plasma concentrations of AMG are increased by estrogens; women of childbearing age have higher concentrations than men of the same age.

Age. Synthesis rates in infants and children are up to three times adult concentrations. High concentrations of AMG may delay clinical signs and symptoms until after puberty in individuals with antithrombin III or C1 inhibitor deficiency.

Nephrotic Syndrome. Hepatic synthesis is increased in the nephrotic syndrome, as is synthesis of most other proteins made by the liver, in attempts to compensate for decreased oncotic pressure. Elevated AMG concentrations may partially compensate physiologically for renal loss of lower molecular weight proteinase inhibitors.[70]

Decreased Plasma Concentrations. Decreased plasma concentrations of AMG result from various genetic conditions, pancreatitis, *and* prostatic carcinoma. AMG does not change markedly in the acute-phase response. AMG has been measured as one component of some multiparameter indices of hepatic fibrosis.[46]

Genetic. See "Genetic Aspects," later in this chapter.

Pancreatitis. In severe attacks of acute pancreatitis, plasma concentrations of antithrombin III and AMG may be markedly decreased; other inhibitors are normal or increased, and protease-antiprotease complexes are increased. In the peritoneal fluid, all major protease inhibitors are decreased or absent.[70]

Prostatic Carcinoma. Plasma concentrations of AMG are decreased before treatment for advanced carcinoma of the prostate and return to normal with successful treatment. AMG binds to prostate-specific antigen (PSA), and concentrations of the complexes are elevated in plasma during active disease, as is the case with PSA-α_1-antichymotrypsin complexes. In vitro, PSA added to serum has a higher affinity for AMG than for α_1-antichymotrypsin. In vivo, the complexes are probably removed very rapidly by the liver, as are other protease complexes with AMG; usually, free PSA and PSA-α_1-antichymotrypsin are the only forms detected.

Genetic Aspects of AMG. The gene for AMG is on chromosome 12, near genes for pregnancy zone protein and for its membrane receptor (LDL-related protein). No individuals with complete genetic deficiency of AMG have been described. Genetic variants are known, however. Two reported heterozygous mutations affected the function of AMG, and one patient with decreased AMG developed chronic lung disease in childhood.

Laboratory Considerations for AMG. AMG and Hp together constitute most of the α_2-globulin zone on routine clinical serum electrophoresis. In the newborn period and with in vivo hemolysis, AMG alone is the major contributor to this zone. Native and cleaved forms of AMG cannot be distinguished on routine electrophoresis. Higher-resolution separations indicate native AMG migrating slightly cathodal to AMG that has split its thioester. Monoclonal antibodies specific for the two forms indicate that normal plasma contains 0.8 to 1.9% of AMG in the complexed form.[70]

Reference Intervals for AMG. The interim recommended reference interval for white adults is 1.3 to 3.0 g/L (130 to 300 mg/dL).[22] Concentrations are approximately twice this in children at a maximum at 2 to 4 years of age; concentrations in women are 20 to 30% higher than in men after age 40.

Ceruloplasmin (Cp)

Cp is an α_2-globulin that contains about 95% of serum copper. Each molecule of Cp contains 6 to 8 copper atoms, most of which are tightly bound. A solution of Cp is blue (*L. caeruleus* = blue), and elevated concentrations of Cp may lend plasma a green tint.

Biochemistry of Cp. Cp has a polypeptide chain with 1046 amino acids and three asparagine-linked oligosaccharides, along with a total carbohydrate content of 8 to 10%. MW of intact Cp is 132 kDa. Size and charge heterogeneity results from variations in glycosylation, the number of copper atoms, peptide chain variations from alternative DNA splicing, and polymerization. Cp is highly susceptible to proteolysis, leading to earlier reports of more than one peptide chain.[70]

Cp is synthesized primarily by hepatic parenchymal cells, with small amounts from macrophages and lymphocytes. The peptide chain is formed first, then copper is added from an intracellular ATPase (absent in Wilson's disease). Copper appears to be essential for the normal folding of Cp and possibly for normal oligosaccharide attachment. Much of apoCp synthesized in the absence of copper or the ATPase is degraded intracellularly; some apoCp reaches the circulation, where it has a shortened half-life of a few hours. Consequently, serum Cp is low in Wilson's disease.[96] The normal half-life of Cp is 4 to 5 days.

Function of Cp. Cp is a catalyst for redox reactions in plasma.[141] Cp oxidizes Fe^{2+} to Fe^{3+} (Figure 21-3), which is important for allowing binding of iron to transferrin. Cp helps control membrane lipid oxidation—probably by direct oxidation of cations—thus preventing their catalysis of lipid peroxidation. In the presence of superoxide, Cp promotes LDL oxidation, which may contribute to atherosclerosis.[39] Neurologic disorders in hereditary Cp deficiency (aceruloplasminemia) may be due to disordered iron transport in the brain.[154] Cp appears to have a limited role in plasma copper transport to tissues. Albumin and transcuprein appear to

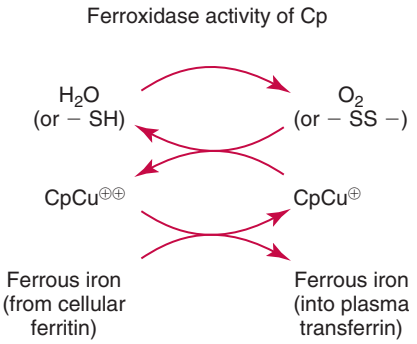

Figure 21-3 Proposed function of ceruloplasmin copper ($CpCu2^+$) as an electron recipient from cellular ferrous iron. The resulting oxidation of $Fe2^+$ to the ferric state permits its binding and transport by plasma transferrin. $CpCu^+$ is oxidized (regenerated to $CpCu2^+$) by reaction with oxygen, oxidized thiol groups, or other oxidizing substances. *(Modified from Johnson AM. Ceruloplasmin. In: Ritchie RF, Navolotskaia O, eds. Serum proteins in clinical medicine, volume I, Laboratory section. Scarborough, Maine: Foundation for Blood Research, 1996:13.01-13.03.)*

be the major copper transport proteins, especially following absorption from the intestinal tract.

Clinical Significance of Cp. Cp is most often measured by immunoassays as a screening test for Wilson's disease. Several factors, including diet, hormone concentrations, and other genetic disorders, may influence plasma concentrations. Immunochemical assays may not distinguish between the active, copper-replete holoCp and apoCp, which is released into the circulation in most of the disorders associated with low total Cp concentrations. Functional assays may be helpful to monitor patients on copper-lowering therapy.[96]

Increased Plasma Concentrations. Synthesis of Cp is increased modestly in the APR. This increase occurs relatively slowly, peaking at 4 to 20 days after a single, acute insult. Synthesis is stimulated markedly by estrogens, with moderate increases seen in women taking estrogen-containing medications, and larger increases noted during pregnancy.

Decreased Plasma Concentrations. Cp concentrations are decreased as a result of various primary and secondary deficiencies.

Genetic Deficiency. Inherited aceruloplasminemia has been reported in several families.[154] Neurodegeneration occurs in these patients associated with iron deposition in the brain. This argues strongly that a major role of Cp is to maintain normal iron transport, particularly in the brain.

Secondary Deficiency. Low plasma Cp concentrations caused by lack of incorporation of Cu^{2+} into the molecule during synthesis are much more common than aceruloplasminemia. Cp deficiency may be due to dietary Cu^{2+} insufficiency (including malabsorption), inability to release Cu^{2+} from the gastrointestinal epithelium into the circulation, or inability to insert Cu^{2+} into the developing Cp molecule. In all cases, apoCp (non–copper containing) is still synthesized, but most apoCp is catabolized intracellularly, and plasma apoCp has a much shorter half-life than Cp. Cp concentrations also may be low in blood loss or in gastrointestinal or renal protein-losing syndromes.

Dietary Cp deficiency is due to nutritional copper deficiency and is associated with neutropenia, thrombocytopenia, low serum iron, and hypochromic, normocytic, or macrocytic anemia unresponsive to iron therapy. The deficiency may be due to inadequate dietary intake, long-term parenteral nutrition without copper supplementation, malabsorption, penicillamine therapy, or combinations of these. Therapy includes dietary changes or copper supplementation, plus treatment of the primary cause of malabsorption if known.[95]

Menkes' disease is an X-linked inherited disorder in which dietary copper is absorbed by gastrointestinal cells that lack an ATPase for copper transfer to plasma.[95] Hence, copper is not available to the liver for incorporation into Cp. Affected infants manifest sparse, brittle, and kinky hair, growth restriction, and neurologic degeneration, with death occurring during the first few years of life if untreated. Subcutaneous injections of copper histidine partially reverse the deleterious effects if started early in life; some residual Menkes' ATPase activity (i.e., incomplete deficiency) may be necessary for this response, however. Patients with deficient gastrointestinal *and* blood-brain barrier transport of copper have been described; neurologic symptoms in these patients are not reversed by copper therapy.[70]

Wilson's disease, or hepatolenticular degeneration, differs from dietary deficiency and Menkes' disease in that body copper is markedly increased and is deposited in tissue, including the hepatic parenchymal cells, the brain, and the periphery of the iris (resulting in the characteristic Kayser-Fleischer rings).[96,97] Copper is absorbed and transported to the liver, but the absence of a hepatocellular P type of ATPase encoded on chromosome 13 prevents incorporation of copper into Cp. Symptoms in patients with Wilson's disease usually begin in the second or third decade of life. However, mutations that eliminate gene function may lead to onset of liver disease as early as 3 years of age. The initial clinical presentation may show acute hepatitis or chronic active hepatitis; neurologic signs (e.g., clumsiness, dysarthria, ataxia, tremors); renal indications (e.g., renal tubular acidosis with aminoaciduria); or, less commonly, hemolysis secondary to acute release of free copper from tissue. Treatment aims to decrease tissue copper overload through chelation with agents such as penicillamine or trientene and inhibition of dietary copper intake with supplemental zinc.[96]

Most patients with Wilson's disease have low plasma Cp concentrations. A cutoff of 0.2 g/L often has been used, but slight adjustment may be indicated for different populations and assays; an optimal cutoff of 0.14 g/L is recommended from one recent study.[97] However, inflammatory diseases or pregnancy may bring Cp concentrations of affected individuals to above cutoff values. Cp concentrations are slightly reduced in obligate heterozygotes. Low Cp concentrations are also seen in other disorders, as noted earlier. Clinical diagnosis of Wilson's disease therefore requires the presence

of classical signs of the disease, documentation of copper excess, or both. Slit-lamp examination of corneas for Kayser-Fleischer rings, assays of urine copper, and, if these are not diagnostic, liver biopsy for quantitative copper assay may be required for definitive diagnosis. Genetic analysis of the defective ATPase also permits definitive diagnosis in most cases, even in the absence of clinical abnormalities.

Genetic Aspects of Cp. Several variants or isotypes of the Cp gene are found on chromosome 3, but none of these, except for genetic deficiency (aceruloplasminemia), has known clinical significance. The most prevalent isotypes are CpA, CpB, and CpC, which are detectable by electrophoresis followed by immunofixation or functional staining; CpB is the common, or "wild," isotype.[70]

Laboratory Considerations for Cp. Cp usually is measured by immunoturbidimetry or immunonephelometry. It is subject to oxidation and proteolytic degradation during storage that may affect immunoreactivity. This lability may create problems with calibrators, controls, and quality control materials, and with patient samples. Depending on the degree of degradation and the assay method used, apparent concentrations may increase or decrease. Serum or plasma from patient samples should be separated as soon as possible after collection and assayed promptly or stored under proper conditions (up to 3 days at 4 °C; longer storage at −70 °C).[70] Cp also can be assessed for oxidase activity. Activity assay may serve as a better indicator of functional protein when therapy for copper chelation or other potential sources of copper deficiency is provided.[96]

Reference Intervals for Cp. Cp is undetectable before 20 weeks' gestation. Plasma concentrations gradually rise by term to 25 to 40% of normal adult concentrations, and by 6 months of age to nearly adult concentrations (Table 21-8). Serum Cp concentrations reach a maximum at 2 or 3 years of age, then fall slowly until adolescence, when adult concentrations are reached. Concentrations are higher in women during their menstrual years (and longer if estrogen replacement therapy is used). A genetic influence on synthetic rates is apparent; concentrations within families vary less than concentrations among families. Studies have examined the optimal cutoff value for detecting Wilson's disease and suggest a cutoff of 0.14 g/L, but this may require adjustment for local populations.[96] The recommended interim reference interval for all adults of both sexes, based on CRM 470, is 0.2 to 0.6 g/L (20 to 60 mg/dL).[22]

TABLE 21-8 Plasma Ceruloplasmin Reference Intervals*

Age	Reference Interval (mg/L)	
Cord (term)	50-330	
Birth-4 months	150-560	
5-6 months	260-830	
7-36 months	310-900	
4-12 y	250-450	
	Male	**Female**
13-19 y	150-370	220-500
Adults	220-400	250-600 (no OC)
		270-660 (OC; estrogens)
		300-1200 (pregnant†)

*Converted to CRM 470 values from multiple references.
†Second and third trimesters; concentrations increase with increasing gestational age.
OC, Oral contraceptives.

Haptoglobin (Hp)

Hp is an α_2-glycoprotein that binds hemoglobin (*G. haptein* = to bind).

Biochemistry of Hp. Hp is synthesized as a single peptide chain by hepatocytes and is cleaved into α- and β-chains. The α-chain has some homology to kringle 5 of plasminogen; the β-chain, with 245 amino acid residues plus oligosaccharides, is related to serine proteases. The protein is polymorphic, with two types of α-chain—α^1 and α^2—leading to three Hp genotypes—Hp 1-1, 2-1, and 2-2—that respectively are homozygous for α^1, heterozygous for α^1 and α^2, and homozygous for α^2. Variable numbers of α- and β-chains combine and become covalently linked by disulfides to form Hp. Hp 1-1 consists of four peptide chains $\alpha^1{}_2\beta_2$ with a total MW of 85 kDa. Hp 2-2 consists of multiple forms, including $\alpha^1{}_2\beta_2$, $\alpha^1{}_2\alpha^2\beta_3$, $\alpha^1{}_2\alpha^2{}_2\beta_4$, $\alpha^1{}_2\alpha^2{}_3\beta_5$, and higher multimers, with MW ranging from 86 to 300 kDa. Hp 2-2 consists of $\alpha^2{}_3\beta_3$, $\alpha^2{}_4\beta_4$, $\alpha^2{}_5\beta_5$, and higher multimers, ranging from 170 to 900 kDa.[87]

Hp scavenges hemoglobin in the vascular space. Hemoglobin released by hemolysis dissociates into αβ dimers at low concentrations, and these dimers of hemoglobin subunits bind to Hp. Each Hp molecule can bind hemoglobin ab dimers, equivalent in number to Hp b-chain binds in the molecule. Hp 1-1 binds hemoglobin with higher affinity than other phenotypes.[70] Hp-hemoglobin complexes are bound by CD163 receptors and are rapidly removed by reticuloendothelial cells, which degrade proteins and heme and reuse iron and amino acids. This process prevents renal clearance of hemoglobin until Hp-binding capacity is exceeded. Because Hp is degraded after complexing with hemoglobin, its concentration drops severely when intravascular hemolysis occurs.[43] The normal plasma half-life of Hp is about 5.5 days. Hemolysis of specimens after blood collection does not decrease amounts of Hp.

Function of Hp. Hp clears hemoglobin from the circulation, thereby preventing iron loss via renal hemoglobin excretion. Hp may have other functions, including antioxidant activity of Hp-hemoglobin complexes, inhibition of cathepsin B release by phagocytes, and bacteriostatic action. Hp synthesis is stimulated by inflammation but not by hemolysis (and depletion of Hp), suggesting important roles of Hp in inflammatory and immune responses.[70] In chronic hemolytic states, such as sickle cell disease, where haptoglobin is depleted, circulating hemoglobin increases, contributing to vascular disorders such as pulmonary hypertension by binding nitric oxide.[43]

Clinical Significance of Hp. Hp has a capacity to bind only about 1% of the hemoglobin in red cells at usual hematocrits, so intravascular lysis of a small proportion of red cells completely depletes plasma Hp.[87] Once Hp capacity is exceeded, free hemoglobin in the circulation increases. Free hemoglobin can oxidize to methemoglobin, followed by dissociation of metheme from globin. Metheme binds to hemopexin (high affinity) or albumin (low affinity), keeping it in solution. Hemopexin-heme complexes are removed by the reticuloendothelial system (as with Hp-hemoglobin complexes, but more slowly), with subsequent intracellular catabolism of the complex and a decrease in the hemopexin concentration in plasma.[70] Hemopexin synthesis is unaffected by other factors (such as estrogen) that decrease Hp synthesis, so low values usually reflect severe or prolonged hemolysis. Similar to Hp, it is a positive (but weak) APR. Disorders with increased red cell breakdown are associated with chronic depletion of Hp and hemopexin. Methemalbumin may be seen when Hp and hemopexin are depleted. Hp depletion may also allow excess hemoglobin αβ dimers to undergo glomerular filtration. Absorption and catabolism of hemoglobin subunits by the proximal tubules can lead to tubular injury from iron toxicity. If the absorptive capacity of the proximal tubules is exceeded, overflow proteinuria of hemoglobin into urine occurs. Evaluation of hemoglobinuria tries to distinguish prerenal, renal, and postrenal sources of hemoglobin.

Hp depletion is usually a sensitive biochemical indicator of intravascular hemolysis, followed by hemopexin depletion and finally by the presence of methemalbuminemia, hemoglobinuria, or both. Hp, therefore, is part of the assessment of possible transfusion reactions or other causes of hemolysis. However, Hp concentrations must be considered together with potential sources of protein loss or an APR, which increases Hp.

Haptoglobin phenotypes 2-1 and 2-2 are associated with increased risk of cardiovascular disease relative to phenotype 1-1, possibly related to lower average Hp concentrations, hemoglobin affinity, and limited extravascular distribution of those genotypes.[20] The Hp 2-2 phenotype is associated with higher serum iron, ferritin, and transferrin saturation, perhaps because of its preferential uptake by CD163 receptors.[70] Possible clinical associations of the Hp polymorphism have been considered in many studies.[15]

Increased Plasma Concentrations. Increased concentrations of Hp are seen in the APR and in protein-losing syndromes and are associated with corticosteroid effects.

Acute-Phase Response. Hp synthesis is increased in the APR 4 to 6 days after stimulation and takes about 2 weeks to fall to normal after the stimulus is removed.

Protein-Losing Syndromes (in Association With Hp 2-1 or 2-2 Phenotype). Most protein-losing syndromes, such as the nephrotic syndromes, compensate by increasing hepatic protein synthesis, including Hp, although Hp 1-1 is relatively small and losses are similar to albumin. Hp 2-1 and 2-2 phenotypes express large forms of Hp that have lower clearance rates, so they are increased in concentration in some protein-losing states.

Corticosteroid Effects. Glucocorticoids and androgens increase synthesis and plasma concentrations of Hp. Exogenous steroids, such as dexamethasone, may enhance the response to interleukins rather than directly affecting synthesis.

Decreased Plasma Concentrations. Decreased concentrations of Hp are seen with genetic deficiency, hemolytic disease, ineffective erythropoiesis, estrogens, and hepatocellular disease, and in neonates.

Genetic Deficiency. Genetic absence (anhaptoglobinemia, or *Hp0*) and hypohaptoglobinemia are rare. Detection of genetic Hp deficiency is complicated by high rates of hemolytic disease, either genetic (e.g., hemoglobinopathies, glucose-6-phosphatase deficiency) or acquired (e.g., malaria).

Hemolytic Disease and Ineffective Erythropoiesis. As discussed previously, Hp concentrations are a sensitive indicator of in vivo hemolysis. Splenomegaly and ineffective hematopoiesis also decrease Hp concentrations. The latter, with increased hemolysis of red cells and their precursors in bone marrow, is seen in megaloblastic anemias (vitamin B_{12} or folate deficiency) and in many hemoglobinopathies.

Estrogens. Endogenous or exogenous estrogens (e.g., in late pregnancy, in oral contraceptive therapy) decrease Hp synthesis and plasma concentrations.

Hepatocellular Disease. Most forms of acute or chronic hepatocellular disease, including acute viral hepatitis and cirrhosis, are associated with decreased concentrations of Hp, possibly caused in part by altered estrogen metabolism. Biliary obstruction is associated with increased Hp concentrations in the absence of severe hepatocellular disease.

Newborn Period. Hp is absent or present in very low concentration in most newborns as a result of hepatic immaturity. In addition, hemopexin concentrations in newborns are on average one fifth adult concentrations.

Genetic Aspects of Hp. The gene encoding Hp is on chromosome 16. Polymorphism of the α-chain accounts for the commonly recognized Hp isotypes. Additional genotype variation, related to point mutations, can be detected by changes in electrophoretic mobility or isoelectric focusing.[87] The distribution of Hp 1-1, 2-1, and 2-2 genotypes varies markedly in different populations (Figure 21-4). The 1-1 genotype occurs in more than 50% of the population in some African and indigenous South American populations, but in only about 10 to 20% of most European and North American whites and in <10% of most Asian populations.[15,87]

Laboratory Considerations for Hp. Immunoturbidimetry and immunonephelometry usually are employed for clinical assays. RID requires correction for Hp genotype because of the different molecular sizes and the diffusion of different Hp genotypes. Traditionally, Hp was measured by assaying peroxidase activity after mixing serum with an excess of free hemoglobin, the so-called hemoglobin-binding capacity. On average, 1 mg hemoglobin is bound by 1.5 mg Hp, depending on the genotype.[70]

Reference Intervals for Hp. The recommended reference interval for Hp in serum for adults is 0.3 to 2.0 g/L (30 to 200 mg/dL).[22] Concentrations are low to absent in the

Figure 21-4 Common phenotypes of haptoglobin, as shown by sieving gel electrophoresis of haptoglobin-hemoglobin complexes. *(From Langlois MR, Delanghe JR. Biological and clinical significance of haptoglobin polymorphism in humans. Clin Chem 1996;42:1589-600.)*

neonatal period and low in women who are pregnant or on exogenous estrogen therapy, including oral contraceptives. For children, the reference interval is approximately 0.2 to 1.6 g/L. Concentrations of Hp vary with genotype as follows: 0.57 to 2.27 g/L in Hp 1-1, 0.44 to 1.83 g/L in Hp 2-1, and 0.38 to 1.50 g/L in Hp 2-2.[70,87]

Transferrin (Tf)

Transferrin (originally named *siderophilin*) is the principal plasma transport protein for iron (Fe^{3+}); Chapter 32 describes iron metabolism.

Biochemistry of Tf. Transferrin (Tf) has a molecular weight of 79.6 kDa, including 5.5% carbohydrate. It is a single polypeptide chain, with two *N*-linked oligosaccharides and two homologous domains, each with an Fe^{3+}-binding site. It is synthesized mainly in the liver, with lesser amounts in the choroid plexus of the brain. Plasma concentrations are regulated primarily by iron; in iron deficiency, plasma Tf concentrations rise and on successful treatment with iron return to normal. Tf has a usual half-life of 8 to 10 days. As with albumin, about half of Tf exists in extravascular fluids. Tf reversibly binds two ferric ions and associated anions, usually bicarbonate. The two binding sites for iron have high affinity at physiologic pH, but lower affinity at decreased pH, allowing release of iron in intracellular compartments. Tf has an absorbance maximum at 470 nm related to its iron complex.

Function of Tf. Iron metabolism is discussed in greater detail in Chapter 32. Apotransferrin binds iron absorbed from the intestine or released from catabolism of hemoglobin after oxidation of ferrous (Fe^{2+}) to ferric (Fe^{3+}) ions by Cp. Tf is bound by surface receptors for Tf and is internalized into intracellular compartments where Fe^{3+} is released from Tf. Fe^{3+} is reduced to Fe^{2+} for storage in ferritin or utilization in iron-containing molecules such as hemoglobin and cytochromes. After delivery of iron, apotransferrin is recycled back into the circulation.

Clinical Significance of Tf

Increased Plasma Concentrations. High concentrations of Tf occur in iron deficiency anemia, as well as in pregnancy and during estrogen administration.[70] Plasma Tf concentrations assist in evaluating hypochromic microcytic anemia and in monitoring treatment. In iron deficiency, Tf is increased but iron saturation is decreased. On the other hand, in anemia of chronic disease, Tf concentration may be normal or low, but iron saturation is high. In iron overload (e.g., hereditary hemochromatosis, recurrent red cell transfusion), Tf concentration is normal, but saturation (normally 30 to 38%) exceeds 55% and may be as great as 100%. Interpreting serum iron and iron saturation is complicated by large diurnal variation. Serum iron concentration is highest in morning and decreases markedly in the evening. In cases of iron overload, some iron may circulate bound to other proteins such as albumin. Saturation >100% may be observed for toxic overdoses of iron or with administration of parenteral iron preparations.

Decreased Plasma Concentrations. Transferrin is a negative APR; low concentrations occur in inflammation or malignancy. Decreased synthesis occurs with chronic liver disease (see Chapter 50) and malnutrition. Protein loss, as in the nephrotic syndrome or protein-losing enteropathies, also results in low concentrations. In hereditary atransferrinemia, a very low concentration of Tf is accompanied by iron overload and severe hypochromic anemia resistant to iron therapy.

Carbohydrate-Deficient Transferrin (CDT). Glycosylation of transferrin may be decreased or absent in certain circumstances. Congenital disorders of glycosylation affect glycosylation of many proteins, including Tf, and result in varying multisystem dysfunction, usually with brain involvement. Disorders of glycosylation can be identified by separations of Tf by electrophoresis or isoelectric focusing due to decreased charge from sialic acids.[9,100]

CDT, which migrates in a β_2 rather the usual β_1 position of Tf, occurs in CSF and has been used as in indicator of CSF leakage in fluid from the ear or nasal passages (see later section on CSF proteins). Increased CDT in plasma also has been used as an indicator of alcohol abuse. Transfer of oligosaccharides is deficient, so that none or one oligosaccharide is attached rather than two as in normal Tf. The decreased amount of sialic acid and the negative charge of CDT allow separation from normal Tf by (1) electrophoresis, (2) capillary electrophoresis, (3) ion-exchange chromatography, or (4) isoelectric focusing. Genetic variants of Tf may complicate interpretation of results based on charge separation. Mass spectrometry analyzes Tf after antibody capture and determines the ratio of CDT to total Tf based on peaks separated by mass/charge.[143] An immunoassay for CDT detects an epitope in CDT that is blocked in Tf by glycosylation.[168] CDT usually is a minor component (<2% of total Tf). Determining the best cutoff value for detecting alcohol abuse may require adjustments per method of analysis, gender, and other factors.

Only about 30% of individuals become positive at four drinks per day, but CDT rises with higher alcohol intake.[168]

Genetic Aspects of Tf. The Tf gene is on chromosome 3. At least 22 genetic variants of Tf have been identified, with up to 25% heterozygotes present in some populations. The wild type is Tf C. Tf variants all bind iron and have no recognized significance except for the rare congenital deficiency, atransferrinemia. However, they may be misinterpreted as monoclonal immunoglobulins or as CDT.

Laboratory Considerations for Tf. Transferrin is commonly assayed by immunoturbidimetry and immunonephelometry. It migrates in the β_1 region on routine serum electrophoresis; genetic variants may have altered mobility. Tf can be estimated from total iron-binding capacity (see Chapter 32).

Reference Intervals for Tf. Serum reference intervals based on CRM 470[22] are as follows:

	g/L	mg/dL
Newborn	1.17-2.50	117-250
Adults (20-60 y)	2.0-3.6	200-360
>60 y	1.6-3.4	160-340

β_2-Microglobulin (BMG)

β_2-Microglobulin is a small protein that increases in immune activation and in renal failure, because its major clearance mechanism is glomerular filtration.

Biochemistry of BMG. BMG is a small protein 99 residues in length with MW of 11.8 kDa. It is the noncovalently bound light chain subunit of class I major histocompatibility complex molecules on the surfaces of all nucleated cells. BMG is shed into the blood, particularly by B lymphocytes and some tumor cells. BMG is a nonglycosylated polypeptide chain with one intrachain disulfide bridge. Its small size allows efficient glomerular filtration, resulting in a plasma half-life of ≈110 minutes. Minor variants can arise from proteolysis in plasma during renal failure and in urine.[19]

Clinical Significance of BMG. High plasma concentrations occur in renal failure, inflammation, and neoplasms, especially those associated with B lymphocytes. Patients with renal failure have a large increase in BMG, because glomerular filtration usually is the primary clearance mechanism.[19,161] For example, compared with a reference interval of 0.7 to 1.8 mg/L,[60] plasma or serum BMG concentrations in patients on low-flux renal dialysis are about 40 mg/L. High-flux renal dialysis yields values of about 20 mg/L.[153] BMG concentrations and efficiency of BMG clearance during dialysis are clinically significant in chronic renal failure, because high plasma concentrations of BMG promote deposition of BMG as amyloid, leading to systemic amyloidosis in many patients on long-term dialysis.[19] In patients with chronic lymphocytic leukemia, high BMG concentrations are a prognostic marker for decreased treatment-free survival and overall survival, although some correction should be made for patients with renal failure.[23] In the International Staging System for multiple myeloma, serum or plasma BMG concentrations are used as a staging criterion.[82] BMG <3.5 mg/L is a criterion for stage I disease and a better prognosis. BMG ≥5.5 mg/L puts patients in stage III with a poorer prognosis of multiple myeloma. Because BMG concentrations are increased in states of immune activation and increased turnover, serial monitoring of serum BMG also has been applied as an indicator of transplant rejection. Urinary BMG serves as an indicator of renal tubular function (see Chapter 25).

C-Reactive Protein (CRP)

Tillet and Francis in 1930 described a substance in the sera of acutely ill patients that bound cell wall C-polysaccharide of *Streptococcus pneumoniae* and agglutinated the organisms. In 1941, the substance was shown to be a protein and named C-reactive protein. A long history of using CRP as a marker for inflammation has been documented.[130]

Biochemistry of CRP. CRP consists of five identical, nonglycosylated polypeptide subunits of 23,028 Da noncovalently associated to form a disk-shaped structure with radial symmetry and total mass of ≈115 kDa. Its pentameric structure leads to the family name pentraxin for CRP and related proteins such as serum amyloid P and pentraxin-3 (PTX3).[99] CRP binds not only the polysaccharides present in many bacteria, fungi, and protozoal parasites but—in the presence of free calcium ions—phosphorylcholine; phosphatidylcholines such as lecithin; and polyanions such as nucleic acids. In the absence of calcium ions, CRP also binds polycations such as histones. CRP has a circulating half-life of 18 to 20 hours.[129]

Function of CRP. CRP aids in nonspecific host defense against infectious organisms and breakdown products of cells. CRP complexes activate the classical complement pathway starting at C1q (see next section), resulting in phagocytosis via C3b receptors. However, CRP complexes bind factor H, a complement inhibitory factor, greatly reducing the activation of late components (C5 to C9) and positive feedback via the alternative pathway (see later section on complement). CRP is catabolized when complexes are engulfed by phagocytes. However, whether CRP is catabolized by any other route is not clear. No genetic abnormalities have been reported for circulating CRP.

Clinical Significance of CRP

Acute-Phase Response (APR). CRP is one of the strongest acute-phase reactants, with plasma concentrations rising up to 1000-fold after myocardial infarction, stress, trauma, infection, inflammation, surgery, or neoplastic proliferation.[21,42] Concentrations >5 to 10 mg/L suggest the presence of an infection or inflammatory process. Concentrations are generally higher in bacterial than viral infection, although concentrations >100 mg/L (10 mg/dL) may be seen in uncomplicated influenza and infectious mononucleosis. The increase with inflammation occurs within 6 to 12 hours and peaks at about 48 hours. It is generally proportional to tissue damage. Because the increase is nonspecific, however, it cannot be interpreted without other clinical information. Umbilical cord blood normally has low CRP (0.01 to 0.35 mg/L), but

with intrauterine (fetal) bacterial infection, concentrations may be as high as 260 mg/L.[70]

Determination of CRP is clinically useful to screen for organic disease; to assess activity of inflammatory diseases, such as rheumatoid arthritis; to detect intercurrent infections in systemic lupus erythematosus (SLE), in leukemia, or after surgery (secondary rise in plasma concentration); to detect rejection in renal allograft recipients; and to detect neonatal septicemia and meningitis.[70] For unknown reasons, CRP responses vary in some diseases that otherwise are apparently similar. For example, the CRP response in SLE and ulcerative colitis, even when signs and symptoms of inflammation are obvious, is slight in contrast to the strong response in rheumatoid arthritis and Crohn's disease.[70]

Risk of Cardiovascular Disease. Epidemiologic studies demonstrate that increased serum CRP concentrations are associated with risk of cardiovascular disease (see Chapter 27).[110] Increased concentrations may reflect low-grade, chronic intimal inflammation. The use of CRP for these purposes requires assays with detection limits <0.3 mg/L that generally are referred to as high-sensitivity CRP assays.[130] Usually, separate assays are used to assess large increases in CRP with inflammation due to the much higher concentrations that must be measured.

Laboratory Considerations for CRP. CRP is normally present in plasma at a concentration <5 mg/L. High concentrations in inflammatory states are measured with direct immunoturbidimetric or immunonephelometric assays using antibody to CRP. High-sensitivity assays to measure CRP in healthy subjects often require particle-enhanced (also termed *latex-enhanced*) immunoturbidimetric or immunonephelometric assays or sandwich-type assay formats. CRP migrates on agarose gel electrophoresis anywhere from the slow-γ to mid-β regions, depending on the calcium ion content of the buffer. Quantities are too small to yield a visibly stained band except in extreme inflammation.

Reference Interval for CRP. The reference interval for CRP in adults is 0-≤5 mg/L (0.5 mg/dL) using less-sensitive assays applied to detection of inflammatory responses.[22] High-sensitivity assays are needed to measure CRP in healthy individuals and to use CRP as an indicator of cardiovascular risk. A cutoff of 2 mg/L or more was used for increased cardiovascular risk in the JUPITER trial.[110]

Complement Proteins

The complement system consists of more than 20 proteins, synthesized primarily by the liver. Complement deficiencies are associated with a variety of disease processes, but diagnosis is often overlooked.[146] The complement system has been divided into six groups by function:

1. The *classical pathway,* which includes C1, C4, C2, and C3 (in order of activation)
2. The *alternative pathway,* which includes C3, factors B and D, and properdin
3. The lectin pathway
4. The *membrane attack complex,* which includes C5 through C9
5. *Inhibitors* and *inactivators* of the previous pathways, including C1 inhibitor, factors H and I, and C4b-binding protein (C4bp)
6. *Cellular regulators and receptors* for activated or cell-bound complement factors

In the late 1800s, Bordet found that heat-labile and heat-stable fractions of serum contributed to in vitro killing of microorganisms and, therefore, protection of animals against infection. Ehrlich termed the labile fraction *complement;* immunoglobulins made up the stable fraction. Protein fractionation in the 1960s identified the nine "classical" components, and the current numbering of components was adopted by the World Health Organization in 1968. Deficiency of any component in the classical pathway can be identified using assays of hemolytic activity commonly expressed as CH50, the dilution yielding 50% hemolysis.[158]

The classical pathway is activated primarily by antibody-antigen complexes. An antibody-independent or alternative pathway, also termed the *properdin pathway,* was initially identified through activation of hemolytic activity with cobra venom factor. The alternative pathway is activated by the classical pathway (providing amplification), by bacterial lipopolysaccharides, cellular proteases, or cobra venom factor. A third pathway, the lectin pathway, is activated by binding of ficolins or mannan-binding protein (MBP; also referred to as mannose-binding protein or lectin, or mannan-binding lectin) to mannose-rich oligosaccharides that are present in the cell walls of many microorganisms.[113,159,173] The three types of ficolin and MBP work analogous to C1q in activating two associated protease zymogens: mannan-binding protein–associated serine protease-I and -II (MASP-I and MASP-II). MASP-II cleaves C4 and C2 analogous to the action of C1s. Activation of pathways generates cascades of protease activation and cleavage products, as outlined in Figure 21-5.

During activation, many of the complement components are enzymatically cleaved into two fragments. The larger fragments are designated by a lowercase *b,* and the smaller ones by a lowercase *a.* The larger fragments usually contain a binding site for membranes, immune complexes, and protein association, or, in several cases, represent proteases that activate subsequent component(s). Thus the larger cell-bound fragment of C3 is C3b, whereas the small fragment C3a is released to serve as an anaphylatoxic and chemotactic peptide. Inactivated fragments are designated by the letter *i* (e.g., C3bi). C3i represents C3 in which the thioester essential for activity has degraded. The persisting membrane-bound portion of C3b after inactivation is called C3d, and the major fragment after enzymatic cleavage in solution is called C3c. Activated complexes often are indicated by a bar over the components.

Complement activation results in opsonization or lysis of microorganisms, immune complexes, and debris, and immune activation and recruitment of white cells through release of inflammatory mediators. A few of the effector pathways are listed here:

1. Release of bioactive peptides, C3a and C5a in particular, which act as anaphylatoxins and chemotaxins.

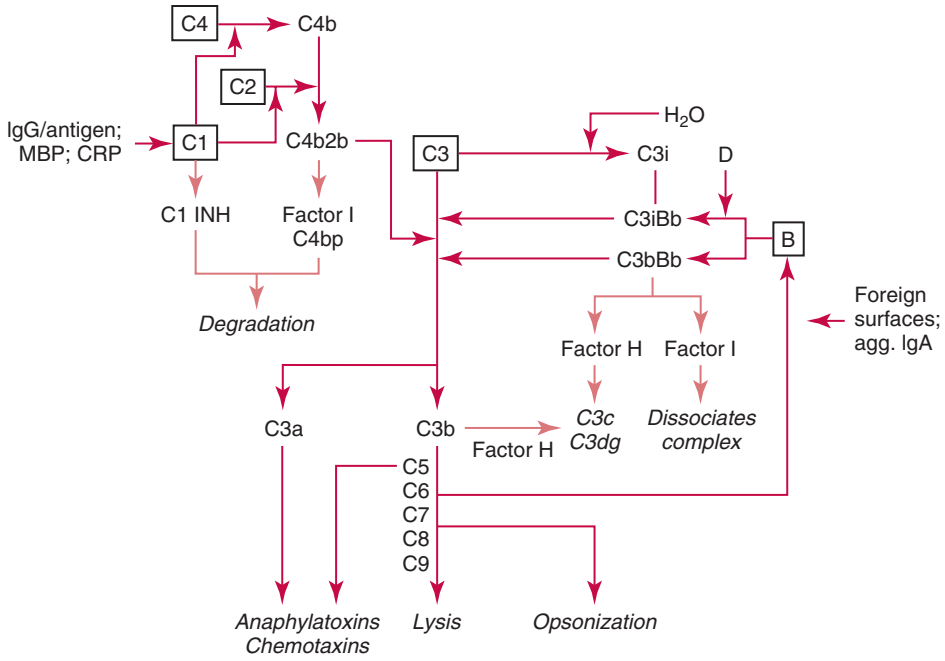

Figure 21-5 The complement cascades. Activation via the classical pathway is shown on the left and via the alternative pathway on the right. Continuous slow hydrolysis of C3 to C3i is shown at the center top. Direct activation of C3 by neutrophil and plasma proteases also may occur. The control mechanisms are shaded. *(Courtesy J.W. Whicher, with modifications.)*

Anaphylatoxins stimulate the release of histamine from mast cells, contraction of smooth muscles, and increased vascular permeability. Chemotaxins attract neutrophils and macrophages into areas of inflammation.

2. Surface-bound C3b and C4b are opsonins, mediating the binding of microbes or immune complexes to complement receptors on phagocytes, which ingest the particles. (*Opsonin* is derived from a Greek word for "preparing food for ingestion.")
3. Activating the membrane-attack complex through C9 is cytolytic by creating holes in cell membranes. This mechanism appears to be important mainly for control of neisserial infections in human beings, as indicated by genetic deficiencies of C6-C9.
4. C4b and C3b solubilize immune complexes by disrupting lattice formation and directing their removal through opsonization.
5. C3d-kallikrein complexes promote the release of neutrophils from bone marrow.
6. Activation of C1s and C2b can activate the clotting, fibrinolytic, and kinin systems and platelets.
7. Interactions of complement complexes with cellular receptors influence antibody responses.

Through these mechanisms, complement factors are major mediators of inflammatory responses to infection or injury. Increased vascular permeability permits the passage of additional antibody, complement, and phagocytes into extravascular spaces, aiding in the killing and removal of infectious agents and immune complexes. Complement activation by the lectin pathway or CRP binding represents innate responses that may be important in early responses to infection, in immunosuppressed patients, and in infancy before high concentrations of antibody are produced versus a pathogen.[159] After antibodies are produced, complement serves as a further effector mechanism. The high incidence of systemic lupus erythematosus and inflammatory disease in patients with complement deficiencies suggests that complement also has roles in suppressing inflammation, possibly through clearance of immune complexes.

The constant slow ongoing activation of complement factors would lead to accumulation of complement factors on cells such as red blood cells and would result in their lysis or clearance if factors were not present on cell surfaces to suppress complement activation and promote removal of C3b and C4b bound to cell surfaces. A few of these factors include decay-accelerating factor (DAF or CD55), protectin (CD59), membrane cofactor protein (MCP), and complement receptor 1. Deficiency of these factors can lead to lysis of red cells or other cells. As an example, in the disorder paroxysmal nocturnal hematuria (PNH), amounts of DAF and CD59 on cell surfaces are decreased by deficiency of enzymes that generate glycosyl-phosphatidylinositol linkages that attach DAF, CD59, and other proteins to cell membranes.[119] Complement regulatory factors on cell surfaces help to prevent destruction of endogenous cells at the same time that foreign cells are destroyed by complement.

The clinical importance of the complement system is demonstrated by the disease associations seen in inherited deficiency of various components, with examples listed in Table 21-9. Deficiencies do not simply increase susceptibility to

TABLE 21-9 Clinical Disorders Associated With Inherited Deficiencies of Complement Components

Component	Frequency of Deficiency	Associated Disorders
Ficolins 1-3	Rare?	Recurrent infection
MBP	5%	Infection in infancy; less effect on adults
MASP	Rare?	Recurrent infection (e.g., pneumococcal); inflammation
C1q*	Relatively rare	SLE; DLE; GN
C1r, C1s	Rare	SLE; DLE; infection
C2	≥0.0003% (homozygous)	Recurrent infection, vasculitis; SLE, DLE (no antinuclear antibody); half of affected individuals are asymptomatic
C3	Rare	Severe and recurrent bacterial infection, especially with encapsulated, pyogenic bacteria
C4A	13% (heterozygous)	SLE, DLE
C4B	13% (heterozygous)	IgA nephropathy; infection
Combined C4	35% one null; 8-10% 2 nulls; ≈1% 3 nulls; <0.1% 4 null alleles	Total deficiency: SLE, GN, DLE (many are anti-dsDNA negative but anti-Ro/SSA positive)
C5-C9	Rare	Severe or recurrent infection with *Neisseria* species
Properdin	Rare	*X*-linked; neisserial infection
Factor D	Rare	Recurrent infection
Factor H or I	Rare	Hypercatabolism of C3; recurrent bacterial infection; hemolytic-uremic syndrome in factor H deficiency
C1 inhibitor	0.002%	Hereditary angioedema (autosomal dominant)
Decay accelerating Factor (DAF, CD 55)	Rare	Paroxysmal nocturnal hematuria (PNH) related to decreased DAF and CD59 on cell surfaces

*Both quantitative and qualitative (functional) deficiencies reported.
DLE, Discoid lupus erythematosus; *GN,* glomerulonephritis; *SLE,* systemic lupus erythematosus (or SLE-like disease).
Modified from Colten HR, Rosen FS. Complement deficiencies. Annu Rev Immunol 1992;10:809-34; and Unsworth DJ. Complement deficiency and disease. J Clin Pathol 2008;61:1013-7.

infectious disease but are also associated with autoimmune disorders such as SLE and Sjögren's syndrome.[158] Despite the redundancy of multiple pathways of complement activation, deficiencies in early components of individual pathways are associated with clinical disorders. As an example, genetic deficiency of just one of the three ficolins is associated with recurrent infection.[113] Deficiency of mannan-binding protein may affect about 5% of many populations and is associated with recurrent infection in childhood, before antibodies reach high concentrations, and in patients with bone marrow transplants.[158,159] Partial deficiency of C4 also is fairly common. Genetic polymorphism is recognized for a number of components. The genetic aspects of C3 and C4 are discussed here.

C3: The Third Component of Complement

C3 is the most abundant complement component and is cleaved by all pathways of complement activation (see Figure 21-5). C3 is homologous to C4, C5, and AMG. A reactive internal thioester in C3 forms covalent bonds to target molecules and surfaces when it is activated.

Biochemistry and Function of C3

C3 is synthesized as a precursor that is cleaved into two disulfide-linked chains, α (110 kDa) and β (75 kDa). An internal thioester forms in the α-chain between sidechains of glutamine and cysteine that are separated by two residues. C3 contains ≈3% carbohydrate. C3 is synthesized mainly by hepatocytes; endotoxin induces synthesis by monocytes and fibroblasts. Activation via any pathway of complement activation results in the cleavage of C3. The small fragment C3a acts as an anaphylatoxin and a chemotactic factor. Upon cleavage of C3, the reactive thioester in the large fragment C3b becomes accessible and rapidly forms covalent bonds with neighboring molecules. C3b anchored to other molecules then participates in the cascade generating the membrane-attack complex. C3b also acts as an opsonin, binding to receptors on phagocytic cells, resulting in the ingestion of bacteria, viruses, and other foreign particles by these cells. C3 has a usual half-life of 2 to 3 days.

Low rates of hydrolysis of the thioester of C3 generate C3i continuously in plasma. C3i can bind factor B, which then is cleaved by factor D. The resulting C3iBb complex is a weak C3 convertase, producing slow activation of C3. Upon activation of the classical pathway, membrane-bound C3b forms similar complexes with factor B; C3bBb is a more active C3 convertase. The resulting positive feedback amplifies the complement activity many-fold. Normal control mechanisms prevent complete activation and depletion of C3. Factor H speeds dissociation of factor Bb from convertases, and factor I cleaves C3b to C3c and C3dg. Hereditary deficiency of factor H or factor I can lead to depletion of C3. Properdin

and so-called nephritic factors (autoantibodies) also increase complement activation by stabilizing C3bBb and protecting it from factors H and I.[70]

Clinical Significance

Increased Plasma Concentrations. C3 concentrations increase with the APR, with biliary obstruction, and with focal glomerulosclerosis.[70]

Acute-Phase Response. C3 synthesis is induced by cytokines IL-1, IL-6, and TNF-α. Concentrations rise modestly after trauma or surgery and during inflammatory processes (Table 21-10).

Biliary Obstruction. C3 concentrations increase in biliary obstruction in direct proportion to hyperbilirubinemia.

Focal Glomerulosclerosis. In contrast to nephritic disorders, in which most patients with active disease have low concentrations of C3, about 30% of patients with idiopathic focal glomerulosclerosis have elevated concentrations, which indicate a favorable prognosis.

Decreased Plasma Concentrations. Decreased concentrations of C3 occur with genetic deficiency, increased turnover, and infancy.

Genetic Deficiency. Inherited primary deficiency of C3 is associated with a greatly increased risk for infection, particularly with encapsulated bacteria. Deficiency of the inactivators of C3, including factors H and I, results in secondary deficiency of C3 and a similar clinical disorder.

Acquired Deficiency. Any process increasing activation of C3 in vivo usually is associated with decreased plasma concentrations; examples are lupus nephritis and severe infection. Turnover is increased and extended by the presence of C3 nephritic factor. In addition to increasing consumption of C3, acute poststreptococcal glomerulonephritis can decrease synthesis for several weeks. Sequential concentrations of C3 can monitor recovery from this disorder. Low C3 concentrations in patients with systemic lupus nephritis suggest risk of active nephritis. Fulminant septicemia, in particular with *Neisseria meningitidis,* is associated with hypocomplementemia, whether or not shock develops.

Infancy. Concentrations in neonates are approximately two thirds of adult concentrations, which are reached by ≈1 year of age.

TABLE 21-10 Diseases in Which Estimates of Complement Factors May Be Useful for Diagnosis

Disease	Complement Status
Systemic lupus erythematosus	C4 usually low, C3 sometimes low*
Rheumatoid vasculitis	C3 usually low*
Subacute bacterial endocarditis	Both C3* and C4 low
Shunt nephritis	Both C3* and C4 low
Poststreptococcal glomerulonephritis	C3 low,* usually returns to normal in 3 months
Mesangiocapillary glomerulonephritis	C3 low* (persistent), C4 normal
Polymyalgia rheumatica	C3 conversion products found
Mixed cryoglobulinemia	C3 conversion products found
Gram-negative bacteremic shock (early diagnosis)	C3 low,* C4 normal, factor B low
Gram-positive bacteremia	Both C3* and C4 low
Disseminated cytomegalovirus infection	C4 very low, C3* normal or increased
	*C3 conversion products also present

Genetic Aspects of C3

C3 is coded by a gene on chromosome 19. More than 25 known inherited variants are demonstrable by prolonged agarose gel electrophoresis of serum; the most common are C3S and C3F (for "slow" and "fast," respectively). Most are associated with normal concentrations and function; one, C3f, has the same mobility as C3F but is present in approximately 50% of the normal concentration. Genetic deficiency is discussed earlier under "Clinical Significance."[70]

Laboratory Considerations for C3

C3 is usually quantified by immunoturbidimetric or immunonephelometric methods. Because of differences in immunochemical reactivity of C3 and C3c, reference materials should be completely converted to C3c and stabilized, as is the case for the international reference material CRM 470.[167] C3 concentrations measured on fresh samples may be lower than after storage for 8 hours or longer, possibly as the result of conversion of C3 to C3i or C3c. Intact C3 in serum migrates on agarose gel electrophoresis in the β_2-region in the presence of free Ca^{2+}. However, it is a relatively labile protein, with conversion to more anodal forms, C3c and C3dg, on extended storage. Electrophoretic variants, including C3F, may be confused with monoclonal immunoglobulins. Assays for complement activation require plasma samples obtained with precautions to limit activation by plasmin, C1s, and leukocyte proteases. Centrifugation should be performed immediately, and the separated plasma should be frozen at below –40 °C.

Reference Intervals for C3

C3 concentrations are low in newborns, then rise and remain relatively constant after the first year of life. The recommended reference interval for adults, based on CRM 470, is 0.9 to 1.8 g/L (90 to 180 mg/dL).[22] Concentrations are slightly lower in fresh serum (assayed within 8 hours after drawing).

The Fourth Component of Complement: C4

C4 is actually a pair of two highly homologous proteins C4A and C4B from closely linked genes that differ only in a few amino acids (note that these are different from the cleavage products C4A and C4B). C4A and C4B are homologous to C3, C5, and AMG.

Biochemistry and Function of C4

C4 has a molecular mass of 206 kDa, including ≈4% carbohydrate. Most synthesis occurs in hepatocytes; some may occur in monocytes or other tissues. C4 is synthesized as a single chain (proC4) that is cleaved into three chains: α, β, and γ, linked by disulfide bonds. The α-chain has an internal thioester that, on activation, becomes accessible and forms covalent bonds with neighboring molecules, resulting in "fixation" to membranes, viruses, and immune complexes.

C4 participates in the classical pathway. However, most individuals with C4 deficiency do not have increased susceptibility to bacterial infection, suggesting that the alternative pathway can compensate for the lack of classical pathway activation in removal of bacterial agents; C4 may be more critical for clearance of infecting viruses and immune complexes. C4b2b bound to immune complexes prevents their precipitation and promotes immune complex clearance by the CRa receptor. C4A and C4B have differential specificities in their surface reactivities and may have differential effects on immune complex clearance. C4a, the small fragment released on activation of C4, is a weak anaphylatoxin.

Clinical Significance of C4

Increased Plasma Concentrations. C4 concentrations are modestly increased by the APR.

Decreased Plasma Concentrations. C4 concentrations are low in genetic deficiency, increased turnover, and infancy.

Genetic Deficiency. Complete deficiency of C4 is rare and is strongly associated with autoimmune or collagen vascular disease, particularly SLE, and, in a few cases, with susceptibility for infection.[158] Partial deficiency of C4 is much more common. Isolated deficiency of C4A is markedly increased in patients with SLE as well, but it is not clear whether this results from decreased clearance of immune complexes or from linkage to other genes. Approximately 20% of individuals with deficiency of IgA also have homozygous deficiency of C4A, as do some with combined IgA and IgG subclass deficiencies, suggesting that the gene for a B-cell maturation factor is linked to C4A.

Acquired Deficiency. Concentrations of C4 are more commonly depressed because of consumption; most individuals with SLE and low C4 concentrations do not have genetic deficiency. Other disorders associated with consumption and low concentrations include hereditary angioedema (C1 inhibitor deficiency), autoimmune hemolytic anemia, and autoimmune nephritis.

Infancy. C4 concentrations in newborn infants are approximately 50 to 75% of adult concentrations.

Genetic Aspects of C4

C4 is coded by two genes, C4A and C4B, in the major histocompatibility complex region of chromosome 6p, closely linked to the genes for C2, factor B, and HLA-DR. Linkage to immune response genes may account for most disease associations of C4 variants with deficiency. The C4A and C4B proteins differ by only four amino acids near the thioester in the α-chain, and these sequence differences alter reactivity. C4A binds more efficiently with amino groups in proteins and C4B with hydroxyl groups in oligosaccharides. C4d fragments of C4A and C4B bound to erythrocytes are the Rodgers and Chido blood group antigens. Both C4 loci are highly polymorphic, mostly because of substitutions in the α-chain. Either or both loci may be deleted, unexpressed, or duplicated; as a result, a given individual may have zero to four copies of each locus. Both the total C4 concentration and the ratio of C4A to C4B depend on the number of copies of each locus. Most C4A variants have 25 to 35% of the hemolytic activity of the C4B alleles.[70]

Laboratory Considerations for C4

C4 usually is measured by immunoturbidimetric or immunonephelometric methods. Low concentrations alone cannot differentiate between genetic and acquired deficiency; tests for breakdown products (e.g., C4a des-arginine) or neoantigens may assist in detecting increased turnover. C4 has β_1 electrophoretic mobility, similar to that of transferrin, but normally is not visualized because of its low concentration. Phenotyping of C4 proteins can be performed by electrophoresis of neuraminidase-treated EDTA plasma, followed by immunofixation. Hemolytic gel overlay can help identify C4B bands. DNA genotyping can also determine the types in most cases but cannot distinguish between synthesizing and nonsynthesizing genes. If C4 concentrations are to be used to monitor disease activity in patients with SLE, genotyping or phenotyping of C4 may be indicated.[70]

Reference Intervals for C4

As with C3, concentrations are low in neonates but relatively constant after the first year of life. The recommended interim reference interval for adults, based on CRM 470, is 0.1 to 0.4 g/L (10 to 40 mg/dL).[22] The baseline plasma concentration of C4 in individuals with one or more null genes is lower.

Immunoglobulins

Immunoglobulins (antibodies) are preferentially generated against foreign immunogens and initiate clearance of the foreign molecule or organism. Failure of regulatory mechanisms sometimes leads to autoantibodies that contribute to autoimmune disease. Immunoglobulins are characterized by tremendous sequence heterogeneity of their antigen-binding sites that allows binding of a diverse range of molecules.

Basic Biochemistry of Immunoglobulins

The major immunoglobulin molecules in humans consist of one or more basic units built of two identical heavy (H) chains and two identical light (L) chains.[70,125] Each of the four chains has one variable and one (L chain) or three to four (H chain) constant domains, with the variable region involved in antigen recognition and binding (see Chapter 16). Extensive diversity in the variable domains is generated by somatic recombination and mutation of the immunoglobulin genes. Individual plasma cells or clonally expanded cells are committed to synthesis of a single variable domain sequence for heavy and light chains. The amino acid sequences of the

variable domains at the N-terminal ends of the four chains form two antigen-binding sites with a high degree of variation in binding specificity, allowing diversity in binding specificity. The constant domains are the same for every immunoglobulin molecule of a given subclass and carry sites for binding to complement receptors and activation of complement.

Immunoglobulins are synthesized by plasma cells, the progeny of B-lymphocyte stem cells in bone marrow (Table 21-11). More mature B lymphocytes, found mainly in lymph nodes and in blood, develop receptor immunoglobulins on their surface membranes. Recombination of segments of the variable regions of genes by the recombinases RAG1 and RAG2 helps generate diversity that allows recognition of a wide range of antigens.[115] Upon binding a target antigen, these B lymphocytes proliferate and develop into a clone of plasma cells producing antibody to the target antigen. Somatic mutation of immunoglobulins by activation-induced DNA deaminase leads to further diversity of immunoglobulin variable region and antibody maturation—generally leading to antibodies with higher affinity. B lymphocytes at first have IgM surface receptors and secrete IgM as the first or "primary" response to an antigen. Membrane and secreted forms of the antibody arise from differential splicing of the messenger RNA for heavy chains, which adds a transmembrane segment to the membrane-bound form. Heavy chains of the IgM surface receptor molecules undergo class switching to produce immunoglobulins with γ- or α-heavy chains (IgG or IgA), but the variable regions remain unchanged; as the cells change into plasma cells, second exposure to the same antigen causes a larger secondary or anamnestic response of IgG secretion.

The variable domains contain the antigen-binding regions, and the constant domains of the heavy chains contain sites for complement activation and receptor binding. Cleavage of immunoglobulins with pepsin or papain can yield antigen-binding fragments (Fab) and constant region fragments (Fc). Variations in the constant domains of heavy chains (Fc region) result in the classes and subclasses into which immunoglobulins are grouped: IgM, IgG (four subclasses), IgA (two subclasses), IgD, and IgE, respectively, containing heavy chains μ, γ, α, δ, and ε.[70,125]

Light chains, which are produced independently and in slight excess of heavy chains, are of two types—kappa (κ) and lambda (λ)—defined by constant domains with different structures. The heavy-chain genes are located on chromosome 14; κ-light chains are encoded by a gene on chromosome 2, whereas the λ-chain gene is on chromosome 22. Each plasma cell expresses only one type of light chain, so that each immunoglobulin molecule contains only one type of light chain. The proportions of κ:λ typically are about 2:1 in immunoglobulins. Light chains are usually synthesized in excess and secreted as free light chains, but concentrations usually remain low because of rapid glomerular filtration (see section on free light chains later).

Biochemistry of Individual Immunoglobulins

The individual immunoglobulins IgG, IgA, IgM, IgD, and IgE actually represent families of proteins with different sequences in their variable regions rather than typical proteins with defined sequences.

Immunoglobulin G (IgG)

IgG accounts for 70 to 75% of the total immunoglobulins in plasma. Only 35% is found in the plasma space, and 65% is extravascular. IgG consists of two γ-heavy and two light chains, linked by disulfides (see Chapter 16); its molecular weight is ≈150 kDa, usually including one N-linked oligosaccharide on each heavy chain. The oligosaccharide structure may change in inflammatory states and affect interactions with receptors.[72] On agarose gel electrophoresis, IgG migrates broadly in the γ- and slow β-regions as a result of its heterogeneity of charge from sequence variation.

Immunoglobulin G has four subclasses: IgG_1, IgG_2, IgG_3, and IgG_4. The circulating half-life of IgG_1, IgG_2, and IgG_4 is about 22 days—much longer than most plasma proteins—because of recycling from pinocytic vesicles via binding to the neonatal immunoglobulin receptor. IgG_3, which does not bind to the receptor, has a half-life of 7 days.[131,165] IgG_1 and

TABLE 21-11 B-Lymphocyte Lineage and Associated Malignant Neoplasms

		Immunoglobulins		
Stages in Maturation and Proliferation	**Principal Site**	**Surface Receptor**	**Secreted Into Blood**	**Associated Malignant Neoplasms**
Stem cell ↓	Bone marrow	None	None	Acute lymphoblastic leukemia
Early B lymphocyte antigen → ↓	Lymph nodes	IgM, IgD	None	Lymphoma, chronic lymphocytic leukemia (85%)
Late B-lymphocyte antigen → ↓	Lymph nodes	IgM ↓	IgM	Lymphoma, chronic lymphocytic leukemia (15%), and Waldenström's macroglobulinemia
Plasma cell	Lymphatic tissue, bone marrow	IgG, IgA	IgG, IgA	Multiple myeloma

IgG_3 strongly activate complement via the classical pathway, IgG_2 is weakly complement fixing, and IgG_4 does not activate complement. Clustering of multiple IgG molecules is required to activate complement. Both IgG_1 and IgG_3 bind Fc receptors on phagocytic cells, activate killer monocytes (K cells), and cross the placenta via receptor-mediated active transport. IgG_1 is the principal IgG to cross the placenta, and neonatal concentrations are similar to maternal concentrations. Neonates have low production of IgG as the result of immaturity of their immune systems, and IgG concentrations fall through infancy as maternally acquired antibody is cleared.

Immunoglobulin M (IgM)

IgM is produced at earlier stages of B-cell development. In the immature immune systems of neonates, IgM is the major immunoglobulin synthesized. In adult serum, it is the third most abundant immunoglobulin, usually accounting for 5 to 10% of total circulating immunoglobulins. IgM as a membrane receptor molecule is monomeric, but most of the serum IgM is a pentamer, which contains five monomers similar to IgG linked via disulfides to the small J chain. Plasma cell malignancies may secrete monomeric IgM in addition to, or instead of, pentamers. The high molecular weight of IgM (970 kDa; ≈10% carbohydrate) prevents its ready passage into extravascular spaces. IgM is not transported across the placenta and therefore is not involved in hemolytic disease of neonates. It activates complement even more efficiently than IgG; binding of one IgM molecule may be adequate to activate complement. In rare hyper-IgM syndromes, class switching to IgG and IgA is deficient, shedding light on the process of class switching. Affected patients have deficiency of IgG and IgA and increased susceptibility to infection.[30]

Immunoglobulin A (IgA)

Approximately 10 to 15% of serum immunoglobulin is IgA, which contains about 10% carbohydrate, with both N- and O-linked oligosaccharides, has a molecular weight of 160 kDa, and has a half-life of 6 days. In its monomeric form, its structure is similar to that of IgG, but 10 to 15% of IgA in serum is dimeric, particularly IgA_2, which is more resistant to destruction by pathogenic bacteria than IgA_1. On electrophoresis, IgA migrates in the β-γ region, anodal to most IgG. IgA is an important component of mucosal immunity.[170] *Secretory* IgA is found in tears, sweat, saliva, milk, colostrum, and gastrointestinal and bronchial secretions. Secretory IgA has a molecular weight of 380 kDa and consists of two molecules of IgA: a secretory component (70 kDa) and a J chain (15.6 kDa). It is synthesized mainly by plasma cells in the mucous membranes of the gut and bronchi and in the ductules of the lactating breast. The secretory component assists with transport of secretory IgA across mucosal epithelium and into secretions. Secretory IgA in colostrum and milk is more abundant than IgG and may aid in protection of neonates from intestinal infection. IgA can activate complement by the alternative pathway (see Figure 21-5), but the exact role of IgA in serum is not clear.

Immunoglobulin D (IgD)

IgD accounts for <1% of serum immunoglobulin. It is monomeric, contains about 12% carbohydrate, and has a molecular weight of 184 kDa. Its structure is similar to that of IgG. Similar to IgM, IgD is a surface receptor for antigen on B lymphocytes, but its primary function is unknown.

Immunoglobulin E (IgE)

IgE is so rapidly and firmly bound to specific IgE receptors on mast cells that only trace amounts of it are normally present in serum. IgE contains 15% carbohydrate and has a molecular weight of 188 kDa; its quaternary structure is similar to that of IgG. IgE binds to mast cells via sites on its Fc region. When the antigen (allergen) cross-links two of the attached IgE molecules, the mast cell is stimulated to release histamine and other vasoactive amines that increase vascular permeability and smooth muscle contraction, mediating type 1 hypersensitivity reactions such as hay fever, asthma, urticaria, and eczema. Rare regulatory disorders with hyperproduction of IgE lead to a primary immunodeficiency disorder, Job's syndrome, with eczema, recurrent infection, and markedly increased IgE.[40] IgE molecules specific for particular allergens are analyzed to identify the specificity of allergies. The total serum concentration of IgE may be increased in allergic disorders.

Free Immunoglobulin Light Chains

Light chains are usually synthesized in slight excess versus quantities required for intact immunoglobulins. Consequently, small amounts of free light chain, representing only about 0.1% of total immunoglobulin, usually are present in serum or plasma. Amounts in plasma are kept low by renal clearance. Free κ-light chains (23 kDa) are cleared about three times faster than free λ-light chains (a disulfide-linked dimer of 46 kDa), which have a half-life of 4 to 6 hours. Consequently, even though production of κ-light chains is about twice as great as that of λ-light chains, the plasma concentration of free λ-light chains is usually higher, except in renal failure.[65] Free light chains usually are not functional, but immunoassays specific for free light chains are applied to detect plasma cell disorders.[27]

Clinical Significance

Normally, serum contains a diverse, polyclonal mixture of antibodies with varying amino acid sequences, which represent multiple "idiotypes" (i.e., the products of many different clones of plasma cells, each producing a specific immunoglobulin molecule). Benign or malignant proliferation of one such clone produces a high concentration of a single monoclonal antibody, which may appear as a sharp, narrow band on protein electrophoresis. Unbalanced production of free light chains might also lead to a second band representing free light chains. If a few clones proliferate, several sharp bands may be seen (e.g., the oligoclonal bands seen in electrophoresis of CSF in demyelinating diseases such as multiple sclerosis, or in serum following successful bone marrow transplantation, or early during a response to such organisms

as *Streptococcus pneumoniae*). Therefore, disease may be associated with a decrease or an increase in normal polyclonal immunoglobulins or an increase in one or more monoclonal immunoglobulins.

Immunoglobulin Deficiency

Immune defense depends on four complex, interactive systems: cell-mediated immunity; humoral antibodies (immunoglobulins); the phagocytic system; and the complement system. The last two systems are nonspecific in that they have no immunologic memory for the antigen. Immunodeficiency states may be the result of deficiency of a single factor or combinations affecting multiple systems of immune defense. Analysis of serum or plasma proteins allows detection primarily of deficiencies of antibody and complement systems. Several genetic disorders with immunoglobulin deficiency are summarized in Box 21-1. Diagnosis of major deficiencies in immunoglobulin production is clinically important because infants will be at increased risk of infection as their maternally acquired antibodies decline, and replacement therapy with IgG will be needed. The most common primary deficiencies involve only one or two immunoglobulin classes (IgA) or subclasses (IgA or IgG subclasses) or ability to generate antibodies versus polysaccharides; such deficiencies may be associated with increased susceptibility to infection, depending on the degree of reduction of immunoglobulin concentrations.[148] IgA deficiency varies markedly in different populations, occurring in about 1:500 whites, and much less frequently in Asian populations. IgA deficiency usually is not associated with severe infection, but the risk of nonsevere infection with *Giardia* or other organisms may be increased. IgA deficiency may lead to false-negative assays for autoantibodies for celiac disease detection, and affected individuals have some risk of anaphylaxis if they receive blood products containing IgA. Detection of antibodies to IgA serves as an indicator of risk of transfusion reactions.[13] Selective deficiency of IgG subclasses is not rare, but it is unclear whether it is an important risk for infection. Deficiency of IgG2 may be related to poorer responses to polysaccharide antigens and increased risk of infection with encapsulated organisms.[148]

Infants have transient physiologic deficiency of IgG, with a nadir at about 3 months of age; prolonged or severe physiologic deficiency may be associated with increased infection rates, especially with encapsulated bacteria. Concentrations of maternal IgG, transferred across the placenta, rise rapidly in the fetus during the last half of pregnancy but then drop over a few months following birth (Figure 21-6). Two groups of neonates are at risk for clinically significant IgG deficiency: premature infants, who start with less maternal IgG, and infants with delayed initiation of IgG synthesis. Monitoring of IgG concentrations can identify this problem. Rising IgM and normal salivary IgA concentrations at 6 weeks of age suggest a favorable prognosis. Contact of the neonate with environmental antigens normally causes B lymphocytes to begin to multiply and IgM concentrations to start to rise, followed weeks to months later by IgA and IgG.[70]

Polyclonal Hyperimmunoglobulinemia

Polyclonal increases in plasma immunoglobulins are the normal response to infection. IgG response predominates in autoimmune responses; IgA in skin, gut, respiratory, and renal infections; and IgM in primary viral infections and bloodstream parasites such as malaria. Chronic bacterial infection may cause increased concentrations of all immunoglobulins. Selective changes in immunoglobulin concentrations assist in the differential diagnosis of liver disease and of intrauterine infection. In *primary biliary cirrhosis,* the IgM concentration is greatly increased; in *chronic active hepatitis,* IgG and sometimes IgM are increased; and in *portal cirrhosis,* IgA and sometimes IgG are increased. In *intrauterine infection,* production of IgM by the fetus increases, and the IgM concentration in umbilical cord blood is increased. Measurements of total IgE are used in the management of asthma and other allergic conditions, especially in children. Measurements of allergen-specific IgE assist in identifying allergens that trigger hypersensitivity responses.[48]

BOX 21-1 Causes of Immunoglobulin Deficiency

Secondary Causes (Common)

Defective Synthesis (IgM Falls First, Then IgA, Finally IgG)

Multiple myeloma, lymphoma, chronic lymphocytic leukemia
Toxic reaction (e.g., renal failure, diabetes mellitus)
Drugs (e.g., phenytoin, penicillamine)
In neonates: prematurity, transient delay in initiation of synthesis

Abnormal Loss of Proteins

Nephrotic syndrome, burns, protein-losing enteropathy

Primary or Inherited Causes (Rare)

Failure of Antibody Production

Generalized (severe pyogenic infections occur)
Infantile X-linked Bruton's type
Acquired, variable, unclassifiable, occurring at any age
Selective immunoglobulin deficiency of

- IgA: most common (1:700), increased allergic or autoimmune disease
- IgG and IgA (IgM increased): recurrent pyogenic infection
- IgA and IgM: giardiasis common
- IgG: recurrent pyogenic infection
- IgM: susceptibility to autoimmune disease and to septicemia following splenectomy

Combined Failure of Antibody- and Cell-Mediated Immunity

Severe combined immunodeficiency. Swiss and sex-linked types, death in infancy from fungal or viral infection
Associated with thymoma, achondroplasia, or thrombocytopenia and eczema (Wiskott-Aldrich syndrome)

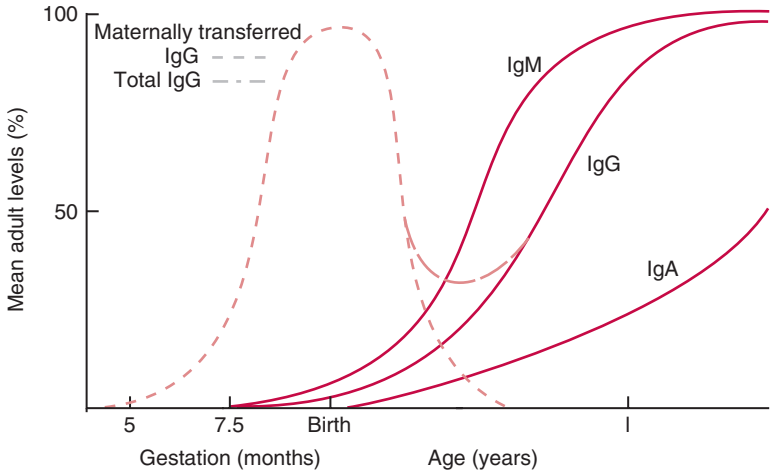

Figure 21-6 Serum immunoglobulin concentrations as percent of mean adult concentrations before birth and for the first year of life.

Monoclonal Immunoglobulins (Paraproteins)

A single clone of plasma cells produces immunoglobulin molecules with a single defined amino acid sequence. If the clone expands greatly, the concentration of its particular protein in the patient's serum may produce a discrete band on electrophoresis, often referred to as an M-spike or M-protein, which stands out from the diffuse background. These monoclonal immunoglobulins, termed *paraproteins,* may be polymers, monomers, individual immunoglobulin chains such as free light chains or heavy chains, or fragments of immunoglobulins. About 60% of paraproteins are associated with plasma cell malignancies (multiple myeloma or solitary plasmacytoma), and approximately 15% are due to overproduction by B lymphocytes, mainly in lymph nodes (lymphomas, chronic lymphocytic leukemia, Waldenström's macroglobulinemia, or heavy-chain disease). Up to 25% of paraproteins are benign and have been termed *monoclonal gammopathy of undetermined significance (MGUS).* The incidence of MGUS increases with age, with 1% incidence for people 50 to 70 years of age and 3% incidence for people older than 70. Occurrence of MGUS is associated with increased risk of progression to multiple myeloma that should be monitored. Multiple myeloma appears to be preceded consistently by MGUS.[86]

The primary clinical interest in identifying paraproteins is to detect or monitor proliferative disorders of B cells. However, from the laboratory standpoint, paraproteins are also significant as a potentially unpredictable source of interference with many assays. Paraproteins may aggregate or precipitate in a variety of photometric reactions and hematology analyzers. Occasionally, specimens with paraproteins form gels that can plug sample probes of and disable automated analyzers (see discussion of cryoglobulins later).

Many patients with paraproteins have nonspecific presentations such as anemia or infection. Identification of paraproteins in serum usually is based on serum protein electrophoresis and immunofixation electrophoresis (described in a later section), and urine protein electrophoresis and urine immunofixation electrophoresis are helpful mainly in identifying patients with free immunoglobulin light chains. Urinary free light chains, as described by Bence-Jones in the 1850s, were the first tumor marker. Free light chains, particularly in urine, are often referred to as *Bence-Jones proteins,* although this term was originally used to refer to a subset of free light chains in urine that precipitated and redissolved upon heating. Introduction of capillary electrophoresis and assays for free light chains in serum has led to a variety of approaches for detecting paraproteins.[82,103] Serum protein electrophoresis together with analysis of free light chains in serum appears to have a diagnostic yield similar to use of immunofixation on serum and urine, except for lower detection of MGUS.[73] Analysis of free light chains tends to detect residual disease or recurrence at lower concentrations than does immunofixation.[73,82]

Malignancies of B cells that commonly express paraproteins are described as follows:

Multiple Myeloma. *Multiple myeloma* is a clonal malignant neoplasm of plasma cells.[70,82] The plasma cells usually proliferate diffusely throughout the bone marrow, but occasionally they form a solitary tumor or *plasmacytoma.* Osteolytic bone lesions are produced and the other bone marrow cells are reduced, so that thrombocytopenia, anemia, and leukopenia develop. Production of normal plasma cells is suppressed; consequently, synthesis of other immunoglobulins is reduced, and recurrent infection may occur. The incidence of multiple myeloma is low in individuals younger than 60 years but increases with age. Patients may present with symptoms of a bone lesion such as pain or fracture, but more often present with nonspecific symptoms such as weight loss, anemia, hemorrhage, recurrent infection, or renal failure. A normal serum alkaline phosphatase concentration may be observed in a patient with destructive bone lesions.[70] Cardinal diagnostic features of the disease include findings of neoplastic plasma cells in bone marrow aspirate, radiologic demonstration of osteolytic lesions, and identification of a paraprotein in serum or urine. All patients who could conceivably have the disease should be screened for paraproteins;

nonsecretory myeloma with undetectable paraprotein occurs but is uncommon.[73,82] Changes in the ratio of free κ- and γ-light chains determined with assays specific for each free light chain also indicate aberrant immunoglobulin production. Table 21-12 lists the paraproteins associated with multiple myeloma.

Waldenström's Macroglobulinemia (WM). Malignant proliferation of plasmacytoid cells producing IgM is distinguished from multiple myeloma by differences in biology, outcome, and treatment.[26] Clonal expansion in WM is of more immature B cells that are characterized by numerous cell surface markers, including surface IgM, CD5, CD19, and CD20, and lacking CD10 and CD23.[82] IgM is a high molecular weight protein, and IgM paraproteins can cause concentration-dependent increases in the viscosity of blood, leading to hyperviscosity syndromes. Serum viscosity measurement helps to assess this problem. Monoclonal IgM also may behave as a cryoglobulin.

Lymphoid Tumors. *Lymphoid tumors,* such as lymphomas or chronic lymphocytic leukemias, arise from less mature stages in B-lymphocyte development; about one in five produce paraproteins, usually of the IgM class.

Classification of Plasma Cell Proliferative Disorders

Analysis of paraproteins and other laboratory studies play an important role in classification and staging of plasma cell proliferative disorders. Evidence of end-organ injury related to paraproteins is provided by hypercalcemia (calcium ≥11.5 g/dL or 2.875 mmol/L), impaired renal function (creatinine >1.95 mg/dL or 172 μmol/L), anemia, and bone lesions. Criteria for diagnosis and classification of plasma cell disorders developed by the International Myeloma Working Group have been summarized.[82]

MGUS

Serum paraprotein <30 g/L. Clonal plasma cells in bone marrow <10%. No other B-cell proliferative disorder. No evidence of paraprotein-related organ injury.

Asymptomatic or Smoldering Multiple Myeloma

No evidence of paraprotein-related organ or tissue injury, but serum paraprotein >30 g/L or bone marrow plasma cells >10%.

Symptomatic Multiple Myeloma

Paraprotein is detected in serum or urine (40% have serum paraprotein <30 g/L); bone marrow or plasmacytoma with clonal plasma cells; organ impairment related to the paraprotein. Rarely (3% of multiple myeloma), nonsecretory multiple myeloma occurs without detectable paraprotein.

Waldenström's Macroglobulinemia (WM)

Monoclonal IgM detected. Bone marrow infiltration with ≥10% small lymphocytes with typical immunophenotype, excluding other lymphoproliferative disorders.

Solitary Plasmacytoma

Solitary localized tumor of bone or soft tissue with clonal plasma cells and normal bone marrow. No other bone lesions or evidence of paraprotein-related organ injury.

Systemic Amyloid Light Chain (AL) Amyloidosis

Four criteria must be met: evidence of organ injury from systemic amyloidosis, positive amyloid staining, evidence of immunoglobulin light chains in amyloid deposits, and paraproteins or other evidence of a monoclonal plasma cell disorder.

TABLE 21-12 Monoclonal Immunoglobulins (Paraproteins) in Multiple Myeloma

Plasma Paraprotein	Incidence,* %	Age of Occurrence,* Mean	Incidence of Free Light Chain in Urine, %	Comments
IgG	50	65	60	Patients more susceptible to infection; paraproteins reach highest concentrations
IgA	25	65	70	Tend to have hypercalcemia and amyloidosis
Free light chain only	20	56	100	Often renal failure; bone lesions; amyloidosis; poor prognosis
IgD	2	57	100	90% λ type; often have extraosseous lesion, amyloidosis, renal failure; poor prognosis
IgM	1	—	100	May or may not have hyperviscosity syndrome
IgE	0.1	—	Most	—
Biclonal	1	—	—	—
None detected	<1	—	0	Usually reduction of normal immunoglobulins

*Approximate.

POEMS Syndrome

POEMS is a syndrome with polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, and skin changes. Three criteria must be met: (1) presence of a monoclonal plasma cell disorder, (2) peripheral neuropathy, and (3) other related features.[82]

A couple of other plasma cell disorders that are not always included with classification lists are light chain deposition disease, in which free light chains are deposited in tissues but lack characteristics of amyloid; and plasma cell leukemia, which is identified by plasma cell counts in peripheral blood >2000/μL and plasma cells >20% of white blood cells.[73]

Heavy-Chain Disease

Heavy-chain disease is a rare disorder in which clonal production of immunoglobulin heavy chains occurs. The heavy chains are shorter than normal and lack a segment that forms disulfide bonds with light chains because of faulty recombination of variable and constant regions of heavy chains during somatic recombination. This explains the failure of heavy chains to form intact immunoglobulins. The most common form is α-chain disease, which may be associated with intestinal infiltration with the clonal population of lymphocytes and problems with malabsorption. Less commonly, heavy-chain disease may result from clonal production of γ-chains or μ-chains.

Staging of Multiple Myeloma and Monitoring of Treatment Responses

The International Staging System has been developed for objective stratification of the risk of rapid progression of multiple myeloma. It does not have a role in staging of other plasma cell disorders. Stage 1 multiple myeloma has β_2-microglobulin <3.5 mg/L and albumin ≥3.5 g/dL. Stage II has BMG ≥3.5 mg/L and <5.5 mg/L or albumin <3.5 g/dL. Stage III has BMG ≥5.5 mg/L.[82] The method of determining albumin has the potential to affect the staging of some patients. For specimens with high paraprotein concentrations, albumin concentrations estimated from serum protein electrophoresis differ from measurements by immunonephelometry or BSG.[147] A more complex staging system, the Durie-Salmon system, has been in use since 1975 and divides patients into three stages based on degree of anemia, hypercalcemia, paraprotein concentration, and number of bone lesions.[82] Recommendations for considering cytogenetic and genetic characteristics as prognostic factors, as well as LDH concentrations and serum free light chain ratios, have been proposed.[82]

Monitoring and classification of treatment responses rely on multiple factors.[82] Detection and quantification of paraproteins are major factors in assessing treatment responses. Increases in serum paraprotein concentration or urine excretion usually indicate disease progression. Decreases in paraprotein usually indicate response to treatment. Negative results from immunofixation electrophoresis for paraprotein detection serve as a major criterion in complete responses.[82] Assessment of the κ:λ ratio of free light chains in serum sometimes serves as a more sensitive indicator of paraproteins than does immunofixation electrophoresis.[73,82]

Cryoglobulinemia and Amyloid Disease

Deposition of monoclonal immunoglobulin light chains or, more rarely, heavy chains in tissues can produce systemic amyloidosis as discussed in a later section of this chapter. Cryoglobulins are serum proteins or protein complexes that precipitate at temperatures lower than normal core body temperature.[142] Precipitation of cryoglobulins in tissues can result in vasculitis and ischemic injury to peripheral tissues at a lower temperature and tissue loss of fingers, toes, nose, and other sites. Patients need to be kept in a warm environment until treatment can lower cryoglobulin concentrations. Type I cryoglobulins consist of monoclonal immunoglobulins, often IgM. Occasionally, specimens with high paraprotein concentrations will gel, and this can present major problems with plugging sample probes of automated analyzers. Most cryoglobulins consist of immunoglobulin mixed with a monoclonal component (type II) or without a monoclonal component (type III cryoglobulin). Mixed cryoglobulins often present with chronic infection, particularly with hepatitis C. Cryoglobulins require transport and processing of specimens at temperatures near body temperature to prevent loss of the cryoglobulin during serum formation and centrifugation. For cryoglobulin analysis, serum usually is stored for 7 days under refrigeration. Cryoglobulins precipitated by centrifugation should redissolve in saline when warmed to 37 °C, whereas cryofibrinogen will not dissolve. Monoclonal immunoglobulins may have unusual solubility characteristics that include not only gelling or precipitating at low temperatures, but also behaving as pyroglobulins (precipitating at 56 °C) or precipitating as a result of pH changes. Unusual solubility or physical characteristics may contribute to unpredictable interferences of paraproteins in a variety of photometric assays due to precipitation and turbidity under assay conditions as described in many reports; a recent example describes interference with the biuret assay.[155] Cryoglobulins also are recognized to interfere with automated hematology analyzers.

Laboratory Considerations

Methodologies

Immunoglobulins are typically quantified by immunoturbidimetry or immunonephelometry (see Chapters 10 and 16). Immunochemical assays of polyclonal immunoglobulins involve determining the concentration of a mixture of protein molecules having similar constant regions but different variable regions (idiotypes). Reagent antisera and reference immunoglobulin calibrators used in most immunochemical assays have been generated against normal human sera containing a mixture of immunoglobulin subclasses and idiotypes. However, a monoclonal immunoglobulin has only a few of the determinants with which the antiserum usually reacts, and antigen excess may be reached at relatively low

IMMUNOGLOBULIN REFERENCE INTERVALS

Body Fluid	IgG, mg/dL	IgA, mg/dL	IgM, mg/dL	IgD, mg/dL	IgE, mg/dL
Serum					
Newborn (4 d)	700-1480	0-2.2	5-30		
20-60 y	700-1600	70-400	40-230	0-8	0-380
>60 y	600-1560	90-410	30-360		
CSF	0-5.5	0-0.6	0-1.3		
Saliva	≈11				

concentrations. If a paraprotein is suspected or previously identified, the assays should be performed at two or more dilutions to check for this; corrected for dilution, the values should agree within ≈10%. Furthermore, if a new batch of antiserum is introduced, the relationship between paraprotein concentration and the calibration curve is likely to change. For these reasons, many laboratories estimate the concentration of paraproteins by electrophoresis and densitometry.

Reference Intervals

Reference intervals for IgG and IgM in various human adult populations differ around the world because of different degrees of antigenic stimulation. IgA concentrations, however, are relatively unaffected by environmental factors. Newborn infants have B lymphocytes with antigen receptors of the IgM type but do not have significant rates of immunoglobulin synthesis. Essentially all of the IgG in neonates has been transferred across the placenta from the mother.

Amyloidosis

Amyloidosis is a pathologic process in which aggregations of proteins as β-sheet structures form deposits in tissues. The aggregates are relatively stable filamentous structures, resistant to proteolysis and normal clearance mechanisms, so they can accumulate over time. *Amyloid* (Greek, "resembling starch") received its name from Virchow because it stained with iodine like starch.

Biochemistry of Amyloid

Amyloid represents primarily an aggregate of misfolded proteins resulting from overproduction of a specific protein or synthesis of fragments or genetic variants of proteins that are more prone to aggregation.[120] At least 26 different proteins are identified as primary components of amyloid. Serum amyloid P, apolipoprotein E, and glycosaminoglycans also are found as minor components of many amyloid deposits. Depending on the site of amyloid deposition, variable injury results to the kidneys, brain, heart, peripheral nerves, or other tissues. In the past, amyloid has often been classified according to the types of tissue injury caused.[70] From a diagnostic standpoint, it may be more useful to classify amyloid according to the protein serving as the primary component of the amyloid deposits, as in Table 21-13. Amyloidosis cannot be diagnosed directly from analysis of plasma proteins, because it is a process occurring in tissues. Diagnosis may be made from analysis of tissues obtained as aspirates of fat, rectal biopsies, or biopsies of affected tissues. The β-sheet structure of amyloid has characteristic staining with Congo red dye. Serum amyloid P (SAP) binds to most types of amyloid deposits, and radiolabeled SAP has been used for nuclear imaging of amyloid deposition, although this technique has been available at only a few centers.[120]

One of the diagnostic challenges that the physician faces after the presence of amyloid is detected is the need to identify the protein that is forming the amyloid deposits.[123] Immunohistochemistry or other analyses of amyloid deposits may assist in identifying the protein. Analysis of plasma proteins may identify monoclonal immunoglobulin light chains or increases in serum amyloid A or β_2-microglobulin that contribute to the deposition of amyloid. Patients with severe inflammatory disorders such as rheumatoid arthritis and with chronic renal failure undergoing dialysis are at high risk of AA and Aβ_2 amyloidosis because of the relatively high concentrations of serum amyloid A and β_2-microglobulin. Patients suspected of having heritable forms of amyloidosis require analysis of plasma protein or gene sequencing to identify genetic variants of proteins such as prealbumin (transthyretin). A combined screening strategy using sequential mass spectrometric analysis of prealbumin and genetic analysis has been described.[8] More than 75 amyloidogenic variants of prealbumin are recognized. Hereditary forms of amyloidosis generally are inherited in an autosomal dominant manner. Variants of many proteins have been associated with amyloidosis—apolipoproteins A-I and A-II, fibrinogen α-chain, gelsolin (Finnish-type amyloidosis), cystatin C (localized deposition in cerebral blood vessels), calcitonin (localized in thyroid medullary carcinoma), amylin (deposition in pancreatic islets of patients with type 2 diabetes), prolactin (deposited in the pituitary), atrial natriuretic factor (in cardiac atria), keratin (cutaneous deposits), lysozyme, and other proteins.[120,150] Alzheimer's disease is associated with deposition of Aβ-peptide in brain tissue, although the pathogenic role of amyloid remains controversial. The Aβ-peptide of about 42 amino acid residues in length is released by proteolytic cleavage of a transmembrane protein, the amyloid β precursor protein. Increased concentrations of Ab -peptide in CSF may serve as an indicator of the production of this amyloidogenic peptide.[112A,172]

TABLE 21-13 Classification and Protein Deposition in Selected Amyloidoses

Protein	Type	Causes
Systemic		
Immunoglobulin light chain	AL	Plasma cell dyscrasias, multiple myeloma
Immunoglobulin heavy chain	AH	Rare, plasma cell dyscrasias
Serum amyloid A	AA	Inflammation as in rheumatoid arthritis, tuberculosis
Prealbumin (Transthyretin)	ATTR	Genetic variants of prealbumin
β_2-Microglobulin	$A\beta_2$	Accumulation of β_2-microglobulin in renal failure
Localized		
Amyloid β-protein	Aβ	Cleavage of amyloid β-precursor protein; Alzheimer's disease
Amylin	IAPP	Type 2 diabetes, accumulation in pancreatic islets
Cystatin C	ACys	Genetic variant of cystatin C, deposition in cerebral vessels
Keratin	Aker	Cutaneous deposition of keratin
Gelsolin		Genetic variant of gelsolin, Finish-type amyloidosis
Procalcitonin		Local deposition in thyroid medullary carcinoma

Clinical Significance of Amyloid

AL and AH Amyloidosis

Monoclonal production of free immunoglobulin light chains or, rarely, heavy chains is associated with benign or malignant expansion of clones of plasma cells.[108] The fibrillar proteins consist of homogeneous immunoglobulin light polypeptide chains mainly of the 8 (especially 8_{VI}) type, their amino-terminal variable fragments, or both. AL proteins have a molecular weight of 14 to 22 kDa and an affinity for clotting factor X, which may decrease plasma concentrations of this factor with associated bleeding.[150] Because they always include the variable portion of the immunoglobulin light chain, they differ from one case to another. AL deposits may occur in the tongue, heart, lymph nodes, spleen, joints, peripheral nerves, and skin.

AA Amyloidosis

Serum amyloid A (SAA) synthesis is strongly induced by inflammation; similar to CRP, its concentration can increase up to 1000-fold.[42] Three different genes for SAA are known. SAA-4 is a constitutively expressed protein not induced by the APR; SAA-1 and SAA-2 are gene products induced by inflammation. SAA-1 is a small nonglycosylated protein of 11,683 Da that also occurs in some truncated forms.[34,56] All forms of SAA bind to high-density lipoproteins and appear to supplant apolipoprotein A-I in inflammatory conditions, because apolipoprotein A-I is a negative acute-phase reactant. Fragments of SAA of 5 to 9 kDa are amyloidogenic. AA amyloidosis occurs in rheumatoid arthritis (incidence up to 20%) and other inflammatory joint diseases, and in chronic infections such as tuberculosis and osteomyelitis. Deposits of AA protein are also observed in nonlymphoid tumors such as renal and gastric carcinomas and in Hodgkin's disease. Deposits of AA protein most often are found in the kidneys, liver, and spleen, usually resulting in nephrotic syndrome and hepatosplenomegaly.[70] Studies have shown that blocking inflammatory responses with inhibitors of TNF-α offers one approach to lower SAA concentrations and to decrease renal injury.[74]

ATTR Amyloidosis

Deposition of prealbumin (transthyretin) has been shown to result from more than 75 different genetic variants.[8,120] One common presentation has been termed *senile amyloidosis* or *senile cardiac amyloidosis* related to cardiac failure resulting from amyloid deposition in the heart; amyloid deposits also occur in other tissues. Other presentations may include polyneuropathies and neurologic disorders that may relate to the relatively high abundance of prealbumin in the central nervous system.

Methods for Analyzing Proteins

Analysis of high-abundance proteins in body fluids depends on a variety of methods for total protein analysis, electrophoretic methods, and specific quantitative immunoassays based on turbidimetry, nephelometry, and radial immunodiffusion. Mass spectrometry is used increasingly for qualitative analysis of high-abundance protein components. Analysis of low-abundance components by functional assays and other immunoassay techniques is described in other chapters.

Immunochemical Methods

Nephelometric and turbidimetric methods are performed as equilibrium or rate methods for measuring the amount of light scattering by antigen-antibody complexes. Limits of detection of ≈10 mg/L are attained with routine nephelometric and turbidimetric methods, adding antibodies in solution. Binding antibodies to particles of latex or other materials enhances light scattering and can lower limits of detection by 10- to 100-fold. Such assays may be described as latex-enhanced or as particle-enhanced assays. Radial immunodiffusion methods usually are able to detect down to a minimum of 10 to 20 mg/L. These methods are generally adequate for the high-abundance plasma proteins described in this chapter. Nephelometric and turbidimetric assays commonly offer within-run coefficients of variation (CVs) of <5%, except as

limits of detection are approached. RID has higher within-run and run-to-run CVs. Turbidimetric methods can be applied on most chemistry analyzers capable of performing photometric methods. Nephelometry requires instrumentation capable of measuring light scattering at an angle.

Calibration of Immunochemical Methods

Older reference preparations such as WHO 6HSP and USNRP for the measurement of complement, immunoglobulins, and a few other proteins had values assigned in international units (IU). Certified reference material 470 was developed through combined efforts of multiple organizations with concentration values versus USNRP for albumin, AMG, complement factors C3 and C4, Cp, Hp, and IgA, IgG, and IgM. Concentration values were assigned for AAT (α_1-protease inhibitor), α_1-antichymotrypsin, AAG (orosomucoid), and transferrin against highly purified and thoroughly characterized purified proteins, and for C-reactive protein against WHO 85/506, using the factor 1 IU = 1 mg/dL. CRM 470 has been used to standardize manufacturers' controls and calibrators, resulting in decreased variation between assays, and tentative reference values for white adults have been established.[22] Minor differences in assays remain based on different antibody specificities.

Specimen Collection and Storage for Immunoassay

Test specimens should be nonhemolyzed, cell-free serum, urine, or CSF. CSF specimens may require centrifugation if cells are present. Serum and CSF samples may be stored at 2 to 8 °C for up to 3 days or at −20 °C for longer periods. Repeated freezing and thawing of specimens may cause denaturation of some proteins and should be avoided.

Electrophoretic Techniques

Electrophoresis is used to separate proteins by charge and thereby to assess protein variants or the concentrations of specific components in serum or other fluids. Electrophoretic techniques commonly performed in clinical laboratories include nondenaturing electrophoresis on cellulose acetate strips or agarose gels, capillary electrophoresis (CE), immunofixation, and "Western blotting." Protein separation in one or two dimensions with polyacrylamide gel is a powerful separation technique frequently used for research.[3]

Serum Protein Electrophoresis

Generally, serum rather than plasma is used for electrophoresis of proteins on agarose gels to avoid the fibrinogen band at the β-γ interface. The principles of electrophoresis are described in Chapter 12. Figure 21-7 illustrates examples of serum electrophoretic patterns for normal and pathologic specimens. Analysis usually is performed with low–ionic strength buffers (≈0.05) at pH ≈ 8.6. For agarose gels, the usual sample is 3 to 5 µL, applied evenly across a lane. Much smaller volumes are injected for capillary electrophoresis via electrokinetic or hydrostatic injection. Separation times are typically about 1 hour for agarose gels and a few minutes for capillary electrophoresis. A variety of stains are used to visualize proteins in gels, including amido black, Ponceau S, Coomassie brilliant blue, and related dyes. Levels of detection and linearity of protein detection vary with different dyes. Only a few of the most abundant proteins are visualized, and intensities of bands with protein stains usually relate to the mass of peptide; oligosaccharides and lipids may reduce rather than contribute to band intensities. Therefore, glycoproteins with a high proportion of carbohydrate (e.g., AAG) have lower detection responses than a nonglycosylated protein such as albumin. Quantitative analysis relies on densitometry, which provides relative proportions of different components rather than absolute amounts. Quantitation of individual components relies on calculations based on total protein concentration. Lipophilic stains such as Sudan black are needed to visualize lipoproteins such as HDL (α_1-lipoprotein), VLDL (pre-β-region), LDL (β-lipoprotein), or chylomicrons (origin) (see also Chapter 27). Capillary electrophoresis detects proteins passing through a flow cell by their light absorbance at wavelengths below 220 nm. This offers a more unbiased assessment of protein concentration than staining intensity, as absorbance of proteins in the low ultraviolet region is more consistently related to mass. Small molecules at high concentrations, such as metabolites, radiocontrast dyes, or drugs, may also yield absorbance peaks, and this presents problems with analysis of urine specimens.

The major clinical application of serum protein electrophoresis is the detection of monoclonal immunoglobulins (paraproteins) to assist in the diagnosis and monitoring of multiple myeloma and related disorders. Most of the monoclonal immunoglobulins are observed in the β-region or γ-region. Quantitation of monoclonal components serves as a means of monitoring disease progression and response to therapy. Identification of paraproteins requires distinction from a variety of other sources of additional bands or pseudoparaproteins by means such as immunofixation electrophoresis as described later. Incompletely clotted specimens contain fibrinogen. Genetic or post-translational variants of proteins such as transferrin, haptoglobin, and C3 may migrate in different than usual positions. Large increases in CRP may yield a detectable band in the β- or γ-region. Increased lysozyme in monocytic leukemia may produce a band in the post-γ-region. Hemoglobin will yield a band in hemolyzed specimens.

Many other findings of potential clinical significance have been reported:

1. Changes in albumin concentration or migration. Decreases in concentration suggest nutritional deficiency, protein-losing disorders, APR, or advanced liver disease. Changes in mobility or bisalbuminemia may indicate genetic variants or increased binding of fatty acids or drugs; usually this is not of great clinical significance.
2. Changes in the α_1-region relate to changes in AAT, and to a lesser degree in AAG or HDL. Decreases are associated with AAT deficiency or protein-losing disorders. Increases are related to inflammation.
3. Changes in the α_2-region usually relate to changes in HPT and AMG. Migration of HPT varies with genotype. HPT

Figure 21-7 Electrophoretic patterns typical of normal conditions and of some pathologic conditions (agarose gel). *Upward- and downward-pointing arrows* indicate increase and decrease from the reference interval, respectively. *Right- or left-slanting arrows* indicate variation from normal to an increase or from normal to a decrease from the reference interval, respectively. The *asterisk* indicates Hp 2-2 phenotype.

decreases with in vivo hemolysis and increases with the APR. AMG and high molecular weight forms of HPT increase in nephrotic syndrome, while most other protein components decrease.

4. Bands in the β-region are related to transferrin, C3, and LDL. Migration of transferrin may change from the β_1-region to the β_2-region with carbohydrate-deficient transferrin. Transferrin decreases and C3 increases in the APR. Transferrin increases in iron deficiency. LDL may increase in dyslipidemias.
5. An increase between β- and γ-bands, so-called bridging of β- and γ-bands, suggests an increase in IgA as seen with cirrhosis, respiratory tract or skin infection, and rheumatoid arthritis.
6. Increases or decreases in the γ-region suggest changes in immunoglobulins. Increases result from chronic infection or paraproteins. Decreases occur with many immunodeficiency states. Multiple myeloma may suppress general production of immunoglobulins other than from the expanded clone. Therefore, a decrease in the γ-region may suggest the need for additional studies such as immunofixation electrophoresis to detect paraproteins.

Immunofixation Electrophoresis

Immunofixation electrophoresis (IFE) has largely replaced immunoelectrophoresis (IEP) for detection of paraproteins. IFE provides easier interpretation. A comparison of IFE and IEP for two patients with monoclonal gammopathies is shown in Figure 21-8. After electrophoretic separation in agarose, IEP relies on antibody diffusion from troughs parallel to lanes, while IFE involves antibody overlaid directly on lanes. To perform IFE, a patient's serum is run in multiple lanes on an agarose gel. One lane is fixed to provide the overall pattern of proteins. Other lanes are overlaid with specific antisera, usually separate antisera versus κ and λ light chains and γ, μ, and α-immunoglobulin heavy chains. Antibody dilutions are adjusted to provide approximate equivalence with immunoglobulins separated in the gel, so as to form immune complexes precipitated in the gel. Proteins not precipitated are washed from the gel to lower background, and precipitated proteins are stained. Paraproteins characteristically yield sharper precipitin bands than the heterogeneous polyclonal immunoglobulins. IFE provides more sensitive detection of paraproteins because of the lower background and signal amplification from immune complex formation, and helps distinguish paraproteins from pseudoparaproteins. Immunofixation helps identify the immunoglobulin type of the paraprotein. Sometimes, more than one clone may be expanded, or free light chain may occur together with intact immunoglobulin. Uncommonly, paraproteins may be of the IgD or IgE class. They should be detected by antisera versus light chains but require δ or ε heavy chain specific antisera to distinguish them from free light chains. High concentrations of paraproteins may yield prozones during immunofixation, requiring specimen dilution for optimal studies. For paraproteins present in high concentrations, quantitative analysis of immunoglobulins can confirm the unbalanced production of a specific class of immunoglobulin and may assist in proper dilution of specimens for immunofixation.

Capillary Electrophoresis

CE of proteins relies on zone electrophoresis in small-bore (10 to 100 μm), fused silica capillary tubes 20 to 200 cm in length (see Chapter 12). Electrokinetic or hydrostatic injection introduces a small amount of protein that is resolved rapidly under high voltage. One of the challenges is to avoid adsorption of proteins to the surface of the capillary. CE is suitable for automation and offers rapid analysis with no need for gel handling or staining. Direct ultraviolet detection offers slightly different specificity than protein staining and offers better reproducibility of quantitation than densitometry. Immunofixation cannot be performed with CE. Immunosubtraction with specific antisera is used as an alternative procedure to identify paraproteins.[103]

Western Blotting

For Western blotting, proteins separated on a gel are transferred by diffusion or electroblotting onto a membrane made of materials such as nitrocellulose or polyvinylidene fluoride. Proteins bound on the membrane are identified with specific antibodies using labels such as peroxidase, alkaline phosphatase, or chemiluminescent probes (see Chapter 12).

Mass Spectrometry (MS)

Multiple types of MS instrumentation provide qualitative or quantitative information about proteins (see Chapter 14). An advantage of MS is the ability to analyze a large number of components in a single analysis, including rapid sequence analysis of peptides. MS, therefore, has been an enabling technology in *proteomics,* defined as the effort to study the complete set of proteins in an organism or in subcompartments of an organism such as plasma.[3,57] Ionization of peptides and proteins has been accomplished by electrospray or matrix-assisted laser desorption/ionization (MALDI) sources. Electrospray sources take a solution containing proteins and form a spray of fine droplets with an applied electrical charge. Solvent is evaporated, generating multiply charged protein ions for mass analysis. In MALDI sources, proteins are deposited on a target surface together with a light-absorbing compound (the matrix) such as dihydroxybenzoic acid.[56] Under a high vacuum, the matrix and proteins are vaporized by pulses of light from a laser; proteins usually are preferentially ionized in a singly charged form. Once proteins are ionized, they can be separated by quadrupoles, ion traps, time-of-flight, and other types of mass analyzers.[29] In general, MS is better suited to analyzing small peptides than proteins, because it provides better resolution, a smaller number of charge states of ions, and better detection sensitivity.[29,56] It is difficult to quantitatively interpret the absolute magnitude of detector responses in MS, but accurate ratios of similar peptides can be determined. Use of stable

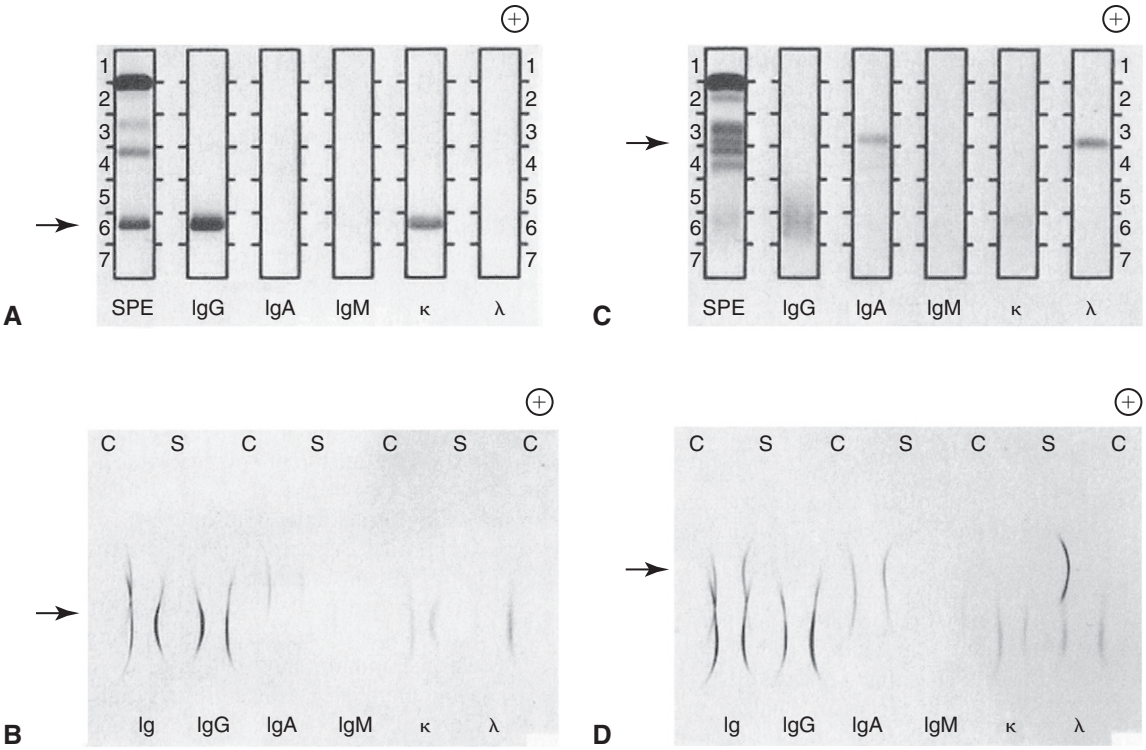

Figure 21-8 Comparison of immunofixation electrophoresis (IFE) and immunoelectrophoresis (IEP) for two patients with monoclonal gammopathies. A, Patient specimen with an IgG (κ) monoclonal protein as identified by IFE. The *arrow* indicates the position of monoclonal protein. After electrophoresis, each track except SPE is reacted with its respective antiserum; then all tracks are stained for visualization of the respective protein bands. (SPE, chemically fixed serum protein electrophoresis; IgG, IgA, IgM, κ, and λ indicate antiserum used on each track.) B, Same specimen as in A, with proteins identified by IEP. The *arrow* indicates the position of monoclonal protein. Normal control (C) and patient sera (S) are alternated. After electrophoresis, antiserum is added to each trough as indicated by the labels Ig (polyvalent Ig antiserum), IgG, IgA, IgM, κ, and λ. The antisera react with separated proteins in the specimens to form precipitates in the shape of arcs. The IgG and κ arcs are shorter and thicker than those in the normal control, showing the presence of the IgG (κ) monoclonal protein. Concentrations of IgA, IgM, and λ-light chains are also reduced. C, Patient specimen with an IgA (λ) monoclonal protein identified by IFE procedure as described in A. D, Same specimen as in C with proteins identified by IEP as described in B. Abnormal IgA and λ-arcs for the patient specimen indicate an elevated concentration of a monoclonal IgA (λ) protein. All separations were performed using the Beckman-Coulter Paragon system.

isotope-labeled internal standards allows the absolute quantitation of peptides or proteins (based on analysis of proteotypic peptides released by proteolysis). Use of tandem MS with an intermediate fragmentation step between two stages of MS separation offers high sensitivity and specificity for the quantitative analysis of peptides, as it does for most small molecules. Quantitative analysis usually uses selected ion monitoring (also referred to as multiple reaction monitoring for multiple components), which selects particular precursor and product ions for analysis. This form of analysis is performed very efficiently by triple quadrupole MS. Qualitative analysis of peptides, identifying their sequences and post-translational modification, often uses mass spectrometers such as ion traps that are well suited for scanning all peptide fragments generated by fragmentation.[29]

Advantages of using MS for quantitative analysis include the ability to analyze components without developing specific antibodies and the ability to multiplex a large number of measurements.[2] MS can provide information about post-translational modifications that is difficult to assess by immunoassays and chromatographic or electrophoretic techniques. Examples of clinical applications include identification of genetic variants of prealbumin and carbohydrate-deficient transferrin.[8] MS techniques are likely to increasingly serve as

reference methods for accurate determination of protein concentrations, such as recently applied for standardization of hemoglobin A_{1c} measurement and for concentrations of peptides such as insulin and C-peptide.[106] For analysis of bioactive peptides, the ability to distinguish between peptides differing in length by one or two amino acids or by a post-translational modification often is critical. MS is likely to find increased use for clinical laboratory analysis of bioactive peptides and other components of the peptidome.

Proteins in Other Body Fluids

Complex mixtures of proteins are present in all biological fluids; analysis of a variety of other specimens is diagnostically useful, including analyses of urine, CSF, pleural and peritoneal fluids, amniotic fluid, saliva, and feces.

Urinary Proteins

Proteins serve as important markers for the assessment of kidney injury. Urinary proteins are discussed in Chapter 25.

Proteins in Amniotic Fluid

See Chapter 57.

Proteins in Saliva

Saliva has a very different protein composition compared with plasma, with amylase and small peptide components representing major components; a variety of diagnostic applications of salivary protein analysis are being explored.[64] Protein composition varies with the site and method of sampling of saliva. In Sjögren's syndrome with lymphoid infiltration of salivary glands, β_2-microglobulin concentrations rise in saliva. Saliva is tested for secretory IgA in infantile hypogammaglobulinemia.

Proteins in Cerebrospinal Fluid

CSF is the extracellular fluid around the brain and spinal column. CSF usually has total protein concentrations about 100-fold lower than plasma and a different protein composition, as most proteins have limited passage across the blood-brain barrier. CSF for testing most frequently is obtained by a spinal tap in the lumbar region.[94,164]

Biochemistry of CSF

CSF is secreted by the choroid plexuses, around the cerebral vessels, and along the walls of the ventricles of the brain. It fills the ventricles and cisternae, bathes the spinal cord, and is reabsorbed into the blood through the arachnoid villi. CSF turnover is rapid, exchanging totally about four times daily. More than 80% of CSF protein content originates from plasma by ultrafiltration and pinocytosis; the remainder is derived from intrathecal synthesis. The lowest protein concentration and the smallest proportion of larger protein molecules are in the ventricular fluid; as the CSF passes down to the lumbar spine (where specimens are usually collected), the protein concentration increases. This gradient in concentration at different concentrations of the CNS is illustrated by the following reference intervals[156]:

TOTAL PROTEIN, MG/DL	
Ventricular fluid	5-15
Cisternal fluid	15-25
Lumbar fluid	15-48

Because CSF is mainly an ultrafiltrate of plasma, low molecular weight plasma proteins such as prealbumin, albumin, and transferrin normally predominate. No protein with a molecular weight greater than that of IgG is present in sufficient concentration to be visible on electrophoresis. The normal plasma/CSF gradient is about 14 for prealbumin, 240 for albumin, 140 for transferrin, 800 for IgG, and >1000 for larger proteins such as IgA, α_2-macroglobulin (AMG), fibrinogen, IgM, and β-lipoprotein.[35] If partial or complete breakdown of the blood-brain barrier occurs, as in meningitis or bleeding into the subdural space, AMG concentrations in CSF are increased.[91] The concentration of AMG alone, or its relationship to concentrations of albumin and IgG, may be helpful in the differential diagnosis of neurologic disorders or of elevated CSF protein. CSF concentrations of AMG normally increase with age, suggesting that partial but progressive breakdown of the blood-CSF barrier occurs with aging. Bleeding into the CSF also raises AMG concentrations in this fluid.

The electrophoretic pattern of normal CSF after concentration of the fluid has two striking features—a prealbumin band and two transferrin bands—one at β_2 in addition to the usual β_1 position. The β_2-transferrin has decreased charge because it is carbohydrate deficient. Both β_2-transferrin and another relatively abundant CSF protein, prostaglandin D synthase or β-trace, have been used to determine whether clear fluids from nasal or ear passages represent leakage of CSF, so-called CSF rhinorrhea and otorrhea.[4] Prostaglandin D synthase is a protein of about 30 kDa that is relatively enriched in CSF relative to serum or plasma, where it normally is cleared rapidly by glomerular filtration. Apolipoprotein E serves as one of the major lipid transport proteins because of the relative lack of other lipoproteins such as HDL and LDL to carry lipids.

Clinical Significance

The blood-brain or blood-CSF barrier limits exchange of many compounds, particularly large compounds such as proteins. Analyses of total protein and specific proteins in CSF are used primarily to detect increased permeability of the blood-CSF barrier to plasma proteins or increased production or release of specific proteins, such as immunoglobulins, myelin basic protein, or amyloid beta peptides in the CNS (Table 21-14).

Increased Permeability. The permeability of the blood-CSF barrier to plasma proteins increases with inflammation in bacterial or viral meningitis, encephalitis, or poliomyelitis and with high intracranial pressure resulting from a brain tumor, intracerebral hemorrhage, or traumatic injury. Highest elevations of CSF total protein are seen in bacterial meningitis. Lumbar CSF protein increases when the CSF

TABLE 21-14 Cerebrospinal Fluid Total Protein in Various Diseases

Clinical Condition	Appearance and Cells × 10^6/L	Total Protein, mg/dL
Normal	Clear, colorless; 0-5 lymphocytes	15-45*
Increased Admixture of Proteins From Blood		
Increased capillary permeability:		
• Bacterial meningitis	Turbid, opalescent, purulent, usually >500 polymorphs	80-500
• Cryptococcal meningitis	Clear or turbid; 50-150 polymorphs or lymphocytes	25-200
• Leptospiral meningitis	Clear to slight haze; polymorphs early, then 5-100 lymphocytes	50-100
• Viral meningitis	Clear or slight haze, colorless; usually up to 500 lymphocytes	30-100
• Encephalitis	Clear or slight haze, colorless; usually up to 500 lymphocytes	15-100
• Poliomyelitis	Clear, colorless; up to 500 lymphocytes	10-300
• Brain tumor	Usually clear; 0-80 lymphocytes	15-200 (usually normal)
Mechanical obstruction:		
• Spinal cord tumor†	Clear, colorless, or yellow	100-2000
Hemorrhage		
Cerebral hemorrhage	Colorless, yellow, or bloody; blood cells	30-150
Local immunoglobulin production:		
• Neurosyphilis	Clear, colorless; 10-100 lymphocytes	50-150
• Multiple sclerosis‡	Clear, colorless; 0-10 lymphocytes	25-50
Both increased capillary permeability and local immunoglobulin production:		
• Tuberculous meningitis	Colorless, fibrin clot, or slightly turbid; 50-500 lymphocytes	50-300 (occasionally up to 1000)
• Brain abscess	Clear or slightly turbid	20-120
After myelography (inflammatory reaction)		Slight increase

*Premature infant: up to 400 mg/dL. Children: 30-100 mg/dL. Old age: up to 60 mg/dL.
†Froin's syndrome: lumbar fluid values are much higher than cisternal fluid values.
‡Similar values may occur in certain other chronic inflammatory conditions of the nervous system.

circulation is obstructed above the collection site (as by a spinal cord tumor). Increased permeability results in CSF composition closer to that of plasma.

Intrathecal Synthesis. Increased intrathecal synthesis of immunoglobulins, particularly IgG, occurs in demyelinating diseases of the CNS, especially multiple sclerosis.[164] In multiple sclerosis, patchy demyelination of axons in the CNS interferes with nerve conduction and leads to varying neurologic symptoms. B lymphocytes that infiltrate the lesions release immunoglobulins, primarily IgG, into CSF.

Laboratory Considerations for CSF

Various analytical techniques are used to assess the increased permeability of the blood-CSF barrier to plasma proteins and to detect intrathecal synthesis of immunoglobulins.

Determination of Total Protein in CSF. The total protein concentration in CSF is an indicator of blood-CSF permeability. The protein concentration of CSF usually is more than 100-fold lower than for plasma, and methods with greater sensitivity or increased specimen volume are required for measuring total serum or plasma protein. In practice, methods commonly used by clinical laboratories to measure total CSF protein include (1) pyrogallol red, (2) benzethonium chloride, (3) reverse-biuret, and (4) biuret. The reverse-biuret method measures free copper remaining after formation of biuret complexes by reduction and complexation with a chelating dye. Analyzers often use the same method, possibly with some adjustment of specimen volume, for CSF and urine protein. The usual reference interval for CSF IgG in adults is 0.8 to 4.2 mg/dL; for total protein, 15 to 45 mg/dL. Total protein concentrations are considerably higher in neonates, and in healthy elderly adults. In CSF from premature and full-term neonates, concentrations up to 400 mg/dL for premature and 130 mg/dL for full-term

neonates); in healthy elderly adults, concentrations up to 60 mg/dL are considered normal. In newborns, a progressive decline in the reference interval CSF protein is seen over the first few weeks of life, with values approaching adult concentrations at >4 months of age.[10] Use of age-adjusted reference intervals for the first few weeks of life is most important.

Increased Permeability. A more specific measure of the permeability of the blood-CSF barrier involves determination of the ratio of albumin concentration in CSF versus plasma. This ratio, the *CSF/serum albumin index,* usually is calculated for CSF albumin in mg/dL and for serum protein in g/L, effectively multiplying values by 1000.

A CSF/serum albumin index <9 indicates an intact blood-CSF barrier. Values of 9 to 14 represent slight impairment, 14 to 30 moderate impairment, and >30 severe impairment. The index helps correct for variation in serum albumin concentration.

Intrathecal Synthesis. Measurement of the CSF/serum immunoglobulin ratio and assessment of oligoclonal immunoglobulin bands on electrophoretic separations of CSF serve as assays for intrathecal immunoglobulin synthesis. At least 90% of cases of multiple sclerosis give positive findings, but increased immunoglobulins and oligoclonal immunoglobulins may be found in other inflammatory diseases of the CNS, such as infection caused by bacteria, viruses, fungi, or parasites; neurosyphilis; subacute sclerosing panencephalitis; and Guillain-Barré syndrome. Multiple sclerosis is less likely if CSF total protein exceeds 100 mg/dL, or if the CSF leukocyte count is >50/μL. The CSF albumin concentration in 70% of cases of multiple sclerosis is within the reference interval.

Increases in CSF IgG concentration or in the CSF/serum IgG ratio may result from increased permeability of the blood-CSF barrier, increased local production of IgG, or both. To identify intrathecal production specifically, correction for increased permeability is necessary. Corrections use *CSF and serum* albumin and IgG concentrations in one of several ways:

1. Concentrations *in CSF* of IgG and albumin are measured, and the IgG/albumin ratio is calculated. A ratio >0.27 is considered indicative of increased synthesis; in about 70% of cases of multiple sclerosis, the ratio exceeds 0.27.

$$\text{Ratio} = \frac{\text{IgG}_{\text{CSF}}\,(\text{mg/dL})}{\text{Albumin}_{\text{CSF}}\,(\text{mg/dL})}$$

2. Concentrations in *CSF and serum* of IgG and albumin are measured, and the CSF immunoglobulin index is calculated.

$$\text{Index} = \frac{\text{IgG}_{\text{CSF}}\,(\text{mg/dL}) \times \text{Albumin}_{\text{serum}}\,(\text{g/dL})}{\text{Albumin}_{\text{CSF}}\,(\text{mg/dL}) \times \text{IgG}_{\text{serum}}\,(\text{g/dL})}$$

   The reference interval for the index is 0.30 to 0.70. Values >0.70 indicate increased IgG synthesis; in more than 80% of cases of multiple sclerosis, this index exceeds 0.70. This CSF immunoglobulin index is now a frequently used index.

3. The rate of intrathecal IgG synthesis can be estimated by the empirically derived Tourtellotte's formula. The rate of synthesis of IgG in milligrams per day is equal to

$$5\ \text{dL/d}\left[\left\{\text{IgG}_{\text{CSF}} - \frac{\text{IgG}_{\text{serum}}}{369}\right\} - \left\{\left(\text{Albumin}_{\text{CSF}} - \frac{\text{Albumin}_{\text{serum}}}{230}\right) \times \frac{0.43\,(\text{IgG}_{\text{serum}})}{\text{Albumin}_{\text{serum}}}\right\}\right]$$

   where protein concentrations are in mg/dL. The first bracketed term represents the difference between IgG found in CSF and the IgG expected if the blood-brain barrier is intact. The second bracketed term represents the same for albumin but is corrected by a factor of 0.43, corresponding to the ratio of molecular weights of albumin to IgG, assuming that 1 mole of IgG accompanies every mole of albumin that passes the blood-brain barrier; 369 and 230 originate from the normal serum/CSF ratios for IgG and albumin. The reference interval for the synthesis rate is 0 to 3.3 mg/d. Values exceeding 8 mg/d are found in most cases of multiple sclerosis. This estimator provides no more clinical information than the IgG index; the complex formula merely rearranges the results for serum and CSF IgG and albumin and then factors in several constants.

Determination of Specific Proteins in CSF

Analyses of albumin and immunoglobulins are applied as described previously. CSF concentrations of a protein component of the fatty myelin sheath, *myelin basic protein,* are an indicator of myelin turnover. CSF concentrations of myelin basic protein appear to correlate with exacerbation and remission of multiple sclerosis, but proteolysis may yield different forms of the protein.[94] A number of other proteins such as S100B and neuron-specific enolase are potential markers for traumatic or ischemic brain injury.[76] In acute leukemia and lymphoma with central nervous system involvement, the concentration of β_2-microglobulin BMG is increased in CSF. Concentrations of tau protein y decrease in Alzheimer's disease.[172]

Reference Intervals for CSF Proteins

The reference interval for albumin in lumbar CSF by RID is 17.7 to 25.1 mg/dL. In normal CSF, IgA, IgD, and IgM are <0.2 mg/dL. Reference intervals for IgG are age related; their means increase from 3.5 mg/dL in the 15- to 20-year-old age group to 5.8 mg/dL in adults aged 60 years or older. A usual reference interval for CSF IgG in adults is 0.8 to 4.2 mg/L.[70,156]

Proteins in Peritoneal and Pleural Fluids

Pathologic accumulations of fluid in the peritoneal and pleural cavities or elsewhere vary greatly in protein content. They may be ultrafiltrates with low protein concentrations relative to plasma and scant amounts of large proteins (transudates) or, in response to local inflammation and increased vascular permeability, fluids (exudates) may have protein concentrations approaching those of plasma and significant amounts of large proteins such as immunoglobulins and

AMG. The distinction between transudates and exudates assists in diagnosing the cause of fluid formation. The major cause of pleural transudates is congestive heart failure. Exudates occur with infection, pleuritis, pulmonary embolism, and cancer. Criteria for identifying exudates in pleural fluid were proposed by Light: pleural fluid protein : serum protein >0.5; pleural LDH : serum LDH >0.6; pleural fluid LDH >200 IU/L.[51] Pleural fluid may be turbid from large numbers of white cells, fibrin particles, or chylomicrons. Chylous effusions (containing chylomicrons) result from lymphatic obstruction related to cancer, surgery, trauma, sarcoidosis, or other causes.[109] Lymphatics, particularly the major trunk, the thoracic duct, serve as the major route for chylomicrons from the intestines to the blood circulation. Entry of chylomicrons into the pleural space, therefore, is related in part to dietary fat intake to generate chylomicrons, and fasting lowers the fat content of chylous effusions. Chylomicrons in fluids may be identified by separation of a cream layer upon standing or by triglyceride analysis.

For peritoneal fluid, the serum-ascites albumin gradient (i.e., the difference between serum and peritoneal fluid albumin) helps distinguish transudates (mainly in portal hypertension from cirrhosis) from infection and other causes of ascites. Usually, the serum albumin-ascites albumin gradient is >1.1 g/dL in portal hypertension and is lower than 1.1 g/dL for other causes that generate exudates.[133]

Fecal Proteins

Assay of fecal α_1-antitrypsin is used as an indicator of protein losses into the gastrointestinal tract in protein-losing enteropathies and inflammatory bowel disease. Fecal AAT preferably is determined as clearance on a timed collection to determine an excretion rate ratioed versus the serum AAT concentration.[6] Correction for serum AAT concentration is necessary because of variation in serum AAT from severe enteric losses or from acute-phase responses. AAT is relatively stable in the lower digestive tract but is digested in the stomach at acid pH. Therefore, suppression of acid secretion is necessary to use AAT excretion as a measure of gastric protein-losing enteropathy.[152] An alternative measure of increased gastrointestinal loss of protein has been injection of radiolabeled albumin with monitoring of radioactivity into stool. For inflammatory bowel disease, it may be more useful to have indicators of inflammation rather than leakage of plasma proteins. Fecal content of products secreted by white cells, such as lactoferrin and calprotectin, has been used as a measure of disease activity in inflammatory bowel disease.[151]

CHAPTER 22

Serum Enzymes

Mauro Panteghini, M.D., and Renze Bais, Ph.D., A.R.C.P.A.

Measurements of enzymes are used in medicine in two major ways. Enzymes are measured in serum and other bodily fluids to detect injury to a tissue that makes up the enzyme. Enzymes are also measured, often within a tissue, to identify abnormalities or absence of the enzyme, which may cause disease.

Injury to tissue releases cellular substances that can be used as plasma markers of tissue damage. Many of the clinically useful markers of cellular damage are enzymes. For a substance to serve as a biochemical marker of damage to a specific organ or tissue, it must arise predominantly from the organ or tissue of interest. Highly specific markers have been identified (e.g., cardiac troponin I, which is found only in cardiac myocytes). Some enzymes are found predominantly in specialized tissue (e.g., lipase in the pancreas); others, more widely distributed, have tissue-specific isoenzymes or isoforms (e.g., the pancreatic isoenzyme of α-amylase, the bone isoform of alkaline phosphatase) that can be evaluated to enhance tissue and organ specificity.

The timing of the enzyme's diagnostic window is another important aspect to be considered when these markers are used to evaluate acute injury. According to Noe,[52] the diagnostic window for an injury marker is the interval of time following an episode of injury during which plasma concentrations of the marker are increased, thereby demonstrating the occurrence of injury. Marker substances that rapidly enter the circulation (i.e., early indicators) tend to have diagnostic windows that begin soon after onset of the injury. On the contrary, those biomarkers that are slowly released into the circulation and/or are slowly cleared from the circulation (i.e., late indicators) generally have diagnostic windows that begin later and last long after the time of injury.

DIAGNOSTIC ENZYMOLOGY

In general, clinical laboratorians are principally concerned with changes in activity in the serum or plasma of enzymes that are predominantly intracellular and physiologically present in the blood at low activity concentrations only. Changes in the serum activities of these enzymes are used to infer the location and nature of pathologic changes in tissues of the body. Therefore, an understanding of the factors that affect the rate of release of enzymes from their cells of origin and the rate at which they are cleared from the circulation is necessary to interpret correctly changes in activity that occur with disease.

Factors Affecting Enzyme Concentrations in Plasma or Serum[35,36]

The measured activity of an enzyme in blood is the result not only of the total amount released from its cells of origin, but also of the rate of enzyme catabolism in the circulation, the escape to the extracellular enzyme pool, and the rate at which it is inactivated or removed.

Leakage of Enzymes from Cells

Enzymes are retained within their cells of origin by the plasma membrane surrounding the cell. The plasma membrane is a metabolically active part of the cell, and its integrity depends on the cell's production of ATP. Any process that impairs ATP production by depriving the cell of oxidizable substrates or by reducing the efficiency of energy production by restricting the access of oxygen (ischemia or anoxia) promotes deterioration of the cell membrane. The earliest sign of impaired energy metabolism is the efflux of potassium with influx of sodium; water thus accumulates within the cell, causing it to swell. The next and most serious stage is the entry of Ca^{2+}, which stimulates intracellular enzymes, leading to both cell damage and disruption of the cell membrane. Finally, free radicals formed during these processes may cause further damage. The membrane becomes leaky; if cellular injury becomes irreversible, the cell will die, although enzyme loss may also occur without the occurrence of irreversible injury. Small molecules are the first to leak from damaged or dying cells, followed by larger molecules, such as enzymes and other proteins. Cytosolic proteins appear early on in the plasma, followed much later by mitochondrial and membrane-bound enzymes. It appears that ATP must decline to below a certain level before substantial enzyme release occurs. Ultimately, the complete content of the necrotic cells is discharged.

Because of very high concentrations of enzymes within the cells—thousands or even tens of thousands times greater than concentrations in extracellular fluid—and because extremely small amounts of enzyme can be detected by their catalytic activity, increased enzyme activity in the extracellular fluid or

plasma is an extremely sensitive indicator of even minor cellular damage, some causes of which are listed in Table 22-1.

A reduction in the supply of oxygenated blood perfusing any tissue will promote enzyme release, such as occurs in myocardial infarction. Cells of the affected region rapidly begin to deteriorate and die, releasing their protein and enzyme contents to the systemic circulation, which accounts for the rapid rise in serum biomarkers that is characteristic of this condition. The liver is also very sensitive to hypoxia, which results from diminished cardiac output (heart failure). Direct attack on the cell membranes by such agents as viruses or organic chemicals also causes enzyme release, which is particularly important in the case of the liver. Skeletal muscles also contribute enzymes to blood. Again, the cause may be poor perfusion, hypothermia, or direct trauma to the muscles (crush injuries). Infection, inflammation (polymyositis), degenerative changes (dystrophies), drugs, and alcohol (alcoholic myopathy) will cause enzyme leakage from myocytes.

TABLE 22-1 Causes of Cell Damage or Death

Category	Examples
Hypoxia (an extremely common accompaniment of clinical disease)	Loss of blood supply due to narrowing (atheromatous plaques) or blocking (thrombosis) of artery or vein; ischemic-perfusion injury; inadequate oxygenation due to cardiorespiratory failure; loss of oxygen-carrying capacity, CO poisoning, and anemia
Chemicals and drugs	Environmental pollutants—lead, mercury; drugs—use and abuse; alcohol; tobacco
Physical agents	Trauma; extremes of heat and radiation; electrical energy; toxic chemicals
Microbiological agents	Bacteria, viruses, fungi, protozoa, and helminths
Immune mechanisms	Immune disorders can cause tissue damage by a number of mechanisms: 1. Anaphylaxis (causing release of vasoactive amines) 2. Cytotoxicity (causing the target cell to be lysed) 3. Immune complex disease (leading to release of lysosomal enzymes) 4. Cell-mediated hypersensitivity (leading to cytotoxicity)
Genetic defects	Disorders with polygenic inheritance—diabetes mellitus, gout Mendelian disorders—X-linked disorders, autosomal dominant and recessive disorders, disorders with variable modes of transmission and inborn errors of metabolism
Nutritional disorders	Protein-calorie malnutrition, vitamin deficiencies, mineral deficiencies; obesity and its consequences

Based on the classification of Robbins and colleagues. In: Basic pathology, 3rd edition. Philadelphia: WB Saunders, 1981.

Efflux of Enzymes from Damaged Cells

Once conditions for leakage of enzymes from cells have become established, the speed and extent to which the process is reflected in enzyme changes in the blood depend on several factors.

The driving force of enzyme release is the steep concentration gradient that exists between the interior and the exterior of the cells. The rate of escape of enzyme molecules is presumably controlled to some extent by diffusion; therefore, smaller enzyme molecules might be expected to appear in the extracellular fluid earlier than larger ones.

The way in which released enzyme molecules are transferred from the interstitial fluid to the blood varies from one tissue to another; they may pass directly through the capillary wall, or lymphatic transfer may occur. Direct transfer occurs to a large extent in the liver, which is a highly vascular tissue with many permeable capillaries, although evidence suggests that liver enzymes may also be subject to lymphatic transfer. On the other hand, the capillaries of skeletal muscle are relatively impermeable, and in this tissue it is probable that released enzymes mainly reach the circulatory system by way of drainage from the lymphatic system. Lymph drainage is also important in transporting enzymes released from damaged intestinal, pancreatic, and myocardial cells to the circulation, although, following myocardial infarction, a minor proportion of myocardial enzymes reaches the circulation by direct capillary transfer.

The intracellular location of the leaking enzymes affects the rates at which they appear in the circulation. As would be expected, the most sensitive indicators of cell damage are the molecules that are present in the soluble fraction of the cell. Release of structurally bound membrane proteins requires both a leaky cell membrane and a dissociation or degradation, which is a slower process.[39] Enzymes associated with subcellular structures, such as mitochondria, are less readily released into the circulation and often indicate irreversible cellular injury. This fact has been used in attempts to distinguish reversible leakage, presumed to reflect damage only to the cell membrane, from necrotic lesions, in which intracellular structures are destroyed.

The relation between tissue injury and the appearance of enzymes in the circulation is most clearly seen in myocardial infarction, in which a relatively short episode of damage is followed by rapid transfer of enzymes to the circulatory system. About 24 hours after a myocardial infarction, the

pattern of relative activity of various enzymes in the circulatory system closely resembles that in myocardial tissue. These relationships are less clearly recognized in other conditions, such as chronic liver disease, in which enzyme release is a process that continues over a period of time. The pattern of relative enzyme activities in serum in chronic disease may also become distorted by differential rates of removal of enzymes from the circulation and possibly by differential changes in rates of enzyme synthesis in affected tissue.

Release of enzymes from damaged or dying cells and changes in the rate of enzyme production constitute the most important mechanisms by which changes in enzyme activity in the serum or plasma are produced. However, other possibilities exist and appear to account for some changes of diagnostic importance. For example, much of the γ-glutamyltransferase activity of liver cells is located on their exterior surfaces. It is possible that ectoenzymes such as this may be eluted from the surfaces, especially where detergent action of the blood is increased through accumulation of bile salts. This process does not involve cell damage in the sense of increased membrane permeability, as evidenced by lack of correlation between activities in the serum of γ-glutamyltransferase and the aminotransferases in liver disease of different types.

Altered Enzyme Production

Small amounts of intracellular enzymes physiologically present in the plasma can be assumed to result from wear and tear of cells or leakage of enzyme from healthy cells. This contribution of enzymes to the circulating blood may decrease as the result of a genetic deficiency of enzyme production (e.g., as is the case for alkaline phosphatase in hypophosphatasia or in individuals homozygous for the "silent" gene for serum cholinesterase), or when enzyme production is depressed as a result of disease (e.g., cholinesterase in liver disease). However, cases in which enzyme production is increased are of more general interest in diagnostic enzymology. For example, an increase in the number and activity of alkaline phosphatase–producing osteoblasts of bone is responsible for the increased concentration of alkaline phosphatase in the serum of normally growing children. Increased osteoblastic activity also accounts for increased concentrations of this enzyme in the serum in various types of bone disease.

The process of enzyme induction also increases enzyme production. An example of such induction is the increased activity of γ-glutamyltransferase in serum, which results from administration of drugs such as barbiturates or phenytoin, and from intake of ethanol.

Clearance of Enzymes

Significant evidence is available about the way in which enzymes are cleared from the circulation. Few enzyme molecules are small enough to pass through the glomerulus of the kidney; therefore urinary excretion is not a major route for elimination of enzymes from the circulation. An exception to this is α-amylase; increased concentrations of this enzyme in the blood (e.g., after *acute pancreatitis*) are accompanied by increased excretion in the urine.

Evidence now suggests that many enzymes are not inactivated in the plasma but are rapidly removed, probably by the reticuloendothelial system, such as the bone marrow, spleen, and liver (Kupffer cells), or, to a lesser extent, by nearly all cells in the body. The mechanism appears to consist of receptor-mediated endocytosis (the process of recognition, specific accumulation, and uptake of protein by specific cell surface receptors followed by fusion with lysosomes, digestion of ingested protein, and recycling of the receptor back to the cell membrane). For example, hepatic Kupffer cells have been shown to take up several tissue-derived enzymes—such as creatine kinase, adenylate kinase, cytoplasmic and mitochondrial aspartate aminotransferase, and malate and alcohol dehydrogenases—by receptor-mediated endocytosis, which may have affinity for lysine residues on these enzymes. The adult isoform of intestinal alkaline phosphatase is a galactosyl-terminal glycoprotein that reacts with a galactosyl-specific receptor on the hepatocyte membrane and undergoes subsequent endocytosis. This process is rapid, accounting for the extremely short plasma half-life of this isoform. However, in hepatic cirrhosis, in which considerable reduction in parenchymal cell mass often occurs, the plasma concentration and half-life of the isoform increase. Other alkaline phosphatase isoenzymes and isoforms are sialoglycoproteins that do not react with the galactosyl receptor and therefore are protected from rapid uptake from blood. Indeed, examples are known of excessive sialylation of alkaline phosphatases produced by malignant cells, prolonging their plasma half-lives and facilitating their detection. This example illustrates the importance of understanding the processes by which enzymes are cleared from plasma.

The half-lives of enzymes in plasma vary from a few hours to several days, but in most cases, the average half-life ($t_{1/2}$) is 6 to 48 hours. Rates of decay may also be expressed as k_d values—the fractional disappearance rate—and the relationship to $t_{1/2}$ values is as follows:

$$k_d = 2.303 \log \frac{2}{t_{1/2}} = \frac{0.693}{t_{1/2}}$$

Typical disappearance rates from human blood for several clinically relevant enzymes are shown in Figure 22-1.

Selection of Enzyme Tests

The selection of which enzyme to measure in serum for diagnostic or prognostic purposes depends on a number of factors. An important factor is the distribution of enzymes among the various tissues, shown, for example, for aspartate aminotransferase, alanine aminotransferase, and creatine kinase in Figure 22-2. The main enzymes of established clinical value, together with their tissues of origin and their major clinical applications, are listed in Table 22-2.

The mass of the damaged or malfunctioning organ, together with the enzyme cell/blood gradient, obviously has a profound influence on the resulting elevation of enzyme

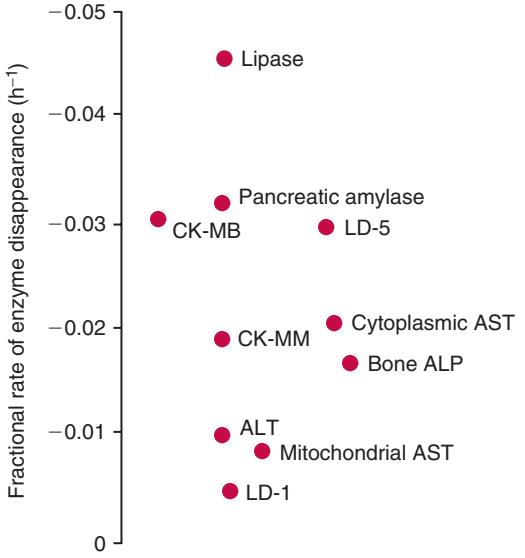

Figure 22-1 Fractional disappearance rates (k_d, in hours^{-1}) from human blood of the most important enzymes.

activity in blood. Thus the gradient of activity of prostatic acid phosphatase between prostate and blood is about 10^3:1, and the mass of that organ is 20 g. By contrast, the cell and/or blood gradient of alanine aminotransferase in the liver cell is 10^4:1, and the mass of the liver can exceed 1000 g. Obviously, fewer cells have to be damaged in the liver than in the prostate for the abnormality to be detected by an enzyme elevation in blood. If on the other hand, total organ involvement occurs, then clearly the vast number of affected liver cells will markedly elevate blood concentrations of any liver enzyme. It has been estimated that if only 1 liver cell in every 750 is damaged, elevation in the blood concentration of alanine aminotransferase would be detectable.

Knowledge of the intracellular location of enzymes can assist in determining the nature and severity of a pathologic process if suitable enzymes are assayed in the blood. For instance, a mild, reversible viral inflammation of the liver, such as a mild attack of viral hepatitis, is likely to increase only the permeability of the cell membrane, while allowing cytoplasmic enzymes to leak out into the blood, whereas a

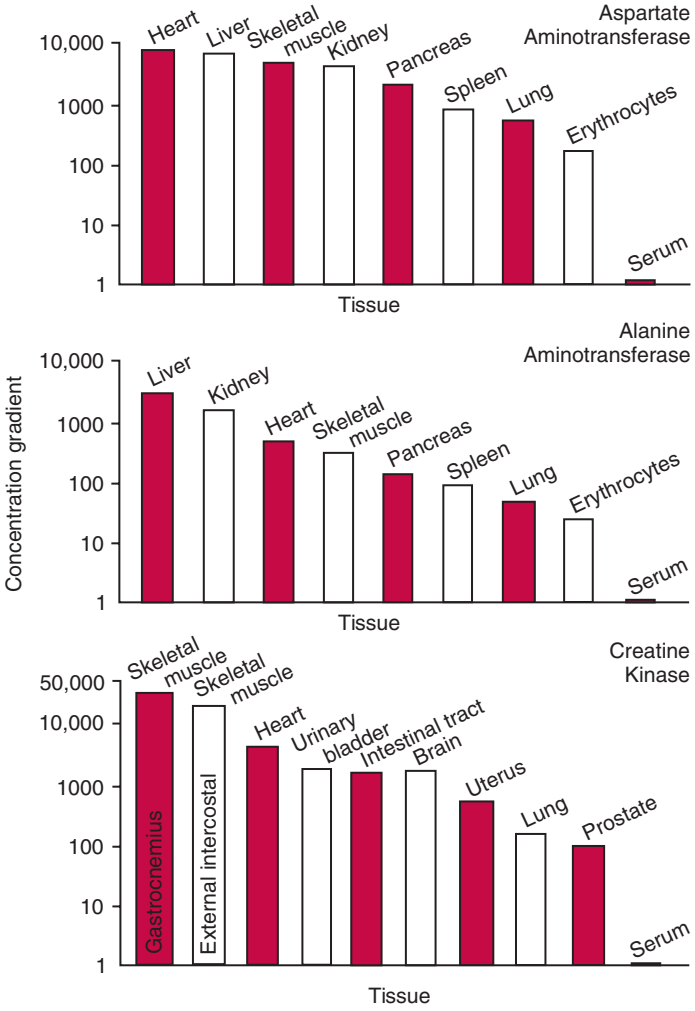

Figure 22-2 The concentration gradients between some human tissues and serum for aspartate transaminase, alanine transaminase, and creatine kinase. The concentration gradient axis is logarithmic.

TABLE 22-2 Distribution of Diagnostically Important Enzymes

Enzyme	Principal Sources of Enzyme in Blood	Principal Clinical Applications
Alanine aminotransferase	Liver	Hepatic parenchymal disease
Alkaline phosphatase	Liver, bone, intestinal mucosa, placenta	Hepatobiliary disease, bone disease
Amylase	Salivary glands, pancreas	Pancreatic disease
Aspartate aminotransferase	Heart, liver, skeletal muscle, erythrocytes	Hepatic parenchymal disease
Creatine kinase	Skeletal muscle, heart	Muscle disease, myocardial infarction
γ-Glutamyltransferase	Liver, pancreas, kidney	Hepatobiliary disease
Lactate dehydrogenase	Heart, erythrocytes, lymph nodes, skeletal muscle, liver	Hemolytic and megaloblastic anemias, leukemia and lymphomas, oncology
Lipase	Pancreas	Pancreatic disease
5′-Nucleotidase	Liver	Hepatobiliary disease

severe attack causing cell necrosis also disrupts the mitochondrial membrane, and both cytoplasmic and mitochondrial enzymes are detected in the blood. Finally, in selecting a suitable enzyme to assay in blood for diagnostic purposes, the clearance way and the rate at which its activity disappears from the blood are of significance. As previously indicated, the most commonly assayed enzymes are those with half-lives in the range of 12 hours or greater.

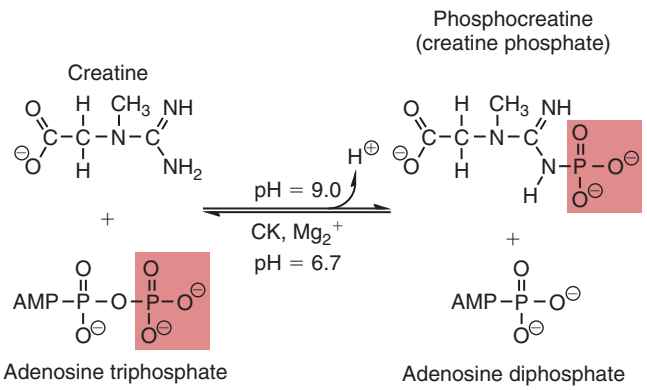
Several enzymes of diagnostic utility are discussed in this chapter. To better clarify their clinical meaning, the individual enzymes are discussed relative to the organ in which they are clinically most important. Overlap may occur for this classification as the same enzyme may be used for investigating disease in several organs.

MUSCLE ENZYMES

Enzymes in this category include creatine kinase, aldolase, and glycogen phosphorylase.

Creatine Kinase

Creatine kinase (EC 2.7.3.2; adenosine triphosphate:creatine *N*-phosphotransferase; CK) is a dimeric enzyme (82 kDa) that catalyzes the reversible phosphorylation of creatine (Cr) by adenosine triphosphate (ATP).



Physiologically, when muscle contracts, ATP is converted to adenosine diphosphate (ADP), and CK catalyzes the rephosphorylation of ADP to ATP using creatine phosphate (CrP) as the phosphorylation reservoir.

Optimal pH values for the forward (Cr + ATP → ADP + CrP) and reverse (CrP + ADP → ATP + Cr) reactions are 9.0 and 6.7, respectively. At neutral pH, the formation of ATP is favored; a pH of 9.0 is optimal for the formation of CrP, another high-energy compound. Mg^{2+} is an obligate activating ion that forms complexes with ATP and ADP. The optimal concentration range for Mg^{2+} is narrow, and excess Mg^{2+} is inhibitory. Many metal ions, such as Mn^{2+}, Ca^{2+}, Zn^{2+}, and Cu^{2+}, inhibit enzyme activity, as do iodoacetate and other sulfhydryl-binding reagents. Activity is inhibited by excess ADP and by citrate, fluoride, nitrate, acetate, iodide, bromide, malonate, and L-thyroxine.[3] Urate and cystine are potent inhibitors of the enzyme in serum. Even chloride and sulfate ions inhibit activity, and the concentrations of these ions should be kept low in any enzyme assay system based on the CrP + ADP (reverse) reaction. The enzyme in serum is relatively unstable, activity being lost as a result of sulfhydryl group oxidation at the active site of the enzyme. Activity can be partially restored by incubating the enzyme preparation with sulfhydryl compounds, such as *N*-acetylcysteine, dithiothreitol (Cleland reagent), and glutathione. The current agent of choice is *N*-acetylcysteine, which has the advantage of being a very soluble substance used at a final concentration of 20 mmol/L in the assay reagent.

CK activity is greatest in striated muscle and heart tissue, which contain some 2500 and 550 U/g of protein, respectively. Other tissues, such as the brain, the gastrointestinal tract, and the urinary bladder, contain significantly less activity, and the liver and erythrocytes are essentially devoid of activity (Table 22-3).

CK is a dimer composed of two subunits, each with a molecular weight of about 40,000 Da. These subunits (B and M) are the products of loci on chromosomes 14 and 19, respectively. Because the active form of the enzyme is a dimer, only three different pairs of subunits can exist: BB (or CK-1), MB (or CK-2), and MM (or CK-3). The Commission

TABLE 22-3 Approximate Concentrations of Tissue Creatine Kinase (CK) Activity (Expressed as Multiples of CK Activity Concentrations in Serum) and Cytoplasmic Isoenzyme Composition

	Relative CK		Isoenzymes, %	
Tissue	**Activity**	**CK-BB**	**CK-MB**	**CK-MM**
Skeletal muscle (type I, slow twitch, or red fibers)	50,000	<1	3	97
Skeletal muscle (type II, fast twitch, or white fibers)	50,000	<1	1	99
Heart	10,000	<1	22	78
Brain	5000	100	0	0
Smooth Muscle				
Gastrointestinal tract	5000	96	1	3
Urinary bladder	4000	92	6	2

on Biochemical Nomenclature has recommended that isoenzymes be numbered on the basis of their electrophoretic mobility, with the most anodal form receiving the lowest number. Accordingly, the CK isoenzymes are numbered CK-1, CK-2, and CK-3. The distribution of these isoenzymes in the various tissues of humans is shown in Table 22-3. All three of these isoenzyme species are found in the cytosol of the cell or are associated with myofibrillar structures. However, there exists a fourth form that differs from the others both immunologically and by electrophoretic mobility. This isoenzyme (CK-Mt) is located between the inner and outer membranes of mitochondria, and it constitutes, in the heart for example, up to 15% of total CK activity. The gene for CK-Mt is located on chromosome 15.

CK activity may also be found in macromolecular form—the so-called macro-CK. Macro-CK is found, often transiently, in the sera of up to 6% of hospitalized patients, but only a minor proportion of these have increased CK activities in serum. It exists in two forms: types 1 and 2. Type 1 is a complex of CK, typically CK-BB, and an immunoglobulin, often IgG, but other complexes have been described, such as CK-MM with IgA. Macro-CK type 1 is not of pathologic significance, but it can be the cause of elevated CK results, resulting in diagnostic confusion and leading to unnecessary further investigation. Prevalence has been estimated as between 0.8 and 2.3%, but this is dependent on the method used and the population studied.[17] Macro-CK type 2 is oligomeric CK-Mt, with a reported prevalence of between 0.5 and 2.6%. It is found predominantly in adults who are severely ill with malignancy or liver disease, or in children who have notable tissue distress. The appearance of this isoenzyme in serum is usually associated with a poor prognosis. Macro-CK can interfere with the assay of CK-MB by some immunoinhibition methods.

Both M and B subunits have a C-terminal lysine residue, but only the former can be hydrolyzed by the action of carboxypeptidases present in blood. Carboxypeptidases B (EC 3.4.17.2) and N (arginine carboxypeptidase; EC 3.4.17.3) sequentially hydrolyze the lysine residues from CK-MM to produce two CK-MM isoforms: CK-MM_2 (one lysine residue removed) and CK-MM_1 (both lysine residues removed). Loss of the positively charged lysine produces a more negatively charged CK molecule with greater anodic mobility at electrophoresis. Because CK-MB has only one M subunit, the dimer coded by the M and B genes is named CK-MB_2 and the lysine-hydrolyzed dimer is named CK-MB_1. The assay of the CK isoforms requires a special technique, such as high-voltage electrophoresis (with gel cooling), high-performance liquid chromatography (HPLC), or immunoassay.[61]

Clinical Significance

Serum CK is increased in nearly all patients when injury, inflammation, or necrosis of skeletal or heart muscle occurs.

Elevation of serum CK activity may be the only sign of subclinical neuromuscular disorders.[43] In case series, 30 to 44% of asymptomatic subjects with persistent hyperCKemia up to fivefold the upper reference limit (URL) have myopathy. Serum CK activity is greatly elevated in all types of muscular dystrophy. In progressive muscular dystrophy (particularly Duchenne sex-linked muscular dystrophy), enzyme activity in serum is highest in infancy and childhood (7 to 10 years of age) and may be increased long before the disease is clinically apparent. Serum CK activity characteristically falls as patients get older and as the mass of functioning muscle diminishes with progression of the disease. About 50 to 80% of asymptomatic female carriers of Duchenne dystrophy show threefold to sixfold increases in CK activity. High values of CK are noted in viral myositis, polymyositis, and similar muscle diseases. However, in neurogenic muscle diseases, such as myasthenia gravis, multiple sclerosis, poliomyelitis, and parkinsonism, serum enzyme activity is not increased. Very high activity is also encountered in malignant hyperthermia, an inherited life-threatening condition characterized by high fever and brought on by administration of inhalation anesthesia (usually halothane) to the affected individual.

Skeletal muscle that is diseased or damaged (such as by extreme exercise) may contain significant proportions of CK-MB owing to the phenomenon of "fetal reversion," in which fetal patterns of protein synthesis reappear. Thus serum CK-MB isoenzyme may increase in such circumstances. This explanation may also account for the elevated CK-MB

values sometimes observed in chronic renal failure (uremic myopathy).

In acute rhabdomyolysis due to crush injury, with severe muscle destruction, serum CK activities exceeding 200 times the URL may be found. If the CK remains below 5000 U/L (about 30 times the URL) during the first 3 days after the insult, the probability of developing acute renal failure appears to be low.[5] Serum CK can also be increased by other direct trauma to muscle, including intramuscular injection and surgical intervention. Finally, a number of drugs when given at pharmacologic doses can increase serum CK activities. The drugs principally responsible are statins, fibrates, antiretrovirals, and angiotensin II receptor antagonists. Varying degrees of myopathy may occur with statin use, ranging from mild myalgic syndrome alone to rhabdomyolysis (0.02%).[86]

Changes in serum CK and its MB isoenzyme following acute myocardial infarction have been the mainstay of diagnosis for many years.[14] However, it is now more advantageous to use more cardiac-specific nonenzymatic markers, such as cardiac troponin I or T. CK-MB determination can still be used with some success to estimate the extent of myocardial necrosis to assist with assessment of infarct prognosis. When peak CK-MB is compared with estimates of infarct size, good correlations can be obtained (Table 22-4). A problem with using CK-MB for this purpose is the requirement for frequent sampling to ensure that peak CK-MB values are correctly identified.

Hypothyroidism is a common cause of endocrine myopathy. About 60% of hypothyroid subjects show an average elevation of CK activity fivefold greater than the URL. The major isoenzyme present is CK-MM, suggesting muscular involvement.

During normal childbirth, a sixfold elevation in maternal total serum CK activity occurs. Surgical intervention during labor further increases the activity of CK in serum. CK-BB may be elevated in neonates, particularly in brain-damaged or very low birth weight newborns. The presence of CK-BB in blood, usually at low concentrations, may however represent a physiologic finding in the first days of life.

Methods for Determination of Creatine Kinase Activity

Numerous photometric, fluorometric, and coupled enzyme methods have been developed for the assay of CK activity, using the forward (Cr → CrP) or the reverse (Cr ← CrP) reaction. Currently, all commercial assays for total CK are based on the reverse reaction, which proceeds about six times faster than the forward reaction.

$$\text{Creatine phosphate} + \text{ADP} \xrightarrow[\text{pH 6.7}]{CK} \text{creatine} + \text{ADP}$$

$$\text{ADP} + \text{glucose} \xrightarrow{HK} \text{glucose-6-phosphate} + \text{ADP}$$

$$\text{Glucose-6-phosphate} + \text{NADP}^{\oplus} \xrightarrow{G6PD} \text{6-phosphogluconate} + \text{NADPH} + \text{H}^{\oplus}$$

CK catalyzes the conversion of CrP to Cr with concomitant phosphorylation of ADP to ATP. The ATP produced is measured by hexokinase (HK)/glucose-6-phosphate dehydrogenase (G6PD) coupled reactions that ultimately convert $NADP^+$ to NADPH, which is monitored spectrophotometrically at 340 nm. Szasz and colleagues optimized the assay by adding *N*-acetylcysteine to activate CK, EDTA to bind Ca^{2+} and to increase the stability of the reaction mixture, and adenosine pentaphosphate (Ap_5A) in addition to AMP to inhibit adenylate kinase (AK).[85] A reference method based on this previous experience was developed by the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) for the measurement of CK at 37 °C.[76]

Specimens for CK analysis include serum and plasma heparin. Anticoagulants other than heparin should not be used in collection tubes because they inhibit CK activity. CK activity in serum is relatively unstable and is rapidly lost during storage. Average stabilities are less than 8 hours at room temperature, 48 hours at 4 °C, and 1 month at −20 °C. Therefore the serum specimen should be chilled to 4 °C if the serum is not analyzed immediately, and stored at −80 °C if analysis is delayed for longer than 30 days. It is not necessary to add any thiol agent for storage because the optimized assay formulation containing EDTA, 2 mmol/L, and *N*-acetylcysteine, 20 mmol/L, reactivates CK in serum to the extent of 99% after it has been stored for 1 week at 4 °C. A moderate degree of hemolysis is tolerated because erythrocytes contain no CK activity. However, severely hemolyzed specimens are unsatisfactory because enzymes and intermediates (AK, ATP, and G6P) liberated from the erythrocytes may affect the lag phase and side reactions occurring in the assay system.

TABLE 22-4 Decision Limits of CK-MB Mass Peak for Infarct Size Definition

Microscopic myocardial infarction (focal necrosis)	<10 µg/L
Small myocardial infarction (<10% left ventricle)	10-60 µg/L
Medium myocardial infarction (10-30% left ventricle)	60-225 µg/L
Large myocardial infarction (>30% left ventricle)	>225 µg/L

Reference Intervals

Serum CK activity is subject to a number of physiologic variations. It is influenced by sex, age, race, muscle mass, and physical activity. The distributions of CK activity are notably skewed toward higher values in reference populations. Men have higher values than women, and blacks have higher values than nonblacks. In white subjects, the reference interval was found to be 46 to 171 U/L for males and 34 to 145 U/L for females, when measured with an assay traceable to the IFCC 37 °C reference procedure.[81] Newborns generally have

higher CK activity resulting from skeletal muscle trauma during birth. Serum CK in infants decreases to the adult reference interval by 6 to 10 weeks.

CK activity in the serum of healthy people is due almost exclusively to CK-MM activity (although small amounts of CK-MB may be present) and is the result of physiologic turnover of muscle tissue. Exercise and muscle trauma can increase serum CK.[7] Sustained exercise, such as that performed by well-trained long-distance runners, increases the CK-MB content of skeletal muscle, which may produce abnormal serum CK-MB concentrations.

Methods for Separation and Quantification of Creatine Kinase Isoenzymes

Electrophoretic methods are useful for separation of all CK isoenzymes. The isoenzyme bands are visualized by incubating the support (e.g., agarose, cellulose acetate) with a concentrated CK assay mixture using the reverse reaction. NADPH formed in this reaction is then detected by observing the bluish-white fluorescence after excitation by long-wave (360 nm) ultraviolet light. NADPH may be quantified by fluorescent densitometry, which is capable of detecting bands of 2 to 5 U/L. The mobility of CK isoenzymes at pH 8.6 toward the anode is BB > MB > MM, with the MM remaining cathodic to the point of application. The discriminating power of electrophoresis also allows the detection of abnormal bands (Figure 22-3). Disadvantages of electrophoresis include that the turnaround time is relatively long, the procedure is highly labor intensive and is not adaptable to clinical chemistry analyzers, and interpretative skills are required.

Immunochemical methods are applicable to the direct measurement of CK-MB. Immunoinhibition techniques measuring the catalytic activity of the B subunit of CK dimer were first introduced. T

Although a modification was developed to avoid these interferences, interferences from CK-BB, macro-CKs, or CK-Mt led to low specificity of most immunoinhibitin methods. Furthermore, because the CK-B subunit accounts for one half of CK-MB activity, the change in absorbance should be doubled to obtain CK-MB activity. This resulted in a significant decrease in the analytical sensitivity of the method.

Currently, the most common approach is to measure concentrations of the CK-MB protein ("mass") by using immunoassays with monoclonal antibodies.[58] Measurements use the "sandwich" technique, in which one antibody specifically recognizes only the MB dimer. The sandwich technique ensures that only CK-MB is estimated because neither CK-MM nor CK-BB reacts with both antibodies. Mass assays are more sensitive than activity-based methods with a limit of detection for CK-MB usually less than 1 µg/L. Other advantages include sample stability, noninterference with hemolysis, anticoagulants or other catalytic activity inhibitors, full automation, and fast turnaround time. With CM-MB mass assays, the upper reference limit for males is 5.0 µg/L, with values for females being less than male values, although many laboratories use a single reference limit (male).

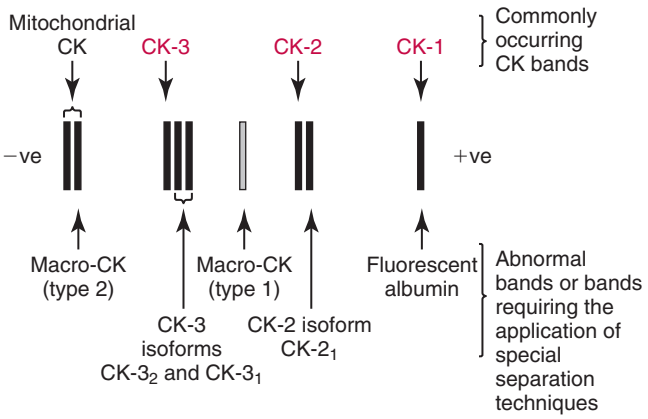


Figure 22-3 A diagrammatic representation of the electrophoretic pattern of CK isoenzymes (some of which are seen, in blood, only in disease) and some of the reported anomalous forms.

Aldolase

Aldolase (EC 4.1.2.13; D-fructose-1,6-bisdiphosphate D-glyceraldehyde-3-phosphate-lyase; ALD) catalyzes the splitting of D-fructose-1,6-diphosphate to D-glyceraldehyde-3-phosphate (GLAP) and dihydroxyacetone-phosphate (DAP), an important reaction in the glycolytic breakdown of glucose to lactate.

ALD is a tetramer with subunits determined by three separate gene loci. Only two of these loci, those producing A and B subunits, appear to be active simultaneously in most tissues, so the most common isoenzyme pattern consists of various proportions of the components of a five-member set of isoenzymes, of which two members correspond to the A and B homopolymers. The locus that determines the structure of the C subunit is active in brain tissue, as is the A locus, so this tissue contains ALD A and C, together with the three corresponding heteropolymers.

Clinical Significance

Serum ALD determinations have been of some clinical interest in primary diseases of skeletal muscle. Some researchers believe that increased ALD activity is useful in distinguishing neuromuscular atrophies from myopathies in combination with the CK/AST ratio.[27] In general, however, measurement of ALD activity in the serum of subjects with suspected muscle disease does not add information to that available more readily from measurement of other enzymes, especially CK.[22] At the time of this book's writing, ALD measurement has largely been discontinued within clinical laboratories and is not routinely available.

Methods for Measurement of Aldolase Activity

All assay methods are based on the forward ALD-catalyzed reaction. In the analytical approach on which all commonly used procedures and kits are based, the ALD reaction is coupled with two other enzyme reactions. Triosephosphate

isomerase (EC 5.3.1.1) is added to ensure rapid conversion of all GLAP to DAP. Glycerol-3-phosphate dehydrogenase (EC 1.1.1.8) is added to reduce DAP to glycerol-3-phosphate, with NADH acting as hydrogen donor. The decrease in NADH concentration is then measured.

ALD activity in serum is quite stable. Activity is unchanged at ambient temperatures for up to 48 hours and at 4 °C for several days. Hemolyzed specimens should not be used; plasma is preferred over serum because of the possible release of platelet enzyme during the clotting process.

Reference Intervals

The reference interval for the activity of ALD in adults is 2.5 to 10 U/L, measured at 37 °C. However, a definite sex difference has been noted, with men having higher values. Serum ALD activity in the neonate is fourfold that seen in adult, and in children is twice that in the adult. Adult values are attained by the time the child reaches puberty.[91]

Glycogen Phosphorylase

Glycogen phosphorylase (EC 2.4.1.1; α-1,4-D-glucan:orthophosphate D-glucosyltransferase; GP) plays an essential role in the regulation of carbohydrate metabolism by mobilizing glycogen. It catalyzes the first step in glycogenolysis, in which glycogen is converted to glucose-1-phosphate. The physiologic role of muscle GP is to provide fuel for the energy supply required for muscle contraction. GP exists in the myocyte in association with glycogen and the sarcoplasmic reticulum, forming a macromolecular complex. The degree of association of GP with this complex depends on the metabolic state of the muscle. With the onset of tissue hypoxia, when glycogen is broken down and disappears, GP becomes soluble and can move from the peri–sarcoplasmic reticulum compartment directly into the extracellular fluid.

GP exists as a dimer composed of two identical subunits (molecular mass as a monomer of about 97,000 Da). Three GP isoenzymes are found in human tissues: GP-LL, GP-MM, and GP-BB. Adult skeletal muscle contains only GP-MM. GP-LL is the predominant isoenzyme in liver and all other human tissues except for heart, skeletal muscle, and brain. GP-BB is the predominant isoenzyme in the human brain. In the heart, the isoenzymes BB and MM are found, but GP-BB is the predominant isoenzyme in the myocardium as well.

Clinical Significance

In preliminary studies, GP-BB was significantly more sensitive than CK-MB and myoglobin for the diagnosis of acute myocardial infarction within the first 4 hours after onset of chest pain.[2] However, GP-BB is not a heart-specific protein, and its specificity as a marker for myocardial damage is limited.

Methods for Measurement of Glycogen Phosphorylase Isoenzyme BB

Manual ELISA assays are available for measurement of the isoenzyme GP-BB. The calculated upper reference limit is 10 µg/L.

LIVER ENZYMES

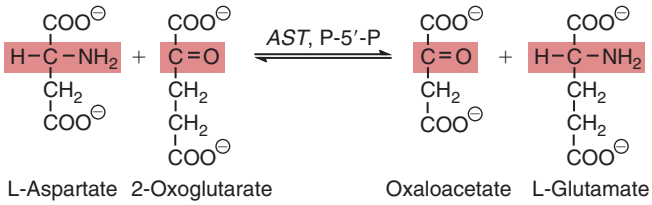
Enzymes in this category include alanine and aspartate aminotransferases, glutamate dehydrogenase, alkaline phosphatase, 5′-nucleotidase, γ-glutamyltransferase, and glutathione S-transferase. The aminotransferases, alkaline phosphatase and γ-glutamyltransferase, are widely used and available on automated analyzers. They have long been mistakenly called, as a group, "liver function tests." They are not, of course, but the habit sometimes persists. The others have not been adopted as widely.

The most common alterations in liver enzyme activities encountered in clinical practice is divided into two major pathophysiology subgroups—hepatocellular damage (elevated transaminase and glutamate dehydrogenase activities) and cholestasis (elevated alkaline phosphatase, 5′-nucleotidase, and γ-glutamyltransferase activities)—although certain liver diseases may display a mixed biochemical picture.

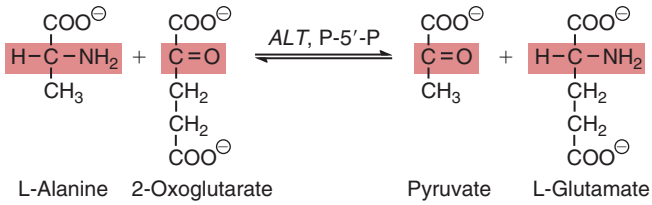
Aminotransferases

The aminotransferases constitute a group of enzymes that catalyze the interconversion of amino acids to 2-oxo-acids by transfer of amino groups. Aspartate aminotransferase (EC 2.6.1.1; L-aspartate:2-oxoglutarate aminotransferase; AST) and alanine aminotransferase (EC 2.6.1.2; L-alanine:2-oxoglutarate aminotransferase; ALT) are examples of aminotransferases that are of clinical interest.

The 2-oxoglutarate/L-glutamate couple serves as one amino group acceptor and donor pair in all amino-transfer reactions; the specificity of the individual enzymes derives from the particular amino acid that serves as the other donor of an amino group. Thus AST catalyzes the following reaction:



ALT catalyzes the analogous reaction as follows:



The reactions are reversible, but the equilibria of the AST and ALT reactions favor formation of aspartate and alanine, respectively.

Pyridoxal-5′-phosphate (P-5′-P) and its amino analog, pyridoxamine-5′-phosphate, function as coenzymes in amino-transfer reactions. The P-5′-P is bound to the apoenzyme and serves as a true prosthetic group. P-5′-P bound to the apoenzyme accepts the amino group from the first substrate, aspartate or alanine, to form enzyme-bound pyridoxamine-5′-phosphate and the first reaction product, oxaloacetate or pyruvate, respectively. The coenzyme in amino form then transfers its amino group to the second substrate, 2-oxoglutarate, to form the second product, glutamate. P-5′-P is thus regenerated.

Both coenzyme-deficient apoenzymes and holoenzymes may be present in serum. Therefore, addition of P-5′-P under conditions that allow recombination with the enzymes usually produces an increase in aminotransferase activity. In accordance with the principle that all factors affecting the rate of reaction must be optimized and controlled, the IFCC recommends addition of P-5′-P in aminotransferase methods to ensure that all enzymatic activity is measured.

Transaminases are widely distributed throughout the body. AST is found primarily in the heart, liver, skeletal muscle, and kidney, whereas ALT is found primarily in the liver and kidney, with lesser amounts in heart and skeletal muscle (Table 22-5). ALT is exclusively cytoplasmic; both mitochondrial and cytoplasmic forms of AST are found in cells. These are genetically distinct isoenzymes with a dimeric structure composed of two identical polypeptide subunits of about 400 amino acid residues.

Clinical Significance

Liver disease is the most important cause of increased transaminase activity in serum. In most types of liver disease, ALT activity is higher than that of AST; exceptions may be seen in alcoholic hepatitis, hepatic cirrhosis, and liver neoplasia. In viral hepatitis and other forms of liver disease associated with acute hepatic necrosis, serum AST and ALT activities are elevated even before the clinical signs and symptoms of disease (such as jaundice) appear. Activities for both enzymes may reach values as high as 100 times the upper reference limit, although 10-fold to 40-fold elevations are most frequently encountered. The most efficient aminotransferase threshold for diagnosing acute liver injury lies at seven times the upper reference limit (sensitivity and specificity >95%). Peak values of transaminase activity occur between the 7th and 12th days; activities then gradually decrease, reaching normal levels by the 3rd to 5th week if recovery is uneventful. Peak activities bear no relationship to prognosis and may fall with worsening of the patient's condition.

Persistence of increased ALT for longer than 6 months after an episode of acute hepatitis is used to diagnose chronic hepatitis. Most patients with chronic hepatitis have maximum ALT less than seven times the upper reference limit. ALT may be persistently normal in 15 to 50% of patients with chronic hepatitis C, but the likelihood of continuously normal ALT decreases with an increasing number of measurements. In patients with acute hepatitis C, ALT should be measured periodically over the next 1 to 2 years to determine if it becomes and stays normal.[15]

The picture in toxic hepatitis is different from that in infectious hepatitis. In acetaminophen-induced hepatic injury, the transaminase peak is more than 85 times the upper reference limit in 90% of cases—a value rarely seen with acute viral hepatitis. Furthermore, AST and ALT activities typically peak early and fall rapidly.[15]

Nonalcoholic fatty liver disease (NAFLD) is the most common cause of aminotransferase increases other than viral and alcoholic hepatitis. NAFLD includes a spectrum of liver pathology, from simple steatosis to nonalcoholic steatohepatitis (NASH), in which inflammatory changes and focal necrosis may progress to liver fibrosis, cirrhosis, and hepatic failure. NAFLD is now considered to be an additional feature of the "metabolic syndrome." Indeed, serum aminotransferase elevation in NAFLD is associated with higher body mass index, waist circumference, serum triglycerides, and fasting insulin and lower HDL cholesterol—all features characteristic of this syndrome.

Aminotransferase activities observed in cirrhosis vary with the status of the cirrhotic process and range from the upper reference limit to four to five times higher, with an AST/ALT ratio (AAR) greater than 1. This appears to be attributable to a reduction in ALT production in a damaged liver, associated with reduced clearance of AST in advancing liver fibrosis. An AAR ≥1 has ≈90% positive predictive value for diagnosing the presence of advanced fibrosis in patients with chronic liver disease. Furthermore, the amount of elevation in the AAR can reflect the grade of fibrosis in these patients.

Twofold to fivefold elevations of both enzymes occur in patients with primary or metastatic carcinoma of the liver, with AST usually being higher than ALT, but activities are often normal in the early stages of malignant infiltration of the liver. Slight or moderate elevations of AST and ALT activities have been observed after administration of various medications, such as nonsteroidal anti-inflammatory drugs, antibiotics, antiepileptic drugs, statins, or opiates.

TABLE 22-5 Transaminase Activities in Human Tissues, Relative to Serum as Unity

	AST	ALT
Heart	7800	450
Liver	7100	2850
Skeletal muscle	5000	300
Kidneys	4500	1200
Pancreas	1400	130
Spleen	700	80
Lungs	500	45
Erythrocytes	15	7
Serum	1	1

From King J. Practical clinical enzymology. London: D Van Nostrand Co Ltd, 1965.

Over-the-counter medications and herbal preparations are also implicated. In patients with increased transaminases, negative viral markers, and a negative history for drugs or alcohol ingestion, the work-up should include less common causes of chronic hepatic injury (e.g., hemochromatosis, Wilson's disease, autoimmune hepatitis, primary biliary cirrhosis, sclerosing cholangitis, celiac disease, α_1-antitrypsin deficiency).[67]

Although serum activities of both AST and ALT become elevated whenever disease processes affect liver cell integrity, ALT is the more liver-specific enzyme. Serum elevations of ALT activity are rarely observed in conditions other than parenchymal liver disease.[34] Moreover, elevations of ALT activity persist longer than do those of AST activity. Thus the incremental benefit of determination of AST, in addition to ALT, may be limited.

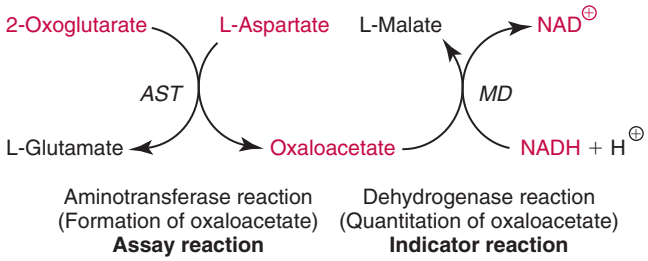
After acute myocardial infarction, increased AST activity appears in serum, as might be expected from the high AST concentration in heart muscle. AST activity also is increased in progressive muscular dystrophy and dermatomyositis, reaching concentrations up to eight times normal; they are usually normal in other types of muscle disease, especially in those of neurogenic origin. Pulmonary emboli can increase AST to two to three times normal, and slight to moderate elevations are noted in acute pancreatitis, crushed muscle injury, and hemolytic disease.

Generally, mitochondrial AST (m-AST) activity in serum shows a marked increase in patients with extensive liver cell degeneration and necrosis. Of particular interest is the usefulness of the ratio between m-AST and total AST activities for diagnosing alcoholic hepatitis. The ratio seems to identify the liver cell "necrotic type" condition (i.e., slight enzyme increase concomitant with relatively high activities of mitochondrial enzymes) typical of alcoholic hepatitis.[56]

Several authors have described AST linked to immunoglobulins, or macro-AST. Typical findings include a persistent increase in serum AST activity in an asymptomatic subject, with absence of any demonstrable pathology in organs rich in AST. Increased AST activity might reflect decreased clearance of the abnormal complex from plasma. Macro-AST has no known clinical relevance. However, identification is important to avoid unnecessary diagnostic procedures in these subjects. Laboratory procedures for the demonstration of macro-AST include electrophoresis with specific enzyme stain (atypical origin band) and differential precipitation with polyethylene glycol (PEG) 6000 (see "Amylase" section later in this chapter).

Methods for Measurement of Transaminase Activity

The assay system for measuring transaminase activity contains two amino acids and two oxo-acids. Because no convenient method is available for assaying amino acids, formation or consumption of the oxo-acids is measured. Continuous-monitoring methods are commonly used to measure transaminase activity by coupling transaminase reactions to specific dehydrogenase reactions. The oxo-acids formed in the transaminase reaction are measured indirectly by enzymatic reduction to corresponding hydroxy acids, and the accompanying change in NADH concentration is monitored spectrophotometrically. Thus oxaloacetate, formed in the AST reaction, is reduced to malate in the presence of malate dehydrogenase (MD).



Pyruvate formed in the ALT reaction is reduced to lactate by lactate dehydrogenase (LD). The substrate, NADH, and an auxiliary enzyme, MD or LD, must be present in sufficient quantity so that the reaction rate is limited only by the amounts of AST and ALT, respectively. As the reactions proceed, NADH is oxidized to NAD^+. The disappearance of NADH is followed by measuring the decrease in absorbance at 340 nm for several minutes, either continuously or at frequent intervals. The change in absorbance per minute (ΔA/min) is proportional to the micromoles of NADH oxidized and in turn to micromoles of substrate transformed per minute. A preliminary incubation period is necessary to ensure that NADH-dependent reduction of endogenous oxo-acids in the sample is completed before 2-oxoglutarate is added to start the transaminase reaction. After a brief lag phase, the change in absorbance (ΔA) is monitored. As already mentioned, supplementation with P-5′-P ensures that all transaminase activity of the sample is measured.

Because of the large numbers of AST and ALT activity measurements performed daily in clinical laboratories throughout the world, standardization of transaminase measurements is a priority need for patient care. As discussed in Chapter 8, the reference system approach, based on the concepts of metrologic traceability and the hierarchy of analytical measurement procedures, gives clinical laboratories and the medical community universal means of creating and ensuring the comparability of results. In this system, the IFCC reference measurement procedure forms the highest metrologic level and thereby constitutes the definition of the respective measurable enzyme quantity.[30] Primary IFCC procedures for the measurement of catalytic activity concentrations of AST and ALT at 37 °C have been published.[79,80] Values assigned to the manufacturer's product calibrators and measurement results of lower metrologic levels, including those used in daily routine practice, should be traceable to these top-level reference measurement procedures, thus improving the accuracy and comparability of transaminase results. It should be remembered that the concept of the reference system is valid only if the reference procedure and corresponding routine procedures have identical, or at least very similar, specificities for the measured enzyme. Thus it will not

be possible to calibrate procedures for aminotransferases that do not incorporate P-5′-P using a procedure that does, such as the IFCC reference procedure, because the ratio of pre-formed holoenzyme to apoenzyme differs among specimens.

AST activity in serum is stable for up to 48 hours at 4 °C. Specimens have to be stored frozen if they are to be kept longer. ALT activity should be assayed on the day of sample collection because activity is lost at room temperature, 4 °C, and −25 °C. ALT stability is better maintained at −70 °C. Hemolyzed specimens should not be used, especially when AST is measured, because of the large amount of this enzyme present in red cells.

Reference Intervals[25,29]

Using methods traceable to the IFCC reference system, the AST upper reference limit for adults, calculated as the 97.5-percentile of the reference distribution, is 35 U/L, with no significant sex-related differences. Conversely, a clear difference in ALT activities has been noted between adult males and females. Corresponding ALT upper reference limits are 60 U/L and 42 U/L respectively. ALT does not reveal a distinct age dependency during childhood, whereas serum AST activity in neonates and in children younger than 3 years old is twice that in adults. Adult values are attained by the time the child reaches puberty.

Methods for Separation and Quantification of AST Isoenzymes

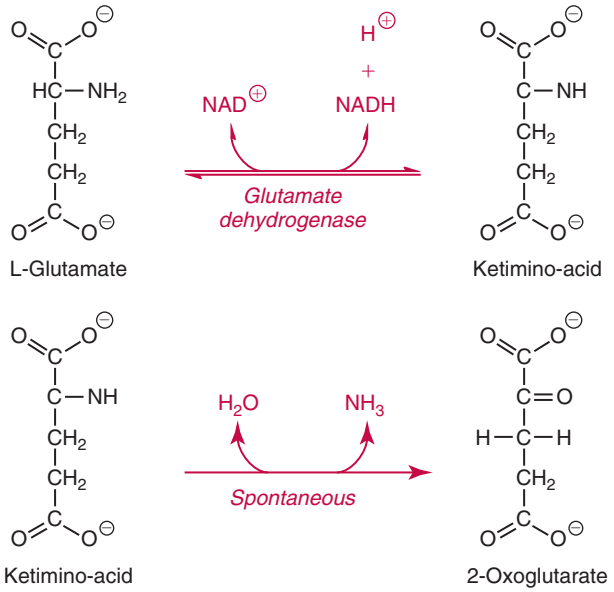
AST isoenzymes can be separated into anionic (cytoplasmic AST) and cationic bands (m-AST) by electrophoresis. However, the low concentration of m-AST in normal sera is usually below the limit of detection of this method. Immunoprecipitation assays using antibodies directed against both mitochondrial and cytosolic isoenzymes allow instead measurement of low concentrations of the m-AST isoenzyme present in serum. A homogeneous inhibition assay using proteinase K (EC 3.4.21.14) for selective proteolysis of cytosolic AST has been described and made amenable to automation, permitting m-AST to be measured with convenience that approaches that of the total AST assay.[63]

About 5 to 10% of the activity of total AST in serum from healthy individuals is of mitochondrial origin. The upper reference limit for m-AST activity measured at 37 °C is 3.0 U/L.

Glutamate Dehydrogenase

Glutamate dehydrogenase [EC 1.4.1.3; L-glutamate: NAD(P)$^+$ oxidoreductase, deaminating; GLD] is a mitochondrial enzyme found mainly in the liver, heart muscle, and kidneys, but small amounts occur in other tissue, including brain and skeletal muscle tissue, and in leukocytes.

GLD is a zinc-containing enzyme that consists of six polypeptide chains. The smallest active molecule has a molecular weight of about 350,000 Da, but larger polymers are also found. The enzyme catalyzes the removal of hydrogen from L-glutamate to form the corresponding ketimino-acid, which undergoes spontaneous hydrolysis to 2-oxoglutarate.



Although NAD$^+$ is the preferred coenzyme, NADP$^+$ also acts as the hydrogen acceptor. GLD is inhibited by metal ions, such as Ag^+ and Hg^+, by several chelating agents, and by L-thyroxine.

Clinical Significance[74]

GLD is increased in the serum of patients with hepatocellular damage. Fourfold or fivefold elevations are seen in chronic hepatitis; in cirrhosis, increases are only up to twofold. Very large rises in serum GLD occur in halothane toxicity, and notable increases are seen in response to some other hepatotoxic agents.

GLD potentially offers differential diagnostic potential in the investigation of liver disease, particularly when interpreted in conjunction with other enzyme test results. The key to this differential diagnostic potential is to be found in the intraorgan and intracellular distribution of the enzyme as discussed earlier in this chapter. As an exclusively mitochondrial enzyme, GLD is released from necrotic cells; therefore, when compared with hepatic disorders with extensive necrosis, release is less in diffuse inflammatory processes, and in these conditions, the release of cytoplasmic enzymes, such as ALT, is quantitatively more pronounced. Together with m-AST, GLD is of value in estimating the severity of liver cell damage.

GLD is more concentrated in the central areas of the liver lobules than in the periportal zones. This pattern of distribution is the reverse of that of ALT. Pronounced release of GLD therefore is to be expected in conditions in which centrilobular necrosis occurs (e.g., as a result of ischemia, in halothane toxicity).

Methods for Determination of Glutamate Dehydrogenase Activity

Continuous-monitoring methods have been developed for determination of GLD using both forward and reverse

reactions. The equilibrium favors the formation of glutamate, and higher reaction rates are observed when 2-oxoglutarate is used as a substrate. Serum is added to a solution of NADH, an ammonium salt, and ADP in buffer at pH 7.5, and the reaction is initiated by the addition of the substrate, 2-oxoglutarate. The rate of decrease in absorbance at 340 nm is measured. The German Society for Clinical Chemistry has published optimum reaction conditions for 37 °C.[13] Oxamate is incorporated into the reaction mixture because this acid inhibits LD activity, avoiding the critical consumption of NADH by this enzyme in serum.

GLD activity in serum is stable at 4 °C for 48 hours and at –20 °C for several weeks.

Reference Intervals

The GLD upper reference limits are 6 U/L (women) and 8 U/L (men) when a method optimized at 37 °C is used.

Alkaline Phosphatase

Alkaline phosphatase [EC 3.1.3.1; orthophosphoric-monoester phosphohydrolase (alkaline optimum); ALP] catalyzes the alkaline hydrolysis of a large variety of naturally occurring and synthetic substrates.

ALP activity is present in most organs of the body and is especially associated with membranes and cell surfaces located in the mucosa of the small intestine and the proximal convoluted tubules of the kidney, in bone (osteoblasts), liver, and placenta. Although the exact metabolic function of the enzyme is not yet understood, it appears that ALP is associated with lipid transport in the intestine and with the calcification process in bone.

ALP exists in multiple forms, some of which are true isoenzymes, encoded at separate genetic loci (Figure 22-4).[47] Bone, liver, and kidney ALP forms share a common primary structure coded for by the same genetic locus, but they differ in carbohydrate content.[45]

Some divalent ions, such as Mg^{2+}, Co^{2+}, and Mn^{2+}, are activators of the enzyme, and Zn^{2+} is a constituent metal ion. The correct ratio of Mg^{2+}/Zn^{2+} ions is necessary to avoid displacement of Mg^{2+} and to attain optimal activity. Phosphate, borate, oxalate, and cyanide ions are inhibitors of ALP activity. Variations in Mg^{2+} and substrate concentrations change the pH optimum. The type of buffer present (except at low concentrations) affects the rate of enzyme activity. Buffers can be classified as inert (carbonate and barbital), inhibiting (glycine and propylamine), or activating [2-amino-2-methyl-1-propanol (AMP), tris (hydroxymethyl) aminomethane (TRIS), and diethanolamine (DEA)].

The ALP activity present in the sera of healthy adults originates mainly in the liver, with most of the rest coming from the skeleton. The respective contributions of these two forms to the total activity are age dependent. Minimal amounts of intestinal ALP may also be present, particularly in the sera of individuals of blood group B or O (i.e., those who are secretors of blood group substances). Because intestinal ALP activity in serum may increase after a meal, ALP should be measured preferentially in fasting sera.

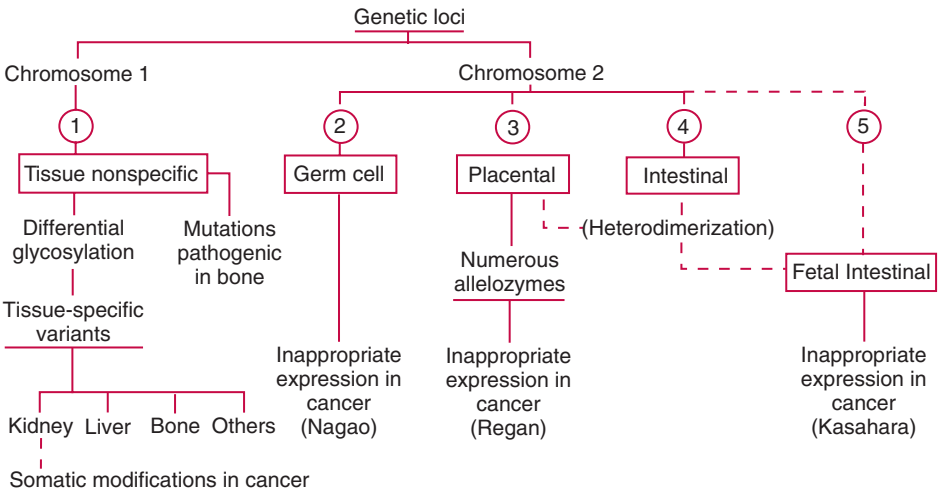


Figure 22-4 Identities, chromosomal assignments, and main physiologic and pathologic expression of genes encoding human alkaline phosphatases. The gene names (and gene symbols) are alkaline phosphatase, liver/bone/kidney (*ALPL*); alkaline phosphatase, intestinal (*ALPI*); alkaline phosphatase, placental (*ALPP*); and alkaline phosphatase, placental-like 2 (*ALPPL2*). *Broken lines* show two alternative proposed origins of the fetal intestinal alkaline phosphatase; the sequence of a cDNA is reportedly identical to that of adult intestinal alkaline phosphatase. All isoenzymes and isoforms are glycoproteins, imposing a further level of microheterogeneity. Different processes of cleavage or preservation of the membrane-anchoring domain can generate additional isoforms. *(Modified from Moss DW. Perspectives in alkaline phosphatase research. Clin Chem 1992;38:2486-92.)*

Clinical Significance

Elevations in serum ALP activity commonly originate from one or both of two sources: liver and bone. Consequently, serum ALP measurements are of particular interest in the investigation of two groups of conditions: hepatobiliary disease and bone disease associated with increased osteoblastic activity (see "Bone Enzymes" section later in this chapter).

Serum ALP was the first enzyme to be used for the investigation of hepatic disease. The response of the liver to any form of biliary tree obstruction induces the synthesis of ALP by hepatocytes. Some of the newly formed enzyme enters the circulation to increase the enzyme activity in serum.[48] Elevation tends to be more notable (greater than threefold) in extrahepatic obstruction (e.g., by stone, by cancer of the head of the pancreas) than in intrahepatic obstruction and is greater the more complete the obstruction. Serum enzyme activities may reach 10 to 12 times the upper reference limit and usually return to normal on surgical removal of the obstruction. A similar increase is seen in patients with advanced primary liver cancer or widespread secondary hepatic metastases. Liver diseases that principally affect parenchymal cells, such as infectious hepatitis, typically show only moderately (less than threefold) increased or even normal serum ALP activities. Increases may also be seen as a consequence of a reaction to drug therapy. Intestinal ALP isoenzyme, an asialoglycoprotein normally cleared by the hepatic asialoglycoprotein receptors, is often elevated in patients with liver cirrhosis.

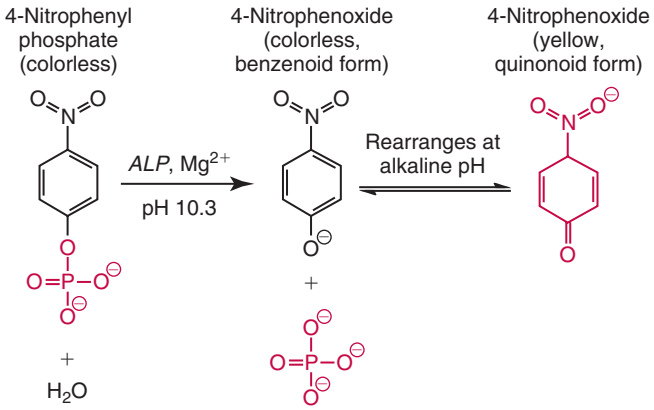
An increase of up to two to three times normal is observed in women in the third trimester of pregnancy, with the additional enzyme being of placental origin. Reports have also described a benign familial elevation in serum ALP activity due to increased concentrations of intestinal ALP.[57] Transient, benign increases in serum ALP may be observed in infants and children, with changes often more than 10 times the upper reference limit. Increases in both liver and bone forms are seen. These changes seem to reflect a reduction in the removal of ALP from blood caused by transient modifications of enzyme glycosylation.[83]

A result of the application of techniques of isoenzyme analysis to the characterization of ALP in serum was the discovery that forms of the enzyme essentially identical to the normal placental isoenzyme appear in the sera of some patients with malignant disease. These carcinoplacental isoenzymes (e.g., Regan isoenzyme) appear to result from de-repression of the placental ALP gene. As described later, the presence of these isoenzymes can be readily detected in serum by their stability at 65 °C. Tumors have also been found to produce ALPs that appear to be modified forms of nonplacental isoenzymes (Kasahara isoenzyme).

Methods for Determination of Alkaline Phosphatase Activity

Numerous methods have been developed for determining ALP activity. In general, methodologic developments have been directed toward increasing the speed and sensitivity of the assay by selecting readily hydrolyzed substrates and phosphate-accepting buffers, and toward the use of continuous-monitoring methods based on "self-indicating" substrates.

The most popular of the chromogenic or self-indicating substrates for ALP is 4-nitrophenyl phosphate (usually abbreviated 4-NPP, or PNPP from the older name, *p*-nitrophenyl phosphate). This ester is colorless, but the final product is yellow at the pH of the reaction:



The enzyme reaction is continuously monitored by observing the rate of formation of the 4-nitrophenoxide ions. With improvement in reaction conditions, this reaction forms the basis of current recommended and standard methods of ALP assay. Other self-indicating substrates include phenolphthalein monophosphate, thymolphthalein phosphate, and α-naphthyl phosphate. With the ALP methods discussed, the liberated phosphate group is transferred to water. The rate of phosphatase action is enhanced, however, if certain amino alcohols are used as phosphate-accepting buffers. Among these activators are compounds such as AMP, DEA, TRIS, ethylaminoethanol (EAE), and *N*-methyl-D-glucamine (MEG). Enzyme activity in the presence of optimal concentrations of these buffers is twofold to sixfold greater than in the presence of a nonactivating buffer, such as carbonate.

ALP catalyzes the hydrolysis of 4-NPP, forming phosphate and free 4-nitrophenol (4-NP, PNP), which in dilute acid solutions is colorless. Under alkaline conditions, 4-NP is converted to the 4-nitrophenoxide ion, which has a very intense yellow color. The rate of formation of 4-NP by the action of the enzyme on 4-NPP at 37 °C is then monitored at 405 nm with a recording spectrophotometer. The (provisional) IFCC-recommended method uses 4-NPP as the substrate and AMP as the phosphate-acceptor buffer. It includes Mg^{2+} and Zn^{2+}, optimal concentrations of which are controlled by the addition of Mg^{2+} and Zn^{2+}, and the chelating agent *N*-hydroxyethylethylenediaminetriacetic acid (HEDTA). Although Zn^{2+} ions are present in a total concentration of 1 mmol/L, most are bound to HEDTA, leaving only a small, experimentally determined optimal concentration of free ions. A similar situation exists for Mg^{2+} ions. Thus HEDTA acts as a metal ion buffer, maintaining optimal concentrations of both ions.[88]

Serum or heparinized plasma, free of hemolysis, should be used. Complexing anticoagulants—such as citrate, oxalate, and EDTA—must be avoided, because they bind cations, such as Mg^{2+} and Zn^{2+}, which are necessary cofactors for ALP activity measurement. Blood transfusion (containing citrate) causes a transient decrease in serum ALP through a similar mechanism. Freshly collected serum samples should be kept at room temperature and assayed as soon as possible but preferably within 4 hours after collection. In sera stored at a refrigerated temperature, ALP activity increases slowly (2%/d). Frozen specimens should be thawed and kept at room temperature for 18 to 24 hours before measurement to achieve full enzyme reactivation.

Reference Intervals[66,90]

ALP activities in serum vary with age. Children show higher ALP activity than healthy adults as a result of the leakage of bone ALP from osteoblasts during bone growth. Using methods traceable to the IFCC procedure at 37 °C, the following reference intervals (central 95-percentiles) have been established:

Sex	Age	Reference Interval
Males/Females	4-15 y	54-369 U/L
Males	20-50 y	53-128 U/L
	≥60 y	56-116 U/L
Females	20-50 y	42-98 U/L
	≥60 y	53-141 U/L

Activities in growing children are highly variable.

Methods for Separation and Quantification of Alkaline Phosphatase Isoenzymes

Assays for ALP isoenzymes are needed when (1) the source of an elevated ALP in serum is not obvious and should be clarified; (2) the main clinical question is concerned with detecting the presence of liver or bone involvement; and (3) it is important to ascertain any modifications in the activity of osteoblasts to monitor disease activity and the effects of appropriate therapies in the case of metabolic bone disorders.

Criteria that have been used to differentiate the isoenzymes and other multiple forms of ALP include (1) electrophoretic mobility; (2) stability to denaturation by heat or chemicals; (3) response to the presence of selected inhibitors; (4) affinity for specific lectins; and (5) immunochemical characteristics.[68]

The same electrophoretic techniques are used for the separation of ALP isoenzymes in serum as for separation of serum proteins. After electrophoresis, ALP zones are made visible by incubating the gel in a solution of buffered substrate (e.g., 1-naphthyl phosphate, to which a chromogenic system, usually represented by a diazonium salt, is added; in the case of electrophoresis on cellulose acetate, the strips are covered with an agar gel layer containing the staining system). The liver ALP typically moves most rapidly toward the anode. Bone ALP, which typically gives a more diffuse zone than the liver form, has slightly reduced anodal mobility, although the two zones usually overlap to some extent. Intestinal ALP migrates more slowly than the bone enzyme, whereas the placental isoenzyme commonly appears as a discrete band overlying the diffuse bone fraction. An additional band, which is frequently present in the serum of patients with various hepatic diseases, contains a high molecular weight form of ALP but is also strongly negatively charged. Therefore it moves slowly in starch gel or may even fail to enter polyacrylamide gel, but it migrates more anodally than the main liver zone on nonsieving media, such as cellulose acetate. Investigations of this form have revealed that it corresponds to the main liver form attached to the membrane moiety *[membrane particle (fragment) ALP]*.[60]

Complexes between ALP and immunoglobulins, or macro-ALP, occur occasionally in serum, giving rise to abnormally migrating bands in the γ-globulin zone; however, they do not provide specific diagnostic information in the present state of knowledge.

Two approaches have been proposed to improve the electrophoretic separation between bone and liver ALPs. Both methods exploit differences in the carbohydrate portions of the two forms of ALP. With one, electrophoresis is carried out in the presence of wheat germ lectin, binding the *N*-acetylglucosamine residues present in different amounts on individual fractions, which retards bone ALP migration more than liver enzyme migration.[72] With the other, serum is treated briefly (i.e., for 15 minutes at 37 °C) with neuraminidase to remove a portion of the terminal sialic acid residues. Because the sialic acid residues of bone ALP are more readily attacked than those of liver ALP, the electrophoretic mobility of the bone form is reduced more than that of liver ALP. The improved separation allows quantitative estimates to be made by densitometric scanning (Figure 22-5).[49] As an alternative to electrophoretic fractionation of ALP, measurement of γ-glutamyltransferase, which is increased in liver disease but not in bone disease, may be a useful rapid tool to distinguish between the two diseases as the explanation for an increased serum ALP.

Overnight incubation of the serum sample with neuraminidase is used to confirm the presence of intestinal ALP. This treatment reduces the anodal mobility of all ALP isoenzymes except that of intestinal origin, which is neuraminidase resistant because terminal sialic acid residues are not present in the molecule. Because placental ALP is heat stable, incubation of the serum sample at a temperature as high as 65 °C for 30 minutes provides a convenient test for the presence of this isoenzyme. Immunologic methods provide the best quantitative measurements of intestinal or placental ALPs. Much more difficult is the production of antibodies that selectively react with different products of the tissue-nonspecific ALP gene, including liver- and bone-derived isoforms, as these antibodies should recognize specific sugar sidechains instead of a particular amino acid sequence. Until now, no monoclonal antibodies have fully discriminated between liver and bone ALPs. Despite lack of complete specificity, commercially available immunoassays of bone ALP

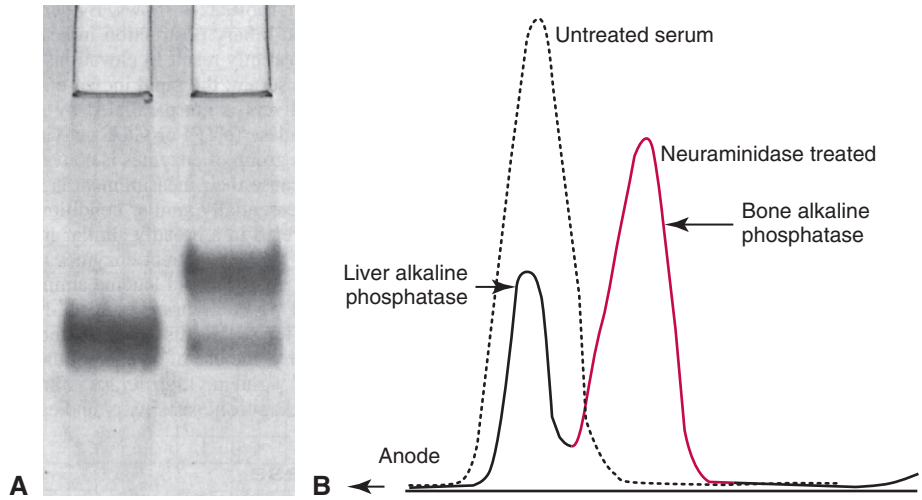


Figure 22-5 **A, Polyacrylamide-gel electrophoresis of bone and liver alkaline phosphatases in human serum. *Left,* Mixture of two sera containing, respectively, entirely bone phosphatase and entirely liver phosphatase. *Right,* Mixture of the same two sera after each has been treated with neuraminidase for 10 minutes at 37 °C. The anodal direction is downward. The more anodal zone is liver phosphatase. B, Densitometric scans of electrophoretic patterns shown in A. *Broken line,* Scan of mixture of untreated sera; *solid line,* scan of mixture of sera treated briefly with neuraminidase.** *(From Moss DW, Edwards RK. Improved electrophoretic resolution of bone and liver alkaline phosphatases resulting from partial digestion with neuraminidase. Clin Chim Acta 1984;143:177-82.)*

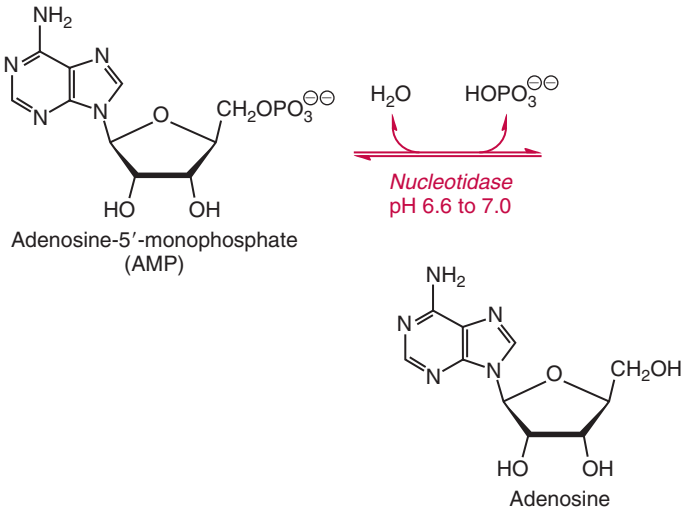
may offer some advantages, but their value has not been convincingly demonstrated, in part because measurements of total ALP provide the required clinical information in many situations.

5′-Nucleotidase

5′-Nucleotidase (EC 3.1.3.5; 5′-ribonucleotide phosphohydrolase; NTP) is a phosphatase that acts only on nucleoside-5′-phosphates, such as adenosine-5′-phosphate (AMP) and adenylic acid, releasing inorganic phosphate.



NTP is a glycoprotein that is widely distributed throughout the tissues of the body and is principally localized in the cytoplasmic membrane of the cells in which it occurs. Its pH optimum is between 6.6 and 7.0.[84]

Clinical Significance

Despite its ubiquitous distribution, serum NTP activities appear to reflect hepatobiliary disease with considerable specificity. NTP is increased threefold to sixfold in those hepatobiliary diseases in which there is interference with the secretion of bile. This may be due to extrahepatic causes (a stone or tumor occluding the bile duct), or it may arise from intrahepatic conditions, such as cholestasis caused by chlorpromazine, malignant infiltration of the liver, or biliary cirrhosis. When parenchymal cell damage is predominant, as in infectious hepatitis, serum NTP activity is only moderately elevated.

The assay of NTP activity has been considered of value as an addition to measurement of nonspecific total ALP in patients with suspected hepatobiliary disease, and abnormal NTP activity is routinely interpreted as evidence of a hepatic origin of increased ALP activity in serum. However, approximately half of individuals in whom liver ALP activity is increased in serum may simultaneously show a normal NTP. On the other hand, increased NTP in the serum of patients with normal liver ALP is very often associated with the presence of liver disease. Thus the frequent dissociation of the two enzyme activities supports the usefulness of determining

both (liver) ALP and NTP to enhance diagnostic efficiency in diseases of the liver.[54]

Methods for Determination of 5′-Nucleotidase Activity

The substrates most generally used in measuring the activity of NTP are AMP and IMP (inosine-5′-phosphate). However, these substrates are organic phosphate esters and thus can be hydrolyzed to an appreciable degree by other nonspecific (alkaline) phosphatases, even at a pH as low as 7.5, which is the pH assumed optimal for NTP activity. Methods for the estimation of NTP in serum therefore must incorporate some means for correcting for the hydrolysis of the substrate by the nonspecific phosphatases.

In a commercially available assay, serum NTP catalyzes the hydrolysis of IMP to yield inosine, which is then converted to hypoxanthine by purine-nucleoside phosphorylase (EC 2.4.2.1). Hypoxanthine is oxidized to urate with xanthine oxidase (EC 1.2.3.2). Two moles of hydrogen peroxide are produced for each mole of hypoxanthine liberated and converted to uric acid. The formation rate of hydrogen peroxide is monitored by a spectrophotometer at 510 nm by the oxidation of a chromogenic system. The effect of ALPs on IMP is inhibited by β-glycerophosphate. This material is substrate for ALP but not for NTP, and by forming substrate complexes with the former enzyme, it reduces the proportion of total ALP activity that is directed to the hydrolysis of the NTP substrate, IMP.[6]

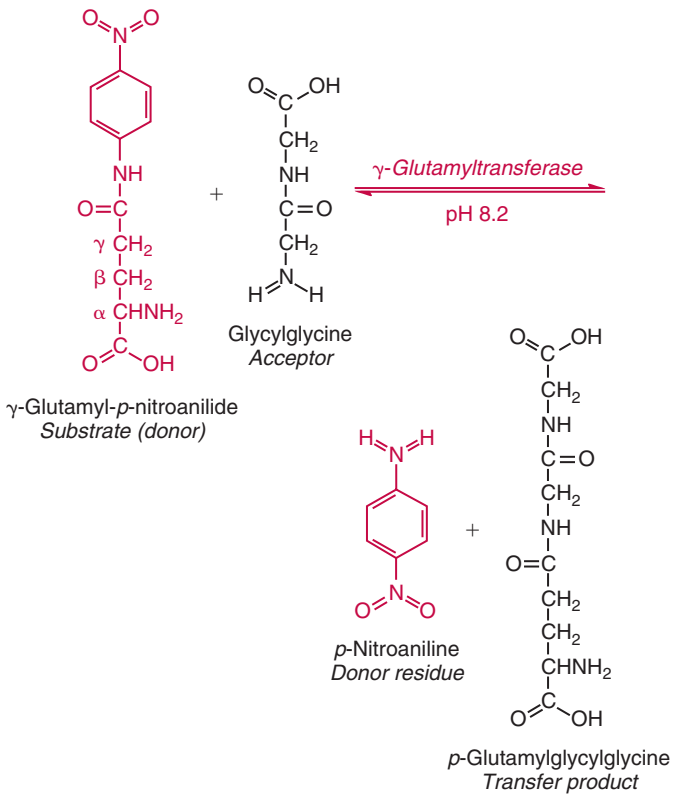
NTP activity in serum or plasma heparin is stable for at least 4 days at 4 °C and 4 months at −20 °C.

Reference Interval

The reference interval for NTP activity at 37 °C is from 3 to 9 U/L, with no sex-related differences.

γ-Glutamyltransferase

Peptidases are enzymes that catalyze the hydrolytic cleavage of peptides to form amino acids or smaller peptides. They constitute a broad group of enzymes of varied specificity, and some individual enzymes act as amino acid transferases and catalyze the transfer of amino acids from one peptide to another amino acid or peptide. γ-Glutamyltransferase (EC 2.3.2.2; γ-glutamyl-peptide : amino acid γ-glutamyltransferase; GGT) catalyzes the transfer of the γ-glutamyl group from peptides and compounds to an acceptor.[21] The γ-glutamyl acceptor is the substrate itself, some amino acid or peptide, or even water, in which case simple hydrolysis takes place. The enzyme acts only on peptides or peptide-like compounds containing a terminal glutamate residue joined to the remainder of the compound through the terminal (-γ-) carboxyl. Glycylglycine is five times more effective as an acceptor than is glycine or the tripeptide (gly-gly-gly), but little is known about the optimal properties of the acceptor cosubstrate. The peptidase transfer reaction is considerably faster than the simple hydrolysis reaction. An example of a reaction catalyzed by the enzyme is shown here:



GGT is present (in decreasing order of abundance) in proximal renal tubule, liver, pancreas, and intestine. The enzyme is present in cytoplasm (microsomes), but the larger fraction is located in the cell membrane and may transport amino acids and peptides into the cell across the cell membrane in the form of γ-glutamyl peptides. GGT is critical for the maintenance of adequate intracellular levels of reduced glutathione, a major antioxidant agent.[93]

GGT activity in serum comes primarily from liver. The enzyme in serum is heterogeneous with respect to both net molecular charge (e.g., shown by electrophoresis) and size. These forms appear to derive from post-translational modifications of a single type of enzyme molecule rather than resulting from the existence of true isoenzymes. For example, high molecular weight forms may represent the release of cell membrane fragments into the circulation. Despite numerous investigations, clear correlations between patterns of multiple forms and particular diseases cannot be discerned.

Clinical Significance

Even though renal tissue has the highest concentration of GGT, the enzyme present in serum appears to originate primarily from the hepatobiliary system. GGT is a sensitive indicator of the presence of hepatobiliary disease, being elevated in most subjects with liver disease regardless of cause, but its usefulness is limited by lack of specificity. Similar to ALP, it is highest in cases of intrahepatic or posthepatic biliary obstruction, reaching activities some 5 to 30 times the upper

reference limit. High elevations of GGT are also observed in patients with primary or secondary (metastatic) liver neoplasm. Moderate elevations (two to five times normal) occur in infectious hepatitis. Patients with chronic hepatitis C infection and high pretreatment serum GGT are unlikely to have a sustained virologic response to interferon treatment. Small increases in GGT activity are observed in more than 50% of patients with NAFLD, and similar but transient increases are noted in cases of drug intoxication. In acute and chronic pancreatitis and in some pancreatic malignancies (especially if associated with hepatobiliary obstruction), enzyme activity may be 5 to 15 times the upper reference limit.

Elevated activities of GGT are found in the sera of patients with alcoholic hepatitis and in the majority of sera from people who are heavy drinkers. Increased concentrations of the enzyme are also found in the serum of subjects receiving anticonvulsant drugs such as phenytoin and phenobarbital. Such an increase in GGT activity in serum may reflect induction of new enzyme activity by the action of the alcohol and drugs and/or their toxic effects on microsomal structures in liver cells.

In acute myocardial infarction, GGT activity is usually normal. If there is a rise, it occurs at about the fourth day, reaches a maximum value in another 4 days, and probably implies liver damage secondary to cardiac insufficiency.

Unlike ALP, GGT is not increased in conditions in which osteoblastic activity is increased.

Recent epidemiologic evidence has shown that serum GGT activity possesses an independent prognostic value for cardiovascular morbidity and mortality. Indeed, experimental work has documented that active enzyme is present in atherosclerotic plaques, and this appears related to the ability of GGT to mediate redox/pro-oxidant reactions at a cellular level.[16]

Methods for Determination of γ-Glutamyltransferase Activity

Early GGT assays used L-γ-glutamyl-*p*-nitroanilide (GGPNA) as the substrate, with glycylglycine serving as the γ-glutamyl residue acceptor. However, GGPNA has limited solubility in the reaction mixture, and it is therefore difficult to obtain saturating substrate concentrations. The *p*-nitroaniline produced in the reaction is determined by its yellow color, which is monitored at 405 nm.

Derivatives of GGPNA are also available and have been used in other methods. With these derivatives, various groups have been introduced into the benzene ring to increase solubility in water. The most useful of these substrates is L-γ-glutamyl-3-carboxy-4-nitroanilide, which is readily soluble in water and is split by GGT at a rate comparable with that observed with GGPNA. In the IFCC reference measurement procedure for GGT, L-γ-glutamyl-3-carboxy-4-nitroanilide serves as the substrate, with glycylglycine serving as an acceptor. Buffering is provided by glycylglycine itself. The temperature of the reaction is 37 °C, and the wavelength of measurement of the reaction product, 5-amino-2-nitrobenzoate, is 410 nm.[78]

GGT is a comparatively stable enzyme in vitro. Activity is stable for at least 1 month at 4 °C and for 1 year at −20 °C.

Nonhemolyzed serum is the preferred specimen, but EDTA plasma has also been used. Heparin may produce turbidity in the reaction mixture; citrate, oxalate, and fluoride depress GGT activity by 10 to 15%.

Reference Intervals

In adults, the upper reference limit for GGT activity in serum is 40 U/L for females and 70 U/L for males, when measured with an assay traceable to the IFCC reference procedure.[29] Reference limits are approximately twofold higher in people of African ancestry. In normal full-term neonates, GGT activity at birth is approximately six to seven times the adult reference range. The activity then declines, reaching adult values by the age of 5 to 7 months.[10]

Glutathione S-Transferase

Cytosolic glutathione S-transferases (EC 2.5.1.18; GST) are dimeric enzymes that catalyze the nucleophilic addition of glutathione to the electrophilic centers of a wide variety of chemical structures, accomplishing detoxification reactions. In addition, GSTs exert part of the glutathione peroxidase activity and have an important function in intracellular binding and transport of a wide variety of both endogenous and exogenous compounds. The family of human enzymes is divided into four main classes: α, μ, π, and θ.[23]

α-GST is found at high concentrations in the human liver and is released quickly and in large quantities from damaged hepatocytes into the bloodstream.

Clinical Significance

α-GST is an emerging marker for assessing hepatocellular damage. Unlike aminotransferases, which are found predominantly in the periportal hepatocytes, α-GST is evenly distributed across the liver acinus and therefore is released in all types of hepatocyte injury. In liver transplant recipients, α-GST was found to be more valuable than AST in detecting early rejection episodes postoperatively and less susceptible to the confounding effects of infection.

Methods for Determination of Glutathione S-Transferase

Several problems have been associated with GST activity measurements. First, normal plasma activity is low and difficult to measure. Second, GST binds a number of anions, such as bile salts and bilirubin, that inhibit enzyme activity. Immunoassays have been described that allow the precise and specific measurement of α-GST concentrations. The only methodologic problem relates to the speed of the assays, which take several hours.

Reference Interval

Using a commercially available enzyme immunoassay for α-GST, the upper reference limit was 11.4 μg/L.[71]

PANCREATIC ENZYMES

The most commonly used serum biomarkers for investigation of pancreatic disease, and more specifically acute pancreatitis, are digestive enzymes. Assays of (P-type) amylase, lipase, and trypsin are applied. Pancreatic function and pathology are discussed in Chapter 51.

Amylase

α-Amylase (EC 3.2.1.1; 1,4-α-D glucan glucanohydrolase; AMY) is an enzyme of the hydrolase class that catalyzes the hydrolysis of 1,4-α-glucosidic linkages in polysaccharides. Both straight-chain (linear) polyglucans, such as amylose, and branched polyglucans, such as amylopectin and glycogen, are hydrolyzed, but at different rates. In the case of amylose, the enzyme splits the chains at alternate α-1,4-hemiacetal (–C–O–C–) links, forming maltose and some residual glucose; maltose, glucose, and a residue of limit dextrins are formed if branched-chain polyglucans are used as substrate. The enzyme does not attack the α-1,6-linkages at the branch points. AMYs are calcium metalloenzymes, with the calcium essential for functional integrity. However, full activity is displayed only in the presence of various anions—such as chloride, bromide, nitrate, cholate, or monohydrogen phosphate—with chloride and bromide being the most effective activators. AMY in human serum has a moderately sharp pH optimum at 6.9 to 7.0.

AMYs normally occurring in human plasma are small molecules with molecular weights varying from 54,000 to 62,000 Da. The enzyme is thus small enough to pass through the glomeruli of the kidneys, and AMY is the only plasma enzyme normally found in urine. AMY is present in a number of organs and tissues.[94] The greatest concentration is noted in the salivary glands, which secrete a potent AMY (S-type) to initiate hydrolysis of starches while the food is still in the mouth and esophagus. The action of the S-AMY, once referred to as *ptyalin,* is terminated by acid in the stomach. In the pancreas, the enzyme (P-type) is synthesized by acinar cells and then is secreted into the intestinal tract by way of the pancreatic duct system. In the intestinal tract, effective action of pancreatic and intestinal AMY is favored by mildly alkaline conditions in the duodenum. Intestinal maltase then further hydrolyzes maltose to glucose. AMY activity is also found in extracts from semen, testes, ovaries, fallopian tubes, striated muscle, lungs, and adipose tissue. The enzyme is present in colostrum, tears, and milk. Epithelial tumors of lung and ovary may also contain considerable AMY activity. Ascitic and pleural fluids may contain AMY as a result of the presence of a tumor or pancreatitis.

The enzyme present in normal serum and urine is predominantly of pancreatic (P-AMY) and salivary gland (S-AMY) origin. These isoenzymes are products of two closely linked loci on chromosome 1. AMY isoenzymes also undergo post-translational modification of deamidation, glycosylation, and deglycosylation to form a number of isoforms. Indeed, nonenzymic deamidation appears to be the mechanism for "aging" that occurs when AMY is sequestered (e.g., pancreatic pseudocysts) or subjected to prolonged in vitro storage. Although P-AMY is not glycosylated, S-AMY may exist in both glycosylated and deglycosylated forms; these isoforms can be separated in both serum and urine using isoelectric focusing or electrophoresis. Individuals with isolated P-AMY deficiency, a rare condition, have carbohydrate maldigestion resulting in abdominal distention, flatulence, loose stools, and poor weight gain.

Clinical Significance

Blood AMY activity is physiologically low and constant and greatly increases in acute pancreatitis and salivary gland inflammation. In acute pancreatitis, a rise in serum AMY activity occurs within 5 to 8 hours of symptom onset; activities typically return to normal by the third or fourth day. A fourfold to sixfold elevation in AMY activity above the upper reference limit is usual, with maximal concentrations attained in 12 to 72 hours. The magnitude of the elevation of serum enzyme activity is not related to the severity of pancreatic involvement; however, the greater the rise, the greater the probability of acute pancreatitis. A portion of the clearance of AMY from the circulation occurs via renal excretion into the urine, and increased serum activity is reflected in an increase in urinary AMY activity. As compared with serum AMY, urine AMY reaches higher concentrations and persists for longer periods. The clinical specificity of AMY for the diagnosis of acute pancreatitis is low (20 to 60%, depending on the mix of the patient population studied) because increased values are also found in a number of acute intra-abdominal disorders and in several extrapancreatic conditions (Table 22-6).

Lack of specificity of total AMY measurement has led to interest in the direct measurement of P-AMY instead of total enzyme activity for the differential diagnosis of patients with acute abdominal pain. By applying the best decision limit (an activity equal to threefold the upper reference limit), the clinical specificity of P-AMY for the diagnosis of acute pancreatitis was greater than 90%.[65] Sensitivity in late detection of this condition is also notably improved with P-AMY. P-AMY values remain elevated in 80% of patients with uncomplicated pancreatitis 1 week after onset, when only 30% still show increased total AMY activity. This long-standing increase in P-AMY activity in serum also makes redundant the traditional measurement of total AMY in urine—a test performed to achieve better diagnostic sensitivity in the late phase of pancreatitis.

Biliary tract diseases, such as cholecystitis, cause up to fourfold elevation in serum P-AMY activity as a result of primary or secondary pancreatic involvement. Various intra-abdominal events can lead to a significant increase in serum P-AMY activities up to a fourfold elevation and sometimes beyond. Such increases may be due to leakage of P-AMY from the intestine into the peritoneal cavity and then into the circulation.

In renal insufficiency, serum AMY activity is increased in proportion to the extent of renal impairment (usually, no more than five times the upper reference limit).

TABLE 22-6 Causes of Hyperamylasemia

Pancreatic disease	Pancreatitis, any cause (P-AMY↑)*
	Pancreatic trauma (P-AMY↑)
Intra-abdominal diseases other than pancreatitis	Biliary tract disease (P-AMY↑)
	Intestinal obstruction (P-AMY↑)
	Mesenteric infarction (P-AMY↑)
	Perforated peptic ulcer (P-AMY↑)
	Gastritis, duodenitis (P-AMY↑)
	Ruptured aortic aneurysm
	Acute appendicitis (perforated)
	Peritonitis
	Trauma
Genitourinary disease	Ectopic, ruptured tubal pregnancy
	Salpingitis (S-AMY↑)
	Ovarian malignancy (S-AMY↑)
	Renal insufficiency (Mixed)
Miscellaneous	Salivary gland lesions (S-AMY↑)
	Acute alcoholic abuse (S-AMY↑)
	Diabetic ketoacidosis (S-AMY↑)
	Macroamylasemia (S-AMY↑ or P-AMY↑)
	Septic shock (S-AMY↑)
	Cardiac surgery (S-AMY↑)
	Tumors (usually S-AMY↑)
	Drugs (usually S-AMY↑)

*Predominant isoenzyme type is shown in parentheses: *P-AMY,* pancreatic; *S-AMY,* salivary; *Mixed,* either or both isoenzymes may be present.

Hyperamylasemia also occurs in neoplastic disease. Tumors of the lung and serous and mixed (serous and mucinous) carcinomas of the ovary can produce hyperamylasemia (with an S-type isoenzyme mobility) with elevations as high as 50 times the upper reference limit. The AMY isoenzyme in cases of ruptured ectopic pregnancy is not well characterized. In severe cases presenting late, the increased isonzyme may be P-AMY (from pancreatic involvement related to peritonitis) despite the fact that S-AMY is present in fallopian tube. Cases of AMY-producing multiple myeloma have been described.

In 1% of the population, macroamylases are present in sera and may cause hyperamylasemia; these are complexes of ordinary AMY (usually S-type) and IgG or IgA. These macroamylases cannot be filtered through the glomeruli of the kidneys because of their large size (greater than MW 200,000) and are thus retained in the plasma, where their presence may increase AMY activity some twofold to eightfold above the upper reference limit. No clinical symptoms are associated with this disorder, but some cases have been detected during investigation of abdominal pain.

A decrease in serum P-AMY activity (less than the lower reference limit) is highly specific for an exocrine pancreatic insufficiency and can make intubation tests for pancreatic function unnecessary. If, however, P-AMY is normal, reduced pancreatic function cannot be excluded.[42]

Methods for Determination of α-Amylase Activity

Historically, saccharogenic, amyloclastic, and chromolytic starch methods were the assays of choice for determining AMY activity. These assays have been completely displaced in favor of ones with well-defined substrates with shorter glucosyl chains. The use of defined AMY substrates and auxiliary and indicator enzymes in the AMY assay has improved the reaction stoichiometry and has led to more controlled and consistent hydrolysis conditions. Substrates used include small oligosaccharides and 4-nitrophenyl (4-NP)-glycoside substrates.

When hydrolyzed by AMY, small oligosaccharide substrates have been found to give better defined products than do starches. For example, both maltopentaose and maltotetraose showed good stability, consistent hydrolysis products, and unambiguous reaction stoichiometry. Several variations of the reaction rate formulation have been devised.[18]

4-NP-glycoside substrates are prepared by bonding 4-NP to the reducing end of a defined oligosaccharide. If the oligosaccharide is maltoheptaose (G7), the substrate is then 4-NP-G7. AMY splits this substrate to produce free oligosaccharides (G5, G4, and G3) and 4-NP-G2 (9%), 4-NP-G3 (31%), and 4-NP-G4 (60%). P-AMY hydrolyzes the substrate at a greater rate than does S-AMY in the ratio 1.8:1. G6, G1, 4-NP-G6, and 4-NP-G5 are not produced in appreciable quantities. In the original assay, the result of combined hydrolysis by AMY in the specimen and by the reagent α-glucosidase (EC 3.2.1.20; maltase) is that more than 30% of the product is free NP. Free NP is detected by its absorbance at 405 nm. α-Glucosidase does not react with any oligosaccharide containing more than four glucose molecules in the chain; G4 is hydrolyzed only very slowly.[70] Problems arose with the use of the 4-NP-glycoside assay with regard to the poor stability of the reconstituted assay mixture, because of slow hydrolysis of the 4-NP-glycoside by α-glucosidase. This effect has been reduced by covalently linking a "blocking" group (i.e., a 4,6-ethylidene group) [ethylidene-protected substrate (EPS)] to the nonreducing end of the molecule. The blocked substrate also shows a different and more advantageous hydrolysis pattern. Thus the ethylidene-4-NP-G7 substrate fragments approximately as 4-NP-G2 (40%), 4-NP-G3 (40%), and 4-NP-G4 (20%). Therefore liberation of 4-NP is increased; however, the reaction rate is reduced in proportion, so these two effects compensate for each other.[37] A novel-type α-glucosidase is also available (recombinant enzyme AGH-211) that completely hydrolyzes nitrophenylated substrates. As a result, cleavage of one α-glucosidic linkage by AMY results in the release of one molecule of 4-NP:

$$5\ \text{ethylidene-4-NP-G}_7 + 5\ \text{H}_2\text{O} \xrightarrow{\alpha\text{-amylase}} 2\ \text{ethylidene-G}_5 + 2\ \text{4-NP-G}_2 + 2\ \text{ethylidene-G}_4 + 2\ \text{4-NP-G}_3 + \text{ethylidene-G}_3 + \text{4-NP-G}_4$$

$$2\ \text{4-NP-G}_2 + 2\ \text{4-NP-G}_3 + 10\ \text{H}_2\text{0} \xrightarrow{\alpha\text{-glucosidase}} 4\ \text{4-NP} + 10\ \text{G}$$

The IFCC has optimized this method at 37 °C, recommending it as a reference measurement procedure for AMY.[75]

An alternative method based on the 2-chloro-*p*-nitrophenol (CNP) indicator uses 2-chloro-*p*-nitrophenyl-α-D-maltotrioside (CNP-G3) as a substrate. This assay does not require glucosidases and is considered a "direct" assay. Its disadvantages have been stated to include its low substrate conversion rate compared with G4, G5, and G7 assays; the variation in molar absorptivity of CNP associated with changes in pH, temperature, and protein content; and the presence of the activator, potassium thiocyanate, causing allosteric changes to AMY and precluding the use of antibodies for P-AMY determination.[87]

With the exception of heparin, all common anticoagulants inhibit AMY activity because they chelate Ca^{2+}; citrate, EDTA, and oxalate inhibit it by as much as 15%. Therefore, AMY assays should be performed only on serum or heparinized plasma. AMY is quite stable; activity is fully retained during storage for 4 days at room temperature, for 2 weeks at −4 °C, for 1 year at −25 °C, and for 5 years at −75 °C.

Reference Interval

Using the IFCC recommended method at 37 °C, the serum reference interval was 31 to 107 U/L.[75]

Analytical Methods and Reference Intervals for Amylase Isoenzymes

Methods for AMY isoenzymes based on electrophoresis, ion-exchange chromatography, isoelectric focusing, selective inhibition of the S-AMY by a wheat germ inhibitor, immunoprecipitation by a monoclonal antibody, and immunoinhibition have been introduced. However, only methods based on selective isoenzyme inhibition by monoclonal antibodies have shown sufficient precision, reliability, practicability, and analytical speed to allow the introduction of P-AMY determination into clinical practice.

A double monoclonal antibody assay is commercially available that uses the synergistic action of two immunoinhibitory monoclonal antibodies to S-AMY.[69] After the S-AMY activity is inhibited by the addition of antibodies, uninhibited P-AMY activity is measured using EPS-4-NP-G7 as a substrate. It is an attractive convenience to have this more specific assay available in full automation today on clinical chemistry platforms with reagent costs similar to total AMY, which permits laboratories to abandon the latter.[65]

False-positive P-AMY results have been reported in subjects with macroamylasemia, in whom immunoglobulin complexed to AMY forms diminishes or voids the ability of monoclonal antibodies included in the test to efficiently inhibit S-AMY. Upon electrophoresis, macro-AMY usually forms a broad migrating band, clearly different from the homogeneous bands that are produced by AMY isoenzymes present in serum (Figure 22-6). If electrophoretic separation is not available, precipitation of the macrocomplex by a PEG 6000 solution (240 g/L) represents a good alternative. Residual AMY activity of less than 30% in the supernatant is indicative of macroamylasemia.[12]

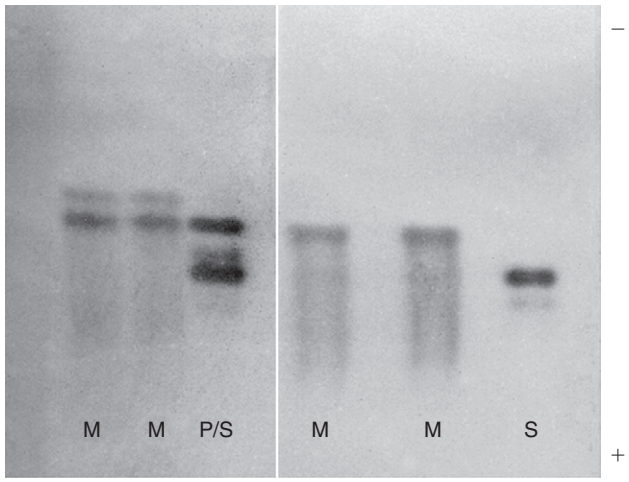


Figure 22-6 Electrophoretic separation of amylase isoenzymes. *M,* Macroamylasemia; *P/S,* mixture of two samples containing, respectively, pancreatic juice and saliva; *S,* saliva. The anodal direction is downward.

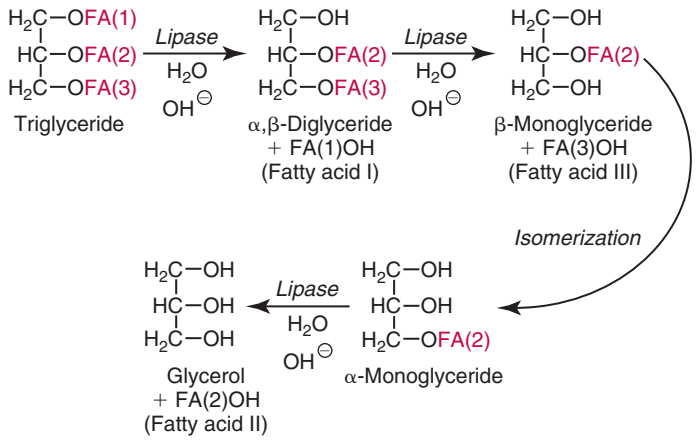
In healthy adults, P-AMY represents approximately 40 to 50% of total AMY activity in serum. Using the immunoinhibition method at 37 °C, the reference interval for P-AMY activity in sera from adults was 13 to 53 U/L.[33] Serum P-AMY activity is not demonstrable in most children younger than 6 months, but activity rises slowly thereafter to reach adult concentrations at 5 years of age, reflecting the postnatal development of exocrine pancreatic function. As a consequence, use of this enzyme for the diagnosis of acute pancreatitis in young children should be avoided and the test should be replaced with the measurement of lipase.

Lipase

Human pancreatic lipase (EC 3.1.1.3; triacylglycerol acylhydrolase; LPS) is a single-chain glycoprotein with a molecular weight of 48,000 Da and an isoelectric point of about 5.8. The LPS gene resides on chromosome 10. LPS concentration in the pancreas is about 5000-fold greater than in other tissues, and the concentration gradient between pancreas and serum is ≈20,000-fold.[59] For full catalytic activity and greatest specificity, the presence of bile salts and a cofactor called *colipase,* which is a small molecular weight protein of 10,000 secreted by the pancreas, are required. Human LPS can be fully activated in vitro by colipases from other species (e.g., porcine colipase); this property is used in analytical formulations of the LPS assay.[89]

Lipases are defined as enzymes that hydrolyze glycerol esters of long-chain fatty acids. Only ester bonds at carbons 1 and 3 (α-positions) are attacked, and products of the reaction include 2 moles of fatty acids and 1 mole of 2-acylglycerol (β-monoglyceride) per mole of substrate. The latter is resistant to hydrolysis, probably because of steric hindrance, but it can spontaneously isomerize to the α-form (3-acylglycerol). This isomerization permits the third fatty acid to be split off but at a much slower rate. A scheme for the steps in complete hydrolysis of a molecule of triglyceride to glycerol and three fatty acids is shown here:



LPS acts only when the substrate is present in an emulsified form at the interface between water and the substrate. The rate of LPS action depends on the surface area of the dispersed substrate. Bile acids ensure that the surface of the dispersed substrate remains free of other proteins, including lipolytic enzymes, by lining the surface of the insoluble substrate and the aqueous medium. LPS seems to gain access to the substrate surface in the following manner: Colipase attaches to a micelle of bile salts, thus forming a colipase–bile salt complex that reconfigures the structure of colipase with exposure of a site with high affinity and high specificity for LPS, which therefore attracts LPS and anchors it to the substrate surface, allowing enzyme action to proceed.

Most LPS activity found in serum derives from the pancreas, but some is secreted by gastric, pulmonary, and intestinal mucosa. LPS is a small enough molecule to be filtered through the glomerulus. It is totally reabsorbed by the renal tubules, and it is not physiologically detected in urine. Evidence suggests that pancreatic LPS may exist in at least two isoforms, although the exact nature of these is unknown.[59] Complete absence of LPS has been reported. Such congenital absence results in fat malabsorption and severe steatorrhea.

Clinical Significance

LPS measurement of serum is used to diagnose acute pancreatitis. The clinical sensitivity is 80 to 100% depending on the selected diagnostic cutoff, and the clinical specificity is 80 to 100% depending on the mix of the patient population studied. After an attack of acute pancreatitis, serum LPS activity increases within 4 to 8 hours, peaks at about 24 hours, and decreases within 7 to 14 days. Elevations between 2 and 50 times the upper reference limit have been reported. The increase in serum LPS activity is not necessarily proportional to the severity of the attack.[89]

Acute pancreatitis is sometimes difficult to diagnose because it must be differentiated from other acute intra-abdominal disorders with similar clinical findings, such as perforated gastric or duodenal ulcer, intestinal obstruction, or mesenteric vascular obstruction. In differential diagnosis, elevation of serum LPS activity to greater than 3 times the upper reference limit, in the absence of renal failure, is a more specific diagnostic finding than increases in serum AMY activity.[19] Furthermore, LPS concentrations remain elevated longer than those of AMY do, which is another advantage over AMY measurement in patients with delayed presentation (Figure 22-7). Therefore, it is recommended that LPS should replace AMY as the initial diagnostic test for acute pancreatitis in the emergency department; obtaining both serum AMY and LPS is not warranted.

Obstruction of the pancreatic duct by a calculus or by carcinoma of the pancreas may increase serum LPS activity, depending on the location of the obstruction and the amount of remaining functioning tissue. In patients with a reduced glomerular filtration rate, serum LPS activity is increased. Thus care should be exercised in the interpretation of elevated serum LPS values in the presence of renal disease. Finally, investigation of the biliary tract by endoscopic retrograde pancreatography or treatment with opiates (which causes the sphincter of Oddi to contract) may increase serum LPS activity.

Methods for Measuring Lipase Activity

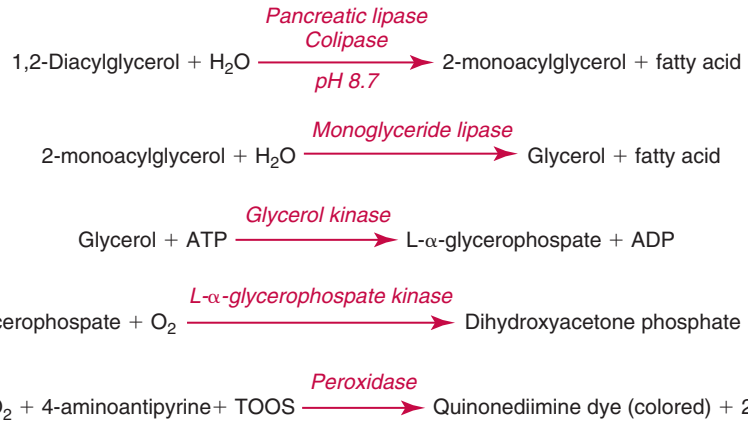
Many LPS methods have been described; they have used both triglyceride and nontriglyceride substrates and titrimetric, turbidimetric, spectrophotometric, fluorometric, and immunologic techniques. In general, long-chain triglyceride (and some diglyceride) substrates have demonstrated correlation of results with the clinical state that is superior to that seen with methods using other substrates.[38]

In titrimetric methods, LPS catalyzes the hydrolysis of fatty acids from an emulsion of olive oil or oleic acid. The fatty acids liberated are titrated with dilute alkali. Kinetic versions use an automated potentiometric titrator (an instrument commonly referred to as a "pH-stat"). The amount of alkali used is recorded as a function of time and serves as a measure of fatty acid produced during the reaction.

In the turbidimetric method, LPS catalyzes the hydrolysis of fatty acids from an emulsion of oleic acid with a simultaneous decrease in the turbidity of the reaction mixture. Absorbance at 340 nm is read and the ΔA/min is taken as a measure of LPS activity. Turbidities have occasionally been observed to increase rather than decrease during the reaction period. Such increases have frequently been observed in specimens containing rheumatoid factor. The method linearity (≈3 times the upper reference limit) is limited, with many clinical samples needing to be diluted.

Numerous substrates and complex auxiliary and indicator systems are used in spectrophotometric methods. In the Ortho Clinical Diagnostics spectrophotometric reaction rate LPS slide method, the (synthetic) substrate is 1-oleoyl-2,3-diacetylglycerol, and the emulsifier dodecylbenzene sulfonate. LPS activity is measured by a complex auxiliary and indicator enzyme system to produce a colored dye detectable at 540 nm. However, the substrate is likely to be more specific for intestinal than pancreatic LPS and may be subject to interference by postheparin lipase and pancreatic carboxylesterase.

In the enzymatic reaction rate diglyceride assay for LPS, the following sequence of indicator and auxiliary enzymes is used:



TOOS is sodium *N*-ethyl-*N*-(2-hydroxyl-3-sulfopropyl)-m-toluidine, and its oxidation produces an intensely colored dye detectable at 550 nm. The suggested upper reference limit is 45 U/L at 37 °C.

More recently, a synthetic substrate [1,2-O-dilauryl-rac-glycero-3-glutaric acid-(4-methyl-resorufin)-ester] consisting of two glycerol ether bonds and one ester bond has been proposed, and assays based on its use are currently gaining widespread use. LPS hydrolyzes the ester bond in an alkaline medium to an unstable dicarbonic acid ester that spontaneously hydrolyzes to yield glutaric acid and methylresorufin; this is a bluish-purple chromophore with peak absorption at 580 nm.

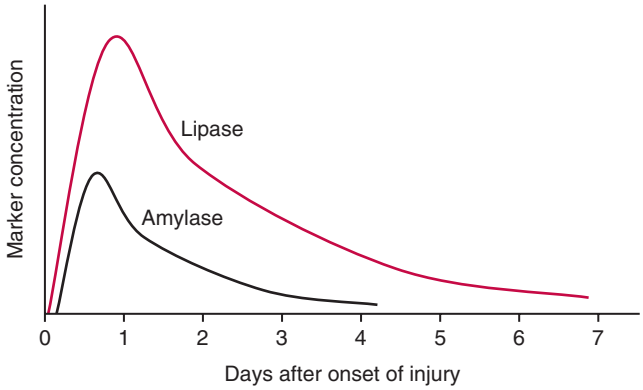


Figure 22-7 Time-dependent changes in serum amylase and lipase after acute pancreatitis.

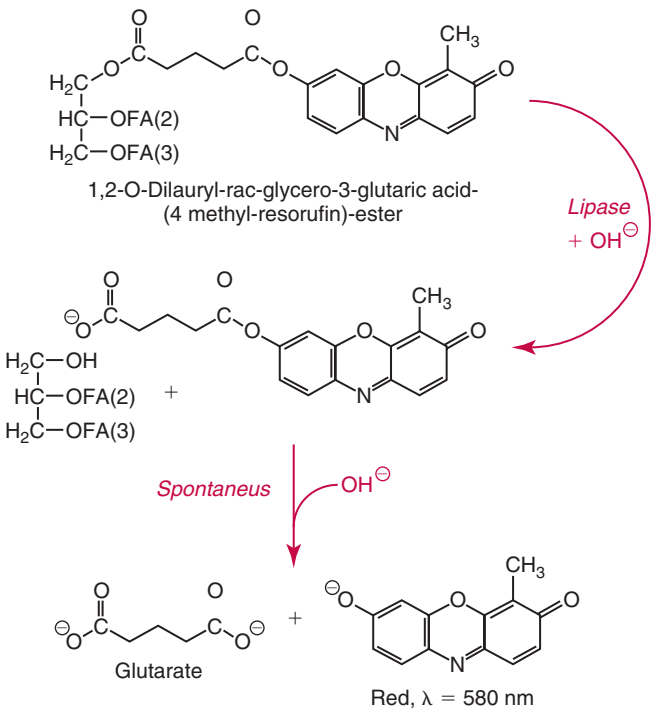

The rate of methylresorufin formation is directly proportional to the LPS activity of the sample. The upper reference limit is 38 U/L at 37 °C, with no gender- or age-related differences. Compared with previous LPS spectrophotometric methods, this assay principle is based on a direct reaction and appears to have increased specificity for pancreatic LPS.[64]

A newly synthesized thioester (2,3-dibutyrylthio-1-propyl oleate) substrate that is believed to be highly selective for pancreatic LPS has also been proposed, but commercial methods are yet not available to permit its clinical validation.

LPS activity in serum is stable at room temperature for 1 week; sera may be stored for 3 weeks in the refrigerator and for several years if frozen.

Trypsin

Trypsin (EC 3.4.21.4; no systematic name; TRY) is a pancreas-specific serine protease characterized by the presence at the active site of serine and histidine, both of which participate in the catalytic process. TRY hydrolyzes peptide bonds formed by the carboxyl groups of lysine or arginine with other amino acids, although esters and amides involving these amino acids are actually split more rapidly than peptide bonds.[55]

The acinar cells of the human pancreas synthesize two major trypsins (1 and 2) in the form of the inactive proenzymes (or zymogens), trypsinogens-1 and -2. These zymogens are stored in zymogen granules and are secreted into the duodenum under the stimulus of the vagus nerve or the intestinal hormone cholecystokinin-pancreozymin. The two trypsinogens represent approximately 19% of the total protein in pancreatic juice; normally, the pancreas secretes trypsinogen-1 at about twofold to fourfold the concentration of trypsinogen-2, but in pancreatic disease, the ratio of trypsinogen-1 and -2 is reversed. In the intestinal tract, the trypsinogens are converted to the active enzyme TRY by the duodenal enzyme enterokinase or by pre-formed TRY (autocatalysis) (Figure 22-8). When trypsinogens are converted to active TRY, a small peptide is cleaved from the *N*-terminal region of trypsinogen [trypsinogen activation peptide (TAP)]. Determinations of urinary TAP may provide information on the severity of acute pancreatitis.[20]

TRY-1 is also described as cationic and TRY-2 as anionic because of their differing electrophoretic mobility; the cationic form predominates and is the better documented enzyme. TRY-1 and TRY-2 have molecular weights of 25,800 and 22,900 Da and pI values of 4.6 to 6.5 and greater than 6.5, respectively. TRY-2 differs from TRY-1 in that it rapidly undergoes autolysis at neutral or alkaline pH values, and Ca^{2+} does not stabilize it against autolysis. Because the two trypsins show little immunologic cross-reactivity, a specific immunoassay for each of them is possible.

Materials such as soybeans, lima beans, and egg whites contain natural TRY inhibitors—small polypeptides such as α_1-antitrypsin (α_1-protease inhibitor) and α_2-macroglobulin—that combine irreversibly with TRY and inactivate it by blocking the active center. Similar nondialyzable TRY inhibitors [e.g., pancreatic secretory trypsin inhibitor (PSTI)] are present in pancreas, pancreatic juice, serum, and urine. These inhibitors protect plasma and other proteins against hydrolysis by TRY and other proteases if for some reason any appreciable quantity of the enzyme enters the vascular system.[55] The absence of α_1-antitrypsin is associated with an increased tendency toward panlobular emphysema in early life; this example illustrates the effects of uninhibited proteases on organ function.

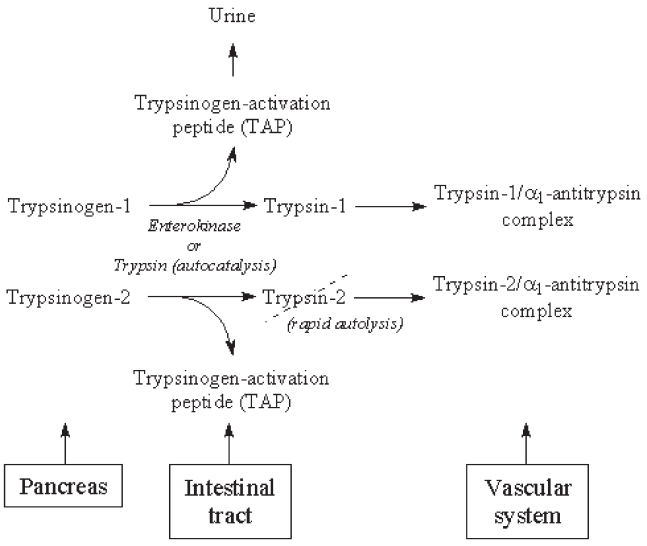

Figure 22-8 A comprehensive representation of the human trypsin system.

Clinical Significance

Trypsin-1 (Cationic Trypsin)[41]

In healthy individuals, free trypsinogen-1 is the major form found in serum. After an attack of acute pancreatitis, serum TRY-1 rises in parallel with serum AMY activity to peak values ranging from 2 to 400 times the upper reference limit. The distribution of the different forms of TRY-1 appears to be related to the type and severity of acute pancreatitis. Thus in the mildest form of acute pancreatitis, 80 to 99% of TRY-1 exists as free trypsinogen-1, with smaller proportions existing as bound TRY-1. In the more severe forms, in which mortality ranges from 20% to more than 50%, the proportion of free trypsinogen-1 may be as low as 30% of the total, with appreciable proportions existing as the α_1-antitrypsin– and α_2-macroglobulin–bound TRY-1.[8]

TRY-1 in serum is elevated in chronic renal failure, as are serum AMY and LPS. Thus renal failure must be ruled out when elevated concentrations are interpreted. In chronic pancreatitis without steatorrhea, plasma concentrations of TRY-1 do not differ from those found in health; when steatorrhea is present, however, fasting concentrations are extremely low. In the relapsing phase of chronic pancreatitis, plasma TRY may be considerably elevated. In carcinoma of the pancreas, TRY concentrations may be high, normal, or even low.

In comparison with P-AMY and LPS measurements, TRY-1 is a more difficult test to perform, requiring several hours to complete. Because TRY estimation has no distinct role in the routine management of patients with acute pancreatitis, this test is considered of limited clinical value.

Cystic fibrosis is a genetic disorder that primarily affects the lungs and digestive system, resulting in the production of thick mucus that blocks ducts in the pancreas, preventing normal transport of trypsinogen. In this condition, plasma TRY concentrations have been reported to be high in neonates; as the disease progresses, activity falls. Newborn screening is done by the measurement of immunoreactive trypsinogen-1 in dried blood specimens. Infants who have a high TRY concentration on initial testing undergo further assessment via a repeat test 1 to 3 weeks later, or by analysis of the initial blood spot for specific DNA mutations.

Trypsin-2 (Anionic Trypsin)

Serum trypsinogen-2 increases more than trypsinogen-1 in acute pancreatitis, the concentrations of the former being on average about 10-fold those of the latter.[31] Consequently, larger amounts of trypsinogen-2 are excreted into urine. Urinary trypsinogen-2 measurement has shown high sensitivity and negative predictive value for the diagnosis of acute

pancreatitis on admission to the hospital. However, the positive predictive value of this test is low.

As noted earlier, newly formed TRY is inactivated by complexing with α_1-antitrypsin. Assays of this serum complex with TRY-2 have shown that this determination could be superior to that of trypsinogen-2 or AMY in acute pancreatitis.[24]

Methods for Determination of Trypsin

Early studies used catalytic assays, but it was soon recognized that other proteolytic enzymes present in serum could also hydrolyze the same substrates. A major advance has been the development of commercial immunoassays to specifically quantify TRY in blood. In the case of TRY-1, immunoassays detect trypsinogen-1, TRY-1, and the TRY-1–α_1-antitrypsin complex. They do not detect the TRY-1–α_2-macroglobulin complex, for which different assays are necessary. Free TRY-1 is not usually found in serum; it is always complexed. Because no assay standardization is available, reference limits are method dependent.

A rapid (5 minute) urinary trypsinogen-2 test strip is available, which is based on the use of immunochromatography with monoclonal antibodies. The test is considered positive at urinary trypsinogen-2 concentrations greater than 50 µg/L.

BONE ENZYMES

Bone enzymes are direct products of active osteoblasts (bone ALP) and osteoclasts (tartrate-resistant acid phosphatase).

Alkaline Phosphatase (Bone Isoform)

Bone, liver, and kidney isoforms of ALP are post-translational modifications of the same gene product and are identified by their unique carbohydrate content (see Figure 22-4). They were described previously in the section on liver enzymes. Bone ALP is produced by the osteoblast and has been demonstrated in matrix vesicles deposited as "buds" derived from the cell's membrane. The enzyme therefore is an excellent indicator of global bone formation activity. Genetic inability to produce tissue-nonspecific ALP, including bone isoform, a rare inherited disorder known as hypophosphatasia, results in severe bone disease and impaired bone growth.

Clinical Significance in Bone Disease

Advantages of using bone ALP concentrations in serum as bone formation markers in clinical practice include low diurnal variability and lack of renal function concerns. Among the bone diseases, the highest concentrations of bone ALP are encountered in Paget's disease (osteitis deformans) as a result of the action of osteoblastic cells as they try to rebuild bone that is being resorbed by uncontrolled activity of osteoclasts. Values from 10 to 25 times the upper reference limit are not unusual, and in broad terms the increase reflects the extent of disease. In vitamin D deficiency (osteomalacia and rickets), concentrations two to four times normal may be observed, and these fall slowly to normal on treatment. Primary hyperparathyroidism and secondary hyperparathyroidism are associated with slight to moderate elevations of bone ALP in serum, with the existence and degree of elevation reflecting the presence and extent of skeletal involvement. Very high enzyme concentrations are present in patients with osteogenic bone cancer. Bone ALP can be slightly increased in osteoporosis, but osteoporotic individuals are not clearly distinguished from age-matched controls even if, over the entire population, concentrations are inversely correlated with bone mineral density. Transient elevations may be found during healing of bone fractures. Physiologic bone growth increases bone ALP in serum, and this accounts for the fact that in the sera of growing children, the enzyme concentration is 1.5 to 7 times that in healthy adult serum, the maximum being reached earlier in girls than in boys.

Methods for Determination of Bone Alkaline Phosphatase

In general, separation of tissue-nonspecific ALP forms (i.e., bone and liver) is difficult because of structural similarity. At present, bone ALP in serum can be measured by electrophoretic and immunochemical methods (see the section on liver enzymes). Immunoassays for bone ALP, which measure enzyme activity or mass, are commercially available; cross-reactivity with the liver isoform, however, has been established:

Assay	Type	Cross-Reactivity, %
Beckman Coulter Tandem-R-Ostase	Mass based IRMA	12.7-16.5
Beckman Coulter Tandem-MP-Ostase	Mass based ELISA	8.1-16.2
Metra Alkphase-B	Activity based EIA	5.9-20.0

This general limitation should be borne in mind when test results are interpreted.

With the use of immunoassays measuring bone ALP concentrations, the enzyme is said to be stable at −20 °C for 2 years.

Reference Intervals

When the electrophoretic procedure is used, the reference interval for bone ALP activity in healthy adults is 10 to 50 U/L.[66] Mean (SD) bone ALP concentrations, determined by immunoassays in healthy adults, were 13 µg/L (5).[9]

Acid Phosphatase (Tartrate-Resistant 5b Isoform)

Under the name of acid phosphatase [EC 3.1.3.2; orthophosphoric-monoester phosphohydrolase (acid optimum); ACP] are included all phosphatases with optimal activity below a pH of 7.0.

ACP is present in lysosomes, which are organelles present in all cells with the possible exception of erythrocytes.

Extralysosomal ACPs are also present in many cells. The greatest concentrations of ACP activity occur in prostate, bone (osteoclasts), spleen, platelets, and erythrocytes. The lysosomal and prostatic enzymes are strongly inhibited by dextrorotatory tartrate ions, whereas the erythrocyte and bone isoenzymes are not. Most of the normally low ACP activity of (unhemolyzed) serum is of a tartrate-resistant type (TR-ACP) and probably originates mainly in osteoclasts. Activities of this fraction are increased physiologically in growing children and pathologically in conditions of increased osteolysis and bone remodeling.[46]

At least four ACP-determining genes have been identified and mapped. The erythrocyte ACP gene is located on chromosome 2 and is polymorphic, and a further gene on chromosome 19 encodes the TR-ACP expressed in osteoclasts and other tissue macrophages, such as alveolar macrophages and Kupffer cells (type 5 ACP). Isoenzyme 5 consists of two structurally related isoforms that differ by their carbohydrate content: TR-ACP 5a, which derives mainly from macrophages and dendritic cells, and type 5b, a more specific marker of osteoclastic activity. Genes encoding the tartrate-inhibited lysosomal and prostatic ACPs, mapped to chromosomes 11 and 13 respectively, exhibit considerable homology.[50]

ACPs are unstable, especially at temperatures above 37 °C and at pH above 7.0. Some of the enzyme forms in serum are particularly labile, and more than 30% of ACP activity may be lost in 3 hours at room temperature. Acidification of the serum specimen to a pH below 6.5 aids in stabilizing the enzyme activity.

Clinical Significance

TR-ACP is a potentially useful marker of conditions with a marked osteolytic component. Slight or moderate elevations in serum TR-ACP activity often occur in Paget's disease, in hyperparathyroidism with skeletal involvement, and in the presence of malignant invasion of the bones by cancers such as breast cancer in women. Increased concentrations of the osteoclast-derived ACP are also present in serum in osteoclastoma (giant cell tumor), an osteoclastic neoplasm, and in osteopetrosis (marble bone disease) in which the osteoclasts fail to resorb bone. High concentrations of TR-ACP in the serum of these patients are proportional to the osteoclast number, suggesting that changes in osteoclast function and number do not always go hand in hand.[26] TR-ACP appears to show relatively small dynamic changes in comparison with other markers of bone resorption (e.g., those related to type I collagen metabolism). This may be attributable to the fact that the enzyme is released into the sealed osteoclast microenvironment, rather than directly into the circulation.

Unlike blood concentrations of other markers of bone resorption (e.g., C-telopeptide of type I collagen), TR-ACP is not affected by renal dysfunction. The only nonbone condition in which elevated activities of TR-ACP are found in serum is Gaucher's disease of the spleen, a lysosomal storage disorder. Its source in this disease is the abnormal macrophages in spleen and other tissues, which overexpress this normal macrophage constituent. The hairy cells of hairy cell leukemia (leukemic reticuloendotheliosis) also express the osteoclast-type ACP, providing a useful histologic marker. However, in this condition, the isoenzyme does not enter the plasma in increased amounts.

Although once widely used to detect or monitor carcinoma of the prostate, determination of ACP (tartrate-inhibited) activity in serum has now been replaced by prostate-specific antigen (PSA).

Methods for Determination of Tartrate-Resistant Acid Phosphatase

Continuous-monitoring methods for assay of TR-ACP activity are based on the principle introduced by Hillmann in which α-naphthol released from its phosphate ester forms a colored product with the stabilized diazonium salt of 2-amino-5-chlorotoluene-1,5-naphthalene disulfonate (Fast Red TR). Alcohols, such as 1,5-pentanediol, accelerate the reaction and increase sensitivity by acting as phosphate acceptors in transfer reactions. The addition of sodium tartrate inhibits the sensitive isoenzymes (i.e., prostatic and lysosomal ACPs) if they are present in the sample.

Immunoassays for serum TR-ACP have been developed that preferentially detect isoform 5b. A first method uses a monoclonal antibody to bind serum TR-ACP in a solid-phase format. After the capture, osteoclastic enzyme (type 5b) is specifically determined by measuring its activity at optimal pH 6.1. Another assay uses two monoclonal antibodies generated against purified bone TR-ACP 5b. One of the antibodies captures active intact isoform while the second eliminates interference of inactive 5b fragments in serum. After the immunoreaction, binding TR-ACP 5b activity is measured (fragments absorbed immunocapture enzymatic assay [FAICEA]).

Serum should be immediately separated from erythrocytes and stabilized by the addition of 50 µL of acetic acid (5 mol/L) per milliliter of serum to lower the pH to 5.4, at which the enzyme is stable. Under these conditions, TR-ACP activity is maintained at room temperature for several hours, for up to a week if the serum is refrigerated, and for 4 months if stored at −20 °C. Hemolyzed serum specimens are contaminated with considerable amounts of the erythrocyte tartrate-resistant isoenzyme and should be rejected.

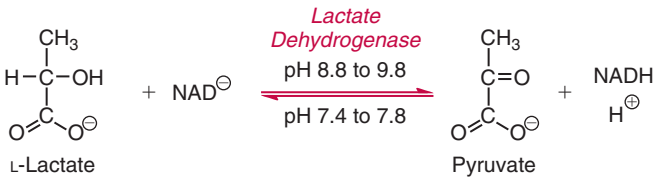
Reference Intervals

In the sera of healthy adults, the reference interval for TR-ACP activity, measured at 37 °C, is 1.5 to 4.5 U/L. Children show higher TR-ACP activities (3.4 to 9.0 U/L).

MISCELLANEOUS ENZYMES

Lactate Dehydrogenase

Lactate dehydrogenase (EC 1.1.1.27; L-lactate: NAD^+ oxidoreductase; LD) is a hydrogen transfer enzyme that catalyzes the oxidation of L-lactate to pyruvate with the mediation of NAD^+ as a hydrogen acceptor.



As indicated, the reaction is reversible, and the reaction equilibrium strongly favors the reduction of pyruvate to lactate (P → L)—the "reverse reaction."

The pH optimum for the lactate-to-pyruvate (L → P) reaction is 8.8 to 9.8, and an assay reaction mixture, optimized for LD-1 at 37 °C, contains NAD^+, 9 mmol/L, and L-lactate, 80 mmol/L. For the P → L assay, at 37 °C, the pH optimum is 7.4 to 7.8, NADH 300 µmol/L, and pyruvate 0.85 mmol/L. The optimal pH varies with the predominant isoenzymes in the sample and depends on the temperature and on substrate and buffer concentrations. The specificity of the enzyme extends from L-lactate to various related 2-hydroxyacids and 2-oxo-acids. The catalytic oxidation of 2-hydroxybutyrate, the next higher homolog of lactate, to 2-oxobutyrate is referred to as 2-hydroxybutyrate dehydrogenase (HBD) activity. LD does not act on D-lactate, and only NAD^+ serves as a coenzyme.

The enzyme has a molecular weight of 134,000 Da and is composed of four peptide chains of two types: M (or A) and H (or B), each under separate genetic control. The structures of LD-M and LD-H are determined by loci on human chromosomes 11 and 12, respectively. The subunit compositions of the five isoenzymes, in order of decreasing anodal mobility in an alkaline medium, are LD-1 (HHHH; H_4); LD-2 (HHHM; H_3M); LD-3 (HHMM; H_2M_2); LD-4 (HMMM; HM_3); and LD-5 (MMMM; M_4). A different, sixth LDH isoenzyme, LD-X (also called LDH_C), composed of four X (or C) subunits, is present in postpubertal human testes. A seventh LD, called LD-6, has been identified in the sera of severely ill patients.

LD is inhibited by reagents with reactivity against thiol groups, such as mercuric ions and *p*-chloromercuribenzoate, the inhibition being reversed by the addition of cysteine or glutathione. Borate and oxalate inhibit by competing with lactate for its binding site on the enzyme; similarly, oxamate competes with pyruvate for its binding site. Both pyruvate and lactate in excess inhibit enzyme activity, although the effect of pyruvate is greater. Inhibition by either substrate is greater for the H form than for the M form, and substrate inhibition decreases with increases in pH. EDTA inhibits the enzyme perhaps by binding Zn^{2+}; however, the postulated activator role for zinc ions is not fully established.

LD activity is present in many cells of the body and is invariably found only in the cytoplasm of the cell. Enzyme concentrations in various tissues are about 1500 to 5000 times greater than those physiologically found in serum. Therefore, leakage of the enzyme from even a small mass of damaged tissue increases the observed serum activity of LD to a significant extent. Different tissues show different isoenzyme composition. In the heart, kidneys, and erythrocytes, the electrophoretically faster moving isoenzymes LD-1 and LD-2 predominate, whereas in liver and skeletal muscle, the more cathodal LD-4 and LD-5 isoenzymes predominate—although skeletal muscle damage may also result in anodic LD patterns. Isoenzymes of intermediate mobility account for the LD activity from many sources (e.g., spleen, lungs, lymph nodes, leukocytes, platelets).

Clinical Significance

Because of its wide tissue distribution, serum LD elevations occur in a variety of clinical conditions, including myocardial infarction, hepatitis, hemolysis, and disorders of the kidneys, lung, and muscle. Serum LD measurement is, however, relevant only in hematology and oncology.[28]

Hemolytic anemias significantly increase LD concentrations in serum. Marked elevations of LD activity—up to 50 times the upper reference limit—have been observed in the megaloblastic anemias. These anemias, usually resulting from the deficiency of folate or vitamin B_{12}, cause the erythrocyte precursor cell to break down in the bone marrow (ineffective erythropoiesis), resulting in the release of large quantities of LD-1 and LD-2 isoenzymes. These elevations rapidly return to normal after appropriate treatment. For monitoring purposes, LD is relevant in predicting disease activity in leukemia, and the survival rate (probability of survival) and duration in Hodgkin's disease and non-Hodgkin's lymphoma.

Patients with malignant disease often show increased LD activity in serum; up to 70% of patients with liver metastases and 20 to 60% of patients with other nonhepatic metastases (e.g., lymph nodes) have elevated LD activity. Notably elevated LD-1 is observed in germ cell tumors (≈60% of cases) such as teratoma, seminoma of the testis, and dysgerminoma of the ovary.[92] The percentage of patients with increased LD depended on the stage of the disease. LD appears to be a useful predictor of outcome in patients with testicular nonseminomatous germ cell tumors, melanoma, and small cell lung cancer.

Elevations of LD activity (predominant LD-4 and LD-5 isoenzymes) are observed in liver disease, but their routine use in a liver profile appears limited and would not appear to add significantly to the aminotransferase activity investigation.

Macro-LD, usually due to the formation of an autoantibody-enzyme complex that leads to a persistent increase in the amount of circulating enzyme, has been estimated to occur in <1 in 10,000 people. Documentation of a macro-LD (e.g., by the presence of an abnormally migrating band at electrophoresis) should be established in suspected individuals to avoid additional follow-up investigation or unnecessary treatment.

Methods for Determination of Lactate Dehydrogenase Activity

Routine methods for quantitation of total LD activity use kinetic spectrophotometry to measure the interconversion of

the coenzyme NAD^+ and NADH at 340 nm. The most widely used procedures employ the L → P reaction, because it is claimed that there is less dependence on the NAD^+ and lactate concentrations and less contamination of NAD^+ with inhibiting products.[4] An L → P reference method, optimized for LD-1, has been developed by the IFCC as a reference procedure for LD at 37 °C.[77]

Serum is the preferred specimen for measuring LD activity. Plasma samples may be contaminated with platelets, which contain high concentrations of LD. Serum should be separated from the clot as soon as possible after the specimen has been obtained. Hemolyzed serum must not be used because erythrocytes contain 4000 times more LD activity than does serum. The different isoenzymes vary in their sensitivity to cold, LD-4 and LD-5 being especially labile. Activity of LD-4 and LD-5 is lost if the samples are stored at −20 °C. Thus serum specimens should be stored at room temperature, at which no loss of activity occurs for at least 3 days.

Reference Intervals

The reference interval for LD activity in adult white subjects, determined at 37 °C with a procedure traceable to the IFCC reference method, was found to be 125 to 220 U/L.[53] LD reference limits are higher in children, with a gradual decrease noted over the whole childhood period.[25]

Methods for Separation and Quantification of Lactate Dehydrogenase Isoenzymes

Electrophoretic separation on agarose gels or cellulose acetate membranes is the procedure most commonly used to demonstrate LD isoenzymes. After the isoenzymes have been separated by electrophoresis, a reaction mixture is layered over the separation medium (typically D,L-lactate, 500 mmol/L, and NAD^+, 13 mmol/L, often dissolved in a suitable pH 8.0 buffer). The NADH generated over the LD zones is detected by its fluorescence, when excited by long-wave ultraviolet light (365 nm), or by its reduction of a tetrazolium salt to form a colored formazan.

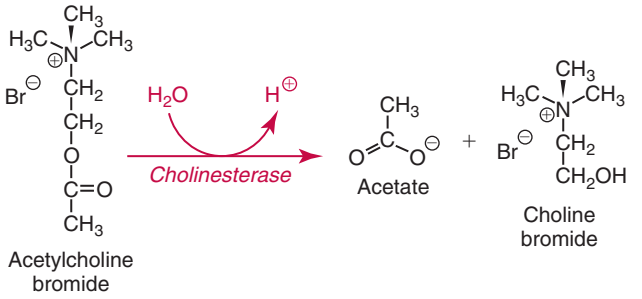
Using an agarose gel technique with fluorometric quantitation of generated NADH, the following reference intervals for isoenzymes were obtained (expressed as percent of total LD): LD-1, 14 to 26%; LD-2, 29 to 39%; LD-3, 20 to 26%; LD-4, 8 to 16%; and LD-5, 6 to 16%.

Cholinesterase

Two related enzymes have the ability to hydrolyze acetylcholine. One is acetylcholinesterase (EC 3.1.1.7; acetylcholine acetylhydrolase), which is called *true cholinesterase* or *choline esterase I.* True cholinesterase is found in erythrocytes, the lungs and spleen, nerve endings, and the gray matter of the brain. It is responsible for the prompt hydrolysis of a cetylcholine released at the nerve endings to mediate transmission of the neural impulse across the synapse. Degradation of acetylcholine is required for depolarization of the nerve, so that it is repolarized in the next conduction event.

The other cholinesterase is acylcholine acylhydrolase (EC 3.1.1.8; acylcholine acylhydrolase; CHE), also called pseudocholinesterase, serum cholinesterase, butyrylcholinesterase, or choline esterase II, which is found in the liver, pancreas, heart, white matter of the brain, and serum. Although CHE activity in the human body is about threefold higher than acetylcholinesterase activity, its exact biological role is unknown. A physiologic role for CHE in deactivation of octanoyl ghrelin, a hormone that stimulates feeding and promotes weight gain through its metabolic actions, has been proposed.

The type of reaction catalyzed by both cholinesterases is shown:



The two enzymes differ in specificity toward some substrates while behaving similarly toward others. The serum enzyme acts on benzoylcholine but cannot hydrolyze acetyl-β-methylcholine; the red cell enzyme acts on the latter but not on the former. The red cell enzyme splits only choline esters; aryl and alkyl esters are not attacked. The red cell enzyme is inhibited by its substrate, acetylcholine, if present at about 10^{-2} mol/L; the serum enzyme is not inhibited by this substrate.

The two enzymes are inhibited by the alkaloids prostigmine and physostigmine, both of which contain quaternary nitrogen (present in choline) in their structures. These two compounds are typical competitive inhibitors, competing with the choline residue of acetylcholine for its binding site on the enzyme surface. Some organic phosphorous compounds, such as diisopropyl fluorophosphate, irreversibly inhibit both enzymes. The phosphoryl group binds very tightly to the enzyme site at which binding of the acyl group normally occurs, thus preventing attachment of the acetylcholine. Both enzymes are also inhibited by a large variety of other compounds, including morphine, quinine, tertiary amines, phenothiazines, pyrophosphate, bile salts, citrate, fluoride, and borate.

CHE in normal sera is separated by electrophoresis into 7 to 12 bands, the number depending on the experimental technique used. The forms of CHE differ in molecular size and appear to be aggregates of different numbers of the same basic unit. Of greater interest are the atypical (genetic) variants of the enzyme, characterized by diminished activity against acetylcholine and other substrates, which are found in the sera of a small fraction of apparently healthy people.

The gene controlling the synthesis of CHE can exist in many allelic forms. Four of the most common forms are designated as E^u, E^a, E^f, and E^s. These four allelic genes can be combined to form one normal and nine abnormal genotypes. At least 40 other forms exist and another gene locus is recognized (E_2). The normal, most common phenotype is designated as E^uE^u, or UU (u for *usual*). The gene E^a is referred to as the *atypical* gene; the sera of people homozygous for this gene (E^aE^a = AA) are only weakly active toward most substrates for CHE and demonstrate increased resistance to inhibition of enzyme activity by dibucaine. The E^f gene (f for *fluoride resistant*) gives rise to a weakly active enzyme but with increased resistance to fluoride inhibition. The E^s gene (s for *silent*) is associated with the absence of enzyme or the presence of a protein with minimal or no catalytic activity. Mutations that give rise to the atypical and fluoride-resistant CHE variants involve a change in the structure of the active center. The variant enzymes (allelozymes) are less effective catalysts than the usual form; the affinity of the enzymes for the substrates is reduced (i.e., K_m is increased), and affinity for competitive inhibitors, such as dibucaine or fluoride, is similarly decreased. This gives rise to the characteristic dibucaine- or fluoride-resistant properties of the genetic variants that are exploited in their characterization.

Homozygous forms, AA and FF, are found in 0.3 to 0.5% of the white population; their incidence among blacks is even lower. Inheritance of increased CHE activity has been reported in a few families. This is apparently due to increased production of the usual allelozyme.

Clinical Significance[40]

Measurements of CHE activity in serum are used (1) as a test of liver function, (2) as an indicator of possible insecticide poisoning, and (3) for the detection of patients with atypical forms of the enzyme who are at risk for prolonged responses to certain muscle relaxants used in surgical procedures.

Measurement of serum CHE activity can serve as a sensitive indicator of the synthetic capacity of the liver. In the absence of genetic causes or known inhibitors, any decrease in CHE activity reflects impaired synthesis of the enzyme by the liver. Serial measurement of CHE has been promoted as an indication of prognosis in patients with liver disease and for monitoring liver function after liver transplantation.

Among the organic phosphorous compounds that inhibit cholinesterase activity are many insecticides, such as parathion, sarin, and tetraethyl pyrophosphate. Workers in agriculture and in organic chemical industries may be subject to poisoning by inhalation of these materials or by direct contact with them. Obviously, if enough material is absorbed to inactivate all the acetylcholinesterase of nervous tissue, death will result. Both cholinesterases are inhibited, but the activity of the serum enzyme falls more rapidly than does that of the erythrocyte enzyme. A 40% drop in CHE activity occurs before the first symptoms are felt, and a drop of 80% is required before neuromuscular effects become apparent. Near-zero concentrations of enzyme activity require emergency treatment with enzyme reactivators such as pyridine-2-aldoxime. Upon retesting, in 3 to 5 days, CHE activity should increase by 15 to 20% if a significant organophosphate-induced inhibition has occurred previously.

Succinyldicholine (suxamethonium) and mivacurium, drugs used in surgery as muscle relaxants, are hydrolyzed by CHE, and their pharmacologic effect normally persists only long enough to meet the needs of the surgical procedure. In patients with low enzyme activities or in those with a weakly active variant, destruction of the drug will not occur rapidly enough, and the patient may enter a period of prolonged paralysis of the respiratory muscles (apnea) requiring mechanical ventilation until the drug effects gradually wear off. Preoperative screening of CHE activity has been advocated to identify patients in whom suxamethonium administration may lead to complications. The degree of drug sensitivity varies with the phenotype of the patient. Total CHE activity is highest in individuals who are homozygous for the usual allele and progressively lower in those who are heterozygous for the usual and a variant allele, those who are homozygous or heterozygous for variant alleles, and those in whom two "silent" alleles are paired and no activity is detected. Subjects who possess one normal allele (i.e., who are heterozygous for the normal and a variant allele) usually produce enough enzyme to protect themselves against suxamethonium sensitivity, whereas patients with paired variant alleles (as homozygotes or heterozygotes) show various degrees of sensitivity. The phenotypes most susceptible to apnea after succinylcholine administration include AA, AS, FF, FS, SS, AF, and to some extent UA. Measurements of total CHE activity and determination of the "dibucaine number" and "fluoride number" are needed to fully characterize CHE variants. The latter values indicate the percentage inhibition of enzyme activity toward specified substrates in the presence of standard concentrations of dibucaine or fluoride. Mutation genotyping may confirm CHE gene abnormalities.

Methods for Determination of Serum Cholinesterase Activity

Many of the contemporary methods use acylthiocholine esters as substrates. The iodide salts of acetylthiocholine, propionylthiocholine, butyrylthiocholine, benzoylthiocholine, and succinylthiocholine all have been used. These substrates are hydrolyzed at approximately the same rate as choline esters, and the thiocholine formed can be measured by reaction with chromogenic disulfide agents, such as 5,5′-dithio-bis(2-nitrobenzoate) (DTNB) (Ellman's reagent). The reaction of the thiocholine product with colorless DTNB forms colored 5-mercapto-2-nitro-benzoic acid, which is measured spectrophotometrically at 410 nm. The clinical question being asked may influence the choice of substrate suitable for measuring the enzyme. Measuring CHE activity using succinyldithiocholine is the method of choice to diagnose succinylcholine sensitivity, purely based on the enzyme activity recorded in serum. This method

is, however, well suited for other clinical applications of the test.[44]

Kalow and Genest, using benzoylcholine as a classic substrate, demonstrated the qualitative difference in CHEs. Based on differences such as sensitivity to inhibition by the local anesthetic dibucaine, they developed a simple test to classify the type of CHE as usual, intermediate, or atypical. With 10^{-5} mol/L dibucaine ("dibucaine number"), the usual CHE is inhibited by 80%, but atypical CHE is inhibited by only 20%. Subjects heterozygous for the normal and atypical gene show about 60% inhibition of CHE. To differentiate other genotypes, sodium fluoride can be used as a CHE inhibitor. Molecular biological methods that can be used to identify various CHE genetic defects have been developed and are being used increasingly in clinical laboratories.

Serum is the sample of choice. Enzyme activity in serum is stable for several weeks if the specimen is stored under refrigeration, and for several years if stored at −20 °C. Moderate hemolysis does not interfere if separated serum has been centrifuged to remove red blood cell ghosts.

Reference Intervals

Using the succinyldithiocholine/DTNB method at 37 °C, the reference interval for healthy adults with the usual CHE genotype was estimated to be 33 to 76 U/L for women and 40 to 78 U/L for men, respectively. The median activity in individuals with heterozygous genotype was 22 U/L (range, 5 to 35 U/L), and for atypical homozygotes 1.5 U/L (range, 1 to 4 U/L).[62] A value <23 U/L was approximately five times as likely to occur in a succinyldicholine-sensitive individual as in a normal one.[44] At birth, CHE activity is lower than adult values by about 50%. It increases during the next 3 to 6 years to exceed adult values by about 30%. From the fifth year of life, the activity starts to decrease before it stabilizes at the adult value, which is reached at puberty. The significant CHE decrease (30%) during pregnancy and early puerperium is explained by hemodilution.

CHE phenotyping, based on determination of dibucaine (DN) and fluoride (FN) numbers, has been established:

Phenotype	DN Range	FN Range
UU	≥77	≥55
UF	72-76	≥53
UA	48-72	≥44
AF	45-59	<44
FF	64-69	<44
AA	<35	*

*Redundant for AA phenotype attribution.

ENZYMES AS CARDIOVASCULAR RISK MARKERS

Several cells typical for atherosclerotic plaque secrete enzyme molecules that mirror plaque destabilization and rupture. Their concentrations in the circulation have been shown to be associated with future cardiovascular (CV) events.

Lipoprotein-Associated Phospholipase A_2

Lipoprotein-associated phospholipase A_2 [EC 3.1.1.47; platelet-activating factor (PAF) acetylhydrolase; Lp-PLA_2], a 45,400 Da monomeric protein, is a Ca^{2+}-independent member of the phospholipase A_2 superfamily. It is produced mainly by monocytes, macrophages, T lymphocytes, and mast cells and has been found to be upregulated in atherosclerotic lesions, especially in complex plaque prone to rupture. Lp-PLA_2 has proatherogenic properties by promoting modification of oxidized LDLs. In particular, the enzyme cleaves oxidized phosphatidylcholine components of the lipoprotein particle, generating two potent proinflammatory and proatherogenic mediators, namely, lysophosphatidylcholine (lysoPC) and oxidized free fatty acids. LysoPC serves as a potent chemoattractant for T cells and monocytes, promotes endothelial dysfunction, and stimulates macrophage proliferation, thus enhancing lesion progression.[96]

Clinical Significance

Several prospective epidemiologic studies have reported an association between increased plasma concentrations of Lp-PLA_2 and future coronary and cerebrovascular events.[1] The strength of association varies and is generally modest (hazard ratios <2). However, because some controversy persists as to its independence from LDL cholesterol, no clear recommendation on Lp-PLA_2 clinical usefulness can be given until definitive data document its incremental value above and beyond traditional CV risk factors. Furthermore, no data show that Lp-PLA_2 reduction improves clinical outcomes. Unlike other emerging CV risk markers, Lp-PLA_2 is not an acute-phase reactant and, thus, is unaffected by systemic inflammatory processes.

Methods for Determination of Lipoprotein-Associated Phospholipase A_2

Risk estimates were similar, whether the mass concentration or the activity of the enzyme was measured. A manual ELISA method for Lp-PLA_2 mass concentration has received U.S. Food and Drug Administration (FDA) clearance for use as an aid in CV risk prediction. An immunoturbidimetric method that uses the same monoclonal antibodies has become commercially available, allowing the assay to be run on automated chemistry analyzers. A panel of national experts has recommended that an Lp-PLA_2 concentration >200 µg/L be used as the threshold for higher risk of CV events.

EDTA plasma is the recommended sample for measuring Lp-PLA_2. Average stabilities are up to 4 hours at ambient temperature, 12 hours at 4 °C, and 6 months at −20 °C.

Myeloperoxidase

Myeloperoxidase (EC 1.11.1.7; donor, hydrogen peroxide oxidoreductase; MPO), a member of the heme peroxidase superfamily, is a tetrameric hemoprotein (MW 144,000 Da) consisting of a pair of heavy (57 kDa) and light (15 kDa) chains. It is stored in azurophilic granules of polymorphonuclear neutrophils and monocytes-macrophages and, when released (typically with inflammation), catalyzes the

conversion of chloride anion and hydrogen peroxide to hypochlorite (HOCl), a metal ion–independent chlorinating oxidant that possesses potent microbicidal activity, thus having a role in host defense against pathogens.

Paradoxically, MPO may have a causative role in plaque destabilization through its ability to activate latent metalloproteinases (MMPs). Infiltrating macrophages and neutrophils participate in the transformation of stable coronary artery plaques to unstable lesions with a thin fibrous cap through secretion of MMPs and MPO, which degrade the collagen layer that protects atheromas from erosion or abrupt rupture. As a result, plaques that have been highly infiltrated with macrophages have a thin fibrous cap and are vulnerable to erosion or rupture, converting late-stage atherosclerosis into acute CV events. MPO could also be involved in the development of endothelial dysfunction because MPO uses the atheroprotective endothelial nitric oxide as a substrate, thus reducing its bioavailability. Finally, MPO-dependent halides, tyrosyl radicals, and reactive nitrogen species may generate proatherogenic oxidized LDLs, thereby promoting subsequent foam cell formation. This combination of detrimental effects has culminated in the concept that MPO may be an active mediator in atherosclerotic CV disease.[51]

MPO is released into the extracellular fluid and general circulation during inflammatory conditions.

Clinical Significance

Several epidemiologic studies indicate that MPO concentrations in plasma may be an important CV risk marker, especially in patients with unstable coronary artery disease. However, uncertainty remains about the additional benefits conferred by MPO beyond those of standard cardiac biomarkers such as troponin.[73]

Increased MPO is not likely to be specific to cardiac disease, as activation of neutrophils and macrophages can occur in any infectious, inflammatory, or infiltrative disease process.

Methods for Determination of Myeloperoxidase

MPO activity has been measured in blood and tissues by assays using hydrogen peroxide and *o*-dianisidine dihydrochloride as substrates. Mass assays based on sandwich ELISA methods have been developed and made commercially available. One of these assays has been approved by the FDA for use in conjunction with clinical history, electrocardiography, and other cardiac biomarkers to evaluate patients presenting with chest pain at risk of major adverse cardiac events. This assay has been licensed to three other companies and has been made suitable for automated platforms or point-of-care instruments.

MPO is reasonably stable, and EDTA is the preferred anticoagulant.[82] MPO is continuously released from white blood cells in heparinized blood with a spurious increase in MPO concentrations when blood collection tubes are left standing at room temperature. Higher MPO concentrations can also be found in serum owing to leakage of enzyme from leukocytes during coagulation. Samples from individuals positive for anti-MPO antineutrophil cytoplasmic autoantibodies (ANCAs) can show spuriously decreased MPO concentrations.

Reference Intervals

An MPO concentration of 640 pmol/L was reported as the upper reference limit, which is not influenced by gender or age. It should be noted that different assays using different MPO antigens for calibration may generate different results.

Pregnancy-Associated Plasma Protein A

Pregnancy-associated plasma protein A (EC 3.4.24.79; pappalysin-1; PAPP-A) is a high molecular mass (≈200,000 Da) zinc-binding glycoprotein mainly synthesized by the placental syncytiotrophoblast and typically measured during pregnancy for screening of Down syndrome. It was reported to be an insulin-like growth factor (IGF)-dependent IGF-binding protein (IGFBP)-4– and IGFBP-5–specific metalloproteinase produced by different activated cells in unstable plaques and released into the extracellular matrix, thus potentially a proatherosclerotic molecule, through its role in disrupting the integrity of the protective fibrous cap of the atheroma.

In pregnancy, PAPP-A circulates in a heterotetrameric complex consisting of two PAPP-A subunits covalently bound with two subunits of the proform of eosinophil major basic protein (proMBP), its endogenous inhibitor. However, PAPP-A present in human fibroblasts and released during atherosclerotic plaque disruption seems to be in a homodimeric active form, uncomplexed with the inhibitor proMBP (free PAPP-A). This makes it difficult to measure PAPP-A as a CV risk marker with immunoassays that have been designed to detect molecules in pregnancy serum using a sandwich formed by two antibodies: one specific for PAPP-A and one specific for proMBP.[2]

Clinical Significance

Increased PAPP-A concentrations in serum may represent a marker for adverse CV events in both acute coronary syndrome (ACS) and chronic stable angina patients. Unfortunately, the use of assays using different combinations of antibodies by different researchers has led to some controversy regarding the importance of this potential marker of plaque instability. Furthermore, no studies have demonstrated a clear improvement in discrimination or reclassification ability with the use of PAPP-A measurements.[11] In a study evaluating total PAPP-A (free and complex bound) in noncardiac conditions, the marker was increased in one fifth of patients admitted to the hospital with diagnoses other than ACS.[32]

Methods for Determination of Pregnancy-Associated Plasma Protein A

Although it has been suggested that the most appropriate method for analysis would be based on specific detection of the free PAPP-A molecule, most clinical studies evaluating

PAPP-A as a CV risk marker were performed using assays mostly measuring PAPP-A/proMBP complexes. Direct methods are not currently available, as they require antibodies that react exclusively with free PAPP-A. An alternative approach has been to perform two assays in conjunction: one that specifically detects total PAPP-A (free and complexed), and another that specifically detects the PAPP-A-proMBP complex, with the difference representing free PAPP-A. Another approach may be to analyze the enzymatic activity of PAPP-A, which is thought to represent activity of the free molecule only.

Only serum should be used as a sample for measuring PAPP-A, because heparin and other anticoagulants (e.g., EDTA) affect the apparent concentration of PAPP-A in body fluids.[2]

Reference Intervals

Using the previously described two-assay approach, median activities (interquartile range) of free PAPP-A were 0.18 mIU/L (0.63) in serum samples from apparently healthy individuals. Enzyme activities did not correlate with age but were significantly higher in men than in women.[95] However, use of this indirect approach cannot accurately measure the very low activities of the marker found in cardio-healthy people.

CHAPTER 23

Enzymes of the Red Blood Cell

Wouter W. van Solinge, Ph.D., and Richard van Wijk, Ph.D.

Erythrocytes perform a variety of functions, the most important being the binding, transport, and delivery of oxygen to all tissues. To do so, they must be capable of passage through microcapillaries—a feat that is achieved by modifications of the erythrocyte's biconcave shape. This shape change is possible because, unlike most other cells in the body, the human erythrocyte loses its nucleus and organelles before entering the circulation from the marrow. In addition, remaining RNA in the reticulocyte is lost within the first 2 days in circulation, thereby making further protein synthesis no longer possible.

Normal human red cells survive in the circulation for approximately 120 days, using energy to maintain the electrolyte gradient between plasma and red cell cytoplasm and to keep hemoglobin and the sulfhydryl groups of red cell enzymes and membrane proteins in the reduced state. Because of the absence of a nucleus and mitochondria, the red cell is incapable of generating energy via the (oxidative) Krebs cycle and depends mainly on the anaerobic conversion of glucose by the Embden-Meyerhof pathway (EMP, or direct glycolytic pathway) and the oxidative hexose monophosphate pathway (HMP, or pentose phosphate shunt) (Figure 23-1). Numerous red cell enzymes are involved in these pathways, thereby providing the cell with the necessary high-energy phosphates (primarily ATP) and reducing power (NADH, NADPH).

Deficiencies of any of these red cell enzymes may result in impaired ATP generation or the inability to withstand oxidative stress and, consequently, loss of function of the erythrocyte. By far, a majority of these disorders are hereditary in nature, although acquired deficiencies have been described, mainly in malignant disorders involving the bone marrow.[37] Hereditary enzymatic defects in these pathways are able to (1) disturb the erythrocyte's integrity, (2) shorten its survival, and (3) produce hereditary nonspherocytic hemolytic anemia (HNSHA). In general, deficiencies of enzymes involved in ATP generation lead to chronic hemolytic anemia. Other enzyme deficiencies cause acute episodes of severe hemolysis [e.g., when oxidative stress on the red cell is increased (as in some types of glucose-6-phosphate dehydrogenase deficiency)]. Red cell morphology is, in general, unremarkable, except for the case of pyrimidine-5′-nucleotidase deficiency, which is characterized by prominent stippling (see later).

Many of these enzymes are expressed in other tissues as well but cause notable symptoms predominantly in red blood cells because of the long life span of the erythrocyte after loss of protein synthesis. Once an enzyme is degraded or otherwise becomes nonfunctional, it cannot be replaced by new or other "compensating" proteins because of the lack of a nucleus, mitochondria, ribosomes, and other cell organelles in mature red cells.

Disorders have been described in EMP, HMP, the Rapoport-Luebering cycle, the glutathione pathway (Figure 23-2), purine-pyrimidine metabolism, and methemoglobin reduction. This section describes the clinically important red cell enzymes involved in these metabolic pathways and the disorders associated with defects in these pathways. In addition, diagnostic strategies and pitfalls of laboratory diagnostics for these enzyme deficiencies are explained. The laboratory methods described have been used for decades and are well documented. During the past few years, however, molecular diagnostics have proven to be an indispensable tool in the diagnosis of hereditary red cell enzyme deficiencies.

THE EMBDEN-MEYERHOF PATHWAY

Glucose is the energy source of the red cell. In the normal situation (without increased "oxidative stress"), 90% of glucose is catabolized anaerobically to pyruvate or lactate by the direct glycolytic pathway, or EMP. Although one mole of ATP is used by hexokinase and an additional mole of ATP by phosphofructokinase, the net gain is 2 moles of ATP per mole of glucose, because a total of 4 moles of ATP is formed per mole of glucose by phosphoglycerate kinase and pyruvate kinase. In addition, reducing energy is generated in the form of reduced nicotinamide-adenine dinucleotide in the step catalyzed by glyceraldehyde phosphate dehydrogenase. This reducing energy can be used to reduce methemoglobin

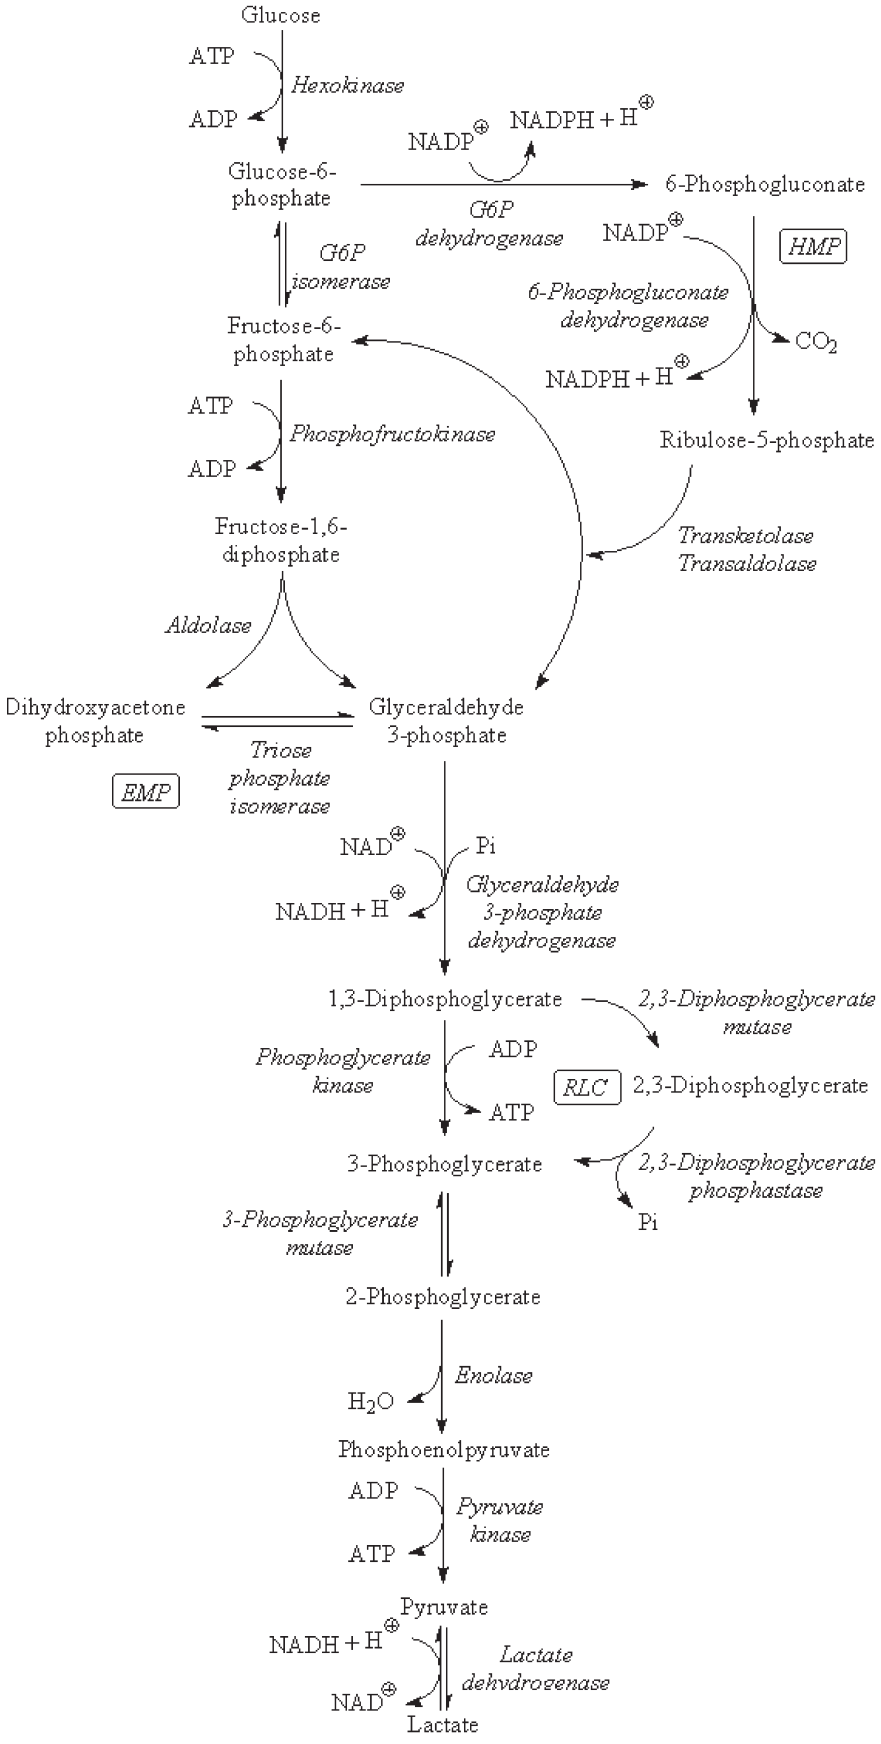

Figure 23-1 Major glycolytic pathways of the erythrocyte. Substrates are in uppercase type, and enzymes are in parentheses. *EMP*, The Embden-Meyerhof pathway; *HMP*, hexose monophosphate pathway or pentose shunt; *RLC*, the Rapoport-Luebering cycle; *ADP*, adenosine diphosphate; *ATP*, adenosine triphosphate; *NAD*$^+$, nicotinamide-adenine dinucleotide; *NADH*, reduced nicotinamide-adenine dinucleotide; *NADP*$^+$, nicotinamide-adenine dinucleotide phosphate; *NADPH*, reduced nicotinamide-adenine dinucleotide phosphate. The step from ribulose 5-phosphate, which is shown as being catalyzed by transketolase and transaldolase, is an abbreviation of this portion of the HMP. Note that diphosphoglycerate and diphosphoglyceric acid are also called bisphophoglycerate and bisphosphoglyceric acid, respectively.

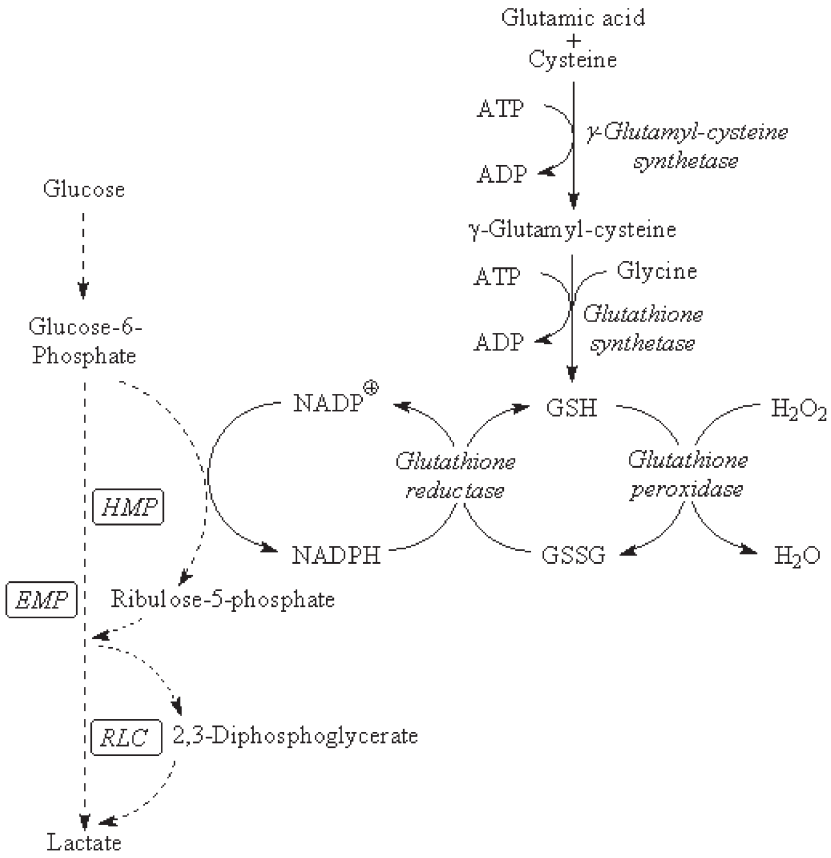

Figure 23-2 Interrelationship of hexose monophosphate and glutathione pathways. *GSH*, Reduced glutathione; *GSSG*, oxidized glutathione.

to hemoglobin by NADH-cytochrome b5 reductase. If this reaction takes place, the end product of the glycolysis is pyruvate. However, if NADH is not reoxidized here, it is used in reducing pyruvate to lactate by lactate dehydrogenase in the last step of the glycolysis.

Although the pathway is reasonably straightforward, it is subjected to a complex mechanism of inhibiting and stimulating factors. Some of the enzymes involved are allosterically stimulated by intermediates of the pathway (e.g., stimulation of pyruvate kinase by fructose diphosphate); others serve as strong inhibitors (e.g., glucose 6-phosphate for hexokinase).

Hexokinase

Hexokinase (HK; EC 2.7.1.1) catalyzes the phosphorylation of glucose to glucose 6-phosphate using ATP as a phosphoryl donor. The activity of HK is significantly higher in reticulocytes than in mature red cells, where it is very low. The HK reaction is one of two rate-limiting steps in this pathway, the other being the phosphofructokinase reaction.

In mammalian tissues, four isozymes of HK with different enzymatic properties exist: HK-I to III with an M_r of 100 kDa, and HK-IV (or glucokinase) with an M_r of 50 kDa. HK-I is the predominant HK isozyme in tissues that depend strongly on glucose for their physiologic functioning, such as brain, muscle, and erythrocytes. HK-I displays unique regulatory properties in its sensitivity to inhibition by physiologic concentrations of the product G6P and, moreover, relief of this inhibition by inorganic phosphate and by high concentrations of glucose.[194] In addition, the enzyme depends on magnesium. HK-I is a homodimer,[7,124] and elucidation of the structures of human and rat HK-I has provided substantial insight into ligand-binding sites and subsequent modes of interaction.[5-7,124,164]

Apart from HK-I, erythrocytes contain a specific subtype of HK: HK-R.[125] Both HKs are encoded by the gene *HK1*, localized on chromosome 10q22 and spanning more than 130 kb.[9] The structure of *HK1* is complex: it encompasses 25 exons that, by tissue-specific transcription, generate multiple transcripts through alternative splicing of different 5′ exons.[9] Erythroid-specific transcriptional control results in the unique red blood cell–specific mRNA that differs from HK-I mRNA at the 5′-untranslated region (5′-UTR) and at the first 63 nucleotides of the coding region.[126,127,158] Consequently, HK-R lacks the porin-binding domain that mediates HK-I binding to mitochondria.[127]

HK deficiency (OMIM 235700)* is a rare, recessively inherited disease with chronic nonspherocytic hemolytic anemia as the predominant clinical feature. The phenotypic expression of the disease is heterogeneous, as with most glycolytic red cell enzyme deficiencies. The spectrum ranges from severe neonatal hemolysis and death to a fully compensated chronic hemolytic anemia. In general, patients benefit from splenectomy. Because HK activity is dependent on red cell age, reticulocytosis, usually present in HK-deficient patients, may obscure the enzyme deficiency. Other age-dependent red cell enzymes (e.g., pyruvate kinase, G6PD) should be measured simultaneously as an internal control to assess the influence of reticulocyte enzyme activity. The *Downeast anemia* mutation in mice represents an animal model of generalized HK deficiency.[142]

Eighteen families with HK deficiency have been described to date, and gene changes have been characterized in only four patients.[32,33,56,90,186] Three amino acid substitutions in HK are known to date to affect enzyme stability (p.Leu529Ser)[32,33] or the enzyme's active site (p.Thr680Ser).[186] The third missense mutation encodes an p.Arg93Gln change and causes aberrant pre-mRNA processing of the *HK1* transcript.[56] A lethal case of HK deficiency was found to be due to an intragenic deletion of 9.5 kb, causing the deletion of exons 5 to 8 of *HK1,* resulting in a null allele.[90] An intriguing mutation was identified in the erythroid-specific promoter. This single NT change downregulates erythroid-specific transcription of *HK1* and, hence, specifically affects HK-R production.[56]

Glucose-6-Phosphate Isomerase

G6P isomerase (GPI; EC 5.3.1.9) [also known as phosphoglucose isomerase (PGI)], catalyzes the interconversion of G6P and fructose 6-phosphate (F6P)—the second step of the EMP. As a result of this reversible reaction, products of the hexose monophosphate pathway can be recycled to G6P. Besides being a housekeeping enzyme of glycolysis, monomeric GPI is identical to neuroleukin and as such exerts lymphokine properties.[101,168] In addition, autoantibodies against GPI seem to be involved in rheumatoid arthritis.[159]

The crystal structure of human GPI has been resolved. The enzyme is a homodimer consisting of two subunits of 63 kDa each. The dimeric form of GPI is a prerequisite for catalytic activity because the active site of the enzyme is composed of polypeptide chains from both subunits.[50,145]

The gene encoding GPI *(GPI)* is located on chromosome 19q13.1 and consists of 18 exons, spanning at least 50 kb, with a cDNA 1.9 kb in length.[197]

GPI deficiency (OMIM 172400) is an autosomal recessive disease and, after G6PD and PK deficiency, the third most common red cell enzymopathy. Patients are homozygous or compound heterozygous, showing mild to severe chronic hemolytic anemia. Neonatal death,[80] hydrops fetalis,[115,144] neurologic symptoms, and granulocyte dysfunction[162] have been reported. The phenotype of homozygous GPI-deficient mice resembles that of human enzymopathy.[120] GPI knockout mice die in the embryologic state.[192]

Usually a marked reticulocytosis is seen. Unlike HK, GPI activity in reticulocytes is only marginally higher than that in older cells. Patients generally benefit from splenectomy.

More than 50 families with GPI deficiency have been described worldwide.[47,102,145,148,149] Most mutations are missense mutations, but nonsense and splice-site mutations have also been reported.[102] Using the three-dimensional model of GPI, many of the missense mutations illustrate just how critical the precise three-dimensional structure is for correct function.[145,149] Most of the mutations disrupt key interactions that contribute directly or indirectly to the active site architecture.[48,145]

It is intriguing to note that combined deficiency of GPI and glucose-6-phosphate dehydrogenase appears to be associated with a more favorable clinical outcome than does either deficiency alone.[47]

Phosphofructokinase

6-Phosphofructokinase (PFK; EC 2.7.1.11) catalyzes the phosphorylation of F6P by ATP to fructose 1,6-bisphosphate (FBP; also called fructose 1,6-diphosphate, FDP). This conversion is rate limiting. The enzyme is a homotetramer or heterotetramer with a molecular mass of around 380 kDa. Three distinct subunits have been identified in humans: PFK-M (muscle), PFK-L (liver), and PFK-P (platelet). In erythrocytes, the L and M subunits are expressed; consequently, five forms of phosphofructokinase can be identified that differ in subunit composition: M_4, M_3L_1, M_2L_2, ML_3, and L_4.

The genes encoding PFK-L *(PFKL)* and PFK-M *(PFKM)* are located on chromosomes 21q22.3 and 12q13.3, respectively. The *PFKM* gene spans more than 30 kb, containing 27 exons and at least 3 promoter regions.[128,198]

PFK deficiency is a rare autosomal, recessively inherited disorder. Because red cells contain both M and L subunits, mutations affecting either of the genes coding for these subunits will affect PFK activity. Thus, when the L subunit is affected, RBCs contain only M_4 PFK homotetramers and are partially PFK deficient. In such cases, patients display a mild hemolytic disorder without myopathy. However, when the M subunit is deficient, partial PFK deficiency in red blood cells is accompanied by virtually absent PFK activity in muscle. Consequently, a deficiency in the M subunit due to mutations in the *PFKM* gene causes myopathy and a mild hemolytic disorder (Tarui disease or glycogen storage disease VII, OMIM 610681). PFK-deficient red blood cells display a metabolic block at the PFK step in glycolysis and have decreased concentrations of 2,3-bisphosphoglyceric acid (2,3-BPG, also

*OMIM stands for Online Mendelian Inheritance in Man. It is a World Wide Web database (http://www.ncbi.nlm.nih.gov/omim) developed under the auspices of the National Center for Biotechnology Information (NCBI). It consists of a catalog of human genes and genetic disorders and contains textual information, pictures, and reference information. It also contains links to NCBI's Entre/database of MEDLINE articles and sequence information. Individual disorders may be found by entering OMIM numbers into the search engine of the database.

called 2,3-diphosphoglyceric acid, 2,3-DPG; see later). In PFK-deficient mice, marked alterations in muscle bioenergetics and erythrocyte metabolism interact to produce a complex systemic disorder, indicating that Tarui disease is not simply a muscle glycogenosis.[67]

To date, 15 different mutations associated with PFK deficiency have been identified. Most are missense mutations or mutations affecting pre-mRNA processing.[64,128] Approximately one third of PFK-deficient patients are of Ashkenazi Jewish origin. In this population, the most frequently encountered mutations are an intronic splice-site mutation in intron 5 and a single base pair deletion in exon 22.[143,165] Most other mutations are confined to unique families.

PFK is relatively unstable, and assays should be carried out on fresh blood samples.

Aldolase

Aldolase (fructose-bisphosphate aldolase; EC 4.1.2.13) catalyzes the reversible conversion of fructose 1,6-bisphosphate to glyceraldehyde 3-phosphate and dihydroxyacetone phosphate. The enzyme is a tetramer of identical subunits of 40 kDa. Three isoenzymes have been identified to date: aldolases A, B, and C. Aldolase A is the isoenzyme that is expressed in the RBC, but also in muscle and brain. The flexible C-terminal region of aldolase A has been implicated in the catalytic function of the enzyme.[53,59] Aldolase activity is markedly influenced by red cell age.

The gene for aldolase A *(ALDOA)* is located on chromosome 16p11.2. It spans 7.5 kb and contains 12 exons. Several transcription initiation sites were identified that direct tissue-specific splicing.[82]

Aldolase deficiency (OMIM 611881) is a very rare disease; only six cases have been described.[29,59,99,100,199] The hallmark of aldolase deficiency is chronic hemolytic anemia. In some patients, hemolysis is the sole clinical feature,[99] whereas in other patients, hemolytic anemia is accompanied by myopathy,[29,59,100] rhabdomyolysis,[199] psychomotor retardation,[100] or mental retardation.[29,100]

Triose-Phosphate Isomerase

Triose-phosphate isomerase (TPI; EC 5.3.1.1) is the enzyme of the anaerobic glycolytic pathway with the highest activity. This ubiquitously expressed enzyme catalyzes the interconversion of glyceraldehyde 3-phosphate and dihydroxyacetone phosphate. TPI is active as a dimer, consisting of two identical 27 kDa subunits of 248 amino acids. The three-dimensional structure of the human enzyme has been obtained by crystallography.[109] No isoenzymes are known; only three distinct electrophoretic forms attributable to minor post-translational modifications have been identified.[141,200] In red blood cells, TPI activity is not related to red cell age.

TPI is transcribed from a single gene *(TPI1),* located on chromosome 12p13. The gene spans more than 5 kb and contains 7 exons that encode the 248 amino acids–long TPI subunit.[39]

TPI deficiency (OMIM 190450) is a relatively rare autosomal recessive multisystem disorder, characterized by hemolytic anemia, severe neuromuscular defects, increased susceptibility to infection, and cardiomyopathy.[48,134,161] Patients usually die in childhood, although intriguing exceptions have been reported.[76] Because of metabolic block at the TPI step, a 20- to 60-fold increase in red blood cell concentration of dihydroxyacetone phosphate occurs.[155] Lipid abnormalities have been implicated in the complex pathogenesis of TPI deficiency.[77] To date, 14 mutations have been identified in the gene encoding TPI.[48,133] Mutations result in decreased enzymatic activity and/or dissociation of the TPI dimer into inactive monomers.[133,134] The most common mutation produces a glutamic acid-to-aspartic acid substitution of residue 104—a mutation detected in several unrelated families. Haplotype analyses suggest a single origin for this mutation with the common ancestor in Northern Europe.[160] The other mutations are detected only in individual families. Mutations have been reported in *TPI* promoter sequences of putative regulatory importance, but they exert little if any effect on TPI enzyme activity.[181]

Phosphoglycerate Kinase

Phosphoglycerate kinase (PGK; EC 2.7.2.3) catalyzes the reversible conversion of 1,3-bisphosphoglycerate (also called 1,3-diphosphoglycerate) to 3-phosphoglycerate, thereby generating one molecule of ATP. The reaction can be bypassed by the Rapoport-Luebering shunt at the expense of one molecule of ATP (see later and Figure 23-1). This alternative routing of glycolytic intermediates has been called the *energy clutch* of glycolysis.[96]

In humans, two isoenzymes (PGK-1 and PGK-2) exist. PGK-1 is ubiquitously expressed in all somatic cells; PGK-2 is expressed only in spermatozoa.[118] PGK-1 is a monomeric enzyme consisting of 417 amino acids.[78] The gene encoding PGK-1 *(PGK1)* is located on the long arm of the X chromosome (Xq13). The gene spans 23 kb and is composed of 11 exons.[122]

PGK deficiency (OMIM 311800) is one of the uncommon causes of HNSHA. Sometimes the deficiency manifests only chronic hemolytic anemia, but in many cases, other clinical findings are present, particularly mental retardation and muscle disease; these may occur with or without the anemia.[19] Twenty-eight families with clinical symptoms of severe PGK deficiency have been described, and in 20 of these families the causative mutation is known.[19,167,170] Most of the mutations are missense ones. They are all unique except for the c.491A>T (p.Asp164Val) change, which has been encountered three times, each in the context of a different haplotype,[62] suggesting independent origins of this mutation.[19] One additional PGK variant (PGK München, p.Asp268Asn) does not seem to result in any clinical or biochemical abnormalities.[63] Review of amino acid substitutions in PGK and the crystal structure of pig muscle PGK[61] revealed that most missense mutations occur in three specific regions of the molecule. No correlation could be found, however, between these different locations and clinical expression of the enzyme deficiency.[130,167] Hence, the reason for the range of manifestations in PGK deficiency remains unclear.

Pyruvate Kinase

Pyruvate kinase (PK; EC 2.7.1.40) catalyzes the conversion of phosphoenolpyruvate to pyruvate with concomitant generation of the second molecule of ATP in glycolysis (see Figure 23-1). Pyruvate is crucial for several metabolic pathways, and PK represents one of the major regulatory enzymes of glycolysis. PK is allosterically activated by its substrate and by FBP (fructose 1,6-bisphosphate), and its enzymatic activity strongly depends on red blood cell age. Therefore, because the youngest red blood cells have the highest activity, a deficiency of PK may be masked by reticulocytosis.

PK is a homotetrameric enzyme. In mammals, four isozymes are expressed: PK-M1 is expressed in skeletal muscle, heart, and brain. It is the only PK isozyme that is not allosterically regulated. PK-M2 is expressed in early fetal tissues and in adult tissues including leukocytes and platelets. Both M1 and M2 subunits are produced from a single gene *(PKM2)* by means of alternative splicing.[131,173] PK-L is predominantly expressed in the liver, whereas expression of PK-R is confined to the red blood cell.[89] The PK-L and PK-R subunits are transcribed from a single gene (*PKLR*, for pyruvate kinase, liver, and RBC) located on chromosome 1q21, by the use of tissue-specific promoters.[89,132] The *PKLR* gene consists of 12 exons and is approximately 9.5 kb in size.[104] Exon 1 is exclusively expressed in erythroid cells, whereas expression of exon 2 is confined to the liver. Hence, the PK-R monomer is composed of 574 amino acids.[88] The PK-L subunit comprises 531 amino acids.[174]

In basophilic erythroblasts, both PK-M2 and PK-R isozymes are expressed. During further erythroid differentiation and maturation, the PK-R isozyme progressively replaces PK-M2.[116,117,172] In addition, in the red blood cell, limited proteolytic degradation of the 63 kDa PK-R subunit produces a subset of PK-R monomers of 57 to 58 kDa.[86] Consequently, in young and mature human red blood cells, two distinct species can be distinguished—PK-R1 and PK-R2—that differ in PK-R and "processed" PK-R subunit composition.[187]

The crystal structure of human red cell PK has been elucidated.[184] Each PK-R subunit is composed of four domains: N, A, B, and C. The active site lies in a cleft between the A domain and the flexible B domain. The B domain is capable of rotating with respect to the A domain, generating the "open" or "closed" conformation. The C domain contains the binding site for FBP. In the PK tetramer, subunit interactions at the interfaces between A and C domains, as well as A/B and A/C domain interactions within one subunit, are considered to be key determinants of the allosteric response, involving switching from the low-affinity T-state to the high affinity R-state.[85,114,183,184,196]

Pyruvate kinase deficiency (OMIM 266200) is the most common cause of nonspherocytic hemolytic anemia caused by defective glycolysis. It is an autosomal recessive disease. In the general white population, the allelic frequency is estimated to be around 2%.[25] The prevalence appears to be higher among blacks.[123]

Two major metabolic abnormalities resulting from PK deficiency are ATP depletion and increased levels of 2,3-BPG. The precise mechanisms by which enzyme deficiency leads to a shortened RBC life span are unknown. An important feature, however, involves the selective sequestration of PK-deficient reticulocytes by the spleen.[119] In addition, metabolic disturbances may affect not only red blood cell survival but also the maturation of PK-deficient erythroid progenitors, resulting in ineffective erythropoiesis.[3,4]

PK-deficient patients display a highly variable degree of chronic hemolysis with variable clinical severity. Clinical symptoms range from severe anemia and death at birth, severe transfusion-dependent chronic hemolysis, or moderate hemolysis with exacerbation during infection, to a well-compensated hemolysis without anemia.[204] Splenectomy is, in general, beneficial.[204] PK deficiency has been treated successfully by stem cell transplantation.[175] Gene therapy strategies have been shown to be able to correct the PK-deficient phenotype in mice.[92,121]

To date, more than 190 mutations in *PKLR* have been reported to be associated with pyruvate kinase deficiency (www.pklrmutationdatabase.com). Most (70%) of these mutations are missense mutations affecting conserved residues in structurally and functionally important domains of PK. The most frequently detected mutations are missense mutants c.1456C>T (p.Arg486Trp), c.1529G>A (p.Arg510Gln), and c.994G>A (p.Gly332Ser), and nonsense mutant c.721G>T (p.Glu241X). Evaluating the protein structural context of affected residues using the three-dimensional structure of recombinant human tetrameric PK has provided a rationale for the observed enzyme deficiency and contributes to a better understanding of the genotype-to-phenotype correlation in PK deficiency.[184,185,203] It is important to note that because most PK-deficient patients are compound heterozygous for two different (missense) mutations, up to seven different tetrameric forms of PK may be present in such patients, each with distinct structural and kinetic properties. This complicates genotype-to-phenotype correlations, as it is difficult to infer which mutation is primarily responsible for deficient enzyme function and the clinical phenotype.[185]

Pyruvate kinase deficiency has a protective effect against replication of the malarial parasite in human erythrocytes.[13,58] This protective effect may be related to reduced ATP levels in PK-deficient red blood cells.[12]

Lactate Dehydrogenase

L-Lactate dehydrogenase (LD; EC 1.1.1.27) catalyzes the conversion of pyruvate to lactate—the last step in the EMP. Deficiency of this enzyme is not associated with hematologic disease. LD is described in Chapter 22.

HEXOSE MONOPHOSPHATE PATHWAY

Normally, approximately 10% of glucose is catabolized through the hexose monophosphate pathway (see Figure 23-1). The primary function of this pathway is to reduce 2

moles of $NADP^+$ to NADPH, by means of oxidizing G6P. The amount of glucose passing through this pathway is regulated by the amount of $NADP^+$ that has been made available by the oxidation of NADPH. In the red blood cell, NADPH is required mainly for the regeneration and preservation of the reduced form of glutathione (GSH), which is crucial to the cell in detoxifying hydrogen peroxide and, thereby, protecting against oxidative stress. NADPH also binds to catalase, thereby affecting its activity.[163] Because the red blood cell has no other way of generating NADPH, it depends strongly on the activity of the prime enzyme of NADPH production: glucose-6-phosphate dehydrogenase (G6PD).

Glucose-6-Phosphate Dehydrogenase

Glucose-6-phosphate dehydrogenase (G6PD; EC 1.1.1.49) is expressed in all cells and catalyzes the first step in the hexose monophosphate pathway—the conversion of glucose-6-phosphate to 6-phosphogluconolactone, which is readily converted to 6-phosphogluconate. In the process, 1 mole of NADPH is generated. G6PD activity is much higher in reticulocytes than in mature red blood cells.

The active enzyme is predominantly a homodimer that comprises 59 kDa subunits of 515 amino acids each. Lowering the pH causes a shift from the dimeric to the tetrameric form.[49] In the absence of $NADP^+$, G6PD dissociates into inactive subunits. Each G6PD subunit is built up by two domains. The extensive interface between the two monomers is of crucial importance for enzymatic stability and activity.[11] The importance of $NADP^+$ for stability is explained by the structural $NADP^+$ site, distant from the active site but close to the dimer interface.[11]

The gene coding for G6PD is located on the long arm of the X chromosome (Xq28). It spans 18 kb and consists of 13 exons. Exon 1 is noncoding. The promoter shares many features common to other housekeeping genes.[112]

G6PD deficiency (OMIM 305900) is the most common enzymopathy, affecting an estimated 400 million people worldwide. The parallel between the high frequency of G6PD deficiency and the worldwide distribution of malaria implies that G6PD deficiency confers a selective advantage.[177] This hypothesis is supported by several lines of evidence,[40,108] indicating that the uniform state of G6PD deficiency in hemizygous males, and possibly homozygous females, confers significant protection against severe, life-threatening malaria.[73,157]

G6PD variants have been grouped into five categories according to the level of enzyme activity and clinical manifestations (Table 23-1).[1] More than 400 variants and 140 different mutations have been reported, most of which encode the substitution of a single amino acid. The most common deficient variant is G6PD A–. This variant is characterized by an Asn-to-Asp substitution at codon 126 (c.376A>G), in most cases accompanied by a second mutation encoding a Val-to-Met change at codon 68 (c.202G>A). The second most common variant is G6PD Mediterranean, characterized by a Ser-to-Phe substitution at codon 188 (c.563C>T). Two other polymorphic variants are G6PD Seattle (c.844G>C; p.Asp282His) and G6PD Union (c.1360C>T; p.Arg454Cys).

TABLE 23-1 Classes of Severity of Glucose-6-Phosphate Dehydrogenase (G6PD) Deficiency[1]

Class	Description
Class I	Severe deficiency associated with chronic hemolytic anemia
Class II	Severe deficiency (<10% residual activity), usually without hemolytic anemia
Class III	Moderate to mild deficiency (10 to 60% residual activity) (e.g., G6PD A)
Class IV	Very mild or no deficiency (e.g., G6PD A)
Class V	Increased activity (only one such variant has been described—G6PD Hektoen)

The clinical expression of G6PD deficiency is heterogeneous; five different clinical syndromes can be recognized:

- Drug-induced hemolysis
- Infection-induced hemolysis
- Favism
- Neonatal jaundice (NNJ)
- Chronic nonspherocytic hemolytic anemia (CNSHA)

Most G6PD-deficient individuals are asymptomatic throughout life. They develop acute hemolysis only during periods of increased oxidative stress, elicited by certain drugs,[18] infection, or the ingestion of fava beans. Clinically, such hemolytic episodes are characterized by anemia and jaundice accompanied by increased concentrations of bilirubin and LDH in plasma and reticuloytosis. The exact mechanism by which increased oxidative stress leads to acute hemolysis is unknown, but it results from the inability of G6PD-deficient red blood cells to withstand oxidative damage induced by the triggers mentioned previously. In general, older red blood cells are more susceptible to destruction than young ones. Consequently, they are selectively removed from the circulation, characterizing a self-limited course of hemolysis.[57] The reticulocytosis that is elicited as a result of hemolysis may obscure the enzyme deficiency, as these very young red blood cells have the highest enzyme activity.

Notably, as a result of (skewed) X chromosome inactivation, heterozygous females may be susceptible to the same pathophysiologic phenotype as their hemizygous male counterparts.[30,93,156]

G6PD-deficient neonates who have coinherited a mutation in the uridine-diphosphate-glucuronosyl-transferase-1 *(UGT1A1)* promoter are particularly at risk for developing neonatal jaundice and even kernicterus.[94,205]

A small proportion of G6PD-deficient individuals display the phenotype of chronic nonspherocytic hemolytic anemia. The hemolytic anemia in these class I G6PD-deficient patients may be severe. Mutations associated with class I G6PD deficiency are clustered in exons 10 and 11, designating the subunit interface.[11]

For further reading on the extensive subject of G6PD deficiency, we refer the reader to excellent reviews.[17,41,107,189]

6-Phosphogluconate Dehydrogenase (Decarboxylating) (EC 1.1.1.44)

Even though the oxidation of phosphogluconate to ribulose 5-phosphate by 6-phosphogluconate dehydrogenase generates one mole of NADPH, the few cases of 6-phosphogluconate dehydrogenase deficiency usually are not associated with hemolysis.[42]

Transketolase

Transketolase (EC 2.2.1.1) is decreased in thiamine deficiency. Low values of it have also been found in chronic alcoholism.

RAPOPORT-LUEBERING SHUNT

Red blood cell 2,3-BPG (also called 2,3-DPG) is important in the regulation of the oxygen affinity of hemoglobin.[15,16,180] 2,3-BPG is synthesized and dephosphorylated in the Rapoport-Luebering shunt. Thus, this unique glycolytic bypass represents an important physiologic means for the regulation of oxygen affinity. At the same time, the Rapoport-Luebering shunt provides the red cell with flexibility with regard to the generation of ATP. From an oxygen transport point of view, the Embden-Meyerhof pathway serves principally the generation of 2,3-BPG, because in terms of quantity, it is the principal glycolytic intermediate: the concentration of 2,3-BPG is about equal to the sum of all other glycolytic intermediates. In PK deficiency, 2,3-BPG is increased as a result of the metabolic block at the PK step and of retrograde accumulation of products of glycolysis. Increased 2,3-BPG levels result in decreased oxygen affinity for hemoglobin, so that oxygen is more readily transferred to tissue. This beneficial circumstance is absent in those glycolytic enzyme defects that cause a decrease in 2,3-BPG levels (e.g., HK and GPI deficiency).

Both reactions in the Rapoport-Luebering shunt are catalyzed by one multifunctional protein: 2,3-BPG mutase (BPGM) (EC 5.4.2.4).[81,153] The mutase activity of this enzyme converts the glycolytic intermediate 1,3-BPG to 2,3-BPG. BPGM also has phosphatase activity (2,3-BPG phosphatase [BPGP]; EC 3.1.3.13), converting 2,3-BPG to 3-phosphoglycerate, which then re-enters the glycolytic pathway (see Figure 23-1). In addition, 2,3-BPG may be converted to 2-phosphoglycerate by multiple inositol polyphosphate phosphatase (MIPP1; EC 3.1.3.62), an enzyme that has recently been shown to expand the regulatory capacity of the Rapoport-Luebering shunt.[45]

BPGM is a homodimer with 30 kDa subunits consisting of 258 amino acids. Elucidation of the crystal structure of human BPGM has provided a structural basis for the different enzymatic activities of this enzyme.[190]

The gene for BPGM *(BPGM)* is located on chromosome 7q31-34. It consists of three exons, spanning more than 22 kb.[84] It is expressed only in erythroid tissue during the late stages of differentiation.[84]

BPGM deficiency (OMIM 222800) is a very rare autosomal recessive disorder, resulting in markedly decreased concentrations of 2,3-BPG in erythrocytes. As a result, the oxygen affinity of hemoglobin is increased, causing a decrease in tissue oxygenation and, consequently, erythrocytosis. Only a few cases of BPGM deficiency have been described, all belonging to one, clinically normal French family.[154] Two mutations have been identified in *BPGM*. One single nucleotide substitution predicts the substitution of the highly conserved Arg89 by Cys (BPGM Creteil I).[154] BPGM Creteil II is characterized by a deletion of nucleotide 205, resulting in a shift in the reading frame and, consequently, leading to a premature stop codon.[103]

GLUTATHIONE PATHWAY

Sulfhydryl-containing tripeptide-reduced glutathione (GSH) is present in high concentrations in most mammalian cells.[106] In red blood cells, GSH protects hemoglobin and other critical red blood cell proteins from peroxidative injury. In this process, which involves the reduction of peroxides or oxidized protein sulfhydryl groups, GSH is converted to GSSH (oxidized glutathione) (see Figure 23-2). Enzyme deficiencies in this pathway, except for glutathione peroxidase deficiency, lead to mild chronic nonspherocytic hemolytic anemia, accompanied by drug- and infection-induced hemolytic episodes. The pathogenesis of such enzyme deficiencies is probably similar to the hemolysis that occurs in G6PD deficiency.

γ-Glutamylcysteine Synthetase

γ-Glutamylcysteine synthetase (GCS; EC 6.3.2.2), or glutamate—cysteine ligase, catalyzes the first step in glutathione biosynthesis. The enzyme mediates the formation of γ-glutamylcysteine, ADP, and P_i from glutamate, cysteine, and ATP. This amide linking is the rate-limiting step in glutathione synthesis. There is a feedback inhibition by glutathione. γ-Glutamylcysteine synthetase is a heterodimer composed of a catalytic heavy chain (GCS_h) of 637 amino acids and 73 kDa, and a regulatory light chain (GCS_l) of 274 amino acids and 30 kDa.[69,70]

The genes for GCS_h *(GCLC)* and GCS_l *(GCLM)* are localized on chromosomes 6p12 and 1p21.1, respectively.

Hereditary γ-glutamylcysteine synthetase deficiency is an autosomal recessive disorder that is very rare. Only nine unrelated families have been described. In about half of patients given a diagnosis of γ-glutamylcysteine synthetase deficiency, hemolytic anemia appears to be accompanied by progressive neurologic manifestations.[110] Four families have been characterized at the molecular level.[26,74,110,150] The causative mutation in all these cases affected the heavy subunit of γ-glutamylcysteine synthetase. The homology model of the catalytic subunit, based on the crystal structure of *Saccharomyces cerevisiae,* has been generated to explain the molecular basis of γ-glutamylcysteine synthetase deficiency.[35]

Glutathione Synthase

Glutathione synthase (EC 6.3.2.3; GSH-S) mediates the second irreversible ATP-dependent step in the synthesis of

GSH. The enzyme catalyzes the addition of glycine to the dipeptide γ-glutamylcysteine. Glutathione synthetase is a homodimer of 52 kDa.[65]

The gene for glutathione synthase (*GSS*) is located on chromosome 20q11.2 and contains 12 exons, spanning 23 kb.[191]

Deficiency of glutathione synthetase is rare, but it is the most common abnormality of glutathione metabolism. The disorder is inherited in an autosomal recessive mode. Three distinct clinical forms of GSH-S deficiency can be distinguished on the basis of their severity.[152] The mildest form displays hemolytic anemia as the only clinical manifestation, whereas in the moderate and severe forms, hemolytic anemia is accompanied by metabolic acidosis and 5-oxoprolinuria.[166] Patients with the severe type of GSH-S deficiency develop, in addition, progressive central nervous system damage. Approximately one third of all patients died in childhood, often in the neonatal period.[151]

More than 30 mutations have been described as associated with glutathione synthetase deficiency.[51,52,129,151,166] Most of these mutations are missense ones. To some extent, the type of mutation can predict a mild versus a more severe phenotype.[129]

Glutathione Reductase

Glutathione reductase (glutathione-disulfide reductase; EC 1.8.1.7; GSR) links the glutathione pathway to the hexose monophosphate pathway through reversible oxidation and reduction of NADP.[195] The enzyme maintains high levels of reduced glutathione in the cell and requires flavin adenine dinucleotide (FAD) as a cofactor. Two GSR isoforms exist: a mitochondrial form and a cytoplasmic form, which may be produced by alternative initiation of translation.[135] The active enzyme is a homodimer, linked by a disulfide bridge. Each subunit (522 amino acids; 56 kDa) is divided into four domains, of which domains 1 and 2 bind FAD and NADPH, respectively. Domain 4 is involved in the dimer interface.[95,176]

The gene encoding GSR *(GSR)* is located on chromosome 8p21.1, spans 50 kb, and contains 13 exons.[97]

Because GSR activity is strongly influenced by diet,[20] acquired GSR deficiency is common in malnourished populations. Except when very severe, the deficiency is not associated with hemolysis. Hereditary glutathione reductase deficiency (OMIM 138300) is a very rare autosomal recessive disease. Only two families have been reported. Red blood cells of patients contained no detectable GSR enzymatic activity. Patients from one family[105] presented with favism and were found to be homozygous for a large genomic deletion of 2242 bp.[87] The patient from the other family displayed severe neonatal jaundice without hemolysis and was found to be compound heterozygous for a mutation encoding a premature stop at residue 287 and a Gly-to-Ala substitution at residue 330.[87]

Similar to other rare red blood cell disorders such as PK deficiency, GSR deficiency may provide protection against malaria.[66]

Glutathione Peroxidase

Glutathione peroxidase (GSH Px; EC 1.11.1.9) catalyzes the conversion of hydrogen peroxide to water, thus reducing peroxidative stress to proteins in the cell. It is active as a homotetrameric enzyme consisting of 21 kDa subunits and encoded by the *GPX1* gene on chromosome 3p21.3.[193] Levels of glutathione peroxidase are regulated by selenium.[75,169] Because red blood cells also have high catalase (EC 1.11.1.6) activity to convert H_2O_2 to water and O_2, the activity of GSH-Px is redundant. In fact, deficiencies of catalase or GSH-Px are without clinical consequences.[21]

Low GSH Px activities occur commonly in healthy persons in some population groups,[28] and although association with hemolysis has been reported,[28,72] a clear cause-effect relationship has not been established.

PURINE-PYRIMIDINE METABOLISM

Pyrimidines and purines are needed in the red blood cell for the formation of coenzymes and as active intermediates in carbohydrate and phospholipid metabolism. Because red blood cells cannot synthesize nucleotides de novo, they have evolved nucleotide salvage pathways to effectively preserve them from the reticulocyte stage. Except for pyrimidine 5′-nucleotidase, deficiencies of enzymes affecting these pathways appear to be without functional consequences for the red cell.[136]

5′-Nucleotidase

Pyrimidine-5′-nucleotidases make up a group of enzymes dephosphorylating pyrimidine nucleotides to the corresponding nucleosides and inorganic phosphates. These nucleosides are able to freely diffuse out of the cell; therefore, their accumulation is prevented. Two cytoplasmic forms of the enzyme were identified in the red blood cell: P5′N-1 and P5′N-2. These enzymes are encoded by different genes and have different molecular properties and substrate specificities.[8,137] Because no known disorders are associated with deficiency of P5′N-2, this enzyme will not be further discussed here.

5′-Nucleotidase-1 (P5′N-1; EC 3.1.3.5) is a monomeric 34 kDa protein consisting of 286 amino acids.[171] Enzyme activity is dependent on magnesium ions, and it has optimal substrate specificity for UMP and CMP.[202] P5′N-1 activity is highly dependent on red blood cell age. Its activity is highest in reticulocytes, and a rapid decline occurs during the first few days of maturation, followed by further decline throughout the life span of the red blood cell.[27]

The gene encoding P5′N-1 *(NT5C3)* maps to chromosome 7p14.3, spans about 50 kb, and consists of 11 exons.[111] Three transcripts are created by means of alternative splicing of pre-mRNAs. Only the 286 amino acids–long protein product can be isolated from red blood cells.[91,111]

P5′N-1 deficiency (OMIM 266120) is a relatively common cause of nonspherocytic hemolytic anemia. Its hallmark is the accumulation and precipitation of pyrimidine nucleotides, leading to a shortened red blood cell life span by as yet unknown mechanisms.[188,202] Because of the relatively mild

phenotypic expression, many cases may remain undetected.[147] The deficiency is inherited in an autosomal recessive manner. It is the only red cell enzyme deficiency in which red cell morphology is helpful: prominent and characteristic basophilic stippling is visible in blood smears from P5′N-1-deficient patients, representing the accumulation of pyrimidine nucleotides.[182]

Several reports have described mutations associated with P5′N-1 deficiency. To date, 24 patients have been characterized at the molecular level.[44] Although some mutations target different regions of the P5′N structure,[36] they produce similar effects on the molecular properties of the enzyme.[44]

Adenosine Deaminase

Adenosine deaminase (ADA; EC 3.5.4.4) is the enzyme of purine metabolism that deaminates adenosine and 2′-deoxyadenosine to inosine and 2′-deoxyinosine, respectively. Deficiency of ADA leads to severe combined immunodeficiency disease (SCID) without hemolysis.

A hereditary increase in red blood cell ADA activity (OMIM 102730) results in depletion of red cell ATP and, consequently, nonspherocytic hemolytic anemia. It is the only red blood cell enzymopathy that is inherited as an autosomal dominant disorder. Only a few cases have been described, displaying a 30-fold to 70-fold increase in ADA activity. The molecular basis of this disorder has not been elucidated. In patients, high levels of normal ADA mRNA were present, suggesting the mutation of an *in cis* transcriptional regulatory element in close proximity to the gene.[43,46]

For unknown reasons, ADA activity is also increased in patients with Diamond-Blackfan anemia.[71]

Adenylate Kinase

Adenylate kinase (AK; EC 2.7.4.3) catalyzes the reversible interconversion of the adenine nucleotides ATP and AMP to ADP. The gene for AK *(AK1)* has been localized to chromosome 9q34.1, is 12 kb in size, and consists of 7 exons. The mRNA codes for a monomeric enzyme of 194 amino acids.[113]

Adenylate kinase deficiency (OMIM 612631) is a rare autosomal recessive disorder. A small number of cases have been described, displaying moderate to severe hemolytic anemia in some patients, accompanied by mental retardation and psychomotor impairment.[34,179] Because of the absence of hemolytic anemia in a case of complete AK deficiency,[24] the causal relationship of this disorder to hemolytic anemia has been the subject of debate.[23] The study of altered properties of mutant adenylate kinases has provided support for the cause-effect relationship between AK1 mutations and hemolytic anemia.[2]

METHEMOGLOBIN REDUCTION

Hemoglobin can bind oxygen only in the reduced ferrous (Fe^{2+}) state. Thus, when hemoglobin is oxidized to the ferric (Fe^{3+}) state, the capacity to bind oxygen is lost. The oxidized state of hemoglobin, called *methemoglobin,* represents less than 1% of total hemoglobin in healthy red blood cells. To preserve oxygen-binding capacity, the red blood cell keeps hemoglobin in the reduced state. This process strongly depends on the NADH-dependent cytochrome b5/cytochrome b5 reductase system.

Cytochrome b_5 Reductase

Nicotinamide adenine dinucleotide (NADH)-cytochrome b_5 reductase (cb5r; EC 1.6.2.2;) uses the NADH generated by glyceraldehyde-3-phosphate dehydrogenase in the Embden-Meyerhof pathway to reduce the 12 kDa electron transport protein cytochrome b5. In turn, cytochrome b5 reduces methemoglobin to hemoglobin.

The enzyme is present in two different forms. The membrane-bound form is a 35 kDa protein of 301 amino acids that is anchored to the endoplasmic reticulum and the outer mitochondrial membrane.[38] The membrane form has a role in desaturation and elongation of fatty acids, cholesterol biosynthesis, and drug metabolism.[98,138,146]

The second, soluble form of cb5r is a red blood cell–specific protein of 275 amino acids.[79] The two isoforms share an identical hydrophilic C-terminal domain, but the N-terminus of the cytoplasmic form lacks the 25 hydrophobic amino acids that constitute the membrane-binding domain.[201]

Both forms of cb5r are transcribed from the *CYB5R3* gene (previously known as *DIA1*) on chromosome 22q 13-qtr. The gene is 32 kb in length and contains 9 exons.[178] Exon 1 is lacking from the red blood cell–specific mRNA.

NADH-cytochrome b5 reductase deficiency (OMIM 250800) is an autosomal recessive disorder, causing hereditary methemoglobinemia. It was the first identified hereditary enzymopathy.[68] Two distinct clinical forms (types I and II) have been detected.[140] The typically blue color of the skin—cyanosis—due to lack of oxygen in the blood is a prominent feature of both types. In patients with type I methemoglobinemia, the enzyme deficiency is confined to the red blood cells. Patients with type II deficiency are more severely affected. They seldom reach adulthood because of progressive microcephaly.[83]

More than 40 different mutations in *CYBR5R3* have been identified in association with hereditary methemoglobinemia.[10,60,139,140] Some of these mutations are common to both types of methemoglobinemia.[140] The development of a heterologous expression system[54,55] and the three-dimensional models of cb5r[14,31] has allowed the study of cb5r variants and has provided insight into the enzyme's function.

DETECTION OF HEREDITARY RED CELL ENZYME DEFICIENCIES

Other than deficiencies of G6PD and PK, red blood cell enzymopathies are rare or very rare. Therefore, no rationale has been put forth for laboratories that perform such tests only rarely to attempt to identify them. Specimens should be shipped by mail to reference laboratories that specialize in performance of these assays. As a rule, whole blood specimens anticoagulated with EDTA are suitable, and the specimens can be shipped chilled to 4 °C.[22] Exceptions are assays for phosphorylated sugar intermediates, 2,3-BPG, and

nucleotide intermediates, which are unstable in freshly drawn blood and require immediate deproteinization in perchloric acid.[22]

Care should be taken to ensure proper removal of leukocytes and platelets because these cells also frequently do contain enzymatic activity, thereby potentially obscuring a deficiency of the red cell enzyme.

Other pitfalls in correct diagnosis of glycolytic enzyme deficiencies include the red blood cell age-dependent behavior of a number of enzymes (in particular, PK, HK, P5′N, and G6PD). For proper evaluation of a single enzyme measurement, its activity should be compared with simultaneous measurement of the activity of a reference enzyme (e.g., HK).

Many patients suffering from severe hemolysis may have already received blood transfusions. In this case, results from red cell enzyme assays must be interpreted with great care, because the presence of donor erythrocytes may obscure an enzyme deficiency. In addition, some mutant enzymes display normal activity in vitro, whereas severe impairment of enzymatic activity may occur in vivo. More sophisticated assays, for example, heat instability tests and enzyme kinetics, are required to identify an enzyme deficiency in those cases.

Over the past few years, most of the genes coding for red cell enzymes have been localized and characterized. This has made molecular diagnostics possible, and many causative mutations have been identified. Molecular diagnostics at the DNA and RNA levels is very attractive in situations in which the diagnosis of enzyme deficiency has been made difficult or impossible by activity measurements, as may occur in transfused patients, as explained previously. In addition, it offers the possibility of prenatal diagnosis. The ability to study the effects of mutations in three-dimensional models of the enzymes and the possibility of expressing recombinant mutant enzymes will lead to a better understanding of the genotype-to-phenotype correlation noted in red blood cell enzymopathies.

METHODS

In this section, methodologic principles and reference values are given for several of the methods used to measure red cell enzymes. Methodologic details of these methods are given in the Evolve site that accompanies this book (http://evolve.elsevier.com/Tietz/textbook).

Method for Determination of Glucose-6-Phosphate Dehydrogenase

Principle

Glucose-6-phosphate dehydrogenase (G6PD) catalyzes the oxidation of glucose-6-phosphate to 6-phosphogluconate with concurrent conversion of $NADP^+$ to NADPH. The activity of G6PD is determined by measurement of the rate of increase in NADPH concentration. Unlike $NADP^+$, NADPH strongly absorbs ultraviolet (UV) light. Therefore, the rate of increase in absorbance at 340 nm is the measure of enzyme activity.

Reference Intervals

The reference interval for G6PD in erythrocytes is 8 to 14 U/g Hb. Values greater than 18 U/g Hb are often encountered in any condition associated with younger than normal RBCs (as in hemolytic anemia not due to G6PD deficiency), but are of no clinical significance.

Method for Screening Erythrocytes for Glucose-6-Phosphate Dehydrogenase Deficiency

In this screening test, $NADP^+$ is reduced to NADPH in the G6PD and 6PGD reactions of the hexose monophosphate pathway. If G6PD activity is low, only a small quantity of NADPH is formed. This is reoxidized to $NADP^+$ by glutathione reductase present in RBCs, and no fluorescence is observed. In the presence of adequate amounts of G6PD, the rate of reduction of $NADP^+$ substantially exceeds the rate of oxidation of NADPH by glutathione reductase, and enough NADPH accumulates in RBCs to be demonstrable by its fluorescence.

Method for Determination of Pyruvate Kinase Activity

Principle

In this assay, the PK reaction is linked with the LD reaction in which NADH is oxidized to NAD^+ in which NADH is oxidized to NAD^+:

$$Phosphoenopyruvate + ADP \xrightarrow{PK} pyruvate + ATP$$

$$Pyruvate + NADH \xrightarrow{LD} lactate + NAD^+ + H^+$$

Because LD is present in excess, the rate of NADH oxidation is limited by the activity of PK. The reaction rate is measured by the rate of decrease in absorbance at 340 nm. Assays are performed at low substrate concentrations with and without the addition of fructose 1,6-bisphosphate, because some PK variants associated with hemolysis have atypical reaction kinetics (and thus may exhibit "normal" activity at high substrate concentrations but lower than normal activity at lower substrate concentrations) or may show absence of enhancement by fructose 1,6-diphosphate, the allosteric activator of PK.

Reference Intervals

Reference intervals for pyruvate kinase are as follows:

- High substrate, 9 to 16 U/g of Hb
- Low substrate, 1.7 to 6.8 U/g of Hb

Method for Determination of Glucose-Phosphate Isomerase Activity

Principle

GPI catalyzes the interconversion of G6P and F6P:

$$F\text{–}6\text{–}P \xleftrightarrow{GPI} G\text{–}6\text{–}P$$

$$NAPH^+ + G\text{–}6\text{–}P \xleftrightarrow{G\text{-}6\text{-}PD} 6\text{–}phosphogluconate + NADPH + H^+$$

In this assay, F6P is used as the substrate for GPI. The GPI reaction is linked to the G6PD reaction. The rate of reduction of $NADP^+$, as indicated by the increase in absorbance at 340 nm, is the measure of GPI activity.

Reference Intervals

The reference interval for GPI is 50 to 70 U/g Hb.

Method for Determination of Erythrocyte Glutathione Concentration

Erythrocyte GSH concentration is diminished in many people who have defects in the hexose monophosphate or GSH synthesis pathway. The GSH stability test, originally devised to permit identification of people susceptible to hemolysis from primaquine (later shown to be the result of G6PD deficiency), remains a useful "stress test" of the intactness of these closely linked pathways. Because deficiencies of GSH synthetase and γ-glutamyl cysteine synthetase are rare disorders, it is not practical for clinical laboratories to contemplate assays for these enzymes unless results of the easily performed GSH stability test are abnormal.

Principle

Virtually all of the nonprotein sulfhydryl groups of RBCs are in the form of reduced GSH. 5,5′-Dithiobis(2-nitrobenzoic acid) (DTNB) is a disulfide chromogen that is readily reduced by sulfhydryl compounds to an intensely yellow compound. The absorbance of the reduced chromogen is measured at 412 nm and is directly proportional to the GSH concentration.

Reference Interval

The reference interval for GSH is 5.5 to 7.5 μmol/g Hb.

Method of Screening for Deficiency of 5′-Nucleotidase Activity

Principle

Pyrimidine-5′-nucleotidase catalyzes the release of phosphate from cytidine-5′-monophosphate and uridine-5′-monophosphate and thus is an enzyme involved in the catabolism of RNA. RNA is a normal constituent of reticulocytes but not of mature RBCs. In the absence (or notable deficiency) of P-5′-N, RNA persists in the RBCs and is manifested by striking basophilic stippling and mild to moderate hemolytic anemia.

Pyrimidine nucleotides, extracted with acid from the RNA remaining in P-5′-N–deficient RBCs, have an absorption peak at 270 nm. This peak is distinct from the peak at 257 nm from purine nucleotides (such as ATP) that are normally present. When P-5′-N is deficient and RNA persists, the P-5′-N deficiency can be inferred by observing a pyrimidine nucleotide peak at 270 nm in an acid extract of RBCs.

Reference Intervals

In normal specimens or in those of any disorder except P-5′-N deficiency, an absorbance curve of low amplitude is present with a peak at about 257 nm (from purines, such as ATP and ADP). No peak is seen at 270 nm. In P-5′-N deficiency, a notably higher amplitude curve is observed, with a peak at 270 nm.

Method for Determination of 2,3-Bisphosphoglycerate in Erythrocytes

Principle

The assay of 2,3-BPG (2,3-DPG) is based on an equilibrium system between 3-phosphoglycerate, 2-phosphoglycerate, and PEP when monophosphoglycerate mutase (MPGM) and enolase are present:

$$3\text{–}Phosphoglycerate \underset{2,3\text{-}DPG}{\overset{MPGM}{\rightleftharpoons}} 2\text{–}phosphoglycerate \overset{enolase}{\rightleftharpoons} PEP$$

The addition of 2,3-DPG (in the sample) shifts the equilibrium so that more 2-phosphoglycerate is converted to 3-phosphoglycerate. This in turn results in the conversion of PEP to 2-phosphoglycerate. The rate of decrease in PEP concentration is measured by the decrease in absorbance at 240 nm, which is proportional to the amount of 2,3-BPG in the specimen.

Reference Intervals

The mean (SD) 2,3-DPG is 12.3 (1.87) μmol/g Hb [0.79 (0.12) mol/mol Hb] or 356 (54) μmol/1012 RBCs [356 (54) amol/RBC].

CHAPTER 24

Tumor Markers

Lori J. Sokoll, Ph.D., F.A.C.B.,
Alex J. Rai, Ph.D., D.A.B.C.C., F.A.C.B.,
and Daniel W. Chan, Ph.D., D.A.B.C.C., F.A.C.B

A tumor marker is a substance produced by a tumor or by the host in response to a tumor, which is used to differentiate a tumor from normal tissue, or to detect the presence of a tumor based on measurements in the blood or secretions. Such substances are found in cells, tissues, or body fluids and are measured qualitatively or quantitatively by chemical, immunologic, or molecular biological methods.[246]

Morphologically, cancer tissue has been recognized by pathologists as resembling fetal tissue more than normal adult differentiated tissue. Tumors are graded according to their degree of differentiation as (1) well differentiated, (2) poorly differentiated, or (3) anaplastic (without form). Tumor markers are the biochemical or immunologic counterparts of the differentiation state of the tumor. In general, some tumor markers represent re-expression of substances produced normally by embryogenically closely related tissue (Table 24-1).

Some tumor markers are associated with one type of cancer; others are seen in several cancer types. Many of the better-known markers are also seen in noncancerous conditions. Consequently, these tumor markers are not diagnostic for cancer. However, it is thought that the concentration of tumor markers in blood reflects tumor activity and volume.

Clinically, an ideal tumor marker should be both specific for a given type of cancer and sensitive enough to detect small tumors for early diagnosis or during screening. Unfortunately, few markers are specific for a single individual tumor (tumor-specific markers); most are found with different tumors of the same tissue type (tumor-associated markers). Tumor markers are present in higher quantities in cancer tissue or in blood from cancer patients than in benign tumors or in the blood of healthy subjects. In practice, current tumor markers are most useful for evaluating the progression of disease status after initial therapy and for monitoring subsequent treatment modalities.[21,22]

This chapter begins with general discussions on (1) cancer, (2) the historical background of tumor markers, (3) their clinical applications, (4) how their utility is evaluated, (5) clinical guidelines for their use, and (6) how they are measured. Several clinically relevant tumor markers from each of these categories are then discussed in detail. These are grouped under the general categories of (1) enzymes, (2) hormones, (3) oncofetal antigens, (4) carbohydrate markers, (5) blood group antigens, (6) proteins, (7) receptors, and (8) genes. More detailed information on tumor markers is found in a 2002 textbook on the subject.[71]

CANCER

In 2010, the estimated number of new cancer cases (excluding skin cancer) was 1.53 million. Prostate cancer was the leader among men, and breast cancer was the leader in women, followed by cancer of the lung, colon-rectum, and bladder (men) or uterine corpus (women).[44] Together, diseases of the heart and malignant neoplasms account for 49% of all deaths in the United States. Heart disease remains the leading cause of death in the United States in men and women over the age of 85; however, for those younger than 85 years, cancer has surpassed heart disease as the leading cause of death.[127] Following peak death rates from all cancers in 1990 for men and 1991 for women, death rates decreased by 21.0% in men and 12.3% in women from 1990/1991 to 2006. Death rate reductions in men from lung, prostate, and colorectal cancers accounted for 80% of the decrease, while in women breast and colorectal cancers accounted for 60% of the decrease.[127] These trends support the conclusion that early detection and more effective treatment combined with prevention (e.g., decreasing smoking, improving diet) could reduce the mortality rate of cancer in the future. The American Cancer Society estimates that in 2010, 171,000 deaths are expected to be caused by tobacco use, and one third will likely be related to excess weight, physical inactivity, and poor nutrition.[44]

A simple definition of *cancer* is "a relatively autonomous growth of tissue."[216] Understanding the cause of autonomous growth would clearly facilitate the search for a cure. A *carcinogen* is an agent that causes cancer. A carcinogen may be physical (e.g., radiation), chemical (e.g., a polycyclic hydrocarbon), or biological (e.g., a virus). Exposure to such an agent may cause cancer by producing direct genotoxic effects on deoxyribonucleic acid (DNA) (e.g., as with radiation) or by increasing cell proliferation (e.g., by a hormone), or both (e.g., through the use of tobacco).

TABLE 24-1 Expression of Oncodevelopmental Tumor Markers

Production of Tumor Markers by Various Tissues				
Marker	**Normal Producing**	**Embryogenically Closely Related**	**Distantly Related**	**Unrelated**
CEA	Colon	Stomach, liver, pancreas	Lung, breast	Lymphoma
AFP	Liver, yolk sac	Colon, stomach, pancreas	Lung	
hCG	Placenta	Germinal tumors	Liver	Epidermal lung
Serotonin	Enteroendocrine carcinoid	Adrenal	Oat cell, lung	Epidermal lung

Modified from Sell S. Cancer markers. In: Moossa AR Schempff SC, Robson MC, eds. Comprehensive textbook of oncology, 2nd edition, volume 1. Baltimore: Williams & Wilkins, 1991:225-38.
AFP, α-Fetoprotein; *CEA*, carcinoembryonic antigen; *hCG*, human chorionic gonadotropin.

Advances in molecular genetics have resulted in a better understanding of the genesis of human cancer. The proliferation of normal cells is thought to be regulated by growth-promoting *oncogenes* and counterbalanced by growth-constraining *tumor suppressor genes*. The development of cancer appears to involve the activation or the altered expression of oncogenes,[1] or the loss or inactivation of a tumor suppressor gene.[297] A pathway to cancer development has been published.[81]

Early detection of cancer offers the best chance for cure. The goal is to diagnose cancer when a tumor is still small enough to be completely removed surgically. Unfortunately, most cancers do not produce symptoms until the tumors are too large to be removed surgically, or until cancerous cells have already spread to other tissue (metastasized).

Although other modes of therapy, such as administration of chemical toxins or irradiation, are effective in destroying most tumor cells, they usually are not curative. The few residual viable tumor cells are able to proliferate, develop resistance to further therapy, and eventually kill the patient.

HISTORICAL BACKGROUND

The first tumor marker reported was the Bence Jones protein. Since its discovery in 1847 by precipitation of a protein in acidified boiled urine,[24] the measurement of Bence Jones protein has been a diagnostic test for multiple myeloma (a tumor of plasma cells). More than 100 years after its discovery, the Nobel Prize–winning studies of Porter and of Edelman and Poulik identified the Bence Jones protein as the monoclonal light chain of immunoglobulin secreted by tumor plasma cells. Monoclonal paraproteins appear as sharp bands in the globulin area in electrophoretic patterns of serum. Multiple myeloma is often diagnosed on the basis of this finding or the finding of an elevated concentration of "monoclonal" immunoglobulin in the serum.[261]

A brief history of tumor markers is shown in Table 24-2.[244] The first period of tumor marker history was the era of the Bence Jones protein. The second era, from 1928 to 1963, included the discovery of hormones, enzymes, isoenzymes, and proteins and their application to the diagnosis of cancer and the beginnings of chromosomal analysis of tumors. Occasionally, such markers were useful in the diagnosis of individual tumors, but the general application of tumor markers for monitoring cancer patients did not start until the third era, with the discovery of α-fetoprotein (AFP) in 1963[2] and carcinoembryonic antigen (CEA) in 1965.[97] The production of such markers during fetal development and in tumors led to use of the term *oncodevelopmental markers*.[85]

The fourth era started in 1975 with the development of monoclonal antibodies and their subsequent use to detect oncofetal antigens and antigens derived from tumor cell lines. Examples include carbohydrate antigens such as CA 125, CA

TABLE 24-2 A Brief History of Tumor Markers

Year	Author	Marker

ACTH, Adrenocorticotropic hormone; *AFP*, α-fetoprotein; *CEA*, carcinoembryonic antigen; *hCG*, human chorionic gonadotropin.

15-3, and CA 27.29. Advances in molecular genetics using molecular probes and monoclonal antibodies to detect chromosome or protein alterations, including the study of oncogenes, suppressor genes, and genes involved in DNA repair,[138] have led to the rapid understanding and use of tumor markers at the molecular level. These markers are becoming increasingly useful at the cellular level. For example, mutated *ras* oncogene can be detected in sloughed cellular DNA in fecal material and thus can be used to detect colon cancer.[250] Discovery of the breast cancer susceptibility genes, *BRCA 1* and *BRCA 2*,[177,304] has led to the possibility of screening for familial breast cancer susceptibility in high-risk individuals.[215]

As we begin the 21st century, new technologies are being applied to the discovery of tumor markers and their clinical applications. Notable among these discoveries is the introduction of genomics and proteomics technologies[202] such as the application of complementary DNA (cDNA), protein and tissue microarrays, and the use of mass spectrometry as a diagnostic and discovery tool. Furthermore, the advent of bioinformatic techniques, including neural networks, logistic regression, support vector machines, and other algorithms, is facilitating the use of multiparametric analysis for cancer diagnosis and prognosis, and for prediction of therapy outcomes.[311]

CLINICAL APPLICATIONS

The potential uses of tumor markers are summarized in Table 24-3. In general, tumor markers may be used for (1) diagnosis, prognosis, and prediction; (2) for monitoring the effects of therapy; and (3) as targets for localization and therapy.[246] Ideally, a tumor marker should be produced by tumor cells

TABLE 24-3 Current Applications of Tumor Markers and Their Limitations

Application	Current Usefulness	Comments
Screening for cancer	Limited	1. For screening, you must have a marker that is elevated at early disease stages, when the disease is localized and potentially curable. Most circulating cancer markers (with the exception of PSA) only are elevated notably in the late stages of disease. Thus diagnostic sensitivity is usually low for early-stage disease. 2. With the exception of PSA, most cancer markers are not specific for a particular tissue, and elevations may be due to diseases of other tissue, including benign and inflammatory diseases. Thus diagnostic specificity may be low, leading to many false positives. In screening, there is a necessity for a definitive diagnostic method that will separate true positives from false positives. If this procedure is invasive (e.g., surgery) and/or expensive, patients will not accept it. 3. Screening, even if effective for early cancer diagnosis, must demonstrate benefit to the screened population in terms of survival or other clinical end points.
Diagnosing cancer	Limited	Same as above. Low diagnostic sensitivity and specificity. However, for selected subgroups of high-risk patients in whom the chance of cancer is high (high prevalence), tumor marker analysis may not aid the clinician in ordering more elaborate testing (e.g., imaging techniques, laparoscopic investigations).
Evaluating cancer prognosis	Limited	Most cancer markers have prognostic value, but their accuracy is not good enough to warrant specific therapeutic interventions. For example, higher preoperative concentrations of PSA are associated with capsular penetration, high Gleason score, positive surgical margins, and positive lymph node status, but the decision to treat with two different modalities (e.g., radical prostatectomy vs. nonsurgical approaches) cannot be made based on tumor marker data alone. Same applies to many other cancers.
Prediction of therapeutic response	Important	Despite the importance of using biomarkers in predicting response to specific therapies, very few known markers have such predictive power. These include the steroid hormone receptors for predicting response to antiestrogens and HERr-2/*neu* amplification for predicting response to Herceptin in breast cancer patients. We must have more predictive markers to individualize therapy and maximize clinical response.

Continued

TABLE 24-3 Current Applications of Tumor Markers and Their Limitations—cont'd

Application	Current Usefulness	Comments
Tumor staging	Limited	Same as for prognosis. The data are not good enough for accurate staging unless the value reflects tumor volume.
Detecting tumor recurrence or remission	Controversial	Despite the importance of using biomarkers to detect cancer relapse, current markers are limited by the following: 1. Lead time is short (weeks to a few months) and does not significantly affect outcome, even if therapy is instituted earlier. 2. Therapies for treating recurrent disease are not effective at present. 3. In certain groups of patients, biomarkers are not produced and do not detect relapses. 4. Sometimes biomarkers provide misleading information (e.g., clinical relapses occur without biomarker elevation, or biomarker is elevated nonspecifically, without progressive disease, leading to overtreatment or discontinuation of a current and successful treatment protocol).
Localizing tumor and directing radiotherapeutic agents	Limited	Only a few biomarkers are available for this application, and success is limited at present.
Monitoring the effectiveness of cancer therapy	Important	For patients with advanced disease, who are treated with various modalities, it is important to know if therapy works. In this regard, biomarkers usually provide information that is readily interpretable and more economical, more sensitive, and safer than radiologic or invasive procedures. For certain cancers, this may facilitate increased enrollment of patients into therapeutic clinical trials.

Modified from Diamandis EP. Tumor markers: past, present, and future. In: Diamandis EP, Fritsche HA, Lilja H, Chan DW, Schwartz MK, eds. Tumor markers: physiology, pathobiology, technology, and clinical application. Washington, DC: AACC Press, 2002:5.

and should be detectable in body fluids. It should not be present in healthy people or in benign conditions. Therefore, it could be used for screening for the presence of cancer in asymptomatic individuals in the general population. However, most tumor markers are present in normal, benign, and cancerous tissues and lack specificity. However, if the incidence of cancer is high among certain populations, screening could be feasible. An example is the use of AFP in screening for hepatocellular carcinoma in China and Alaska.[174] Prostate-specific antigen (PSA) has been used in conjunction with digital rectal examination (DRE) for early detection of prostate cancer. Because of elevation of serum PSA in benign prostatic hyperplasia (BPH), PSA velocity and free PSA have been used to improve the detection of prostate cancer.[99]

The clinical staging of cancer is aided by quantification of the marker (i.e., the serum concentration of the marker reflects tumor burden). Marker concentration at the time of diagnosis may be used as a prognostic indicator for disease progression and patient survival. This is possible for an individual patient, but different concentrations of markers produced by different tumors do not usually allow one to determine the prognosis of a tumor from the initial concentration. However, after successful initial treatment, such as surgery, the marker concentration should decrease. The rate of this decrease can be predicted by using the half-life of the marker. For example, the half-life of total PSA is 2 to 3 days, that of human chorionic gonadotropin (hCG) is 12 to 20 hours, and that of AFP is 5 days. If the half-life after treatment is longer than the expected half-life, then treatment has not been successful in removing the tumor. The magnitude of reduction may, however, reflect the degree of success of treatment or the extent of disease involvement.

Targeted therapy in oncology is becoming more effective and will be the therapeutic choice of the future. Tumor markers capable of guiding targeted therapy will improve therapeutic efficacy and will generate less toxicity. Examples in breast cancer are the estrogen and progesterone receptors for the selection of hormonal therapy, HER-2 for the selection of breast cancer patients for trastuzumab (Herceptin) therapy, and Onco*type* DX (Genomic Health, Inc., Redwood City, Calif) for the identification of those patients who most likely will benefit from adjuvant tamoxifen or chemotherapy.

Detecting cancer recurrence may be helpful in initiating early treatment or in changing therapy. The breast cancer marker CA 27.29 has been shown to detect recurrent disease before any clinical evidence is noted in breast cancer patients receiving adjuvant chemotherapy.[54]

Most tumor marker concentrations correlate with effectiveness of treatment and responses to therapy. In breast cancer, the concentration of markers, such as CA 15-3 or CA 27.29, changes with treatment and the clinical outcome of the patient. Concentrations usually increase with progressive

tahir99-VRG & vip.persianss.ir

disease, decrease with remission, and do not change significantly with stable disease. In reality, tumor marker kinetics in the monitoring of cancer may be more complicated. Marker concentrations in response to treatment may show an initial delay before demonstrating the expected pattern of change.[134]

In addition, antibodies to tumor markers labeled with a radioactive tag are used to localize the tumor masses (radioimmunoscintigraphy)[66] or to provide direction for labeled antibodies to attack the tumor site. Examples include the use of radiolabeled antibodies to CEA to localize colon tumors and the application of labeled antibodies against ferritin to target hepatocellular carcinoma. This approach is also used for treatment by allowing the antibody to bind to the tumor marker epitopes and kill the tumor cell with the dose of radioactivity.[296]

EVALUATING CLINICAL UTILITY

To evaluate the clinical usefulness of a tumor marker, it is necessary to establish reference intervals, calculate predictive values, evaluate the distribution of marker concentrations, and determine its role in disease management.

Reference Intervals

Reference intervals of a tumor marker are obtained from a healthy population, preferably using individuals of the same age and sex as those with the cancer of interest.[35] Determination of reference intervals is time-consuming and requires a large healthy population (n = 120 subjects). Statistical analysis based on the mean ± 2 standard deviations (SD) for a population with a Gaussian (normal) distribution is a frequently used method. For a non-Gaussian distribution, the percentile method is a simple approach that is often used (for further discussion of reference intervals, see Chapter 5).

Reference intervals determined using healthy subjects in this fashion are applicable to analytes with physiologically well-defined concentrations. For testing with relatively specific applications, such as the use of tumor markers in the diagnosis and management of cancer, a decision cut point may be more appropriate than the upper limit of the reference population. In most cases, using benign patients as the nondisease group is more appropriate than using a healthy population. The decision cut point can be determined using a predictive value model.

Predictive Value Models

The predictive value model includes the clinical sensitivity and specificity and the predictive value of a test. By varying the decision cut point, clinical sensitivity and specificity will change in opposite directions. An optimal decision cut point can be selected on the basis of strategies outlined in Chapter 3.

A useful approach to evaluating multiple tests for the same analyte or multiple markers for the same type of cancer is the *receiver operating characteristic* (ROC) curve.[253] The ROC curve can be constructed by plotting sensitivity versus 1 minus specificity, or the true-positive rate versus the false-positive rate. The advantage of the ROC curve is the display of performance over the entire range of decision points. One can pinpoint the decision cut point at which optimal sensitivity and specificity can be achieved. By superimposing the ROC curves of several markers, the best predictive marker can be selected. An example is shown in Figure 24-1. Preparation of an ROC curve has been discussed in detail by Zweig and Robertson[314] and is covered in Chapter 3 of this text.

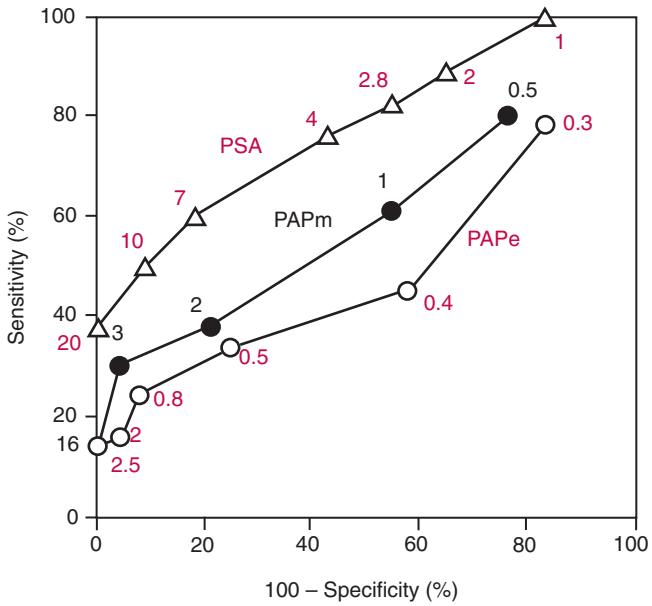

Figure 24-1 Receiver operating characteristic (ROC) curves for prostate-specific antigen (PSA), prostatic acid phosphatase by monoclonal immunoassay (M-PAP), and enzymatic prostatic acid phosphatase (E-PAP). Data for all 128 patients with prostatic disease are plotted, with several quantitative decision cut points (as indicated in the figure) for each assay. Units are µg/L for M-PAP and PSA, and U/L for E-PAP. *(From Rock RC, Chan DW, Bruzek DJ, et al. Evaluation of a monoclonal immunoradiometric assay for prostate-specific antigen. Clin Chem 1987;33:2257-61.)*

Distribution of Markers

Application of the predictive value model is difficult for analytes that are not diagnostic for a single disease. Concentrations of most, if not all, tumor markers are elevated in more than one disease condition. When the predictive value model is used, it is necessary to select a population that includes groups with and without disease. What patients should be included in these two groups? The decision should be based on the specific clinical questions asked. If the question concerns the diagnostic sensitivity of CEA for active colorectal carcinoma, the disease group should include only those patients with active colorectal carcinoma. Selection of the nondisease group is more challenging. Should healthy individuals and those with benign conditions be included? If so, how many benign condition groups should be included?

From Chan DW, Beveridge RA, Bruzek DJ, et al. Monitoring breast cancer with CA 549. Clin Chem 1988;34:2000-4.

Should patients with no evidence of disease be included as well, because they do not have active disease? Values calculated for sensitivity and specificity greatly depend on the types of groups included and on the number of patients in each group (see Chapter 3 for a discussion on the effect of spectrum on sensitivity and specificity).

The distribution of tumor marker concentrations is usually shown as the percentage of patients with elevated concentrations as determined using various cutoffs in healthy, benign, and cancerous groups. When available, international staging criteria should be used to classify cancer patients. Diagnosis should be based on pathologic findings. In breast cancer, for example (Table 24-4), normal women are used as the healthy population for comparison. Nonmalignant or benign groups are selected to include people with the most likely causes of marker elevation: benign liver and breast diseases, and pregnancy. Nonbreast metastatic cancer groups are selected to show the specificity of the marker using endometrial, colon, lung, prostate, ovarian carcinoma, and others.

Grouping all breast cancer patients into a single category is not satisfactory because most markers are elevated in active breast cancer. The adjuvant group consists of patients who had no metastasis, underwent mastectomy and treatment with adjuvant chemotherapy, and have no evidence of disease. The marker concentration is not expected to be elevated. The metastasis group includes patients' complete remission, partial remission, or with progressive breast cancer accompanied by local or distant metastases. The progressive breast cancer group should have the highest percentage of elevated marker concentrations. The partial remission group should have an intermediate percentage of elevated marker concentrations. The complete remission group should have the lowest percentage of elevated marker concentrations.

Disease Management

Most tumor markers are used to monitor treatment and progression of cancer. Selection of patient groups is important to illustrate the usefulness of the marker in various clinical settings. Markers may be used to determine the success of initial treatment (e.g., surgery, radiation), to detect the recurrence of cancer, and to monitor the effectiveness of the treatment modality.

An elevated marker concentration before surgery should fall after a successful operation. The extent of the decrease in marker concentration depends on pretreatment tumor involvement.

With recurrence of cancer after successful initial treatment, the marker concentration may not fall within the expected time according to its half-life. It may fall to a steady concentration that is higher than normal, or it may fall within

tahir99-VRG & vip.persianss.ir

the reference interval of healthy individuals. A subsequent rise in the marker concentration suggests cancer recurrence.

In monitoring the effectiveness of cancer therapy, marker concentration should increase with the progression of cancer, decrease with the regression of cancer, and not change in the presence of stable disease. When candidate markers are evaluated, all events related to the progression, stability, and regression of disease can be grouped; whether the marker concentration changes in the predicted direction in all these situations can be evaluated next.

The Working Group on Tumor Marker Criteria of the International Society for Oncodevelopmental Biology and Medicine has published the following criteria for the interpretation of changes in tumor markers.[35]

> "If no therapy is given, at least a linear increase in three consecutive samples (i.e., two time intervals) on a log scale should be registered to establish a recurrence. Usual intervals could be three months but are clinically determined. After a first increase, next samples should be taken after 2 to 4 weeks, irrespective of the absolute concentration."

If therapy is given, changes in marker concentrations should reflect the clinical progression of the disease. "Progressive disease is defined by an increase in the marker concentration of at least 25%. Sampling should be repeated within 2 to 4 weeks for additional evidence … The sampling interval during therapy may depend on the type of tumor and should be related to clinical follow-up." A decrease in marker concentration of at least 50% is indicative of partial remission "with the concept that tumor load is related to the changes in serum tumor marker concentrations." The Working Group also provided the general opinion that "a complete remission cannot be determined by marker concentrations, but if tumor marker concentrations are elevated, the clinical decision of complete remission based on conventional methods should be considered incorrect unless an explanation for the presence of the elevated concentration is given."

CLINICAL GUIDELINES

The diagnosis and staging of cancer involve a number of tools, including (1) physical examination, (2) imaging, and (3) laboratory studies. Application of these tools has resulted in several tumor markers that are used for screening, diagnosis, staging, and prognosis, and for directing treatment modalities. However, not all tumor markers are appropriate for all uses, and not all cancers have established tumor markers. Therefore, each type of cancer and each tumor marker must be properly evaluated for use, and clinicians must be educated regarding proper use of tumor markers to conserve resources.

Several national and international groups have released guidelines on the selection and clinical use of tumor markers. These groups include the National Academy of Clinical Biochemistry (NACB), the European Group on Tumor Markers (EGTM), the American Cancer Society (ACS), the American Society for Clinical Oncology (ASCO), and others. All of these groups are composed of experts in the areas being assessed, and a number of criteria are used to form the recommendations, including the level of evidence for the tumor marker and the tumor marker utility grading system (TMUGS).[71] Table 24-5 summarizes the recommendations of several groups.

ANALYTICAL METHODS

Tumor markers are measured by a variety of analytical techniques, including enzyme assay (see Chapters 15 and 22); immunoassay (see Chapter 16); receptor assay and instrumental techniques such as chromatography (see Chapter 13); electrophoresis (see Chapter 12); and mass spectrometry interfaced with liquid or gas chromatographs (see Chapter 13) and microarrays (see Chapter 18). Details of these techniques are found in the indicated chapters. Here we expand on the use of mass spectrometry and microarrays for the assay of protein and genetic tumor markers.

Mass Spectrometry

Mass spectrometry for small molecules has been used in the clinical laboratory for many years. However, developments have allowed for the mass spectrometric identification of high molecular weight compounds, including proteins and nucleic acids. The new ionization technologies were recognized by the Nobel Prize in Chemistry in 2002. These advances triggered investigations toward using the technology for cancer diagnostics or for discovery of new cancer biomarkers. In one approach, sera or other fluids from cancer patients or controls are treated with various adsorbing surfaces, such as ion-exchange, hydrophobic, or metal-binding chips. After excess proteins are washed out, the chips are subjected to mass spectrometric analysis by using MALDI (matrix-assisted laser desorption ionization) or SELDI (surface-enhanced laser desorption ionization)-TOF (time-of-flight) mass spectrometry. This analysis generates many peaks of various M-Z (mass-to-charge) ratios. By comparing these proteomic patterns with patterns obtained from samples from individuals without cancer, and by using sophisticated bioinformatic and computational tools, it is possible to identify patterns that are associated only with cancer. This technology has been investigated for the detection of ovarian,[212,222,312] prostate,[3,214] bladder, and many other cancers,[230] and its use has been reviewed.[202,213,214,267] However, the method has not as yet been prospectively evaluated, and clinical trials are in progress.

A more promising approach is to use this technology to identify novel cancer biomarkers.[155,222,230,312] To date, several molecules have been identified, including (1) apolipoprotein A1, (2) transthyretin fragment, (3) inter-α-trypsin inhibitor, (4) haptoglobin-α subunit, (5) vitamin D–binding protein, and others. Most of these molecules are present in serum at concentrations higher than concentrations of traditional cancer biomarkers. In most cases, these candidate biomarkers are in the process of being validated. OVA1 (Vermillion, Inc., Austin, Tex), a panel of biomarkers for ovarian cancer,[222,312] is the first proteomic IVDMIA (in vitro diagnostic multivariate

index assay) cleared by the U.S. Food and Drug Administration (FDA).

Microarrays

A microarray uses a solid material such as a microchip of silicon that contains a large number of elements ("spots") in a two-dimensional array. To each of these spots are attached different molecules of immobilized short oligonucleotides (e.g., Affymetrix chips; Affymetrix, Santa Clara, Calif) and cDNAs of various genes, proteins, antibodies, etc.[159,188,237] It is possible to immobilize up to 20,000 to 40,000 elements on such chips; consequently, genome-wide analysis at both messenger ribonucleic acid (mRNA) and protein concentrations is now possible. Commercially available protein microarrays such as the ProtoArrays from Life Technologies Inc. (Carlsbad, Calif) contain as many as 10,000 immobilized proteins. Applications of microarrays include quantitative assessment of gene expression, detection of mutations and polymorphisms (such as single-nucleotide polymorphisms), DNA sequencing, the study of protein expression and protein-protein interactions, and the detection of autoantibodies.

These devices have been used to discover new candidate biomarkers. For example, Welsh and colleagues used microarray analysis of gene expression profiles of normal and cancerous tissues and identified highly overexpressed genes in ovarian and other cancers.[298,299] These overexpressed genes were then to be evaluated further with more quantitative techniques, such as reverse-transcriptase polymerase chain reaction, to confirm the overexpression. Identification of an overexpressed gene can be followed by development of assays to measure the protein and then evaluate it as a serologic or tissue biomarker.[298] Some successes of this process have been reported (e.g., the identification of osteopontin and HE4 as ovarian cancer biomarkers).[116,153]

Another application of microarrays is their use in the classification of cancers based on their gene expression profiles. Numerous examples of subclassifying breast, ovarian, prostate, brain, hematologic, and other cancers using this technology have been described.[133,211] Especially for breast cancer, it has been realized that tissue microarray analysis may stratify patients according to prognosis.[290,291] Van de Vijver and associates showed that a relatively small number of genes (about 70) can be used to classify patients into high- and low-risk groups. This method has been applied clinically to select breast cancer patients for adjuvant chemotherapy.

The application of microarrays for cancer classification and prognosis and for discovery of new cancer biomarkers is relatively new. This method has the potential to revolutionize cancer prognosis and prediction of therapy by using dedicated chips. However, further standardization is necessary.

ENZYMES

Enzymes were one of the first groups of tumor markers identified. Their elevated activities were used to indicate the presence of cancer.[101] Measurement of enzymes was relatively easy using spectrophotometric determination of enzymatic activities. With the introduction of radioimmunoassay (RIA) in the late 1950s, the mass of an enzyme could be measured as a protein antigen instead of its catalytic activity.

With few exceptions, an increase in the activity or mass of an enzyme or isoenzyme is not specific or sensitive enough to be used to identify the type of cancer or the specific organ involvement. An exception is PSA. PSA has mild protease

tahir99-VRG & vip.persianss.ir

activity and amino acid sequence homology with serine proteases of the kallikrein family.[60,70] It is expressed by normal, benign, hyperplastic, and cancerous prostate glands and minimally by other tissue.[32] Until the application of PSA as a marker for prostate cancer, tumor enzymes had lost most of their popularity for use as cancer markers.[101,243] Enzymes were used historically as tumor markers before the discovery of oncofetal antigens and the advent of monoclonal antibodies.[242] Abnormalities of enzymes as a marker for cancer include expression of the fetal form of the enzyme (isozyme) and ectopic production of enzymes.

Enzymes are present in much higher concentrations inside the cell. Enzymes are released into the systemic circulation as the result of tumor necrosis or following a change in membrane permeability of cancer cells. Increased enzymes are also observed in the blockage of pancreatic or biliary ducts and in renal insufficiency. The intracellular location of the enzyme may determine the rate of release. By the time enzymes are released into the systemic circulation, tumor metastasis may have occurred. Most enzymes are not unique for a specific organ. Therefore, enzymes are most suitable as nonspecific tumor markers. Elevated enzymes may signal the presence of malignancy.

Isoenzymes and multiple forms of enzymes may provide additional organ specificity. Table 24-6 summarizes various enzymes, their associated types of malignancy, and the assays used to measure their activity (Act) or their mass concentration (immunoassay). Enzymes are traditionally measured by their activities. With the introduction of antibody techniques, some enzymes, such as PSA, are measured as protein antigens rather than by their enzyme activity.

Alkaline Phosphatase

Alkaline phosphatase may arise from liver, bone, or placenta. The alkaline phosphatase in the sera of normal adults comes primarily from the liver or biliary tract. Elevated alkaline phosphatase is seen in primary or secondary liver cancer. Quantification may be helpful in evaluating metastatic cancer with bone or liver involvement. Greatest elevations are seen in patients with osteoblastic lesions, such as in those with prostatic cancer with bone metastases. Minimal elevations are seen in patients with osteolytic lesions, such as those with breast cancer with bone metastases.[84,278]

In liver metastases, serum alkaline phosphatase shows a better correlation with the extent of liver involvement than the results of other liver tests. To determine the origin of elevated alkaline phosphatase, tests of other liver enzymes may be performed. Elevations in 5′-nucleotidase or γ-glutamyltransferase suggest that the elevated alkaline phosphatase is of liver, not bone, origin. Determination of alkaline phosphatase isoenzymes may provide additional specificity. The liver isoenzyme is thermally more stable than the bone isoenzyme (see Chapter 22 for a more detailed discussion). Other malignancies, such as leukemia, sarcoma,

TABLE 24-6 Enzymes as Tumor Markers

Enzyme	Assay	Type of Cancer
Alcohol dehydrogenase	Act	Liver
Aldolase	Act	Liver
Alkaline phosphatase	Act	Bone, liver, leukemia, sarcoma
Alkaline phosphatase—placental	Act	Ovarian, lung, trophoblastic, gastrointestinal, seminoma, Hodgkin's
Amylase	Act	Pancreatic, various
Aryl sulfatase B	Act	Colon, breast
Creatine kinase-BB	IMA	Prostate, lung (small cell), breast, colon, ovarian
Esterase	Act	Breast
Galactosyltransferase	Act	Colon, bladder, gastrointestinal, various
γ-Glutamyltransferase	Act	Liver
Hexokinase	Act	Liver
Lactate dehydrogenase	Act	Liver, lymphoma, leukemia, various
Leucine aminopeptidase	Act	Pancreatic, liver
Neuron-specific enolase	IMA	Lung (small cell), neuroblastoma, carcinoid, melanoma, pheochromocytoma, pancreatic
5′-Nucleotidase	Act/IMA	Liver
Prostatic acid phosphatase	Act/IMA	Prostate
PSA	IMA	Prostate
Pyruvate kinase	Act	Liver, various
Ribonuclease	Act	Various (ovarian, lung, large bowel)
Sialyltransferase	Act	Breast, colon, lung
Terminal deoxytransferase	Act	Leukemia
Thymidine kinase	Act/IMA	Various, leukemia, lymphoma, lung (small cell)

Act, Activity; *IMA*, immunoassay.

tahir99-VRG & vip.persianss.ir

and lymphoma complicated with hepatic infiltration, may also elevate alkaline phosphatase.

Placental alkaline phosphatase (PALP) is synthesized by the trophoblast and is elevated in the sera of pregnant women. PALP was first identified as the Regan isoenzyme in 1968 by Fishman and colleagues[85] and was recognized as one of the first oncodevelopmental markers, along with AFP and CEA. It is elevated in a variety of malignancies, including ovarian, lung, trophoblastic, and gastrointestinal cancers; seminoma; and Hodgkin's disease.

Creatine Kinase

Creatine kinase catalyzes the phosphorylation of creatine by adenosine triphosphate. CK is a dimer consisting of two subunits—M (muscle) and B (brain)—and three isoenzymes—CK1 (BB), CK2 (MB), and CK3 (MM). CK1 is present in the (1) brain, (2) prostate gland, (3) gastrointestinal tract, (4) lung, (5) bladder, (6) uterus, and (7) placenta. Cardiac muscle has the highest concentration of CK2 (>20%). CK3 is present in skeletal and cardiac muscles.

Elevations in CK1 have been demonstrated in prostate cancer and small cell carcinoma of the lung. Although it is also elevated in other malignancies, such as those of the breast, colon, ovary, and stomach, the clinical usefulness of CK1 as a tumor marker requires further investigation.[243] CK isoenzymes have been included in a prostate cancer panel, "ProstAsure."[14,269] The ProstAsure Index is a neural network–derived algorithm for the early detection of prostate cancer that also includes PSA PAP, and age.

Lactate Dehydrogenase

Lactate dehydrogenase (LD) is an enzyme in the glycolytic pathway that is released as the result of cell damage. Elevation of LD in malignancy is rather nonspecific. It has been demonstrated in a variety of cancers, including liver cancer, non-Hodgkin's lymphoma, acute leukemia, nonseminomatous germ cell testicular cancer, seminoma, neuroblastoma, and other carcinomas, such as breast, colon, stomach, and lung cancer. Serum LD has been shown to correlate with tumor mass in solid tumors and provides a prognostic indicator for disease progression. Its value in the monitoring of therapy is rather limited. The LD isoenzymes provide only marginal specificity for organ involvement. For example, elevation of the LD5 isoenzyme is associated with liver metastases. Elevation of LD5 in the spinal fluid may be an early indication of central nervous system metastases.[243]

Neuron-Specific Enolase

Neuron-specific enolase (NSE) is the γ subunit of the glycolytic enzyme phosphopyruvate hydrolase, which exists as a homodimer (γγ) and a heterodimer (αγ). The enzyme is found in neuronal tissue and cells of the diffuse neuroendocrine system. NSE therefore is associated with tumors of neuroendocrine origin. NSE is released into the blood as a result of cell lysis as opposed to secretion. NSE is also released into CSF with neuronal injury. NSE is found in tumors associated with neuroendocrine origin, including small cell lung cancer (SCLC), neuroblastoma, pheochromocytoma, carcinoid, medullary carcinoma of the thyroid, melanoma, and pancreatic endocrine tumor.

Serum NSE concentrations have been measured by immunoassay. Using a cutoff of 12.5 μg/mL, NSE has a clinical sensitivity of 80% in patients with SCLC with a clinical specificity of 80 to 90%. The NSE concentration appears to correlate with stage and provides a useful prognosis for disease progression. The value of NSE in detecting disease relapse has not been proved. Although the findings are mixed, NSE appears to be useful in monitoring chemotherapy and correlates with disease state. Immunostaining of NSE may provide the differential diagnosis between SCLC and other histologic carcinoma types.

Among children with advanced neuroblastoma, more than 90% have been reported to have elevated serum concentrations of NSE. High concentrations of NSE are associated with poor prognosis, and concentrations seem to correlate with the stage of the disease. Monitoring therapy using serum NSE is controversial, particularly with respect to the issue of specificity. However, elevated concentrations of NSE in children with stage IV neuroblastoma were associated with a poorer outcome.[309]

Prostatic Acid Phosphatase

The acid phosphatases include all phosphatases that hydrolyze phosphate esters with an optimum pH of less than 7.0. They are present in the lysozymes of secretory epithelial cells. Although acid phosphatase is produced primarily by the (1) prostate gland, it is also found in (2) erythrocytes, (3) platelets, (4) leukocytes, (5) bone marrow, (6) bone, (7) liver, (8) spleen, (9) kidney, and (10) intestine.

Prostatic acid phosphatase (PAP), with an optimum pH of 5 to 6, is very labile at a pH of greater than 7.0 and a temperature greater than 37 °C. It can be distinguished from other acid phosphatases by using tartrate, which strongly inhibits the prostatic form. Another approach is to select substrates that are more specific for PAP, including thymolphthalein monophosphate (Roy method—most specific) and β-naphthol phosphate. Acid phosphatase was first used as a tumor marker in 1938 by Gutman and colleagues.[101] PAP was measured first by its enzymatic activity, then with the use of counterimmunoelectrophoresis, and subsequently, in the late 1970s, by RIA. Elevated serum PAP may be seen in malignant conditions such as osteogenic sarcoma, multiple myeloma, and bone metastases of other cancers. It also may be elevated in some benign conditions, such as BPH, osteoporosis, and hyperparathyroidism. For clinical use, PAP has been replaced by PSA.[40] PAP is not as sensitive as PSA for detection of early cancer. It is less likely to be elevated in BPH than is PSA. However, as an individual marker, PAP may be useful for disease management in the rare patient whose tumor does not secrete PSA, and it may have utility when combined with other markers for improving prostate cancer detection[15] or predicting recurrence after radical prostatectomy.[108] Currently, the method of choice for PAP is measurement of its enzymatic activity.

tahir99-VRG & vip.persianss.ir

Kallikreins

Kallikreins constitute a subgroup of the serine protease enzyme family, three members of which have been assigned a specific biological role.

Biochemistry

The human kallikrein (hK) gene locus spans a region of approximately 300 kb of chromosome 19q13.4, which contains 15 tandemly localized kallikrein genes (*KLK1* to *KLK15*) with no intervention from other genes. This is the largest cluster of serine proteases within the human genome. Members of the kallikrein family are identified by various similar features.[73] All have a nearly identical genetic structure (5′ untranslated region, intron-exon size and organization), and the catalytic triad of serine proteases is conserved by all members, with the histidine always occurring near the end of the second exon, the aspartate in the middle of the third exon, and the serine residue at the beginning of the fifth exon. All kallikreins are produced as prepropeptides with a 17 to 20 amino acid signal sequence and a 4 to 9 amino acid activation peptide. They contain 10 to 12 conserved cysteines that form 5 to 6 disulfide bonds. Finally, most if not all genes are under steroid hormone control.

Kallikreins are expressed in a wide variety of tissues, including (1) prostate, (2) breast, (3) ovary, and (4) testis.[306] For example, KLK3 (PSA) is highly expressed in prostate and is discussed in detail later in the chapter. KLK3 also has minor expression in breast, thyroid, salivary glands, lung, and trachea, and KLK11 and KLK12 are highly expressed in more than 10 tissues, with minor expression in at least four others.

Only 3 of the 15 kallikreins have been assigned a specific biological role. The major biological role of hK1 is the release of lysyl-bradykinin (kallidin) from low molecular weight kininogen; however, it has been implicated in the processing of peptide hormones, including proinsulin, low-density lipoprotein (LDL), prorenin, the precursor of atrial natriuretic peptide, and vasoactive intestinal peptide. The role of hK2 has only recently been investigated with seminal plasma hK2 found to cleave seminogelin I and II, but at different sites than hK3 (PSA). Furthermore, a role for hK2 in the regulation of growth factors through the proteolysis of insulin-like growth factor binding protein 3 (IGFBP-3) has been suggested. hK3, also known as PSA, is found not only in prostate tissue (discussed later), but in relatively high concentrations in nipple aspirate fluid, breast cyst fluid, breast milk, amniotic fluid, and tumor extracts.[32] Its presence in these fluids and tissues suggests a biological function in the breast and a possible role in fetal development; however, no specific function in these tissues has been identified to date.

Clinical Applications

The role of kallikreins as tumor markers is rather varied.[79] Several kallikreins have been associated with hormonal malignancies such as (1) prostate, (2) breast, (3) testicular, and (4) ovarian cancers. The roles of hK3 (PSA) and hK2 are discussed in detail later in the chapter. hK6 has been investigated as a serum marker for the diagnosis, prognosis, and monitoring of ovarian cancer,[72] and as a cytosolic marker for prognosis in breast cancer. Serum hK5, hK6, hK10, and hK11 have also been investigated for the diagnosis and monitoring of ovarian cancer,[168,307,308] and a high concentration of cytosolic hK10 in ovarian tumor and breast cells is a poor prognostic marker.[166,167] Kallikrein gene expression is associated with both positive and negative prognoses in various cancers, including prostate, ovarian, and breast cancers.[73]

Analytical Methods

Reverse-transcriptase polymerase chain reaction (RT-PCR), Northern and Western blotting, and immunoassays have been used for detection of kallikrein mRNA and protein in tissue extracts of (1) ovarian, (2) breast, (3) testicular, and (4) prostate tumors. Immunohistochemical techniques have been used for the detection of KLK7 in ovarian tumors and KLK10 in ovarian and testicular tumors. Serum concentrations of KLK3 (PSA) and KLK11 are evaluated by immunoassay.

Prostate-Specific Antigen

Prostate cancer is the leading cancer in older men. When detected early (organ confined), it is potentially curable by radical prostatectomy. Therefore, early detection is important and PSA is widely used for this purpose. It is considered one of the most promising tumor markers available.

In the 1970s, several groups independently discovered prostate antigens for use in forensics and as tumor markers.[257] In 1971, Hara and colleagues identified a protein in seminal plasma that they named γ-*seminoprotein*. Li and Beling isolated the same protein from seminal plasma and called it *protein E1* because it had slow β-mobility in electrophoresis and a molecular weight (MW) of 31,000 Da. In 1978, Sensabaugh characterized this glycoprotein with isoelectric points between 6.5 and 8.0 and MW of approximately 30,000 Da and called it *p30*. In 1979, Wang and coworkers purified a protein from prostatic tissue and called it *prostate-specific antigen*. γ-Seminoprotein, p30, and PSA are biochemically very similar. PSA is found in normal, benign, hypertrophic, and malignant prostatic tissues. Originally, it was thought that PSA was solely expressed in prostate tissue. However, it was later found that PSA also is expressed in numerous other tissues, most notably hormonally regulated tissue such as breast tissue. Low concentrations of PSA are detectable in sera from women as well as in nipple aspirate fluid.

Biochemistry

PSA is a single-chain glycoprotein that is 7% carbohydrate. It has 237 amino acid residues and four carbohydrate side-chains with linkages at amino acid 45 (asparagine), 69 (serine), 70 (threonine), and 71 (serine). The N-terminal amino acid is isoleucine, and the C-terminal residue is proline. Its MW is 28,430 Da,[23] and it has isoelectric points from 6.8 to 7.2 because of its various isoforms. The three-dimensional structure and the antigenic domain of PSA have been characterized.[60]

tahir99-VRG & vip.persianss.ir

The complete gene encoding PSA has been sequenced and located on chromosome 19.[165] It is similar to the kallikrein-1 gene with 82% homology. Functionally, PSA is a serine protease of the kallikrein family. It is produced exclusively by epithelial cells of the acini and ducts of the prostate gland. PSA is secreted into the lumina of the prostatic duct. In seminal fluid, PSA cleaves seminal vesicle–specific proteins into several low molecular weight proteins as part of the process of liquefaction of the seminal coagulum. Therefore, PSA possesses chymotrypsin-like and trypsin-like activity. Autodigestion of PSA has been reported at three possible locations: *LYS* 148, *LYS* 185, and *ARG* 85. The addition of protease inhibitors may be important to prevent autohydrolysis of PSA in solution.[60] The PSA promoter contains three androgen response elements and can be activated by androgens, progestins, and glucocorticoids.

Molecular Forms of Prostate-Specific Antigen

PSA exists in two major forms in blood circulation. Most PSA is complexed with the protease inhibitors α_1-antichymotrypsin (ACT) (MW, 100,000 Da) and α_2-macroglobulin (AMG), and a minor component is free PSA (MW, 28,430 Da).[156,275] Most immunoassays measure both free and ACT-complexed PSA but not PSA-AMG, which is sterically inhibited. In human seminal fluid, approximately 60 to 70% of PSA is enzymatically active, and the remainder inactive. Inactive forms of free PSA are composed of three distinct molecular forms: BPSA, pPSA, and iPSA.[178] BPSA is a degraded form of free PSA containing two internal peptide bond cleavages at Lys 145 and Lys 183; BPSA in tissue is relatively localized in the transition zone of the prostate and contributes to free PSA in BPH serum. pPSA is the proenzyme or precursor form of PSA that has a 7 amino acid pro-leader peptide. Additional truncated forms of pPSA with varying amino acids exist. Activation of pPSA, resulting from cleavage of the leader sequence by hK2 and trypsin, becomes more resistant as the number of amino acids in the pro-leader peptide decreases. pPSA is localized in the peripheral zone of the prostate and contributes to free PSA in cancer serum. iPSA consists of minor variants of intact PSA that is enzymatically inactive as the result of conformational changes.

Physiologic Properties

The metabolic clearance rate of PSA follows a two-compartment model, with initial half-lives of 1.2 and 0.75 hours for free PSA and total PSA and subsequent half-lives of 22 and 33 hours.[206] Because of this relatively long half-life, at least 2 to 3 weeks may be necessary for the serum PSA to return to baseline concentrations after certain procedures, including transrectal biopsy, transurethral resection of the prostate, and radical prostatectomy. Benign prostatic conditions, such as BPH and prostatitis, can also elevate PSA concentrations. Although the DRE typically causes no clinically important effects on serum PSA concentrations in most patients, in some it may lead to a twofold elevation. 5α-Reductase inhibitors, such as finasteride, for treatment of BPH cause a decrease in PSA concentrations of approximately 50%; thus results should be adjusted. Significant physiologic variation in serum PSA concentrations (up to 30%) has also been noted.

Clinical Applications

PSA is an extremely useful tumor marker and is used to detect and monitor treatment of prostate cancer.

Screening and Early Detection of Prostate Cancer

PSA testing by itself is limited in the screening or detection of early prostate cancer because PSA is specific for prostatic tissue but not for prostatic cancer. BPH is a common disease in men 50 years of age and older. Studies have shown that PSA concentrations in patients with BPH are similar yet statistically different from those associated with early prostatic cancer (i.e., those of patients with organ-confined cancer).[193] Unfortunately, the overlap of PSA concentrations between these two groups is so extensive, particularly between 4 and 10 μg/L, that selecting an optimum cutoff of PSA for the recommendation of a prostate biopsy is almost impossible. Results from the Prostate Cancer Prevention Trial showed the presence of prostate cancer over all ranges of PSA.[286] The clinical sensitivity of PSA is 78% at the typically used cutoff of 4.0 μg/L. By lowering the cutoff to 2.8 μg/L, sensitivity increases to 92%, whereas specificity decreases from 33 to 23%. Raising the cutoff to 8 μg/L improves the specificity to 90%.[55] Cutoffs lower than 4 μg/L have been suggested, such as by the National Comprehensive Cancer Network (NCCN).[185]

The use of serum PSA together with DRE is more accurate and sensitive than digital examination alone.[49] DRE testing has been determined to be optional aacording to recent ACS guidelines.[256,303A] PSA for screening is still controversial with recommendations for annual screening put forth by the American Cancer Society (revised in 2010)[256,303A] and by others,[280] and lack of a recommendation by the U.S. Preventive Services Task Force among others. The American Cancer Society[256,303A] emphasizes informed choice utilizing decision-making tools with screening discussions between patients and their physicians at age 50 for men at average risk with a 10-year life expectancy, and at earlier ages for men at high risk. Men at high risk include black men and men with a strong family history of prostate cancer. Definitive recommendations have awaited results from ongoing prospective randomized trials designed to determine whether PSA screening could reduce mortality from prostate cancer. However, initial results from the European Randomized Study of Screening for Prostate Cancer (ERSPC)[241] and the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial (PLCO),[10] published in 2009, were conflicting. The European trial showed that PSA screening reduced deaths from prostate cancer by 20%, while in the U.S. study, in which men were followed for a shorter period of time and many of the men in the control arm underwent PSA testing, the rate of death from prostate cancer was low overall and did not differ between men screened and those not screened.

tahir99-VRG & vip.persianss.ir

To improve the ability of PSA testing to detect early prostate cancer (clinical sensitivity) and/or spare unnecessary biopsies (clinical specificity), several approaches have been suggested. One approach is to use age-adjusted reference intervals as follows: 0 to 2.5 μg/L for men aged 40 to 49 years, 0 to 3.5 μg/L for those 50 to 59 years, 0 to 4.5 μg/L for men 60 to 69 years, and 0 to 6.5 μg/L for those 70 to 79 years.[194] By lowering the upper limit of the reference interval, more cancer will be detected in younger men, for whom potential cure by radical prostatectomy is most beneficial, although this may increase the overdetection of insignificant tumors. Increasing the upper limit for older men takes into account increases in PSA with aging due to BPH. However, 25% of men with a PSA between 2 and 4 μg/L[16,287] may have cancer, similar to the 4 to 10 μg/L range; thus use of age-specific ranges may result in missed clinically significant tumors in older men.

Another approach is to use PSA density (i.e., divide PSA concentration by prostatic volume as determined by transrectal ultrasonography) to account for more PSA from larger prostates, as in men with BPH.[25] Patients with PSA between 4 and 10 μg/L, a negative DRE result, and elevated PSA density (typical cutoff, 0.15) have increased risk for prostate cancer. The third approach is to use PSA velocity, that is, the rate of PSA increase as a function of time. It is recommended that velocity be calculated using at least three PSA results determined over at least 18 months. Increases in PSA in health, BPH, and prostatic cancer appear to be different, with the highest rate (>0.75 μg/L/y) observed in patients with prostate cancer.[47] Specificity improved to 90% for BPH, and sensitivity is 72% for prostate cancer. The PSA velocity cutoff of 0.75 μg/L/y is recommended for men with a total PSA concentration of 4 to 10 μg/L; lower cutoffs of 0.35 to 0.4 μg/L/y are suggested when PSA concentrations are <4 μg/L.

The most successful approach has been the use of molecular forms of PSA and free PSA. Percent free PSA (free PSA/total PSA*100) has been used to improve the clinical sensitivity and specificity of detecting prostate cancer, particularly for patients in the diagnostic "gray" zone of PSA between 4 and 10 μg/L or between 2 and 20 μg/L.[48,204] Men with cancer have less circulating free PSA (≈10 to 30%) and more PSA bound to protease inhibitors (≈70 to 90%) compared with men without cancer. Percent free PSA results can be interpreted using a single cutoff or a continuum of values to determine the relative risk of prostate cancer in individual men. In biopsied men with a total PSA between 4 and 10 μg/L and a DRE nonsuspicious for cancer, sensitivity for cancer detection is 95% using a %free PSA cutoff of ≤25%. Using this same cutoff (>25%), 20% of biopsied men with benign disease could be spared from biopsy. Percent free PSA may have particular utility in evaluating men who had a previous negative biopsy. A 1996 study of free PSA velocity found that percent free PSA is the earliest serum marker for predicting subsequent diagnosis of prostate cancer.[210] Studies have shown that %pPSA (pPSA/free PSA*100) can represent an improvement over %free PSA for the detection of prostate cancer, with particular utility when total PSA is in the 2.5 to 4.0 μg/L range.[259,260] Complexed PSA (cPSA) showed improved specificity over total PSA for prostate cancer detection in specific PSA subranges in a multicenter clinical trial.[203]

In addition to the approaches described previously, several algorithms using PSA and other analytes, and often clinical and demographic characteristics, have been developed to (1) aid in prostate cancer detection, (2) determine risk for prostate cancer (biopsy outcome), and (3) predict prognosis in men with prostate cancer undergoing therapy. They include nomograms and artificial neural networks. The ProstAsure Index, developed by Zhang, Stamey, and Chan,[14,269] was derived from several parameters, including age, total PSA, creatine kinase isoenzymes, and prostatic acid phosphatase, which were used as inputs for a neural network–derived, nonlinear algorithmic procedure. The resulting zone reflected the probability of prostate cancer and subsequent consideration for prostate biopsy.

Staging of Prostate Cancer

PSA has been found to correlate with clinical stages of prostate cancer.[270] For example, higher PSA concentrations and higher percentages of patients with elevated PSA concentrations are associated with advanced stages. PSA has also been found to correlate with pathologic stages of tumor extension and metastases, cancer volume, and cancer grade (Gleason score). Approximately 80% of men with PSA concentrations <4 μg/L at diagnosis have organ-confined disease; this decreases to 70% and 50% for PSA concentrations of 4 to 10 μg/L and >10 μg/L, respectively. Because significant overlap occurs in PSA concentrations among stages, PSA cannot be used to determine the pathologic stage in a given individual. Therefore, PSA by itself should not be used to decide whether a patient has prostate cancer confined to the organ and therefore is a likely candidate for radical prostatectomy or other treatment, or active surveillance. The concentration of PSA can serve as a guide and is more useful in evaluating the presence of metastases. Patients with PSA concentrations less than 20 μg/L rarely have bone metastases. Studies have shown that PSA can replace the staging radionuclide bone scan in newly diagnosed untreated prostate cancer patients who have a serum PSA concentration <20 μg/L and are asymptomatic. PSA contributes to the prediction of prostate cancer pathologic stage as part of a nomogram (the Partin tables) that also includes clinical stage and biopsy Gleason score. Multivariate logistic regression is used to estimate the probability of organ-confined disease, extraprostatic extension, seminal vesicle involvement, or lymph node involvement.[169]

Monitoring Treatment

The greatest clinical use for PSA is in the monitoring of definitive treatment of prostate cancer. This treatment includes radical prostatectomy, radiation therapy, and antiandrogen therapy.

PSA is produced almost exclusively by prostatic tissue; thus after radical prostatectomy, the PSA concentration

tahir99-VRG & vip.persianss.ir

should fall below the detection limit of the assay. This may require 2 to 3 weeks owing to the half-life of PSA. If the half-life is longer than usual, it must be assumed that residual tumor is present,[193,270] although detectable PSA may also reflect benign prostatic tissue. Biochemical recurrence has been defined as two postprostatectomy PSA concentrations ≥0.2 μg/L.[99] A cut point of 0.4 μg/L is also used. Increasing PSA after radical prostatectomy is a strong indication of disease recurrence. The time between PSA concentration elevation and clinical evidence of recurrence (metastases) averages 8 years. PSA doubling time is also useful in assessing risk of progression to metastasis with a low likelihood if the doubling time is greater than 10 to 15 months.

Unlike surgery, treatment with external beam radiation does not affect all tissues; therefore, PSA concentrations fall but do not become undetectable. The American Society for Therapeutic Radiology and Oncology (ASTRO) has defined failure as three successive rises above the nadir.[8] The more recent Phoenix guidelines[227] for defining biochemical failure after radiotherapy, which also includes interstitial prostate brachytherapy, advocate a PSA rise of 2.0 μg/L or greater over the nadir.

Hormone therapy includes (1) bilateral orchiectomy, (2) treatment with luteinizing hormone–releasing hormone agonists, and (3) antiandrogen therapy. PSA testing is useful for predicting prognosis and monitoring treatment response to this type of therapy in patients with metastatic prostate cancer. The concentration of PSA is inversely proportional to the survival time and increases with cancer progression, decreases in remission, and remains unchanged in stable disease. Androgen deprivation therapy may have a direct effect on PSA concentration that is independent of the antitumor effect. Production of PSA may be under the influence of androgenic hormones such as dihydrotestosterone. Thus PSA concentrations in patients who receive antiandrogen therapy may have a different meaning than they do in patients receiving other types of therapies.[192]

Analytical Methods

Sandwich immunoassays are used to measure PSA and are commercially available. Most of them use nonisotopic labels, such as enzyme, fluorescence, or chemiluminescence. Most of these assays are automated on an immunoassay system. Different assays and even the same assay with different lots of reagent may produce different results. Such differences are due to changes in (1) assay calibration, (2) production lot variation, (3) assay reaction time, (4) reagent matrices, (5) assay limit of detection, and (6) imprecision. Antibodies react with different PSA epitopes; therefore, some antibodies react dissimilarly with various molecular forms of PSA. Currently, most PSA assays are standardized to the Hybritech (now Beckman Coulter, Inc., Brea, Calif) PSA method or to standards introduced by the World Health Organization in 1999. The two international preparations consist of 100% free PSA (code 96/668) and 90% PSA-ACT complex and 10% free PSA (code 96/670).[58] Because of differences in the molar absorptivities used, PSA results from Hybritech standardized assays are approximately 20% higher than results from WHO standardized assays.

One of the most valuable applications of PSA is the detection of residual or recurrent disease following radical prostatectomy. Traditionally, 0.1 μg/L has been used as the lower limit of detection, which was based on assay analytical characteristics as well as clinical need. Ultrasensitive PSA assays can be defined as those with a functional sensitivity (20% CV) of 0.01 μg/L or lower. One PSA assay has been labeled as a third-generation assay, and many automated assays now achieve limits of detection close to 0.001 μg/L. Although cancer recurrence may be detected earlier, the effect on clinical management is unclear, and no assay has a specific FDA claim for earlier detection of recurrence.

Free PSA is not typically used as a single measurement but is expressed as a ratio or percentage of total PSA. Because of assay differences among manufacturers, total and free PSA should be measured in the same specimen using assays from the same diagnostics company. %fPSA is approved by the FDA as an aid in distinguishing prostate cancer from benign prostatic conditions in men aged 50 and older with a total PSA between 4 and 10 μg/L with a nonsuspicious DRE. The complexed PSA (cPSA) assay (Siemens Healthcare Diagnostics, Deerfield, Ill) measures PSA-ACT and other minor PSA complexes by rendering free PSA nonreactive with a free PSA-specific antibody. The two FDA intended uses are the same as for total PSA: (1) as an aid in the detection of prostate cancer in men aged 50 years or older in conjunction with DRE, and (2) for serial measurements to aid in the management of prostate cancer patients. A cPSA concentration of 3.2 μg/L is equivalent to a PSA cutoff of 4.0 μg/L, and a PSA threshold of 2.5 μg/L corresponds to a cPSA concentration of 2.2 μg/L.

Human Glandular Kallikrein 2

Human kallikrein 2 (hK2) and PSA (human kallikrein 3) are serine proteases that share 80% identity in protein sequence[236] and are almost exclusively found in prostatic epithelium.

Biochemistry

Similar to PSA, hK2 concentrations are 100,000-fold higher in seminal fluid than in serum.[162] hK2 has the ability to form complexes with endogenous antiproteases. One important inhibitor is the protein C inhibitor (PCI), which is the major ligand complexed to hK2 in seminal fluid, but in vitro, hK2 also forms complexes with α_2-antiplasmin, α_2-macroglobulin, ACT, antithrombin III, C1-inactivator, and plasminogen activator inhibitor-1.[179] Gel filtration studies have suggested that hK2 occurs mainly in a free, noncomplexed form in serum, whereas only a minor proportion (5 to 20%) may be complexed with protease inhibitors. In vitro, recombinant hK2 activates proPSA into mature, catalytic active form.

Clinical Applications

Immunohistochemical studies have demonstrated that tissue expression of hK2 shows intense staining in high-grade cancers and lymph node metastases, whereas it shows weaker

tahir99-VRG & vip.persianss.ir

staining for low-grade cancers and BPH.[65] Serum hK2 alone or hK2*total PSA/free PSA has been shown to be a significantly better predictor of organ-confined disease than tPSA.[103] In addition to the improvement in staging accuracy, hK2 discriminated aggressive, poorly differentiated prostate cancer from less aggressive, well-differentiated prostate cancer.[223] Although serum hK2 is independently indicative of prostate cancer of unfavorable prognosis, a model combining total and free PSA and total hK2 had superior discrimination.[277]

Analytical Methods

Currently, two major hK2 immunoassays are available. Haese and colleagues found notable differences in results when measuring by the two immunoassays for hK2 in identical patient samples.[104] Calibration of the two assays with the use of a common, ek-rhK2–based calibrator resulted in a substantial gain in agreement between the assays.

The Urokinase-Plasminogen Activator System

The urokinase-plasminogen activator system consists of three main components: urokinase-plasminogen activator (uPA, a 53 kDa serine protease), the uPA membrane-bound receptor (uPAR), and the uPA inhibitors, PAI-1 and PAI-2.[9,229]

Biochemistry

The urokinase-plasminogen activator is produced as a single inactive polypeptide, which is activated by cleavage between lysine 158 and isoleucine 159. The cleavage is catalyzed by a number of proteases, including cathepsins B and L and hK2. The active form of uPA consists of an A chain, which interacts with its cell surface receptor, uPAR, and a catalytically active B chain. The most thoroughly characterized activity of uPA is the conversion of plasminogen to active plasmin, which degrades extracellular matrix (ECM) components and activates matrix metalloproteinases (MMPs), which further degrade the ECM and activate and release specific growth factors [fibroblast growth factor (FGF)2 and transforming growth factor (TGF)-β]. The activity of uPA is controlled in vivo by two inhibitor molecules: PAI-1 and PAI-2. PAI-1 and PAI-2 not only act to inhibit uPA but also have a number of other functions, including angiogenesis, cell adhesion and migration, and inhibition of apoptosis.

Clinical Applications

uPA has been used as a prognostic marker in breast cancer and a number of other cancers.

Breast Cancer

uPA was the first protease implicated in metastasis evaluated for prognostic value in humans. At least 20 independent groups have demonstrated that breast cancer patients with high activity of uPA in their primary tumors have a worse disease-free pattern than those patients with low uPA activity.[75] The prognostic impact of uPA appears to be independent of other traditionally used markers, such as (1) axillary node status, (2) tumor size, (3) tumor grade, and (4) estrogen receptor (ER) status. In most studies,[110,310] uPA is a more potent predictor of overall survival than tumor size, tumor grade, or ER status, and is equally powerful as nodal status. Patients who benefit most from uPA measurement are those who are newly diagnosed with histologically negative local nodes. The long-term survival of this group is 70 to 80% with local therapy alone, and no further benefit is gained from adjuvant chemotherapy. uPA may be able to detect the small number of patients most at risk for recurrent disease and spare other cured patients from unnecessary chemotherapy. A prospective, randomized, controlled trial[126] of 674 node-negative breast cancer patients demonstrated that women with high concentrations of uPA and/or PAI-1 had a notably shorter disease-free period than those with low concentrations of both proteins. A pooled analysis of 8377 breast cancer patients showed an independent association between tissue uPA and PAI-1 concentrations in poor relapse-free and overall survival in both lymph node–negative and lymph node–positive patients.[161] ASCO[113] has recommended uPA/PAI, measured by ELISA on 300 mg of breast cancer tissue, to determine prognosis in newly diagnosed node-negative patients; concentrations of both markers may aid in determining the benefit of chemotherapeutic treatment.

Other Cancers

uPA has also demonstrated its usefulness as a prognostic marker in colorectal cancer. For example, in one study,[75] uPA was found to be a marker of disease outcome in patients with tumor invasion but negative node status (Dukes' B stage). High concentrations of uPA were also found to correlate with aggressive disease in both gastric and esophageal cancers. Preliminary studies have implicated uPA as a prognostic marker in (1) ovarian, (2) renal, (3) hepatocellular, (4) pancreatic, (5) urinary, (6) bladder, (7) lung (adenocarcinoma), and (7) cervical cancers and (8) gliomas. Thus uPA may function as a general prognostic marker in cancer.

Analytical Methods

The original assay developed for uPA measured its catalytic activity. This assay has been replaced by enzyme-linked immunosorbent assay (ELISA), and several research and commercially available kits have been developed for detection of uPA and PAI-1 in tumor tissue. Generally, increased concentrations of uPA, PAI-1, or both indicate poor prognosis. A uPA concentration below 3 ng/mg total tissue and a PAI-1 below 14 ng/mg total tissue have a notably better prognosis.[126] Most studies showing a prognostic value for uPA have used ELISA for detection; however, some were performed using immunohistochemistry. Immunohistochemical detection is easier and requires less tissue; however, interpretation is subjective and only semiquantitative.

Cathepsins

The cathepsins are lysosomal proteases; cathepsins B, D, and L have been investigated for their role in tumor development and progression.

tahir99-VRG & vip.persianss.ir

Biochemistry

Similar to other proteases, cathepsins are synthesized as high molecular weight precursors that require processing for activation. Cathepsin B (CB) is a thiol-dependent protease normally found in lysosomes; it is activated by cathepsin D (CD) and matrix metalloproteinases. Activated CB in turn can activate uPA and specific metalloproteinases. Cathepsin L (CL) is similar in specificity to CB; however, it shows little activity toward small molecular substrates. Cathepsin D, similar to CB, is a lysosomal protease; however, CD belongs to the aspartyl group of proteases.

Expression and localization of CB appear to be altered in tumors relative to normal tissue. In tumor tissue, CB can be associated with the plasma membrane or secreted. Increased expression has been demonstrated in (1) breast, (2) colorectal, (3) gastric, (4) lung, and (5) prostate carcinomas, (6) gliomas, (7) melanomas, and (8) osteoclastomas, suggesting a link with tumor development and/or progression.[139] Altered localization of CB has been seen in various tumor tissues, such as (1) colon (2) carcinomas, (3) thyroid cancers, (4) gliomas, and (5) breast epithelial tumors. Altered expression and localization are thought to be involved in tissue invasion through ECM degradation and growth promotion. ECM degradation occurs through activation of CB and other proteases, such as MMPs and uPA. In addition to ECM degradation, CB releases growth factors: basic fibroblast growth factor (bFGF), insulin-like growth factor-1 (IGF-1), epidermal growth factor (EGF), and TGF-β associated with the ECM.

Stromal cells were originally thought to be passive bystanders in tumor development; however, evidence suggests an active role. Increased expression of ECM proteases, including CB, has been demonstrated in stromal cells at the border between tumor cells and normal tissue. Expression of both CB and CD is upregulated by various growth factors (bFGF, EGF, IGF-1) and by direct contact with tumor cells. This suggests that as tumor cells invade the stroma, stromal cells are induced to participate directly in matrix degradation.[139] Therefore, detection of CB in stromal cells and tumor cells may have prognostic value.

Clinical Applications

A limited number of studies have associated high values of CB in multiple tumor types with aggressive disease. All, with one exception, are retrospective studies with low numbers of patients. However, in one large study (n = 1500 patients), CB was shown to be an independent prognostic marker for both relapse-free and overall survival in breast cancer patients; however, it is not as good a marker as uPA.

Most data related to the prognostic value of CD are expressed in relation to breast cancer[228]; however, its usefulness in squamous cell carcinoma (SCC) of the head and neck, hepatocellular carcinoma, and gastric adenocarcinoma has been investigated in limited studies. For breast cancer, a 1999 report of 2810 patients confirmed the prognostic value of CD.[86] The authors, using an RIA to detect cytoplasmic CD in tumor tissue, showed that tumors with high CD had notably poorer relapse-free survival than those with low CD concentrations.

In contrast to RIA detection of CD in tissue extracts, immunohistochemical detection has led to conflicting results. Some investigators have reported a significant association between immunohistochemically determined CD and poor outcomes; others have found no relationship. Possible reasons include (1) differences in antibody specificity, (2) different scoring systems used to quantify CD staining, (3) different discrimination cutoff points, and (4) different types of tissue: fresh versus formalin-fixed and paraffin-embedded.[71] Therefore, the prognostic usefulness of CD in SCC and other malignancies needs further study to determine the utility of CD as an independent marker.

The use of CL as a prognostic indicator has been best studied in breast cancer. Most studies measured CL from tumor extracts and correlated high concentrations of CL with a decrease in relapse-free survival. CL appears to be an independent prognostic marker in both node-negative and node-positive breast cancer, especially when combined with other prognostic markers such as CB, CD, node status, and steroid hormone receptor status.

Analytical Methods

Initial assays for detection of CB used chromogenic substrates containing an Arg-Arg sequence and 2-naphthylamide and 7-amino-4-methylcoumarin as chromophores. These early assays lacked specificity and were likely to have suffered from interference by endogenous inhibitors (e.g., cystatins, stefins). CB and CL are now measured by ELISA; however, to date no comparison has been made with older CB methods. Immunohistochemistry has also been used to detect CB in tissue; however, no detailed evaluations have been conducted.

Most studies correlating CD with tumor progression and prognosis have used an immunoassay that detects both the proforms and the mature forms of CD. This assay can be used to measure CD in tissue extract generated for detection of steroid hormone receptors. CD has also been measured by Western blot, by immunohistochemistry, and by activity.

Matrix Metalloproteinases

Matrix metalloproteinases (MMPs) are a family of 23 structurally related zinc-dependent endopeptidases capable of degrading components of the ECM.[195,264]

Biochemistry

Most MMPs are secreted as a zymogen; once activated, their proteolytic activity is inhibited by tissue inhibitors known as tissue inhibitors of metalloproteinases (TIMPs). MMPs have been functionally grouped into four subgroups, based on their ECM specificity: (1) collagenases, (2) gelatinases, (3) stromelysins, and (4) membrane MMPs.

Clinical Applications

MMPs are involved in many functions, including tissue remodeling and wound repair; however, they have also been associated with tumor growth, invasion, and metastasis.[294]

tahir99-VRG & vip.persianss.ir

Direct evidence for the role of MMPs in the development and progression of tumors has been provided by mouse knockout studies in which mice lacking various MMPs showed reduced tumorigenesis and progression. Conversely, increased expression is associated with tumor aggressiveness and poor prognosis. Increased expression of MMP-2 and MMP-9 is associated with accelerated tumor progression in (1) oral carcinoma; (2) lung adenocarcinoma; and (3) bladder, (4) ovarian, and (5) papillary thyroid carcinoma. Similarly, increased staining of MMP-3 and MMP-9 is seen in high-grade versus low-grade endometrial sarcoma. In esophageal carcinoma, MMP-7 expression correlates with tumor aggressiveness. In addition, plasma TIMP-1 concentrations have been found to be higher in patients with colon cancer compared with controls and to be improved over CEA for cancer detection.[120,121]

MMPs also act as predictors of recurrence or metastatic risk. Elevated preoperative serum MMP-2 or MMP-3 is predictive of recurrence in patients with advanced urothelial carcinoma. Furthermore, high MMP-2 expression in ovarian tumor cells can predict tumor recurrence. Expression of certain MMPs is predictive of metastatic risk. For example, expression of MMP-1 is associated with lymph node metastasis in cervical cancer and peritoneal metastasis in gastric cancer. MMP inhibition may be a therapeutic strategy for cancer.[195]

Analytical Methods

Gelatin zymography is a technique commonly used to detect MMPs, such as MMP-2 and MMP-9. Zymography is an electrophoretic technique used to identify proteolytic activity in enzymes separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis under nonreducing conditions. The SDS is removed, allowing the MMPs to refold and subsequently digest gelatin at the position of the separated protein. This technique, although tedious, has the advantage of specifically detecting the active form of the protease. MMPs are also detected in tissue sections by immunohistochemistry using specific antibodies, and in tissue extracts and serum by immunoassay.

Tumor-Associated Trypsin Inhibitor

Tumor-associated trypsin inhibitor (TATI) is a 6 kDa trypsin inhibitor that was first identified from the urine of an ovarian cancer patient.

Biochemistry

TATI is identical to the previously identified pancreatic secretory trypsin inhibitor (PSTI), which is also known as the Kazal inhibitor. TATI is strongly expressed by pancreatic acinar cells, together with trypsinogen. It is secreted into the pancreatic juice, where it constitutes 0.1 to 0.8% of the total protein. It is expressed at lower concentrations in other healthy tissue, such as (1) the gastrointestinal and urogenital tracts, (2) the gallbladder, (3) the biliary tract, (4) kidney, (5) lung, (6) liver, and (7) breast. TATI also acts as an acute-phase reactant and is induced under strong inflammatory conditions, as would be expected, as its promoter contains an interleukin (IL)-6 response element. TATI function in vivo is thought to protect against autodigestion of body tissue by trypsinogen secreted by the pancreas and other tissue. TATI is rapidly cleared from the circulation by the kidneys with a half-life of approximately 6 minutes. Therefore, patients with renal disease can have extremely high serum concentrations of TATI (greater than 1000 μg/L).

Clinical Applications

Although pancreatitis, severe injury, and inflammation all can increase its concentration, TATI can still function as a relatively good tumor marker for various cancers. In most cancers, the increase in TATI is due to tumor production; however, inflammation associated with tissue destruction contributes to the overall TATI increase. Serum and urine concentrations correlate well, but because of greater variation in urine, serum is preferred.

Increases in both serum and urine TATI are common in ovarian cancer. In mucinous ovarian cancers, approximately 45% of patients have increased TATI in stage I, and 90 to 100% have increases by stage IV.[273] Fifty-five to 60% of patients with late-stage endometrial cancer have increased serum TATI; however, only 20% show an increase in early stages. TATI is increased in cervical cancer, but squamous cell carcinoma antigen (SCCA) and CEA are better markers.

TATI is useful in gastrointestinal and urologic cancers. As may be expected because of its pancreatic production, TATI is a useful marker for pancreatic cancer and is increased in 75 to 90% of patients. In gastric cancer, TATI is increased in 40 to 65% of patients, and high preoperative concentrations correlate with a poor prognosis. Patients with hepatocellular (60 to 80%) or biliary tract cancer (75 to 100%) show an increase in TATI. The clinical sensitivity of TATI in hepatocellular cancer is similar to that of AFP and is useful in AFP-negative cancers. Colorectal cancers also increase TATI, with approximately 34 to 74% of patients showing an increase. However, CEA is a better marker of disease. In bladder cancer, TATI has been shown to be more useful than other serum markers and is a strong prognostic indicator. In renal cell carcinoma, TATI is a more sensitive marker than CEA, CA 15-3, CA 125, and CA 19-9, and is useful in monitoring disease progression and after surgery.

Analytical Methods

TATI in serum or urine is typically measured by radioimmunoassay. The reference interval for TATI is 3 to 21 μg/L in serum and is method dependent, as a method employing monoclonal antibodies gives a slightly lower reference interval (3.1 to 16 μg/L). The urine concentration is more variable, with a reference interval of 7 to 51 μg/L.

Telomerase

Telomeres are specialized structures at the termini of eukaryotic chromosomes.

Biochemistry

Telomeres are composed of hexanucleotide repeats (TTAGGG) that signal the end of a chromosome and inhibit the DNA repair mechanism from joining the ends of chromosomes together. They also appear to function as a mitotic clock that records the replicative history and sets a finite life span for normal somatic cells. During each replication, cycle telomeric DNA is lost because of inability of the replication machinery to overcome the loss of terminal RNA primers. However, expression of functional telomerase is a mechanism to overcome telomeric DNA loss in germline cells and stem cells. Telomerase is a ribonucleoprotein reverse transcriptase that elongates telomere ends using a segment of its own RNA as a template. Two main components are required for telomerase activity: human telomerase RNA (hTR), which contains the template for reverse transcription, and human telomerase reverse transcriptase (hTERT), which consists of the enzyme's catalytic subunit.

Telomerase is normally active during embryogenesis but is repressed in most somatic cells before or shortly after birth. Germline cells, activated lymphocytes, and other immortal cells show no shortening of telomere length and possess telomerase activity. Thus tumor cells should also show telomerase activity that can act as a specific marker of transformation. In 2009, the Nobel Prize in Physiology or Medicine was awarded for the discovery of telomerase.

Clinical Applications

Telomerase activity has been detected in more than 80% of cancers, including (1) lung, (2) breast, (3) pancreatic, (4) bladder, and (5) many other cancers; however, it does not seem to be necessary for cancer development.[118] Its activity does, however, correlate with tumor progression and prognosis.

Detection of telomerase activity or hTERT mRNA in excretion, secretion, brushings, and washings has been evaluated. In pancreatic secretion samples, which contain freshly exfoliated cells, detection of telomerase activity was associated with cancer detection. Telomerase activity was also found to be useful in distinguishing between adenoma and carcinoma in intraductal papillary-mucinous tumors, which sometimes can be difficult to diagnose. In bronchial brushing samples, the clinical sensitivity of cancer detection is below 70%, and false-positive results are commonly encountered because of contamination with lymphocytes, which contain measurable telomerase activity. Measurement of telomerase may be a useful marker in cervical cancer, because most cervical cancers express telomerase. In cancers such as non–small cell lung cancer, gastric cancer, and neuroblastoma, and adenocarcinomas of the stomach and colon, telomerase activity is upregulated during tumor progression and is useful in the evaluation of malignant grading and patient prognosis.

Analytical Methods

The TRAP (telomeric repeat amplification protocol) assay is a widely used method for detection of telomerase activity. This technique measures the telomerase activity present in cell extracts. Briefly, cellular extract containing telomerase activity is incubated with a telomeric substrate (a short strand of DNA onto which the telomerase will attach the telomeric repeats), followed by polymerase chain reaction (PCR) amplification of the elongated telomere. The PCR product is detected by various methods, including gel electrophoresis, radiometric detection, ELISA, and real-time PCR detection.[117,233]

HORMONES

Hormones have been recognized as tumor markers for more than 50 years. The introduction of specific RIA methods for a particular hormone that has very little cross-reactivity with similar hormones made it possible to monitor the treatment of cancer patients.

With the introduction and use of monoclonal antibodies, measurement of hormones is now accurate and precise. The production of hormones in cancer involves two separate routes. First, the endocrine tissue that normally produces it can produce excess amounts of a hormone. Second, a hormone may be produced at a distant site by a nonendocrine tissue that normally does not produce the hormone. The latter condition is called *ectopic syndrome*. For example, the production of adrenocorticotropic hormone (ACTH) is normotropic by the pituitary and is ectopic by the small cell of the lung. Consequently, elevation of a given hormone is not diagnostic of a specific tumor, because a hormone may be produced by a variety of cancers.

Multiple endocrine neoplasia (MEN) syndromes (MEN-1, MEN-2A, and MEN-2B) are familial disorders inherited in an autosomal dominant fashion that are manifested by both benign and malignant tumors. Various polypeptide hormones, such as (1) ACTH, (2) calcitonin, (3) gastrin, (4) glucagon, (5) insulin, (6) secretin, and (7) vasoactive intestinal polypeptide, may be produced by the pancreatic islet cell and pituitary tumors found in MEN-1 and by medullary thyroid cancer found in MEN-2A and -2B and in familial medullary thyroid cancer (FMTC), a variant of MEN-2A.[145,258] Examples of hormones that are used as tumor markers are listed in Table 24-7. ACTH, calcitonin, and hCG are discussed in greater detail later.

Adrenocorticotropic Hormone

ACTH is a polypeptide hormone with 39 amino acids and an MW of 4500 Da that is produced by corticotropic cells of the anterior pituitary gland (see Chapter 53). In 1928, a patient who had the signs and symptoms of what is now known to be cortisol excess was described as having a small cell carcinoma of the lung.[38] A small number of these carcinomas can produce pro-ACTH, the precursor to ACTH. This precursor has an MW of 22,000 Da, 5% bioactivity, and most of the immunoactivity of ACTH. Traditional RIA measures precursors pro-ACTH and pro-opiomelanocortin (POMC), as well as the intact molecule and ACTH fragments that may be

TABLE 24-7 Hormones as Tumor Markers

Hormone	Type of Cancer
ACTH	Cushing's syndrome, lung (small cell)
Antidiuretic hormone	Lung (small cell), adrenal cortex, pancreatic, duodenal
Bombesin	Lung (small cell)
Calcitonin	Medullary thyroid
Gastrin	Glucagonoma
Growth hormone	Pituitary adenoma, renal, lung
hCG	Embryonal, choriocarcinoma, testicular (nonseminoma)
Human placental lactogen	Trophoblastic, gonads, lung, breast
Neurophysins	Lung (small cell)
Parathyroid hormone	Liver, renal, breast, lung, various
Prolactin	Pituitary adenoma, renal, lung
Vasoactive intestinal peptide	Pancreas, bronchogenic, pheochromocytoma, neuroblastoma

beneficial for ectopic ACTH-producing tumors, whereas reactivity of the immunometric assay depends on the antibodies used and may measure ACTH as well as its precursors.

Elevated plasma concentrations of ACTH could be the result of pituitary or ectopic production. A high concentration of ACTH (>200 ng/L) is suggestive of ectopic origin. Failure of dexamethasone to suppress cortisol is also indicative of ectopic production. About half of the ectopic production of ACTH is a result of small cell carcinoma of the lung. Other conditions that elevate ACTH concentrations have been reported, including pancreatic, breast, gastric, and colon cancer, and benign conditions, such as chronic obstructive pulmonary disease, mental depression, obesity, hypertension, diabetes mellitus, and stress. The value of ACTH in the monitoring of therapy is still unknown.[21]

Calcitonin

Calcitonin is a polypeptide with 32 amino acids; it has an MW of about 3400 Da and is produced by C cells of the thyroid.[13] Normally, calcitonin is secreted in response to increased serum calcium. It inhibits the release of calcium from bone and thus lowers the serum calcium concentration. The serum half-life is about 12 minutes. The concentration in healthy individuals is less than 0.1 μg/L. An elevated concentration is usually associated with medullary carcinoma of the thyroid.

Approximately 75% of MTC cases are sporadic, and 25% are familial. Most familial MEN-2A, MEN-2B, and FMTC cases are the result of mutations of the *RET* proto-oncogene, a receptor tyrosine kinase, and almost all develop MTC. Calcitonin is most useful for diagnosing sporadic MTC or for identifying the index case in familial MTC; genetic testing has supplanted calcitonin for screening family members of the index case. Calcitonin is used for monitoring MTC. Provocative testing with intravenous administration of calcium and/or pentagastrin produces increased calcitonin concentrations and is used to increase the sensitivity and specificity of MTC detection. Microscopic or occult malignancy has been detected in patients having a negative radioisotopic scan and normal thyroid glands on physical examination.

Calcitonin concentrations appear to correlate with indicators of the extent of disease, such as tumor volume and tumor involvement in local and distant metastases. Calcitonin is useful for monitoring treatment and detecting the recurrence of disease.

Calcitonin concentrations are also elevated in some patients with carcinoid tumors and cancers of the lung, breast, kidney, and liver. The usefulness of calcitonin as a tumor marker in these malignancies has not been proven. Calcitonin elevation has been reported in other nonmalignant conditions, such as (1) pulmonary disease, (2) pancreatitis, (3) hyperparathyroidism, (4) pernicious anemia, (5) Paget's disease of bone, and (6) pregnancy.

Human Chorionic Gonadotropin

Elevated hCG concentrations are seen in pregnancy, trophoblastic disease, and germ cell tumor. It is a useful tumor marker for tumors of the placenta (trophoblastic tumors) and for some tumors of the testes. It is also useful for diagnosing and monitoring pregnancy (see Chapter 57 for a discussion of hCG and pregnancy).

Biochemistry

Human chorionic gonadotropin is a glycoprotein secreted by the syncytiotrophoblastic cells of the normal placenta. hCG consists of two dissimilar α and β subunits. The α subunit is common to several other hormones: luteinizing hormone (LH), follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH). The β subunit is unique to hCG, and the 28 to 30 amino acids making up the carboxyl terminal are antigenically distinct. hCG has an MW of 45,000 Da.[289] Additional serum forms, including hyperglycosylated (hCGh) and nicked hCG (hCGn) and the urine form hCGβ core fragment (hCGβcf), have relevant clinical usefulness.[68] The upper reference limit in men and nonpregnant women is 5.0 IU/L. hCG assays with a detection limit <2 IU/L, cross-reactivity with LH <2%, and equimolar recognition of hCG and hCGβ (or a separate assay for hCGβ) are desired for tumor marker use.[280]

Production of the two hCG subunits is under separate genetic control. In early pregnancy, the free β subunit is produced together with intact (a whole molecule of) hCG. In late pregnancy, the free α subunit predominates. Trophoblastic tumors of placental and germ cell origin primarily produce intact hCG, while differential production of the subunits, primarily the free β subunit, has been observed in nontrophoblastic cancer patients.[274]

Clinical Applications

Patients with trophoblastic tumors typically have elevated concentrations of hCG (>1 million IU/L). It is also elevated in 70% of those with nonseminomatous testicular germ cell tumors, and less frequently in those with seminoma. Elevated serum concentrations of hCG[274] are also found in 45 to 60% of (1) biliary and (2) pancreatic cancers and in 10 to 30% of many other cancers, including (3) bladder, (4) renal, (5) prostate, (6) liver, (7) colorectal, (8) non–small cell lung, (9) breast, and (10) head and (11) neck cancers, and (12) hematologic malignancies. Most neuroendocrine tumors produce hCGβ, while carcinoid tumors produce hCGα. Elevations have also been reported in benign conditions, such as cirrhosis, duodenal ulcer, and inflammatory bowel disease.

hCG is useful in identifying patients with trophoblastic tumors and, together with AFP, in detecting nonseminomatous testicular tumors. Concentrations of hCG correlate with tumor volume and disease prognosis. The hyperglycosylated form of hCG may aid in the early detection of new or recurrent active trophoblastic malignancy and may discriminate quiescent gestational trophoblastic disease from active gestational trophoblastic neoplasia/choriocarcinoma.[62] Because hCG does not cross the blood-brain barrier, the normal cerebrospinal fluid-to-serum ratio is 1 : 60. Higher concentrations in cerebrospinal fluid may indicate metastases to the brain. Furthermore, the response to therapy for patients with central nervous system metastasis may be observed by monitoring the CSF hCG concentration.

hCG is most useful for monitoring treatment and progression of trophoblastic disease.[27] Concentrations of hCG correlate with tumor volume. A patient with an initial hCG concentration greater than 400,000 IU/L is considered at high risk for treatment failure. After surgical removal of the tumor, hCG concentration is expected to decline. The normal half-life of serum hCG is about 12 to 20 hours. Slowly decreasing or persistent concentrations of hCG may indicate the presence of residual disease. During chemotherapy, weekly hCG measurement is recommended. After remission is achieved, yearly hCG measurement is recommended to detect relapse. The detection limit of the assay is important, because any residual hCG activity may indicate the presence of a tumor.

Analytical Methods

Measurement of serum hCG improved greatly in the 1970s. Assay specificity was improved by use of an antibody to the β subunit of hCG that had little cross-reactivity with other glycoprotein hormones, LH, FSH, and TSH. Currently, most hCG assays use an immunometric ("sandwich") format. The hCG assay measures the intact (whole) molecule when an antibody for the α subunit and an antibody for the β subunit are used in the immunometric format. This type of assay does not measure free α or β subunits, because free subunits cannot form a sandwich with both antibodies. The total β-hCG assay measures both intact hCG and free β subunits. As a tumor marker, a total β-hCG assay is preferred, because many cancer patients produce notable amounts of free β subunit. World Health Organization (WHO) international reference reagents (IRRs) for hCG isoforms, including (1) intact hCG, (2) nicked hCG, (3) hCGβ, (4) nicked hCGβ, (5) hCGβcf, and (6) hCGα, have been developed,[30] and studies with these preparations have indicated that varying specificity of these variants in commercial hCG assays contributes to methodologic differences.[279,301] None of the commercially available hCG assays have been approved by the FDA for use as a tumor marker assay. Heterophile antibodies and antianimal antibodies such as human antimouse antibodies (HAMAs) can cause false-positive or -negative results in immunoassays, including those for hCG. Urine hCG testing, among other approaches, can help distinguish true positives from assay interference.

ONCOFETAL ANTIGENS

Oncofetal antigens are proteins produced during fetal life. These proteins are present in high concentration in the sera of fetuses and decrease to low concentration or disappear after birth. In cancer patients, these proteins often reappear, revealing that certain genes are reactivated as the result of the malignant transformation of cells.

Discovery of the oncofetal antigens AFP and CEA in the 1960s revolutionized the modern era of tumor markers. Oncofetal antigens that have been used as tumor markers are listed in Table 24-8.

α-Fetoprotein

AFP is a marker for hepatocellular and germ cell (nonseminoma) carcinoma.[283]

TABLE 24-8 Oncofetal Antigens as Tumor Markers

Name	Nature	Type of Cancer
AFP	Glycoprotein, 70 kDa, 4% CHO	Hepatocellular, germ cell (nonseminoma)
Oncofetal antigen	80 kDa	Colon
Carcinofetal ferritin	Glycoprotein, 600 kDa	Liver
CEA	Glycoprotein, 22 kDa, 50% CHO	Colorectal, gastrointestinal, pancreatic, lung, breast
Pancreatic oncofetal	Glycoprotein, 40 kDa	Pancreatic
Squamous cell antigen	Glycoprotein, 44 to 48 kDa	Cervical, lung, skin, head and neck (squamous)
Tennessee antigen	Glycoprotein, 100 kDa	Colon, gastrointestinal, bladder
Tissue polypeptide antigen	Cytokeratins 8, 18, 19	Various (breast, colorectal, ovarian, bladder)

CHO, Carbohydrate.

Biochemistry

AFP was found first in the sera of mice with liver cancer[2] and later[285] in the sera of humans with hepatocellular carcinoma. AFP is a glycoprotein with a molecular mass of 70 kDa. It consists of a single polypeptide chain and is 4% carbohydrate. AFP is synthesized in large quantities during embryonic development by the fetal yolk sac and liver. It is one of the major proteins in the fetal circulation, but its maximum concentration is about 10% that of albumin. AFP is closely related both genetically and structurally to albumin, having extensive homologies in amino acid sequence. The genes coding for both proteins have been localized to chromosome 4q. As albumin synthesis increases during later fetal development, AFP concentrations in fetal serum begin to decline. They finally reach the trace concentrations found in normal adults 18 months after birth.

For tumor-derived AFP, the composition of carbohydrate on AFP depends on the activity of saccharide transferase within tumor cells. Differences in carbohydrate sidechains on AFP may be determined by the binding of AFP to lectins, such as concanavalin A (Con A) and lens culinaris agglutinin (LCA). Molecular variants of AFP can be separated into the liver type and the yolk sac type; they differ from each other in terms of their carbohydrate moiety. The yolk sac type of AFP contains an additional sugar, *N*-acetylglycosamine; this blocks the Con A binding site on the AFP. Therefore, the yolk sac type of AFP shows a high percentage (50 to 70%) of Con A nonreactive (CNR) fraction, whereas the liver type, which lacks this additional sugar, shows a low CNR fraction (10 to 20%).[57] LCA binds to the fucosylated form of the first core *N*-acetylglucose, which is present in both liver and yolk sac types of tumor-derived AFP, but not in AFP generated by benign liver disease.

Clinical Applications

The serum AFP concentration is less than 10 μg/L in healthy adults.[56] During pregnancy, maternal AFP concentrations increase from 12 weeks' gestation to a peak of about 500 μg/L during the third trimester. Fetal serum AFP reaches a peak of 2 g/L at 14 weeks and then declines to about 70 mg/L at term. The use of AFP for detecting fetuses with neural tube defects is discussed in Chapter 57. In addition to pregnancy, elevated concentrations of serum AFP are associated with benign liver conditions, such as hepatitis and cirrhosis. Most patients with these benign diseases (95%) have AFP concentrations less than 200 μg/L.

Except in the pregnant patient, AFP concentrations greater than 1000 μg/L are indicative of cancer. At these concentrations of AFP, about half of hepatocellular carcinomas may be detected. However, because the serum concentration of AFP correlates with the size of the tumor,[132] detection of hepatocellular carcinoma is more useful at the earlier stages, when the tumor is small enough to be resectable (<5 cm) than when the tumor is large. To detect small tumors, the cutoff for AFP is typically set at a low concentration; a cutoff point of 10 to 20 μg/L has been recommended. However, at this concentration, hepatitis and cirrhosis must be considered as possible causes of elevation.

Screening for hepatocellular carcinoma has been attempted in high-incidence areas, such as Africa, China, Taiwan, Japan, and Alaska.[174] Initial large-scale screening in China using less sensitive techniques (e.g., agglutination and immunodiffusion, which have cutoffs of 400 to 1000 μg/L) was able to detect new cases of this type of cancer. More sensitive immunoassay methods having cutoffs of 10 to 20 μg/L and ultrasonography have been used in Taiwan and Japan with improved sensitivity in detecting hepatocellular carcinoma at earlier stages.

AFP is also useful for determining prognosis and for monitoring therapy for hepatocellular carcinoma.[132] The concentration of AFP is a prognostic indicator of survival. Elevated AFP concentrations (>10 μg/L) and serum bilirubin concentrations greater than 2 mg/dL are associated with shorter survival time.

Differential binding of AFP to the lectin LCA forms the basis of the AFP-L3% test for hepatocellular carcinoma that was cleared by the FDA for clinical use in 2005. Total AFP can be separated into three glycoforms: AFP-L1, AFP-L2, and AFP-L3, based on reactivity to LCA.[152] The L1 fraction of total AFP is present in patients with chronic hepatitis and liver cirrhosis, and it constitutes the majority of total AFP in nonmalignant liver disease. AFP-L1 has low reactivity with LCA. AFP-L2 is mostly derived from yolk sac tumors and has an intermediate affinity to LCA. AFP-L3 is produced by cancer cells and has an additional α-1-6-fucose residue attached at the reducing terminus of *N*-acetylglucosamine. AFP-L3% is calculated as the proportion of measured AFP-L3 to total AFP.

The AFP-L3% test is indicated for use in risk assessment for the development of hepatocellular carcinoma in patients who have chronic liver disease. A cutoff of 10% is used, and those patients with chronic liver disease and an elevated AFP-L3% have a sevenfold increased risk of developing hepatocellular carcinoma within 21 months. The test is useful for early detection, particularly in the AFP range of 20 to 200 μg/L, as has been shown in patients with hepatitis C–related cirrhosis, where hepatocellular incidence was higher in patients with elevated AFP-L3% compared with those with elevated AFP concentrations.[276] AFP-L3% correlates with tumor staging and aggressiveness. Although AFP-L3% is useful in detection and prognosis, it can be used only when AFP concentrations are elevated.

The AFP concentration is a good indicator for monitoring therapy and the change in clinical status. Elevated AFP concentrations after surgery may indicate incomplete removal of the tumor or the presence of metastasis. Falling or rising AFP concentrations after therapy may determine the success or failure of the treatment regimen. A notable increase in AFP concentrations in patients considered free of metastatic tumor may indicate the development of metastasis.

The combination of AFP and hCG is useful in classifying and staging germ cell tumors. Germ cell tumors may be predominantly one type of cell or may be a mixture of seminoma,

yolk sac, choriocarcinomatous elements (embryonal carcinoma), and teratoma.[19] Serum concentrations of AFP are elevated in yolk sac tumors, whereas hCG is elevated in choriocarcinoma. Both are elevated in embryonal carcinoma. In seminomas, AFP is not elevated, whereas hCG is elevated in 10 to 30% of patients who have syncytiotrophoblastic cells in the tumor. Neither marker is elevated in teratoma. One or both of the markers are elevated in about 90% of patients with nonseminomatous testicular tumor. Elevations were noted in less than 20% of patients with stage I disease, 50 to 80% with stage II disease, and 90 to 100% with stage III disease. These markers correlate with tumor volume and the prognosis of disease.

The combined use of these markers is useful in monitoring patients with germ cell tumors: elevation of either marker indicates recurrence of disease or development of metastasis. The success of chemotherapy can be assessed by calculating the decrease in concentration of both markers using the half-lives of AFP (5 days) and hCG (12 to 20 hours).

Analytical Methods

Serum AFP is determined by immunometric assay on many automated immunoassay systems. A reference material for AFP [First WHO International Standard (IS)] is available from the National Institute for Biological Standards and Control (NIBSC) in the United Kingdom. AFP is reported using units of ng/mL (μg/L) primarily and kIU/L. One international unit (IU) of AFP is equivalent to 1.21 ng. A detection limit of 1 ng/mL is recommended for clinical use.[280] AFP-L3% is measured using a liquid-phase binding method (LiBASys, Wako Diagnostics, Richmond, Va) that incorporates LCA binding and anion-conjugated antibodies separated by anion-exchange chromatography and detected fluorometrically. AFP-L3% is calculated from the concentration of AFP-L3 fraction and the sum of the two fractions that constitute total AFP.

Carcinoembryonic Antigen

CEA is a marker for colorectal, gastrointestinal, lung, and breast carcinoma. CEA was discovered by Gold and Freeman in 1965 and was known initially as the Gold "antigen."[96] Rabbits were immunized with extracts of human colon cancer tissue, and the resultant antisera were absorbed with extracts of normal human colon. Some antisera reacted with the tumor extracts but not with the extracts of normal tissue. The antigen, which was also found in embryonic tissue, was named *carcinoembryonic antigen*.

Biochemistry

CEA is a glycoprotein with a molecular mass of 150 to 300 kDa; it contains 45 to 55% carbohydrate. It is a single polypeptide chain consisting of 641 amino acids, with lysine in the *N*-terminal position. The heterogeneity of CEA can be demonstrated by using isoelectric focusing to separate the variants.

CEA consists of a large family of related cell surface glycoproteins. CEA proteins are encoded by about 10 genes located on chromosome 19. Up to 36 different glycoproteins have been identified in the CEA family. The major proteins are CEA and nonspecific cross-reacting antigen (NCA).[122] The domain structures of CEA, NCA 50, and the heavy chain of IgG are very similar. Thus CEA is part of the immunoglobulin gene "superfamily."

Clinical Applications

The CEA concentration is elevated in a variety of cancers, such as colorectal (70%), lung (45%), gastric (50%), breast (40%), pancreatic (55%), ovarian (25%), and uterine (40%) carcinomas. Because of the elevations associated with benign disease (i.e., false-positive results) and the number of tumors that do not produce CEA (i.e., false-negative results), CEA testing should not be used for screening.[252]

CEA testing may be useful as an adjunct to clinical staging. Persistently elevated concentrations that are 5 to 10 times the upper reference limit strongly suggest the presence of colon cancer but may be associated with other cancers. In colon cancer, CEA concentrations correlate with the stage of disease. CEA concentrations are elevated in 28% of patients with Dukes' stage A colorectal cancer and in 45% of those with stage B. The pretreatment CEA concentration is prognostic of the development of metastasis. A high concentration of CEA is associated with a greater likelihood of developing metastasis. Evidence suggests that CEA is a cellular adhesion molecule that may potentiate invasion and metastasis.[122]

After successful initial therapy, CEA concentrations decline. During remission, CEA concentrations are stable. Rising CEA concentrations may indicate recurrence of disease. The lead time from CEA elevation to clinical recurrence is about 5 months. A repeat laparotomy can be performed to confirm the relapse, which is detected in 90% of cases. In the monitoring of metastatic colon cancer, CEA is useful in following patients throughout therapy and the clinical course of the disease.

CEA is also useful in monitoring breast, lung, gastric, and pancreatic carcinomas. In breast cancer, elevated CEA is associated with metastatic disease. Early or localized breast cancer does not show CEA elevation and is less sensitive than CA 15-3 and CA 27.29. CEA is most useful in monitoring metastatic breast cancer during therapy and in detecting the development of bone or lung metastasis. An increasing serum CEA concentration may reflect treatment failure when measurable disease is not present.[160] In lung cancer, CEA determination is helpful in diagnosing non–small cell lung carcinoma (>65% of patients have elevated CEA) and in monitoring lung cancer.

Analytical Methods

As with AFP, most assays use the immunometric format for determination of serum CEA. Polyclonal and monoclonal antibodies and combinations of the two types have been used in CEA immunoassays.

In the healthy population, the upper limit of CEA is about 3 μg/L for nonsmokers and 5 μg/L for smokers. Because the concentration of CEA measured is method dependent, values

should always be compared using the same method. When methods are changed, all patients who are being monitored should be tested in parallel using both old and new methods. CEA concentration is elevated in some patients with benign conditions, such as cirrhosis (45%), pulmonary emphysema (30%), rectal polyps (5%), benign breast disease (15%), and ulcerative colitis (15%).

CYTOKERATINS

The cytokeratins are a group of approximately 20 proteins that make up the cytoskeletal intermediate filaments of epithelial cells and cells of epithelial origin. The cytokeratins can be grossly divided into two groups: type 1 is smaller and acidic, and type 2 is larger and neutral to basic. Clinically useful members of this family are tissue polypeptide antigen (TPA), tissue polypeptide-specific antigen (TPS), and cytokeratin 19 fragments (CYFRA 21-1).

Tissue Polypeptide Antigen

The discovery of TPA preceded that of AFP and CEA, but TPA is not a specific tumor marker.[31] It was found later that TPA could be identified by antibodies that react with cytokeratins 8, 18, and 19. TPA is produced by both normal and cancerous cells. Elevated serum concentrations of TPA are related to the proliferative activity and turnover of cells, allowing it to be used as a proliferation marker.[39,191] In pregnancy, TPA increases throughout gestation. After pregnancy, the concentration returns to normal after 5 days. TPA is also elevated in inflammatory diseases and in cancer; thus it is not useful for diagnosis. In monitoring of metastatic disease, TPA is useful when combined with CEA and CA 15-3 in breast cancer, with CEA and CA 19-9 in colon cancer, and with CA 125 in ovarian cancer. TPA may be helpful in the differentiation of cholangiocarcinoma (in which TPA concentration is elevated) from hepatocellular carcinoma (in which TPA is not elevated).

Tissue Polypeptide-Specific Antigen

TPS is actually an antigenic site on cytokeratin 18 that is specifically recognized by the M3 monoclonal antibody. This epitope has been proposed as a specific marker of cell proliferation and is detectable in serum using a specific immunoassay. TPS appears to correlate with proliferation activity of lung tumors, irrespective of histology and tumor volume, with increasing TPS concentrations with advancing stage.[29] Elevated concentrations of TPS correlate with a poorer outcome.

Cyfra 21-1

CYFRA 21-1 immunoassays use two monoclonal antibodies—BM 19.21 and KS 19.1—to detect cytokeratin 19 fragments. CYFRA 21-1 is elevated in all types of lung cancer, although it is most sensitive for non–small cell lung cancer, primarily SCC. Concentrations of CYFRA 21-1 positively correlate with advancing stage and are useful in monitoring the disease course and in providing postsurgical follow-up. In a study of non–small cell lung cancer patients, CYFRA 21-1 was shown to independently correlate with decreased survival, nodal status, and tumor stage, and a meta-analysis has further indicated a role for CYFRA 21-1 as a prognostic marker.[217,218] Blood concentrations are not affected by smoking status and may be increased in renal failure, liver cirrhosis, and benign pulmonary disease.[18,240]

Squamous Cell Carcinoma Antigen

As its name implies, SCCA is useful in monitoring a wide variety of SCCs.

Biochemistry

SCCA is a glycoprotein previously referred to as *tumor-associated antigen 4*. Subfractions of SCCA have been separated by isoelectric focusing into neutral and acidic fractions. Molecular weights range from 42,000 to 48,000 Da. Both malignant and nonmalignant squamous cells have been shown to contain the neutral fraction, whereas the acidic fraction is found mainly in malignant cells. The acidic fraction is the one released into the blood circulation. Expression of SCCA appears to correlate with the grade of differentiation of SCCs.[131]

Clinical Applications

SCCA is elevated in a variety of SCCs, including those of the (1) cervix, (2) lung, (3) skin, (4) head, (5) neck, (6) digestive tract, (7) ovaries, and (8) urogenital tract. In general, the concentration of SCCA is proportional to advancing stages of cancer. Screening is not effective, because only a small percentage of patients with early stages of cancer show elevated serum SCCA concentrations. High pretreatment SCCA concentrations appear to be associated with a poor prognosis. SCCA is useful in detecting the recurrence of cancer and in monitoring treatment and disease progression.[131]

Analytical Methods

SCC antigen is measured using immunoassay, including the microparticle enzyme immunoassay on the IMx analyzer (Abbott Diagnostics, Abbott Park, Ill). Healthy, nonpregnant women have SCC antigen concentrations below 1.5 µg/L. Serum SCC antigen concentrations may be elevated (>1.5 µg/L) in certain benign conditions, including pulmonary infection, skin disease, renal failure, and liver disease. SCC antigen is also present in saliva, sweat, and respiratory secretions.

CARBOHYDRATE MARKERS

Carbohydrate-related tumor markers may be (1) antigens on the tumor cell surface, or (2) secreted by the tumor cells.[106,245] Monoclonal antibodies against these antigens have been developed. These markers have been found to be clinically useful as tumor markers and tend to be more specific than naturally secreted markers, such as enzymes and hormones. Biochemically, they are high molecular weight mucins (Table 24-9) or blood group antigens (Table 24-10).

TABLE 24-9 Mucin Tumor Markers

Name	Antigen and Source	Antibody	Type of Cancer
CA 125	Glycoprotein, >200 kDa, OVCA 433	OC 125	Ovarian, endometrial
Episialin			
• CA 15-3	Glycoprotein, 400 kDa, membrane-enriched BRCA	DF3 and 115D8	Breast, ovarian
• CA 549	High-MW glycoprotein	BC4E549, BC4N154	Breast, ovarian
• CA 27.29	High-MW glycoprotein	B27.29	Breast
MCA	350 kDa glycoprotein	b-12	Breast, ovarian
DU-PAN-2	Mucin, 1000 kDa peptide epitope	DU-PAN-2	Pancreatic, ovarian, gastrointestinal, lung

BRCA, Breast cancer.

TABLE 24-10 Blood Group Antigen–Related Cancer Markers

Name	Antigen and Source	Antibody	Type of Cancer
CA 19-9	Sialylated Le^{xa}, SW-1116 colon CA	19-9	Pancreatic, gastrointestinal, hepatic
CA 19-5	Le^{a} and sialylated Le^{ag}	19-5	Gastrointestinal, pancreatic, ovarian
CA 50	Sialylated Le^{a} and afucosyl form	C50	Pancreatic, gastrointestinal, colon
CA 72-4	Sialylated Tn	B27.3, cc49	Ovarian, breast, gastrointestinal, colon
CA 242	Sialylated CHO	C242	Gastrointestinal, pancreatic

CHO, Carbohydrate.

CA 15-3, CA 549, and CA 27.29 assays detect a high molecular weight glycoprotein mucin expressed by the mammary epithelium known as *episialin,* and thus are used as markers for breast carcinoma. Circulating episialin antigen is a heterogeneous molecule. CA 15-3, CA 549, and CA 27.29 assays detect similar yet different epitopes on the episialin. The main differences are the antibodies used for detection. The specific CA 15-3 and CA 27.29 antibodies are described in the following sections.

CA 15-3

CA 15-3 is a marker for breast carcinoma.

Biochemistry

CA 15-3 is detected by a murine monoclonal antibody (MAb) DF3 produced against a membrane-enriched extract of a human breast cancer metastatic to liver. Another monoclonal antibody, 115D8, was developed against the human milk fat globule membrane. Circulating DF3-reactive antigen is a heterogeneous molecule with a molecular mass of 300 to 450 kDa. The gene for this molecule is located on chromosome 1q. cDNA cloning indicates that the DF3 peptide core consists of a highly conserved 60-bp tandem repeat sequence. The polymorphism of the antigen is the result of different numbers of repeats in the peptide core. The DF3 antibody recognizes the epitope within this 20 amino acid repeating sequence of the peptide core. Recognition of the epitope is also affected by glycation.[114]

Clinical Applications

In healthy subjects, the upper limit of CA 15-3 concentrations is 25 kU/L. When this cutoff is used, 5.5% of normal subjects, 23% of patients with primary breast cancer, and 69% of those with metastatic breast cancer have elevated CA 15-3 concentrations.[114] Elevated CA 15-3 concentrations are also found in other malignancies, including pancreatic (80%), lung (71%), breast (69%), ovarian (64%), colorectal (63%), and liver (28%) cancers. CA 15-3 is reported to be elevated in benign disease, although with less frequency [e.g., in benign liver disease (42%) and benign breast disease (16%)].

CA 15-3 should not be used to diagnose primary breast cancer because the incidence of elevation (23%) is fairly low. CA 15-3 is most useful in monitoring therapy and disease progression in metastatic breast cancer patients. Significant change of at least 25% correlates with disease progression in 90% of patients, with regression in 78%. No change correlates with disease stability in 60%.

Analytical Methods

Two antibodies are used in CA 15-3 immunoassays. The MAb 115D8 is attached to a solid support, whereas MAb DF3 is labeled. Assays using alternative antibodies against the same common antigen are also available for clinical use.

CA 549

CA 549 is a marker for breast carcinoma.

Biochemistry

CA 549 is an acidic glycoprotein with an isoelectric point of pH 5.2. By sodium dodecyl sulfate/polyacrylamide gel electrophoresis under reducing conditions, CA 549 can be separated into two species with molecular masses of 400 and 512 kDa. One monoclonal antibody, a murine IgG_1 termed BC4E 549, was raised by immunizing mice with partially

purified membrane preparations from the T417 human breast tumor cell line. The other antibody, BC4N 154 (a murine IgM), was developed against human milk fat globule membranes.[37]

Clinical Application

In a population of healthy women, 95% of the population has CA 549 concentrations below 11 kU/L. Pregnancy and benign breast disease show minimum elevation. Some patients with benign liver disease show a slight elevation (see Table 24-4). CA 549 has been shown to be elevated in a variety of non-breast metastatic carcinomas, including ovarian (50%), prostate (40%), and lung (33%) carcinomas.

Similar to CA 15-3, CA 549 is not useful in detecting early breast carcinoma, because the proportion of patients with elevated CA 549 concentrations is low. Using ROC analysis, CA 549 is better than CEA in identifying active breast cancer.[52] CA 549 is useful in detecting recurrence of breast cancer in patients after initial therapy followed by adjuvant therapy. Increasing CA 549 concentration after an initial decrease or stabilization indicates the development of metastases. In the monitoring of advanced breast cancer patients, CA 549 correlates with disease progression and regression and helps detect metastases.[52,53]

CA 27.29

CA 27.29 is a marker for breast carcinoma.

Biochemistry

CA 27.29 is recognized by a monoclonal antibody, B27.29, which is produced against an antigen in ascites of patients with metastatic breast carcinoma. The minimum epitope to which B27.29 reacts is the 8 amino acid sequence (SAPDTRPA) within the 20 amino acid tandem repeating sequence of the mucin core. The reactive sequence of the B27.29 overlaps with the sequence of DF3 used in the CA 15-3 assay. In inhibition studies using labeled MAb, B27.29 effectively competes with DF3 for binding to both CA 27.29 and CA 15-3 antigens.[224]

Clinical Applications

CA 27.29 has been approved by the FDA for clinical use in the detection of recurrent breast cancer in patients with stage II or stage III disease and for monitoring response to therapy in patients with stage IV (metastatic) disease. In a multicenter study over a 2-year period in which 166 breast cancer patients were monitored, 26 patients developed recurrent disease. When two consecutive CA 27.29 antigen test results above 37.7 kU/L (99th percentile) were considered positive, the CA 27.29 assay had a clinical sensitivity of 57.7%, a clinical specificity of 97.9%, a positive predictive value of 83.3%, and a negative predictive value of 92.6% for the detection of recurrent breast cancer. Its performance appeared to be better than that of CA 15-3 in detecting patients with recurrent breast cancer.[54] In a group of metastatic breast cancer patients, CA 27.29 and CA 15.3 showed similar clinical performances.[63]

Analytical Methods

The CA 27.29 immunoassay has both competitive and sandwich formats that incorporate the B27.29 monoclonal antibody. Assays utilizing alternative antibodies against the same common antigen are also available for clinical use.

Mucin-like Carcinoma-Associated Antigen

Mucin-like carcinoma-associated antigen (MCA) is a marker for breast carcinoma.[34]

Biochemistry

MCA was identified on the surface of a breast carcinoma cell line by the monoclonal antibody b-12. MCA is a glycoprotein with a molecular mass of 350 kDa. Epitopes on this molecule are also recognized by DF3 and 115D8 antibodies of the CA 15-3 assay.

Clinical Applications

In a study of 100 healthy women, the upper reference limit for MCA was found to be 14 kU/L. MCA concentrations increase throughout pregnancy. In contrast, CA 15-3 increases only slightly during pregnancy. MCA concentration is elevated in 60% of metastatic breast cancer patients. However, elevated concentrations are also found in (1) ovarian, (2) cervical, (3) endometrial, and (4) prostate carcinoma. Minimum elevation is observed in benign breast disease. MCA concentrations correlate with CA 15-3 concentrations but not with CEA concentrations. In monitoring metastatic breast cancer patients, changes in MCA concentrations parallel changes in CA 15-3 concentrations.

CA 125

CA 125 is a marker for monitoring ovarian cancer.[119,248]

Biochemistry

CA 125 is a high molecular mass (greater than 200 kDa) glycoprotein recognized by the monoclonal antibody OC 125. It contains 24% carbohydrate and is expressed by epithelial ovarian tumors and other pathologic and normal tissues of müllerian duct origin. The molecule has been cloned and designated CA 125/MUC 16.[305] Its physiologic function is unknown.

Bast and associates developed the MAb OC 125 using a cell line (OVCA 433) from a patient with a serous papillary cystadenocarcinoma of the ovary.[136] The OC 125 clone was selected for its reactivity with the OVCA 433 cell line, and for its lack of reactivity with a B-lymphocyte line from the same patient.

Clinical Applications

The primary FDA-indicated use for CA 125 is to monitor response to therapy in patients with epithelial ovarian cancer. The second FDA-indicated use is to detect residual or recurrent disease in patients who have undergone first-line therapy and would be considered for second-look procedures. However, second-look laparotomy is now considered

controversial except for use in clinical trials, or when surgical findings would alter disease management. In a healthy population, the upper limit of CA 125 is 35 kU/L. CA 125 is elevated in nonovarian carcinoma, including endometrial, pancreatic, lung, breast, and colorectal and other gastrointestinal tumors. CA 125 is useful for determining the prognosis of endometrial carcinoma. It is also elevated in women in the follicular phase of the menstrual cycle and with benign conditions such as cirrhosis, hepatitis, endometriosis, pericarditis, and early pregnancy. It cannot be used to differentiate ovarian cancer from other malignancies. CA 125 is not useful in screening for ovarian cancer in asymptomatic populations,[125] but screening is recommended in at-risk women with a family history of hereditary ovarian cancer, in conjunction with pelvic examination and ultrasound testing. Strategies to improve the clinical usefulness of CA 125 for screening/early detection of ovarian cancer to achieve needed high sensitivity and very high specificity include combining with transvaginal sonography, assessing changes in concentrations measured over time, and using multimarker panels.[20]

In ovarian carcinoma, CA 125 is elevated in 50% of patients with stage I disease, 90% with stage II, and more than 90% with stages III and IV. The concentration of CA 125 correlates with tumor size and staging. CA 125 is also useful in differentiating benign from malignant disease in patients with palpable ovarian masses. This differentiation is important because surgical intervention for malignant ovarian masses is far more extensive than that for benign masses. Einhorn and colleagues studied 100 patients undergoing diagnostic laparotomy for palpable adnexal masses; of these, 23 were found to have a malignancy.[77] With 35 kU/L used as the cutoff, predictive values for malignant disease were 78% clinical sensitivity, 95% clinical specificity, 82% positive predictive value, and 91% negative predictive value. Preoperative CA 125 concentration less than 65 kU/L is associated with a significantly greater 5-year survival rate (42%) when compared with a concentration greater than 65 kU/L (5%). Postoperative CA 125 concentrations and rate of decline are also predictors of survival. The half-life of CA 125 is normally 4.8 days. A group of patients with a CA 125 half-life of 22 days responded poorly to chemotherapy as compared with another group with a CA 125 half-life of 9 days.

CA 125 is useful for detecting residual disease in cancer patients following initial therapy. The sensitivity of CA 125 for detecting tumors before repeat laparotomy is 50%, and the specificity is 96%. After chemotherapy, CA 125 concentrations provides an indication of disease prognosis. A decrease in the CA 125 concentration by a factor of 10 after the first cycle of chemotherapy is indicative of response. Persistent elevation of CA 125 concentrations after three cycles of chemotherapy indicates a poor prognosis.

In the detection of recurrent metastasis, use of CA 125 concentration as an indicator is about 75% accurate. The lead time from CA 125 elevation to clinically detectable recurrence is about 3 to 4 months. CA 125 correlates with disease progression or regression in 80 to 90% of cases.[125]

Analytical Methods

An immunoradiometric assay for CA 125 was first developed and manufactured by Centocor, Inc., now Fujirebio Diagnostics (Malvern, Pa), which incorporated the OC 125 antibody for both capture and detection, allowing recognition of multiple CA 125 determinants. A second-generation assay (CA 125II) typically uses the monoclonal antibody, M11, as the capture antibody and OC 125 as the conjugate antibody. Other FDA-cleared assays for CA 125, which employ antibodies other than the OC 125 and M11 antibodies, are available on automated immunoassay platforms. Results from different assays are not interchangeable, and individual patients should be monitored with a single assay.

Other Ovarian Cancer Biomarkers

HE4

HE4 is a marker for ovarian cancer.

Biochemistry

The gene for HE4, *Homo sapiens* epididymis specific, *WFDC2*, was initially discovered using microarrays to be overexpressed in epididymal tissue and later in ovarian cancer tissue.[116,153] Tumor expression is histologic dependent with most serous and endometrioid tumors expressing HE4 and only 50% of clear cell and 0% of mucinous tumors.[74] The protein is characterized as part of the four-disulfide core protein family and contains whey acid protein domains (WAPs). These proteins typically are secreted and are protease inhibitors, although this function has not been ascribed to HE4, and its physiologic role is unknown. Subsequent studies have shown that HE4 is not specific for ovarian tumors. Generation of the monoclonal antibodies 2H5 and 3D8 to epitopes on HE4 has allowed development of a sandwich ELISA and measurement in serum.[116]

Clinical Applications

At an HE4 concentration of 150 pM, 95% of healthy women were below this cutoff, while 79% of women with ovarian cancer were above this cutoff. Elevations in other subjects include breast (13%), endometrial (26%), gastrointestinal (16%), and lung cancers (42%), as well as benign gynecologic disease (7%) and other benign disease (24%). The assay is FDA cleared for monitoring recurrence or progressive disease in patients with epithelial ovarian cancer. In serial samples from 80 ovarian cancer patients in which a 25% increase in HE4 concentration was used to define a positive change, 60% of patients with disease progression had an increase greater than 25%, and 75% had a change of 25% or less or did not have disease progression. Results comparing HE4 and CA 125 to distinguish women with ovarian cancer from normal women or those with benign processes appear to depend on the population studied, although combining the two markers may allow more accurate prediction of cancer than use of the individual markers. An algorithm incorporating HE4 and CA 125 has been reported to successfully classify women with a pelvic mass as at high or low risk for epithelial ovarian cancer.

The algorithm was accurate in classifying a high percentage (93.8%) of women with cancer as high risk.[182] The algorithm, termed Risk of Malignancy Index (ROMA), has been marked for use in Europe. HE4 may also have usefulness as a marker in endometrial cancer.[181]

Analytical Methods

HE4 is measured by an enzyme immunoassay, with 2H5 as the capture antibody and 3D8 as the detector antibody (Fujirebio Diagnostics). This assay is not recommended for patients with mucinous or germ cell ovarian cancer.

OVA1: An IVDMIA for Ovarian Cancer

Based on the proteomics biomarker discovery approach using mass spectrometry, Zhang and colleagues identified several proteins that, when combined with CA 125, provide diagnostic value for ovarian cancer. Vermillion Inc. licensed the combination of markers and conducted a clinical trial with 516 patient specimens collected from 27 clinical sites. Data were submitted to the FDA and were cleared for clinical use as the OVA1 test—the first IVDMIA proteomic diagnostic for cancer. The OVA1 test is a qualitative serum test that combines the results of five immunoassays into a single numeric score. The five markers are (1) CA 125, (2) prealbumin (transthyretin), (3) apolipoprotein A1 (Apo A1), (4) transferrin (Tfr), and (5) β2M (beta 2-microglobulin). It is indicated for women who meet the following criteria: over age 18, ovarian adnexal mass present for which surgery is planned, and not yet referred to an oncologist. The OVA1 test is an aid in further assessment of the likelihood that malignancy is present when the physician's independent clinical and radiological evaluation does not indicate malignancy. This test is not intended as a screening or stand-alone diagnostic assay. The OVA1 score is calculated using OvaCalc software (Vermillion Inc.) with values between 0 and 10. Expected values for the probability of malignancy in premenopausal women are (1) high OVA1 ≥5.0, and (2) low OVA1 <5.0, and for postmenopausal women, (1) high OVA1 ≥4.4, and (2) low OVA1 <4.4. The addition of OVA1 to the presurgical clinical assessment improved the sensitivity of predicting malignancy from 72 to 92% for non–gynecologic oncologist (GO) patients and from 78 to 99% for GO patients.

DU-PAN-2

DU-PAN-2 is a marker for pancreatic cancer.[173,176]

Biochemistry

The epitope recognized by the antibody DU-PAN-2 is a mucin. Its molecular mass is between 100 and 500 kDa, and it is 80% carbohydrate. The core protein (cDNA) has been cloned and sequenced, and the predicted amino acid sequence reveals a protein of 126 kDa containing 1295 amino acid residues with 42 tandem repeats. DU-PAN-2 antigen is found mainly in the (1) glandular epithelia of the pancreatic and biliary systems and in the (2) breast and (3) bronchial ducts. Less expression is found in cells of the (4) salivary glands, (5) stomach, (6) colon, and (7) intestine.[173]

Clinical Applications

Serum DU-PAN-2 concentrations are elevated in patients with pancreatic (54 to 61%), biliary tract (44 to 47%), and hepatocellular (44%) carcinomas. Comparative studies between DU-PAN-2 and CA 19-9 concentrations in pancreatic cancer show similar elevations in 70 to 80% of patients. DU-PAN-2 and CA 19-9 concentrations correlate well, except in patients who are Le^{a-b-} and therefore do not express CA 19-9.

Analytical Methods

An RIA assay was developed by Metzgar and coworkers,[173] and an immunoenzymetric assay was developed by Kyowa Medex (Tokyo, Japan). The serum concentration of DU-PAN-2 in a healthy population is less than 100 kU/L. The cutoff used to differentiate the presence of cancer from health is 300 or 400 kU/L.

BLOOD GROUP ANTIGENS

Blood group carbohydrates identified by monoclonal antibodies that have been used as markers of cancers are listed in Table 24-10. These include (1) CA 19-9 (sialylated Le^{xa}), (2) CA 50 (sialylated Le^{x-1}, afucosyl forms), (3) CA 72-4 (sialyl Tn), and (4) CA 242 (sialylated carbohydrate coexpressed with CA 50).

CA 19-9

CA 19-9 is a marker for gastrointestinal cancers and is used primarily to test for pancreatic carcinoma.[146] CA 19-9 has been approved by the FDA for quantitative measurement in serum and as an aid in monitoring pancreatic cancer patients.

Biochemistry

This carbohydrate antigen is a glycolipid, specifically, sialylated lacto-*N*-fucopenteose II ganglioside, that is a sialylated derivative of the Le^a blood group antigen and is denoted as Le^{xa}. Expression of the antigen requires the Lewis gene product, 1,4-fucosyl transferase. CA 19-9 is synthesized by normal human pancreatic and biliary ductular cells and by gastric, colon, endometrial, and salivary epithelia. In serum, it exists as a mucin—a high molecular mass (200 to 1000 kDa) glycoprotein complex. Patients who are genotypically Le^{a-b-} (about 5%) do not express CA 19-9. The monoclonal antibody against CA 19-9 was developed from a human colon carcinoma cell line, SW-1116.[140]

Clinical Applications

The CA 19-9 upper reference limit is 37 kU/L, as determined from the 99th percentile of normal subjects. This cutoff discriminates between pancreatic cancer and benign pancreatic disease with clinical sensitivities of 69 to 93% and clinical specificities of 76 to 99%. Elevated CA 19-9 concentrations (>37 kU/L) are found in patients with pancreatic (80%), hepatobiliary (67%), gastric (40 to 50%), hepatocellular (30 to 50%), colorectal (30%), and breast (15%) cancers. Some patients (10 to 20%) with pancreatitis and other benign

gastrointestinal diseases have elevated concentrations up to 120 kU/L. CA 19-9 is useful in monitoring pancreatic and colorectal and gastric cancers. CA 19-9 concentrations correlate with pancreatic cancer staging. With a cutoff of 37 kU/L, 67% of patients with resectable and 87% of those with unresectable pancreatic cancers have elevated concentrations. When the cutoff is raised to 1000 kU/L, 35% of patients with unresectable tumors and only 5% of those with resectable tumors have elevated CA 19-9 concentrations. CA 19-9 is also useful for establishing prognosis for pancreatic cancer at initial diagnosis, as concentrations have independent predictive value for determination of respectability and of overall survival. Elevated or increasing concentrations can indicate recurrence 1 to 7 months before it is detected by radiographs or clinical findings.[272] Unfortunately, early detection of relapse may not be useful because effective therapy for pancreatic cancer is not available.

Analytical Methods

Several companies have produced CA 19-9 immunoassays. Considerable differences among assays are noted,[123] and assay results are not interchangeable for individual patients. Typically, the CA 19-9 antibody is used as both the capture and the signal antibody.

CA 50

CA 50 is a marker for pancreatic and colorectal carcinoma.[105]

Biochemistry

CA 50 is a monoclonal antibody developed against the human colon adenocarcinoma cell line COLO 205. The CA 50 antibody recognizes an epitope on two carbohydrate moieties: sialosylfucosyllactotetraose (sialylated Le^a) and sialosyllactotetraose (sialylated Le^a lacking fucose). This antigen exists as a glycoprotein in serum and also as gangliosides in tissue. Sialylated Le^a is the predominant form of CA 50 in epithelial carcinoma and is recognized by CA 19-9.

Clinical Applications

Elevated CA 50 concentrations have been reported in benign diseases of the pancreas (12 to 46%), biliary tract (35 to 38%), and liver (22 to 59%). In pancreatic cancer, 80 to 97% of patients have elevated concentrations. In colon cancer, elevated concentrations were reported in Dukes' A (19 to 43%), B (30 to 59%), C (53 to 73%), and D (53 to 73%) stages. In digestive tract carcinoma, elevated concentrations were seen in esophageal (41 to 71%), gastric (41 to 78%), biliary (58 to 70%), and hepatocellular (14 to 78%) cancers. Other malignancies were reported to have lower percentages of elevation, including breast, lung, renal, prostate, bladder, and ovarian cancers. Similar performances and good correlations were reported between CA 50 and CA 19-9 concentrations.

Analytical Methods

The original inhibition test has been replaced by an immunoradiometric assay and a time-resolved fluorescent immunoassay. The upper reference interval for healthy subjects varies from 14 to 20 kU/L, depending on the method.

CA 72-4

CA 72-4 is a marker for carcinomas of the gastrointestinal tract and of the ovary.[238]

Biochemistry

The 72-4 assay utilizes the monoclonal antibody B72.3 developed from the membrane-enriched fraction of breast carcinoma in a patient with liver metastasis. The B72.3 reactive antigen was purified and called TAG-72 (tumor-associated glycoprotein). Further purification of TAG-72 from LS-174T human colon carcinoma xenograft produced a new generation of monoclonal antibodies with higher affinity. These antibodies, denoted "cc" for "colon carcinoma," were used in subsequent studies.

Clinical Applications

A cutoff of 6 kU/L is used in the CA 72-4 assay. The following percentages of elevation were observed: in health (3.5%); in benign gastrointestinal disease (6.7%); in gastrointestinal carcinoma (40%); in lung cancer (36%); and in ovarian cancer (24%). A poor clinical correlation between CEA and CA 72-4 concentrations was found in gastric cancer. CEA and CA 72-4 concentrations may be complementary. The plasma clearance of TAG-72 was studied by measuring serial TAG-72 concentrations in patients with primary carcinoma of the breast and with gastric, colorectal, and ovarian cancers. After removal of the tumor, the average time required for the concentration to decrease to 4 kU/L was 23.3 days. This suggests that TAG-72 may be useful in detecting residual tumor in these cancer patients.

Analytical Methods

CA 72-4 is measured using an immunoradiometric assay (IRMA) manufactured by Fujirebio Diagnostics. It uses two monoclonal antibodies that were developed at the National Cancer Institute. B72.3 is the conjugate, whereas cc49 is the capture antibody. An automated eletrochemiluminescence method is also available from Roche Diagnostics (Indianapolis, Ind).

CA 242

CA 242 is a marker for pancreatic and colorectal cancer.[143]

Biochemistry

CA 242 is a monoclonal antibody developed from a human colorectal carcinoma cell line, COLO 205. The antigenic determinant is a sialylated carbohydrate. CA 242 recognizes the epitopes of CA 50 and CA 19-9. CA 242 is found in the apical border of ductal cells of the human pancreas and in epithelial and goblet cells of the colonic mucosa.

Clinical Applications

At a concentration of 20 U/L, elevated CA 242 concentrations were found in 5 to 33% of patients with benign colon, gastric,

hepatic, pancreatic, and biliary tract disease; in 68 to 79% of patients with malignant pancreatic cancer; in 55 to 85% of patients with colorectal cancer; and in 44% of patients with gastric cancer. The correlation coefficients (R^2) of CA 242, CA 50, and CA 19-9 concentrations in patients with colorectal, liver, pancreatic, and biliary tract disease ranged from 0.81 to 0.95. CA 242 and CEA appeared to have higher percentages of elevation in colorectal cancer than did CA 50 and CA 19-9. CA 242 seems to be less efficient than CA 19-9 or CA 50 in the detection of pancreatic cancer; however, this may depend on the cutoff.

Analytical Methods

An immunometric assay (Fujirebio Diagnostics) uses the C 241 antibody against sialylated Lewis[a] as the capture antibody and the CA 242 antibody as the conjugate. The upper reference limit is 29 U/mL.

PROTEINS

Several proteins having tumor marker potential are listed in Table 24-11. Included in this group of tumor markers are proteins that are not enzymes or hormones, and are not high in carbohydrate content. Additional research is required to assess the clinical usefulness of most of these markers.

Immunoglobulin

Monoclonal immunoglobulin has been used as a marker for multiple myeloma for longer than 100 years.[24] Monoclonal paraproteins appear as sharp bands in the globulin region of serum electrophoretic patterns. More than 95% of patients with multiple myeloma have such an electrophoretic pattern. Appearance of nonmalignant monoclonal immunoglobulins increases with age, reaching 5% in patients older than 75 years. These nonmalignant monoclonal bands are usually lower in concentration than malignant bands and are not associated with Bence Jones protein. Bence Jones protein is a free monoclonal immunoglobulin light chain in the urine. The concentration of monoclonal immunoglobulin at initial diagnosis is a prognostic indicator of disease progression.[261] During treatment, the serum concentration of urinary Bence Jones protein may reflect the success of therapy. Lower concentrations are associated with more favorable outcomes. Serum paraproteins are discussed in Chapter 21.

Bladder Cancer Markers

It is estimated that 600,000 Americans are currently affected by bladder cancer, and 70,000 new cases will be diagnosed each year. Symptoms range from intermittent hematuria to voiding problems or dysuria. The most common type of cell seen is transitional cell carcinoma (TCC), and the most frequent symptom is hematuria. Bladder cancer is staged pathologically and is treated on the basis of the extent of tumor invasion. Carcinoma in situ (stage Tis) and superficial bladder cancers (stages Ta and T1) occur on the epithelial lining and do not invade the muscle layer. Stage Ta tumors are confined to the mucosa, and stage T1 tumors superficially invade the lamina propria. Stage T2 tumors extend into the muscle layer, and T3 tumors invade beyond the muscle layer. Stage T4 tumors have metastasized to local nodes or distant organs.

Urinary Bladder Tumor Markers

Bladder cancer is detected through cystoscopy or cytology of shed cells, or by noncellular markers, such as NMP22, complement factor-H (CFH), and fibronectin.[89,251] Tumor antigens present in urine are the easiest to analyze; however, they cannot be used as the sole mechanism for tumor detection. They should be used in a complementary manner with cystoscopy and cytology. NMP22, in a series of 300 patients with hematuria, with a cutoff of 10 U/mL, detected 100% of

TABLE 24-11 Proteins as Tumor Markers

Name	Nature	Type of Cancer
β_2-Microglobulin	11 kDa	Multiple myeloma, B-cell lymphoma, chronic lymphocytic leukemia, Waldenström's macroglobulinemia
C-peptide	3.6 kDa	Insulinoma
Ferritin	450 kDa iron-binding protein	Liver, lung, breast, leukemia
HER-2/*neu*	97 to 115 kDa, 20% CHO	Breast
Immunoglobulin	160 to 900 kDa, 3 to 12% CHO	Multiple myeloma, lymphomas
Melanoma-associated antigen	90 to 240 kDa	Melanoma
Pancreas-associated antigen	100 kDa, 20% CHO	Pancreatic, stomach
Pregnancy-specific protein 1	10 kDa, 30% CHO	Trophoblastic, germ cell
Pro-gastrin releasing peptide	Amino acid residues 31 to 98	Small cell lung
Prothrombin precursor	Des-γ-carboxy prothrombin	Hepatocellular
Soluble mesothelin-related peptides	Mesothelin/megakaryocyte potentiating factor peptides	Mesothelioma, ovarian
Tumor-associated trypsin inhibitor	6 kDa polypeptide	Lung, gastrointestinal, ovarian

From Sarosdy MF, Schellhammer P, Bokinsky G, et al. Clinical evaluation of a multi-target fluorescent in situ hybridization assay for detection of bladder cancer. J Urol 2002;168:1950-4.

bladder cancer cases, with a specificity of 85%.[313] In another study, NMP22 and fibronectin were found to have superior clinical sensitivity to that of cytology; however, NMP22 and cytology have the highest clinical specificity.[78] Telomerase, cytokeratins, and survivin have also been evaluated as markers for bladder cancer.

Two bladder cancer–related tests that are fluorescence based have been cleared by the FDA. ImmunoCyt (Scimedx Corporation, Denville, NJ) uses three fluorescently labeled monoclonal antibodies and microscopy to identify bladder cancer markers on cells found in urine. This test appears most useful with cytology in identifying low-grade tumors. UroVysion (Abbott Molecular, Abbott Park, Ill), a fluorescence in situ hybridization (FISH) technique, uses fluorescently labeled probes to detect aneuploidy of chromosomes 3, 7, and 17, and deletion of the 9p21 locus that contains the tumor suppressor p16, which is the most common alteration seen in urothelial carcinoma. Table 24-12 compares cytology with that of UroVysion for the detection of bladder cancer.[235]

Nuclear Matrix Protein (NMP22)

Nuclear matrix proteins (NMPs) make up the internal structure of the nucleus. Their function has been associated with regulating key reactions in the nucleus, such as DNA replication and RNA synthesis. NMPs released by the cancer cell may be different from those in the normal cell. Furthermore, different types of cells may have different NMPs. In one study, soluble NMPs were detected in the sera of cancer patients in higher concentrations than in the sera from normal subjects.[205] In a multicenter follow-up study (125 cystoscopies) of 90 patients with 33 pathologically confirmed TCCs of the urinary tract, 70% of 33 recurrences had urinary NMP greater than 10 U/mL. Among patients with NMP less than 10 U/mL, 86% had no malignancy at subsequent cystoscopy.[263]

An ELISA for the measurement of an NMP, called *nuclear mitotic apparatus protein (NuMa)* in urine, has been approved by the FDA for the management of patients with TCC of the urinary tract, to aid in diagnosis of symptomatic patients or those with risk factors and to identify patients with recurrent TCC. This test is called NMP22 and is manufactured by Alere North America, Inc., (Princeton, NJ). A qualitative, immunochromatographic point-of-care version of the test is available as an aid in monitoring patients with a history of bladder cancer.

Bladder Tumor–Associated (BTA) Analytes

A qualitative, lateral flow immunoassay for BTA analytes in urine, termed the BTA *stat* test, has been developed. The antigen detected in the BTA stat assay is human complement factor H–related protein (hCFHrp), which is a variant of human complement factor H (hCFH). hCFH functions in the alternative complement pathway by interacting with complement factor C3b to prevent cell lysis. Bladder tumor–associated antigen may allow tumor cells to evade the host immune system. A multicenter trial compared the BTA *stat* test with voided urine cytology studies in 499 patients undergoing surveillance cystoscopy for recurrent bladder cancer. The BTA *stat* test identified 40% of patients with positive cystoscopy results, and cytology detected 17%. A positive test may provide a higher degree of suspicion for recurrence.[234] A quantitative test in ELISA format, BTA TRAK, is also available. Both tests have FDA-approved indications for use as an aid in conjunction with cystoscopy in the management of bladder cancer patients.

Soluble Mesothelin-Related Peptides (SMRPs)

Mesothelioma is a rare cancer of the mesothelial surfaces of the pleural and peritoneal cavities or the pericardium that is linked to asbestos exposure. Mesothelin is a cell surface glycoprotein expressed on mesothelial cells, and mesothelin fragments, which are soluble mesothelin-related peptides, can be found in the circulation of patients with mesothelial tumor. An ELISA assay has been developed (Mesomark, Fujirebio Diagnostics) that measures serum soluble molecules related to the mesothelin/megakaryocyte potentiating factor (MPF) family of proteins recognized by the monoclonal antibody OV569. The assay also incorporates the 4H3 monoclonal antibody. This test is approved by the FDA under the Humanitarian Device Exemption, which is used for medical devices for diseases affecting fewer than 4000 individuals a year; demonstration of effectiveness is not required. It is intended as an aid in monitoring patients who have been diagnosed with epithelioid mesothelioma. A cutoff of 1.5 nmol/L was derived from the 99th percentile of healthy subjects. In addition to patients with mesothelioma (52%), approximately 10 to 15% of patients with other cancers, including ovarian, lung, colon, and pancreas cancers, may have elevations in SMRP[29] compared with 5% of individuals exposed to asbestos. SMRP increases with increasing stage of malignant pleural mesothelioma.[207] Using ROC analysis, an AUC of 0.81 was obtained to distinguish malignant pleural mesothelioma patients (n = 90) from asbestos-exposed individuals (n = 66) with clinical sensitivity, specificity, and

accuracy of 60%, 89%, and 73%, respectively, at a cutoff of 1.9 nmol/L. The AUC for distinguishing malignant pleural mesothelioma from lung cancer (n = 170) was 0.82. SMRPs have also been reported to be higher in malignant pleural mesothelioma pleural effusions compared with benign or other nonmalignant pleural mesothelioma pleural effusions.

Des-γ-Carboxy Prothrombin (Pivka-II)

Des-γ-carboxy prothrombin (DCP), also called PIVKA-II (proteins induced by vitamin K absence or antagonism II), is an abnormal form of prothrombin and a tumor marker for hepatocellular carcinoma. Prothrombin is a vitamin K–dependent coagulation factor produced in the liver that undergoes a post-translational modification in which the 10 glutamic acid (glu) residues in the N-terminus are carboxylated to form γ-carboxy glutamic acid (gla) to be functional. The γ-glutamyl carboxylase requires vitamin K as a cofactor, and in cases of dietary deficiency or antagonism, such as by warfarin, DCP is produced. Obstructive jaundice with an effect on vitamin K may result in increased DCP. In hepatocellular carcinoma, gene expression of the enzyme is defective, resulting in DCP.

DCP is most commonly used clinically for early detection, monitoring, and recurrence in countries with a high prevalence of hepatocellular carcinoma, such as Japan. When ELISA was used to compare patients with hepatocellular carcinoma versus those with cirrhosis or chronic hepatitis, sensitivity for detection was 48% and specificity 96%.[90] DCP and AFP are independent markers, and in a case control study of patients with hepatocellular carcinoma or cirrhosis,[171] clinical sensitivity for cancer detection in early-stage disease increased to 78% compared with 53% for AFP alone and 61% for DCP alone. DCP correlates with tumor size, although it is less sensitive for detecting small tumors, tumor stage, and prognosis. In the United States, the Wako DCP assay has been FDA cleared as an aid in the risk assessment of patients with chronic liver disease for progression of hepatocellular carcinoma. The liquid phase binding assay (Wako Diagnostics, Richmond, VA) on the Wako LiBASys platform uses separation of monoclonal antibody–bound DCP from serum using anion-exchange chromatography and fluorometric detection. When this assay was used in a prospective study of 334 patients with hepatitis C virus (HCV) cirrhosis, the relative risk of developing hepatocellular carcinoma was 5.7 with a cutoff of 7.5 μg/L. Results from the LiBASys and an electrochemiluminometric assay commonly used in Japan correlate well.[196]

Heat Shock Proteins

Heat shock proteins (HSPs) constitute a conserved group of proteins that were first identified by their ability to be induced by heat and other stressors. Numerous functions have been associated with HSPs, most notably as chaperones to stabilize cellular proteins during periods of unfavorable conditions. HSPs associate with many cellular components, including signal transduction proteins (kinases and phosphatases), steroid receptors, and components of the apoptotic machinery. The ability of HSPs to interact with various cellular components and to protect them from stressors, coupled with the fact that increased expression is seen in a number of tumors, suggests that they may play a role in tumorigenicity. Increased expression of HSP27 is seen in breast cancer, endometrial cancer, and leukemia. HSP70 is increased in breast cancer, endometrial cancer, osteosarcoma, and renal cell tumor. High expression of HSP27 and HSP70 in breast, endometrial, or gastric cancer is correlated with metastasis, poor prognosis, and resistance to chemotherapy.[93] HSP60 and HSP90 are also overexpressed in breast and lung cancers, leukemias, and Hodgkin's disease.

S-100 Proteins

The S-100 proteins constitute a group of at least 19 related calcium-binding proteins. All contain two high-affinity and selective EF-hand calcium-binding domains. Their physiologic role is uncertain; however, some members have been associated with cancer progression, namely, S-100A4, S-100A2, S-100A6, and S-100β.[172] S-100A4 is normally expressed in selected immune cells, with faint expression in keratinocytes, melanocytes, and Langerhans' cells. It is not expressed in breast, colon, thyroid, lung, kidney, or pancreas. Expression of S-100A4 in breast cancer, esophageal-squamous carcinoma, and gastric cancer correlates with a worse outcome and more aggressive disease, and was shown to be an independent marker of prognosis in multivariate analysis. Lack of expression in normal tissue and expression in cancer tissue make it an excellent candidate for routine histologic use as a cancer marker.

S-100β is routinely used as a diagnostic histologic marker of melanoma and melanoma metastases. The measurement of serum concentrations of S-100β has been investigated for monitoring disease recurrence. In the absence of melanoma, serum S-100β concentrations are normally undetectable; however, with recurrent disease, S-100β concentrations rise. With the use of an immunoassay, clinical sensitivity and specificity of 0.29 and 0.93, respectively, with diagnostic accuracy of 0.84, were obtained using a cutoff of 0.12 μg/L.[91] S-100β is a more sensitive and specific marker for recurrent melanoma that is able to detect recurrence earlier than LD or alkaline phosphatase (traditional markers of melanoma recurrence). An automated assay is available on the LIAISON analyzer (DiaSorin, Inc., Stillwater, MN).

Autoantibodies

Autoantibodies are antibodies that specifically recognize self-antigens, or proteins. They are normally thought of in the context of autoimmune disease; however, autoantibodies have been used for the detection and monitoring of cancer.[71] The event that triggers the development of autoantibodies can be an infection that through molecular mimicry breaks self-tolerance in a susceptible individual, or inappropriate expression of a self-antigen, such as a cancer antigen. Various cancers produce proteins or antigens that are recognized by the immune system and are targets for the development of autoantibodies. Detection and monitoring of cancer with the

use of circulating tumor markers mainly consists of the detection of proteins or antigens that are not normally present in the circulation, or that notably change in concentration. Various cancers express new antigens (abnormally glycosylated MUC1, detected by CA 15-3) or overexpress existing antigens, such as HER-2/*neu;* autoantibodies that recognize these tumor antigens can also be detected.

Healthy individuals typically do not have autoantibodies or have them at a very low titer, and a change or rise can signify the development of cancer or another disease state. Several cancer antigens have been investigated for their ability to induce detectable autoantibodies, including p53, MUC1, c-myc, and c-erbB-2. For example, accumulation of mutant p53 proteins within tumor cells may lead to the development of autoantibodies. Nine to 48% of primary breast cancer patients have detectable anti-p53 antibodies, as do 11 to 64% of lung cancer patients[71] and almost 100% of ovarian cancer patients. Anti-p53 antibodies have been detected in hepatocellular, bladder, colorectal, gastric, and other cancers.[11]

Many cancers are heterogeneous and do not consistently express tumor markers. It is clear that no single tumor marker will detect all cancers. Therefore, the detection of multiple antigens should increase the clinical sensitivity of cancer detection. This is also the case with autoantibody detection. Using a single autoantibody, detection of primary breast cancer was between 35 and 47%; however, when four autoantibodies were used (p53, MUC1, c-myc, and c-erbB-2), sensitivity was increased to 82%.[71]

Autoantibodies are also useful in prognosis and monitoring of disease. Elevated autoantibodies to p53 are associated with a poor prognosis, independent of tumor-related antigens.[71] This may be due to the fact that expression of the tumor antigen at a distant and/or abnormal site triggers an immune response. The titer of the autoantibodies also tends to follow the amount of tumor antigen, which can provide information about tumor volume. In addition, the concentration of autoantibodies decreases in relation to the antigen load, but will quickly rise again in recurrent disease because of a secondary immune response when the antigen is reintroduced (recurrent disease). Autoantibodies with the greatest potential are used for the early detection of cancer, because a small amount of the antigen has the ability to generate a vigorous humoral immune response; however, more research is needed before autoantibodies will be part of the standard tests ordered.

Markers of Angiogenesis

Angiogenesis, the formation of blood vessels, is a highly regulated and ordered process; however in tumor tissue, this process is disordered. The development of tumors is thought to involve inactivation of tumor suppressor genes and/or uncontrolled activation of oncogenes. Subsequently, another step in the progression toward malignancy has been identified and has been referred to as the *angiogenic switch*.[26,46] The first phase of tumor development is an avascular phase, with a lesion size of 1 to 2 mm. At this point, the tumor is in a vascular steady state. The vascular state occurs next with rapid and unregulated angiogenesis. The architecture of the newly developing vasculature is very different from that of normal vasculature. It is irregularly shaped and dilated and can have dead ends, with irregular blood flow patterns, that make tumors relatively easy to identify histologically.[45] In normal tissue, a balance is noted between proangiogenic signals (VEGF, FGF, PDGFB, EGF, Ets-1, and LPA) and antiangiogenic signals (thrombospondin-1, angiostatin, endostatin, canstatin, and tumstatin).[208] It is believed that in tumors, proangiogenic signals are increased. Therefore, measurement of proangiogenic markers may provide prognostic information related to tumor status.

Increases in blood vascular endothelial growth factor (VEGF) and soluble Tie-2 receptor (sTie2) correlate with the development of metastases, with VEGF being the most powerful predictor of outcome.[59] Ets-1, a transcription factor that activates numerous angiogenic genes, also may serve as a prognostic indicator of uterine cervical cancers. Thrombospondin-1 (TSP-1), an antiangiogenic marker, has been found to be a positive prognostic marker in ductal carcinoma of the breast. Other markers of angiogenesis considered as prognostic markers in cancer have been reviewed.[26]

Thyroglobulin and Antibodies

Biochemistry

Thyroglobulin (Tg) is produced by the thyroid gland as the precursor to thyroid hormone (see Chapter 55).

Clinical Applications

The main use of Tg measurement is as a tumor marker for patients with a diagnosis of differentiated thyroid cancer. Approximately two thirds of these patients have an elevated preoperative Tg concentration. An elevated preoperative concentration of Tg confirms the tumor's ability to secrete Tg and validates the use of postoperative measurement of Tg to monitor for tumor recurrence. Postoperatively, the most sensitive time to detect residual tumor or metastasis is after TSH stimulation. In well-differentiated tumors, a tenfold increase in Tg concentrations is seen after TSH stimulation.[265] Poorly differentiated tumors that do not concentrate iodide may display a blunted response to TSH stimulation. Tg monitoring generally is not useful in patients who do not have elevated preoperative Tg.

Antithyroglobulin antibodies have been proposed to monitor residual disease and/or recurrence. Serial anti-Tg measurements may be an independent prognostic indicator of therapy, because an increase in anti-Tg antibodies may suggest recurrence of the tumor.[266]

Analytical Methods

Immunometric assays (IMAs) and RIAs are the two main methods used for the measurement of Tg. IMA assays have the advantage of having a shorter incubation time and are automatable; however, they suffer from greater interferences. The main interferants in both assays are antithyroglobulin antibodies, which typically cause an underestimation of Tg concentrations in the IMA. Antithyroglobulin antibodies can

be measured directly in all patients; if both IMA and RIA are used to measure Tg, a discordant result suggests the presence of antithyroglobulin antibodies.

Chromogranins

Chromogranins are a family of proteins that are major components of the secretory granules of most neuroendocrine cells.

Biochemistry

The granin family consists of three members: (1) chromogranin A (CgA); (2) chromogranin B (CgB); and (3) secretogranin II, III, IV, and V.[83] Chromogranins are found in neuroendocrine cells throughout the body, including the neuronal cells of the central and peripheral nervous systems. Intracellularly located chromogranins have been suggested to play a role in the regulation of secretory granules. In addition, secreted chromogranins can be proteolytically processed to form bioactive peptides. Chromogranin A has been the best studied of the chromogranins, has been shown to be widely expressed by neuroendocrine tissue, and is cosecreted by neuroendocrine cells, along with peptide hormones and neuropeptides. This wide distribution and cosecretion make it an excellent histochemical and plasma marker of neuroendocrine tumors.

Clinical Applications

Both CgA and CgB are useful in detecting various neuroendocrine tumors, including carcinoid tumor, pheochromocytoma, and neuroblastoma. In most cases, CgA is produced at higher concentrations than CgB; however in some cases, CgB is positive when CgA is negative; therefore, both should be measured when possible. In the case of carcinoid tumor, foregut and midgut tumors are normally functional tumors producing serotonin. CgA is as specific for the detection of both foregut and midgut carcinoid tumors as the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA), and it is the preferred marker in hindgut tumors, which commonly are nonfunctional.[71] Although nonfunctional tumors have lost the ability to secrete serotonin, they retain the ability to secrete chromogranins. For detection of pheochromocytomas, CgA is at least as sensitive and specific as plasma catecholamines or urinary metanephrines.[28]

Analytical Methods

CgA is measured by immunoassay. Depending on the assay, polyclonal or monoclonal antibodies are used. Care must be taken in choosing an assay because CgA and the other chromogranins are heavily processed after release, which may render them nondetectable by the assay and may produce false-negative results. Therefore, an assay that recognizes both intact and processed molecules may be desirable. Commercial assays for CgB are not yet available.

RECEPTORS AND OTHER MARKERS

Other tumor markers, including catecholamines, polyamines, lipid-associated sialic acid, and receptors, have been used clinically with various degrees of success (Table 24-13). Receptors are probably the most successful of this group of markers. Catecholamines and their metabolites are discussed in Chapter 30.

Estrogen and Progesterone Receptors

Estrogen and progesterone receptors are used in breast cancer as indicators for hormonal therapy.[302] Patients with positive estrogen and progesterone receptors tend to respond to hormonal treatment. Those with negative receptors will be treated using other therapies, such as chemotherapy. Hormone receptors also serve as prognostic factors in breast cancer. Patients positive for hormone receptors tend to survive longer.

Biochemistry

Estrogen receptors (ERs) and progesterone receptors (PRs) are members of the nuclear steroid hormone receptor family, and are involved in hormone-directed transcriptional activation. The general structure of nuclear steroid hormone receptors, including ERs and PRs, consists of a large N-terminal domain containing transcriptional activation domains, a DNA-binding domain, a hinge region, and the hormone-binding domain at the C-terminus. Both ERs and PRs are present in a large protein complex, and upon hormone binding, some members of the complex dissociate, and the receptors bind to their respective response elements and activate transcription.

TABLE 24-13 Other Tumor Markers

Name	Nature	Type of Cancer
Estrogen and progesterone receptors	(Tissue)	Breast
Catecholamine metabolites	(Urine) VMA, HVA, metanephrines	Neuroblastoma, pheochromocytoma
Hydroxyproline	(Urine)	Bone metastasis (breast), multiple myeloma
Lipid-associated sialic acid	Sialic acid bound to lipid	Gastrointestinal, lung, rheumatoid
Polyamine	(CSF)	Brain
	(Urine)	Various
PCA3	(Urine)	Prostate

CSF, Cerebrospinal fluid; *HVA*, homovanillic acid; *VMA*, vanillylmandelic acid.

Estrogen and progesterone each have at least two separate receptors. Estrogen has ERα and ERβ, which are transcribed from separate genes. ERα and ERβ show 96% and 58% homology in their DNA- and hormone-binding domains, respectively, with a more divergent sequence in the N-terminal region.[141] Two forms of PR—PR-A and PR-B—also exist, and both are transcribed from the same gene. PR-A lacks the first 165 amino acids of PR-B.

ERs and PRs are found in target tissue cells, such as the uterus, pituitary gland, hypothalamus, and breast, and appear to be involved in tumor development and progression. Furthermore, ER status and PR status correlate with both prognosis and treatment response; therefore, ER and PR measurement is clinically useful.

Clinical Applications

Measurement of ER content in breast tumor tissue is useful primarily in determining the probability of hormonal therapy and also as a prognostic indicator. ERs and PRs are routinely measured in all newly diagnosed breast cancers. Of patients with carcinoma of the breast, 60% have tumors that are ER positive. ER-positive tumors are seven to eight times more likely to respond to endocrine therapy, such as tamoxifen, toremifene, and droloxifene. Furthermore, the U.S. National Cancer Institute Consensus Statement suggests that all breast cancer patients who have positive ER findings should undergo hormonal treatment regardless of their age, menopausal status, nodal status, or tumor size. Ninety-five percent of patients with ER-negative tumors fail to respond. The greater the ER content of the tumor, the higher the response rate to endocrine therapy. Approximately one third of women with metastatic breast carcinoma obtain an objective remission following various types of endocrine therapy directed at lowering their estrogen concentrations. Such therapy includes oophorectomy, hypophysectomy, and adrenalectomy (ablative therapy), as well as administration of antiestrogens and androgens (additive therapy). As a prognostic indicator, ER positivity suggests a better 5-year outcome; however, after 5 years, ER-negative tumors have a better prognosis.[71]

Occasionally, a tumor is defined as ER negative, but the patient responds to endocrine therapy (false-negative results yielded in an ER assay). False-positive results of ER assays (ER-positive tumor but no response to endocrine therapy) are more common than false-negative results. The most frequent explanation is heterogeneity of tumor with biopsy of a site that is not representative of the other tumor deposits. In addition to this problem, evidence suggests that some tumor cells have receptor defects distal to the initial binding step (e.g., variant cells are able to bind steroid in the cytoplasm but cannot transport the receptor to the nucleus).

In 1996, ERβ was identified as a second ER; it is thought to modulate the activity of ER (now renamed ERα). When bound to hormone, ERα and ERβ signal differently at the activator protein-1 (AP-1) site: ERα activates transcription, and ERβ represses transcription.[198] This ability may have implications as to which isoform of ER is measured and may affect its prognostic use. It was reported that ERβ expression is greatly decreased in breast carcinoma tissue as compared with breast fibroadenoma tissue, but expression of ERα is not. The routinely used ELISA method for quantitation of ER predominantly detects ERα.[71] The fact that ERβ seems to attenuate ERα signaling, coupled with the fact that there is an inverse relationship between ERβ and PR and ERα proteins, suggests a possible mechanism for ER-positive tumors that do not respond to hormonal treatment.[71]

The PR assay is a useful adjunct to the assay of ERs. Because PR synthesis appears to be dependent on estrogen action, measurement of PR activity provides confirmation that all steps of estrogen action are intact. Indeed, metastatic breast cancer patients with both ER- and PR-positive tumors have a response rate of 75% to endocrine therapy, whereas those with ER-positive and PR-negative tumors have a 40% response rate. In addition, only 25% of ER-negative/PR-positive patients respond to endocrine therapy, whereas less than 5% of ER-negative/PR-negative patients respond. The percentage of positive specimens is greater in postmenopausal women than in those who are premenopausal.

Analytical Methods

Immunohistochemistry assay[50,186,232] is used to measure steroid hormone receptors in breast tumor tissue specimens. The classical quantitative biochemical method, the multiple-point dextran-coated (DCC) titration assay, and enzyme immunoassays are obsolete.[280] Immunohistochemical assays are simple and less expensive and can use small amounts of tissue from frozen tissue sections, paraffin-embedded tissue, fine-needle aspirates, and malignant effusions. However, assay interpretations can be subjective, and use of different antibodies can yield different results.

The primary monoclonal antibody is incubated with a thin section of tissue mounted on a microscope slide. Localization and visualization of receptor material are subsequently accomplished by an indirect immunoperoxidase technique. Semiquantitative scoring is based on the percentage of cells with nuclear staining and may include the intensity of staining. Specimens with staining in at least 20% of malignant cells are usually considered to have a favorable response, with 10 to 19% borderline, and <10% unfavorable. Immunohistochemistry is not influenced by the presence of estrogens, antiestrogens, or steroid-binding proteins and can evaluate receptor content specific to malignant cells and not in other nonmalignant breast tissue.

Androgen Receptors

Androgens, namely, testosterone and dihydrotestosterone (DHT), are involved in growth and maintenance of the prostate gland. Testosterone and DHT exert their effects through the androgen receptor, a classical nuclear steroid hormone receptor. The AR activates the transcription of genes containing androgen response elements, and thereby modulates prostate growth and development. The role of the AR in development and progression of prostate cancer is suggested

by the fact that antiandrogen therapy is highly but transiently effective, and antiandrogen therapy can stimulate prostate cancer cells, as seen in antiandrogen withdrawal syndrome.

Two polymorphic repeats have been identified: a CAG repeat and a GGN repeat that correlate with prostate cancer development. Shorter CAG repeats are associated with greater cancer risk and increased prostate cancer aggressiveness. Also, mutations have been found that cause inappropriate activation of the AR by estrogens, progestins, glucocorticoids, and antiandrogens that promote prostate cancer cell growth, suggesting that these mutations play a role in cancer progression and development of resistant tumors.

Hepatocyte Growth Factor Receptor (c-Met)

The hepatocyte growth factor (HGF) receptor, also known as c-Met, is a proto-oncogene tyrosine kinase receptor predominantly expressed on healthy epithelial cells. The natural ligand for c-Met is hepatocyte growth factor/scatter factor, and upon activation by its ligand, it induces a wide array of cellular responses, including proliferation, survival, angiogenesis, wound healing, scattering, motility, invasion, and branching morphogenesis. c-Met was originally identified as a fusion gene between the TRP locus and the c-Met locus in a human osteogenic sarcoma cell line treated with a chemical carcinogen. This fusion produced a constitutively active receptor that activates downstream proliferation, survival, and migration pathways.

Involvement of c-Met in the progression of cancer has been investigated in numerous types of tumors. Overexpression of c-Met in (1) prostate, (2) colorectal, (3) breast, and (4) hepatocellular cancers, (5) malignant melanoma, and (6) uterine cervix cancer is associated with increased stage, metastatic potential, and a poor prognosis. Increased mRNA copy number of c-Met in colorectal cancer has been correlated with the depth of invasion.[284] In addition, its increased expression in breast cancer tumors correlates with a shortened survival time and is an independent prognostic marker for HER-2, EGFR, and hormone receptor status.[288] Overall, inappropriate expression and overexpression of c-Met appear to be involved in metastases and invasion and correlate with a worse clinical outcome. Given the potential role that c-Met plays in cancer progression and metastases, it is being studied by various investigators as a potential target for drug therapy.

Epidermal Growth Factor Receptor

The EGFR is a prototype of a family of tyrosine kinase receptors. Natural ligands for the EGFR include epidermal growth factor and transforming growth factor-α. In cancerous tissue, these growth factors promote growth in both a paracrine and autocrine fashion. In an analysis of more than 200 studies completed between 1985 and 2000, it was determined that overexpression of EGFR had prognostic value in several cancers.[187] The EGFR was found to be a strong prognostic indicator in (1) head and neck, (2) ovarian, (3) cervical, (4) bladder, and (5) esophageal cancers. Patients with elevated EGFR showed reduced overall survival in 70% of studies. In breast, colorectal, gastric, and endometrial cancers, elevated EGFR was found to be a moderate prognostic indicator, with 52% of studies showing reduced survival. Because EGFR is implicated in the progression of various tumor types, it represents a potential point of intervention and treatment for these cancers. Several compounds have been developed that inhibit EGFR signaling by blocking ligand binding or inhibiting tyrosine kinase activity. EGFR is identified in tissue by immunohistochemistry and FISH. Detection of the EGFR protein (HER1) in EGFR-expressing cells by immunohistochemistry has been approved by the FDA for use as a companion diagnostic to aid in identifying colorectal cancer patients for treatment with the EGFR inhibitors cetuximab and panitumumab.

GENETIC AND MOLECULAR MARKERS

Cancerous growth is an inheritable characteristic of cells that is thought to be the outcome of genetic changes.[109,262] Multiple genetic alterations may be necessary for the transformation of a cell from a normal state to a cancerous one and, finally, for metastatic spread. Therefore, evaluation of chromosomal changes may fill the gap left by traditional serum biochemical markers in establishing cancer risk and screening for cancer (see Chapters 17 and 37).

Classes of genes implicated in the development of cancer are (1) oncogenes (cell activation genes—Table 24-14) and (2) tumor suppressor genes (genes involved in the recognition and repair of damaged DNA—Table 24-15).[109,297] *Oncogenes* are derived from proto-oncogenes that may be activated by dominant mutations, such as point mutations, insertions, deletions, translocations, or inversions. Most oncogenes code for proteins that function at some stage of activation of cells for proliferation, and their activation leads to cell division. Most oncogenes are associated with hematologic malignancies such as leukemia and, to a lesser extent, solid tumors. Tumor genes of the other class, *tumor suppressor genes,* have been isolated from mostly solid tumors. The oncogenicity of tumor suppressor genes is derived from loss of the gene rather than from their activation, as with oncogenes. Deletion or monosomy may lead to loss of tumor suppressor genes. The major tumor suppressor gene, *p53,* functions to repair damaged DNA through apoptosis (programmed cell death). Repair is mediated by activation of the production of p21, which blocks the cell cycle in late G_1 to allow repair to take place.[129] Loss of function of this gene caused by loss or mutation may result in an impaired DNA repair process, leading to the development of tumorigenesis.

It is expected that knowledge of the sequence of the human genome[147,292] and identification of all genes will allow determination of which genes are differentially or aberrantly expressed in cancer and identification of the role of mutations or rearrangements of these genes in the development and progression of cancer (see Chapter 44). For example, identification of single-nucleotide polymorphisms and other genetic differences between individuals may allow the development of models for predicting individual predisposition to cancer and the deployment of effective prevention strategies,

TABLE 24-14 Some Oncogenes Found in Human Tumors

Oncogene	Function	Product	Type of Cancer
N-*ras* mutation	Signal transduction	Guanine diphosphate (GDP)/ guanine triphosphate (GTP) binding protein	Acute myeloid leukemia, neuroblastoma
K-*ras* mutation	Signal transduction	GDP/GTP binding protein	Leukemia, lymphoma
c-*myc* translocation	Transcription regulation	Binds to DNA	B- and T-cell lymphoma, small cell lung carcinoma
c-*erb* B-2 amplification	Growth factor receptor	Tyrosine kinase	Breast, ovarian, gastrointestinal
c-*abl*/*bcr* translocation	Signal transduction	Tyrosine kinase	Chronic myelocytic leukemia
N-*myc* amplification	Transcription regulation	Binds to DNA	Neuroendocrine
BCL-2	Blocks apoptosis	Mitochondrial membrane protein	Leukemia, lymphoma

TABLE 24-15 Tumor Suppressor Genes: Chromosomal Location and Tumor Types

Chromosome Region	Tumor Type	Gene*
3p	Kidney	*VHL* mutation
5q21	Colorectal	*APC* mutation
9p21	Bladder, glioblastoma, melanoma	*p16 (cdkn2)* mutation
11p13	Wilms' tumor	*WT1* mutation
11p15	Wilms', breast, hepatoblastoma, rhabdomyosarcoma, bladder	Loss of heterozygosity
13q	Breast	*BRCA2*, *RB1*
13q14	Retinoblastoma, osteosarcoma, small cell lung	*RB1* mutation
16q	Breast	*P16* E-cadherin mutation
17q	Neurofibromatosis 1, melanoma, breast	*BRCA1* mutation
17p13	Breast, colorectal, lung, liver, renal cell, bladder, sarcoma	*p53* mutation
18q21	Colorectal	*DCC* mutation
22q	Neurofibromatosis 2, meningioma	*NF2* mutation

*Other genes indicated by loss of heterozygosity include 1p, 8p, 9q, 10q, and others.

such as frequent surveillance, chemoprevention, nutritional and lifestyle modifications, etc.[124]

Advances in technologies (both hardware and software), coupled with robust expansion of nucleotide and protein databases, have led to the development of new tools that allow the simultaneous interrogation of hundreds to thousands of variables simultaneously. In particular, microarray-based analyses are at the forefront of translation to clinical practice. In addition to providing discussion of single gene–based markers that are oncogenes and tumor suppressors, this section on genetic markers ends with discussion of a group of microarray tests that are being used in current clinical practice. Highlighted are four such tests: Amplichip P450 from Roche Diagnostics, Onco*type* Dx from Genomic Health Inc., MammaPrint from Agendia Inc. (Amsterdam Science Park, The Netherlands), and the Tissue of Origin test from Pathwork Diagnostics (Redwood City, Calif). Although relative newcomers to the field of clinical diagnostics, it is anticipated that these organizations will revolutionize the future of cancer therapy by providing biomarkers for better stratification of a patient's disease, and by triaging individuals to the most appropriate therapy based on their genetic makeup. These genetic profiles, which allow for the design of custom-tailored therapies, will help to usher in the new era of personalized medicine.

Oncogenes

Proto-oncogenes are normal cellular genes that are similar to tumor virus genes. Activation of proto-oncogenes is found to be associated with cancer. These genes code for products that are involved in normal cellular processes, such as growth factor signaling pathways. Overexpression of the oncogene will lead to abnormal cell growth, resulting in malignancy. Of the more than 40 proto-oncogenes recognized, only a few have been shown to be useful tumor markers (see Table 24-14).[246]

RAS Genes

The *RAS* genes were first identified as being responsible for the tumorigenic properties of the Harvey (H-*ras*) and Kirsten (K-*ras*) sarcoma viruses, which produce tumors in animals, and provided the first evidence that cellular counterparts in human cells might be involved in the development of human tumors.[17] Proteins coded for by the *ras* genes are located at the inner face of the plasma membrane, as well as in other internal cellular membranes.[82] They bind to guanine

nucleotides and function as molecular switches that regulate mitogenic signals from growth factors to the nucleus via signal transduction pathways.[61] *Ras* proteins are activated in association with protein-tyrosine kinase receptors and are required for growth factor proliferation or differentiation of a number of cell types.[163] *NRAS* is found on the short arm of human chromosome 1. Changes in *NRAS* appear to be the critical step in carcinogenesis. The mutated N-*ras* gene is found in neuroblastomas and acute myeloid leukemia. For more information on *RAS* genes in hematopoietic malignancies and myelodysplastic syndromes, see Chapter 44. Mutated *KRAS* is present in 95% of pancreatic cancers, 40% of colon cancers, and 30% of lung and bladder cancers, and in lower percentages in other tumors.[61] A single point mutation at the twelfth K-*ras* codon changes the coded amino acid from glycine to valine in the p21 protein. This mutation is by far the most frequently found in cancer, but other mutations have also been demonstrated, including those at codons 13 and 61.[180] *KRAS* mutations appear to correlate with poor prognosis and shorter disease-free survival in patients with adenocarcinoma of the lung and endometrial carcinoma. Activated *ras* is detected by expression of the *ras* gene product, p21, in cancer tissue. By immunohistochemistry, the *ras* product is found not only in about 40% of colon cancers, but also in colon polyps believed to be premalignant. Higher relative intensity of staining for p21-*ras* may differentiate malignant from normal tissues or benign lesions in (1) breast, (2) pancreas, (3) stomach, (4) lung, (5) uterus, or (6) thyroid tissues.[100] Expression in tissue appears to correlate with stage or grade of the tumor, but p21-*ras* may also be seen in some normal tissue, and other studies show no significant difference between benign and malignant tumors. Use of p21 as a tumor marker in tissue or serum is not well established. Mutations of *ras* oncogenes have been detected in DNA in the stool of symptomatic and asymptomatic patients with colorectal tumors, suggesting a novel, noninvasive paradigm for population screening.[150,250]

Several studies have underscored the importance of *KRAS* mutations in therapeutic regimen selection. As discussed at ASCO 2007-2009 and formalized in a provisional clinical opinion article,[7] individuals with a diagnosis of metastatic colorectal cancer with wild-type *KRAS* tumors are much more likely to benefit from monoclonal antibody treatments targeting the EGFR pathway, such as cetuximab and panitumumab, than individuals whose tumor carries mutated *KRAS* (at codons 12 and 13). Thus, *KRAS* mutation testing is advocated in patients suffering from metastatic colorectal carcinoma who are candidates for anti-EGFR treatments. Further, if the tumor tests positive for mutation at codon 12 or 13, the patient should not receive anti-EGFR treatments.

c-*myc*

The *MYC* gene is the proto-oncogene of avian myelocytoma virus. It binds to DNA and is involved in transcription regulation. The gene product, p62, is located in the nucleus of transformed cells, and expression of c-*myc* correlates with the rate of cell division. The c-*myc* protein is essential for DNA replication and enhances mRNA transcription. Activation of the c-*myc* gene is associated with B- and T-cell lymphoma, sarcoma, and endothelioma.[249] In leukemias and lymphomas, increased c-*myc* expression may be due to amplification or chromosomal translocation of the gene. In acute T-cell leukemias, an (8:14) (q24:q11) translocation results in activation of the gene, and is associated with a poor prognosis. A decrease in expression of c-*myc* after initiation of chemotherapy suggests a favorable response. Overexpression of p62 may be seen in 70 to 100% of primary breast cancers with the use of immunohistochemistry, and the intensity of staining is greater with increasing stages of the tumor. Amplification in lung carcinomas and gliomas correlates with clinical aggressiveness. A fivefold to 40-fold higher expression of c-*myc* may be seen in colon cancer when compared with normal mucosa, but the amount of expression does not correlate with progression. A similar relationship has been found for cervical, gastric, liver, and other cancers. Serum concentrations of c-*myc* have been used to detect recurrence, but not to differentiate cancer from benign conditions. Several reviews have highlighted recent developments in application of the c-*myc* tumor marker to breast, cervical, and colorectal cancers.[36,226,231]

Her-2/*neu* (*ERBB2*)

The HER-2/*neu* gene (also known as c-erbB-2, symbol *ERBB2*) is named for its association with neural tumors *(neu)*.

Biochemistry

The *ERBB2* gene codes for a 185 kDa transmembrane protein expressed on epithelial cells and belongs to the EGF family of tyrosine kinase receptors. The EGF family includes four members: the EGFR (also known as *ErbB1/HER-1*), *ERBB2* (HER-2/*neu*), *ERBB3*, and *ERBB4*. Members of the EGF family of receptors have the same overall structure consisting of an extracellular ligand-binding domain (ECD), a single transmembrane domain, and an intracellular tyrosine kinase domain. The extracellular domain can undergo proteolytic cleavage by metalloproteases, releasing the ECD (known as p105) into the blood, which can be detected. All are involved in cell proliferation, differentiation, and survival. HER-2/*neu* is normally expressed on the epithelia of numerous organs, including (1) lung, (2) bladder, (3) pancreas, (4) breast, and (5) prostate, and has been found to be elevated in cancer cells.

Clinical Applications

Amplification of *ERBB2* is found in (1) breast, (2) ovarian, and (3) gastrointestinal tumors. In breast cancer, it appears to be as useful a prognostic indicator of overall survival and tumor size as ER and PR expression, but not as good as the number of lymph nodes involved in metastases.[255] Of the three oncogenes—*ERBB2, RAS,* and *MYC*—*ERBB2* has the strongest prognostic value in breast cancer. Herceptin treatment is administered only to those breast cancer patients who have HER2/*neu* amplification.

Serum concentrations of HER2/*neu* are most useful in breast cancer, with some use in ovarian cancer patients.[164] The

assay is cleared by the FDA for use in follow-up and monitoring of patients with metastatic breast cancer with a HER-2/*neu* concentration >15 μg/L. Approximately 30% of patients have elevated concentrations. HER2/*neu* concentrations in breast cancer correlate with a worse prognosis and a shorter disease-free state. Elevated HER2/*neu* concentrations also correlate with large tumor size, lymph node positivity, and high grading score. One study of 719 breast cancer patients showed that patients with ER-positive cancers and elevated concentrations of HER2/*neu* derived less clinical benefit from hormonal therapies.[158] Furthermore, the study showed a trend toward improved outcomes with aromatase inhibitors for patients with elevated serum HER2/*neu*. Serum concentrations of HER2/*neu* may also be useful in monitoring the response of breast cancer patients to treatment.

Analytical Methods

Immunohistochemistry is used to detect increased expression of the HER2/*neu* protein. FISH is used for detection of HER2/*neu* gene amplification. ASCO and the College of American Pathologists (CAP) collaborated to develop comprehensive guidelines for HER2/*neu* testing.[303] The ECD of HER2/*neu* in serum is detected by ELISA and automated immunoassay. Both assays use the same monoclonal antibodies, recognizing different epitopes of the ECD, which does not cross-react with any other member of the EGF family. It is important to note that there is no interference from the therapeutic monoclonal antibody, Herceptin, with either assay.[164] The ELISA has a lower detection limit of 1.5 μg/L and an upper limit of 35 μg/L, and the automated immunoassay has a linear range from 0.5 to 350 μg/L. The cutoff for both assays has been set at 15 μg/L.

BCL-2

The product of the *BCL2* oncogene is a 239 amino acid, 25 kDa integral membrane protein that localizes primarily to the mitochondrial membranes and to other cellular membranes. This protein is known to inhibit apoptosis (programmed cell death) and to contribute to survival of cancer cells, especially lymphoma and leukemic cells.[173] The *BCL2* proto-oncogene was identified in follicular lymphomas wherein a 14:18 translocation results in formation of a *BCL-2*–immunoglobulin heavy chain fusion gene. Activation of the *BCL-2* gene through the immunoglobulin promoter results in production of high concentrations of *BCL-2* protein. The protein is normally expressed on cells that have a long life span (e.g., neurons) and on proliferative cells in rapidly renewing cell lineages, such as basal epithelial cells. The *BCL2* oncogene is highly expressed in a variety of hematologic malignancies, including lymphomas, myelomas, and chronic leukemias (malignancies characterized by prolonged cell survival). In the normal colon, *BCL-2*2–positive cells are restricted to basal epithelial cells, whereas in dysplastic polyps and carcinomas, many positive cells may be found in parabasal and superficial regions.[254,262] Abnormal expression of the *BCL*-2 gene appears to be an early event in colorectal carcinogenesis. In addition, overexpression of the *BCL2* gene is associated with development of resistance to cytotoxic cancer chemotherapy in a variety of tumors, including epithelial tumors and lymphomas. Thus detection of the *BCL2*-gene product in tumors is an indication of progression. Future studies may determine its usefulness for predicting resistance to chemotherapy. A meta-analysis strongly suggested a prognostic role for BCL-2 (as detected by immmunohistochemistry) in breast cancer, independent of several clinical variables. Additional studies using a large prospective cohort are needed to fully establish its clinical usefulness for this application.[43]

BCR-ABL

Chronic myelogenous leukemia (CML) is a myeloproliferative disorder resulting from the clonal expansion of a transformed multipotent hematopoietic stem cell. In approximately 90% of CML patients, the transforming event is the formation of the Philadelphia chromosome—a balanced translocation between chromosomes 9 and 22 [t(9;22)(q34;q11)] creating the *BCR-ABL* fusion gene. The protein derived from this fusion is a constitutively active cytoplasmic tyrosine kinase that activates several signaling pathways, leading to uncontrolled growth, inhibition of apoptosis, and other aspects of neoplastic transformation.[219]

Detection of the *BCR-ABL* gene is useful in diagnosing CML and in directing treatment, because several strategies target the *BCR-ABL* gene by oligonucleotides (antisense or ribozyme based)[95] or the *BCR-ABL* kinase domain by the tyrosine kinase inhibitor STI571 (also known as Gleevec or Imatinib mesylate). *BCR-ABL* detection by RT-PCR is useful in monitoring minimal residual disease in patients who have undergone bone marrow transplantation. In the subset of acute lymphoblastic leukemia patients who harbor the Philadelphia chromosome, a positive RT-PCR for the *BCR-ABL* gene carries a much higher risk of relapse compared with a negative result. In CML patients after bone marrow transplantation, positive RT-PCR results at 6 to 12 months were associated with a 26-fold elevated risk of relapse, and a positive result at 3 months was not predictive of risk.[221] Also, the amount of BCR-ABL transcript per μg of RNA correlated with risk of relapse; less than 1% of patients with fewer than 50 transcripts per μg of RNA relapsed, and 72% of patients with more than 50 transcripts per μg of RNA relapsed.[157] For more information on BCR-ABL, see Chapter 44.

RET

The *RET* proto-oncogene encodes a tyrosine kinase receptor involved in kidney morphogenesis, maturation of the peripheral nervous system, and differentiation of spermatogonia.[144] RET stands for "rearranged during transfection." The RET receptor exists in a multimeric complex that includes one of four glycosyl-phosphatidylinositol (GPI)-linked coreceptors (GFRα 1, 2, 3, and 4). The complex responds to four ligands: glial-derived neurotrophic factor (GDNF), neurturin (NTN), persephin (PSP), and artemin. Activation of RET appears to occur through dimerization and transphosphorylation of the receptor that recruits numerous signaling molecules. RET,

similar to other tyrosine kinase receptors, activates downstream growth pathways, and with uncontrolled signaling, cancer can result.

Inappropriate activation of RET has been extensively studied in (1) papillary thyroid cancer, (2) multiple endocrine neoplasia type 2 (MEN-2), and (3) familial medullary thyroid carcinoma (FMTC).[144] In each, the mechanism of activation of RET is through unregulated dimerization and transphosphorylation of the RET receptor.[6] In the case of papillary thyroid cancer, a genetic event creates a fusion between the *RET* tyrosine kinase domain and a dimerization domain that can be donated by a number of genes. In MEN-2A and FMTC, point mutations of the extracellular domain induce disulfide linkages between receptors, thus inducing dimerization. In MEN-2B, a point mutation in the kinase domain appears to alter the substrate specificity of the tyrosine kinase and presumably leads to inappropriate activation of downstream growth pathways. Specific mutations are highly correlated with disease phenotype and are also important for diagnostic and prognostic purposes. The molecular basis underlying the mutations has provided great insight into separable functional features of this tyrosine kinase protein.[144]

Tumor Suppressor Genes

Several tumor suppressor genes associated with human cancer are listed in Table 24-15. Historically, evidence of tumor suppressor genes was derived from the study of hybrid cells of normal and malignant cells that behaved normally.[271] It was concluded that normal cells contained a gene that suppressed the expression of malignancy.[112] Reversion to malignancy occurred when the cultured cells lost normal chromosomes. The study of tumor suppressor genes may provide a clue as to the development of cancer from normal cell status to benign and cancerous status and to metastasis. The development of colon cancer requires multiple steps that involve several mutations. Loss of a chromosome 5 gene leads to an increase in cell growth. Early adenoma is associated with loss of methyl groups on the DNA strand. With the *RAS* gene mutation and loss of the *DCC* gene on chromosome 18, adenoma advances to the late stage. Carcinoma is found with loss of the *p53* gene on chromosome 17. Finally, metastasis occurs with other chromosome losses.[81] The clinical usefulness of detection of mutations in tumor suppressor genes lies not only in the diagnosis and prognosis of cancer, but also in the prediction of susceptibility when the mutation is carried in the germline, such as with the breast cancer genes *BRCA1* and *BRCA2*.

Retinoblastoma Gene

Retinoblastoma (RB) is a rare tumor of children that occurs both in families and sporadically. The work of Alfred G. Knudson on the familial-specific incidence of RB led to the two-hit hypothesis.[137,138] He reasoned that in the inherited form of the tumor, one mutation was present in the germline and in all cells of the body, the other mutational event occurring somatically in one of the cells of the developing retina. In the sporadic form, both mutations occur somatically in the same developing retinoblast—a relatively rare event. The two-hit hypothesis has served as a model for other tumor suppressor genes. The *RB* gene *(RB1)* has been localized to chromosome 13q by loss of a chromosomal banding region in the peripheral blood lymphocytes of patients with the familial form and by loss of heterozygosity studies in both RBs and some osteosarcomas. However, most tumors do not have gross deletions but point mutations or small insertions and deletions that result in premature truncation of the protein product.[96] The protein product of the *RB1* gene is a nuclear phosphoprotein with a molecular mass of about 105 kDa (p105-RB).[148] This protein binds to a product of a DNA tumor virus, such as the E1A protein of murine tumor virus or the E7 protein of human papillomavirus. When p105-RB is hypophosphorylated, it complexes with transcription factors such as E2F and blocks transcription of genes in S-phase cells. E2F dimerizes with a DP protein and regulates the transcription of several genes involved in DNA synthesis. Inactivation or loss of p105-RB deregulates DNA synthesis and increases cellular proliferation. Thus RB is a tumor suppressor gene, as it suppresses DNA synthesis. Detection of mutations in RB is useful in determining the susceptibility of an individual to development of RB in the familial form, but it is not used as a tumor marker.

p53 Gene

Of particular interest is the *p53* gene,[130,170] *TP53* (tumor protein 53), which lies on chromosome 17q. Native or wild-type p53 is believed to control cell division by regulating entry into the S phase.[129] This controlling effect of p53 protein may be lost by deletion of the gene or production of a competing mutant protein. Seventy-five to 80% of colon carcinomas show deletion in one *TP53* allele and a point mutation in the other allele; thus, no wild-type p53 protein is expressed in these tumors. Allelic deletion of *TP53* occurs only rarely in adenomas (10%), suggesting that p53 inactivation may be a relatively late event in colon carcinogenesis. In addition, up to 70% of breast cancers also have deleted *TP53*. Mutations in *TP53* produce proteins that inactivate the wild-type p53 protein and allow cells to move through the cell cycle and contribute to the autonomous growth of cancer. Several different mutations of *p53* have been found in human cancers.[151] Most point mutations affect one of four regions of the protein (amino acid residues 117 to 142, 171 to 181, 134 to 158, and 270 to 286); three "hot spots" affect residues 175, 248, and 273.[151] In addition, selective guanine-to-thymine mutations are found at codon 249 in human hepatocellular carcinomas taken from patients in high-incidence areas of Africa, and those at codon 197 are associated with aflatoxin exposure. Mutations at codons 245 and 258 are found in Li-Fraumeni syndrome, a rare autosomal dominant syndrome characterized by diverse neoplasms at many different sites in the body.[197,268]

Monoclonal antibodies to mutated p53 proteins have been developed. Wild-type p53 is normally present in very small amounts that are not detected by immunohistochemistry, whereas the mutant protein accumulates and is

easily detected. Overexpression of the mutant proteins has been detected in up to 70% of primary colorectal cancers. Overexpression of p53 in breast cancers is associated with poor prognosis, but this association is not as strong as the association with c-*erb*B-2.[187,189] Up to 75% of small cell lung carcinomas appear to overexpress a mutant (missense mutation) protein. Finally, circulating antibodies to mutant p53 proteins have been found in sera from patients with breast and lung cancer and B-cell lymphomas. This antibody response may be useful in this subset of patients for monitoring relapse.[170] Hall and McCluggage review methodologic issues of the different assays for interrogating p53 and its downstream effectors in several clinical contexts.[107]

p21 *(WAF1)*

The wild-type p53 protein activates transcription of various genes, including the *WAF1/CIP1* gene (symbol *CDKN1A* for cyclin-dependent kinase inhibitor 1A). The p21 protein product of the gene binds to and inhibits the cyclin-dependent protein kinases (CDKs) that are active in the G_1 phase of the cell cycle. The cell-cycle arrest function of p53 in response to DNA damage is mediated by p21. Monoclonal antibodies to the p21 protein are now available and are being used to determine whether expression of p21 in tumors may be clinically useful. Recent work assessing the role of p21 suggests that additional data are required before the efficacy of p21 for predicting outcomes in rectal cancer can be validated.[142]

APC

One of the first events in the putative steps of progression of precursor lesions to colon cancer is loss of the adenomatous polyposis coli *(APC)* gene in premalignant polyps.[81] The *APC* gene encodes a 300 kDa protein that may be truncated in cancer cells. The normal function of the *APC* gene product is not known, but it interacts with proteins, such as α- and β-catenin, involved in cell-cell interactions in epithelial cells. This gene is mutated in hereditary colorectal cancer syndromes—polyposis and nonpolyposis types. In the polyposis types, hundreds and even thousands or more benign tumors (polyps) arise before the development of cancer. Among nonpolyposis types, very few polyps are seen, but the elevated risk of cancer is essentially similar. The *APC* gene was detected by an interstitial deletion on chromosome 5q in a patient with hundreds of polyps.[149] More than 80% of individuals with hereditary colorectal cancer have germline mutations in one of the *APC* alleles, including gross deletions or localized mutations. Hereditary forms of colorectal cancer are relatively uncommon, but somatic mutations appear to be of great importance in the development of nonhereditary colorectal cancers. More than 70% of colorectal tumors, regardless of size or histology, have a specific mutation in one of the two *APC* alleles, and mutation may be found in other types of tumors, including breast, esophageal, and brain tumors. The usefulness of loss of the APC protein for diagnosis and prognosis is the subject of ongoing investigation. However, recent evidence suggests the importance of APC functional activity for prognostic purposes, as well as for directing therapy in colorectal cancer.[220]

Neurofibromatosis Type 1

Neurofibromatosis type 1 (NF1), or von Recklinghausen's disease, is a dominantly inherited syndrome manifested mainly by proliferation of cells from the neural crest, resulting in multiple neurofibromas, café au lait spots, and Lisch nodules of the iris.[247] Mutations in the *NF1* gene have been found in about 20% of NF1 patients.[295] The *NF1* gene has been localized to the pericentromeric region of chromosome 17q, band 11. It is a large gene coding for a p300 protein, called *neurofibromin*. This protein has a high degree of similarity to GTPase-activating proteins, and is thought to act as a negative regulator of *Ras*.[300] Although the exact mechanism of action of the protein is not known, it appears likely that loss or inactivation of neurofibromin function leads to alterations in signal transduction pathways regulated by small *ras*-like G proteins, resulting in constitutive signaling from this pathway. Inactivating mutations of *NF1* have also been found in colorectal cancer, melanoma, and neuroblastoma.

WT1

The Wilms' tumor suppressor gene, *WT1*, is located on chromosome 11p13. Its loss plays a causal role in the development of a childhood kidney malignancy, and it is involved in normal and abnormal hematopoiesis.[12] The *WT1* gene encodes a 45 kDa protein that appears to function in transcriptional regulation by suppressing the expression of growth-inducing genes, such as early growth response, insulin-like growth factor-2, and platelet-derived growth factor A chain genes.[102] Other chromosomal changes in Wilms' tumors indicate that mutations of *WT1* may be only one step in the process of carcinogenesis. Thus identification and understanding of one tumor suppressor gene in a given cancer may provide only part of the information eventually required to understand the carcinogenic process.

nm23

The nm23 gene *NME1* was found overexpressed in a nonmetastatic murine melanoma cell line but present in low amounts in a highly metastatic cell line. The *NME1* gene product appears to be elevated in metastatic breast, colon, and prostatic cancer and now is being evaluated as a new marker for metastases.[88]

BRCA1 and *BRCA2*

A subset of breast cancer patients have been shown to have an inherited predisposition to developing breast and ovarian cancer that is inherited as an autosomal dominant trait.[135] Two genetic loci have been identified: *BRCA1* on chromosome 17q, and *BRCA2,* which localizes to 13q12-13.[177,304] *BRCA1* encodes an 1863 amino acid protein that may act as a transcription factor. The ability to detect mutations in *BRCA1* and *BRCA2* in the germline permits the identification of individuals in breast cancer families who carry the mutated gene. It is estimated that as many as 1 in 200 women in the

United States may have a germline mutation in the *BRCA1* gene. This has created an ethical dilemma for physicians, patients, and their families, and for insurance companies and health maintenance organizations, as it is now possible to predict with reasonable certainty that an individual who carries a mutation in one of these genes will develop breast and/or ovarian cancer. What should be done if an otherwise healthy individual is shown to carry a *BRCA* gene mutation? Carriers of a *BRCA1* gene mutation have an 85% risk of developing breast cancer and a 45% risk of developing ovarian cancer by the age of 85.[87] Should such patients have preventive mastectomy or ovariectomy? Should insurance companies and healthcare maintenance organizations have higher rates for carriers? It has always been a goal of cancer research to be able to identify individuals at risk. Now that this is possible, a policy must be developed on how to deal with the information (see Harper[111] or Petty and Killeen[215]). The recently passed GINA legislation (Genetic Information Nondiscriminatory Act) prohibits discrimination based on genetic information and is an important step in the right direction. Although detection of the mutation is not useful as a tumor marker per se, with further understanding of how the mutated gene products act, it may be possible to understand the molecular events for development of some breast and ovarian cancers.

Deleted in Colorectal Carcinoma

The "deleted in colorectal carcinoma" *(DCC)* gene, located on chromosome 18q, encodes a membrane protein of the immunoglobulin superfamily. The exact function of DCC has yet to be elucidated. However, studies have suggested a role in axonal development as a component of the Netrin-1 receptor, and others have suggested a role in promoting apoptosis.[98] Many cellular processes co-opted in oncogenesis are also critical in nervous system development, thus suggesting the possibility of the DCC protein to function in both pathways.[76] In colon cancer, DCC is thought to act as a tumor suppressor; thus deletion or reduced expression correlates with increasing stage and a poorer prognosis.[190] Conversely, loss of *DCC* expression in gastric cancer was associated with a better prognosis and improved tumor cell differentiation.[190] However, the function of DCC and how it fulfills its role as a tumor suppressor are controversial.[175] More work is necessary to determine the exact role of DCC in colon cancer and other cancers.

PTEN

The *PTEN* tumor suppressor gene, located at human chromosome 10q23, is mutated in numerous cancers, and is probably underestimated in terms of its importance in tumor formation and progression.[281] Primary sequence analysis suggested that it encodes a protein tyrosine phosphatase with extensive homology to the cytoskeletal protein tensin.[154] PTEN functions as a phosphatase that negatively regulates phosphoinositide 3-kinase (PI 3-K) signaling by dephosphorylating the D3 position of phosphatidylinositol (3,4,5)-triphosphate [PtdIns(3,4,5)P_3]. PI 3-kinase and its product PtdIns(3,4,5)P_3 are involved in activation of signaling pathways leading to inhibition of apoptosis, cell migration, cell size, and chemotaxis. Mutation or inactivation of *PTEN* allows uncontrolled activation of the downstream pathways, which contribute to tumorigenesis.[183]

Germline mutations in *PTEN* cause the (1) Cowden, (2) Lhermitte-Duclos, (3) Bannayan-Zonana, and (4) Proteus autosomal dominant syndromes, all of which are characterized by the development of hamartomas and an increased likelihood of tumor development, along with other growth-related symptoms. In general, *PTEN* mutation or loss of expression is associated with a more advanced stage and is a poor prognostic indicator in various cancers, including breast, hepatocellular, endometrial, and cervical.

Other Molecular Tests

Single-Nucleotide Polymorphisms

The Human Genome Project identified all of the approximate 25,000 transcriptional units in the human genome and determined the sequences of the 3 billion chemical base pairs that constitute human DNA. A byproduct of the sequencing effort was the identification of a very large number of single-nucleotide polymorphisms (SNPs; single nucleotides that differ between individuals and are inherited), formalized and detailed through the efforts of a related genomic project, the HapMap Project.[124] It has been estimated that one SNP can be found in every approximately 300 bases of human DNA. Most of these SNPs are present in introns, and only a relatively small number (approximately 60,000 of the 2,000,000 SNPs) are within exons. Groups of SNPs (called *haplotypes*) are inherited together in blocks. It has been hypothesized that it may be possible to correlate SNP composition (e.g., various haplotypes) with disease predisposition. Until now, very few SNPs or haplotypes have been associated consistently with human cancers. Many scientists are currently investigating SNPs and are attempting to correlate them with various diseases. Large numbers of SNPs can be surveyed by using hybridization-based technologies such as microarrays, or can be interrogated using targeted approaches utilizing separation techniques such as capillary electrophoresis and mass spectrometry. The hope is to identify characteristic SNPs or haplotypes that can be used for diagnostic purposes or for determining future risk (predisposition) for developing certain diseases.

Cell-Free Nucleic Acids

Circulating DNA and RNA have been recognized since the 1970s, but it was not until the late 1980s that the neoplastic characteristics of DNA were recognized.[128] Circulating DNA and RNA have been proposed as a marker for certain types of cancer.[51,282] To use circulating DNA as a cancer marker, a mechanism must differentiate normal DNA from neoplastic DNA. This is achieved by detecting mutations in circulating DNA that are present in cancer cells (e.g., *ras* mutations that occur in various cancers), by performing microsatellite analysis of circulating DNA, or by detecting common cancer-causing chromosomal translocations. Epigenetic alterations

of circulating DNA, such as altered methylation patterns, can also be detected. In recent years, cell free nucleic acids have been detected in bronchial lavage fluid from lung cancer patients and in plasma from colorectal cancer patients.[92,239] Over the next decade, detection of circulating DNA will likely join a growing number of clinically useful markers. In the future, this technology may have the ability to provide a more global picture of the abnormalities present in the patient.

Circulating Tumor Cells

A majority of all cancers are derived from epithelial cells. Under appropriate conditions, these cells break from the primary tumor and shed into the circulation. These circulating tumor cells (CTCs) are very rare (approximately 1 CTC per 5 to 10 million red blood cells and lymphocytes), but they can be captured, enriched, and enumerated. Quantification of CTCs has been demonstrated to be an independent predictor of overall survival and progression-free survival in patients suffering from metastatic breast, colon, and prostate cancers. This technology, as applied using the Veridex CellSearch platform (Veridex LLC, Raritan, NJ),[293] is FDA approved for these applications. It is hoped that this procedure will assist with early detection of disease and enable personalized therapy for targeted management and improved outcomes.

The assay uses a combination of positive and negative selection methods to isolate circulating epithelial cells from whole blood. Specifically, anti-EpCAM antibodies are used to selectively capture epithelial cells from whole blood. This step is followed by a negative selection step using anti-CD45 antibodies to remove white blood cells from the preparation. The remaining cells then are stained for cytokeratin positivity and are analyzed by immunofluorescence microscopy. Cells are enumerated by assessing positivity for cytokeratin, negativity for CD45, and positive DAPI staining. This procedure allows the identification of nucleated epithelial cells from whole blood. Two advantages of this technology are that it is noninvasive, requiring only a blood sample, and it can be performed essentially in real time. Thus, it allows rapid assessment of therapeutic response and hence, adjustment of therapy as needed. For patients not responding to a particular line of therapy, alternative regimens can be prescribed, or dosages can be adjusted as needed. In addition, unnecessary treatment can be avoided. The greatest demonstration of the use of this technology is seen in breast cancer patients.[64] In metastatic breast or prostate cancer, a CTC count of five or more cells per 7.5 mL of blood is associated with a poor prognosis and is predictive of shorter progression-free survival and overall survival. The same is true in metastatic colorectal cancer with a CTC count of three or more cells per 7.5 mL of blood. The CellSearch system has been validated for analytical performance and robustness.[225]

PCA3

PCA3 (prostate cancer gene or antigen 3) is a molecular urine test for prostate cancer. The *PCA3* gene, also known as $PCA3^{DD3}$ or $DD3^{PCA3}$, was first described in 1999.[41] *PCA3* mRNA is noncoding, and its function is unknown. *PCA3* is highly overexpressed in prostate cancer tissue compared with healthy or benign prostate tissue, which has low expression. It is not detectable in healthy tissue or in tumors from bladder, testis, and other organs.[67] PCA3 score correlates with biopsy outcome in men undergoing a first or a repeat biopsy. In a prospective study of 570 men undergoing prostate biopsy, a PCA3 score of 35 yielded 54% clinical sensitivity and 74% specificity for prostate cancer detection.[69] Unlike PSA, PCA3 is independent of prostate volume, and PCA3 scores have been associated with both grade and extent of prostate cancer. In 2006, the PCA3 assay (Gen-Probe PROGENSA; Gen-Probe Inc., San Diego, Calif) received marketing clearance in Europe. Urine specimens for PCA3 are collected following digital rectal exam (DRE) with three strokes per prostate lobe (to release prostate cells) and are mixed with a stabilization buffer to lyse cells and stabilize the RNA. PCA3 and PSA mRNA are quantitated using transcription-mediated nucleic acid amplification. The PCA3 mRNA copy number is normalized with the PSA mRNA housekeeping gene to generate the PCA3 score (PCA3 mRNA/PSA mRNA × 1000).

Microarray-Based Markers

Roche Amplichip P450

The Roche Amplichip P450[80,115] is the first FDA-cleared microarray-based pharmacogenetic assay with application to the clinical management of patients. It detects variations in the cytochrome *P450 2D6* and *2C19* genes, which are involved in the metabolism of many clinically prescribed drugs, including beta blockers, antidepressants, antipsychotics, and, most important for this chapter, chemotherapeutic agents such as tamoxifen and cyclophosphamide. Variation includes the presence of single-nucleotide polymorphisms in the *CYP2D6* and *CYP2C19* genes, as well as deletions and duplications in *CYP2D6*. With this chip, up to 33 2D6 alleles and 3 2C19 alleles can be interrogated simultaneously.

From a technical perspective, the assay is conducted in five steps: (1) PCR amplification of appropriate segments of patient genomic DNA, (2) fragmentation and labeling of the amplified products, (3) hybridization to the microarray and staining of the bound products, (4) scanning of the microarray, and (5) interpretation to give a predicted phenotype based on genotypic results. By determining the patient's genotype, a phenotype is predicted, thus allowing for tailored treatments. The test is used to classify individuals as poor, intermediate, extensive, or ultrarapid metabolizers, and this knowledge can be used to select appropriate therapy. Appropriate triage of patients is useful for optimizing efficacy and minimizing adverse drug reactions.

Drugs that are metabolized through the cytochrome P4502D6 pathway can be inactivated or activated through enzymatic action of 2D6. In the case of inactivation, as exemplified by the antidepressant paroxetine, the following effects may be noted on the basis of patient genotype. Individuals who are poor or intermediate metabolizers of 2D6 may experience toxic side effects as the result of overmedication when given a standard dose. Such individuals may benefit from smaller doses than standard. Extensive metabolizers will be

able to properly metabolize their medication with standard doses and should have the expected response to their medication. In contrast, ultrarapid metabolizers metabolize medication quickly and may not respond to standard doses of medication. Such patients may benefit from higher doses of medication. Not all drugs will fit this scenario. In other cases, a drug may be activated through the cytochrome P4502D6 pathway. One example is that of tamoxifen, which is used currently as the standard of care treatment for estrogen receptor–positive (ER+) breast cancer. Tamoxifen is a prodrug that undergoes a series of modifications leading to its activation. Clinically, endoxifen is the most important active metabolite; it has been shown to have 50 to 100 times greater antitumor activity compared with tamoxifen in in vitro assays and higher affinity for the estrogen receptor. Endoxifen is produced by the action of the cytochrome P4502D6 enzyme in the liver.

Poor and intermediate metabolizers of 2d6 will experience suboptimal effects because of reduced endoxifen concentrations. In contrast, ultrarapid metabolizers may experience toxic effects caused by high concentrations of the active metabolite. Because tamoxifen is a prodrug, the effects are the opposite of those given in the previous example, where the drug (paroxetine) is inactivated by CYP2D6.

Similarly, for cytochrome P4502C19, two thoroughly-characterized alleles result in reduced enzymatic activity. These are the *2 and *3 SNPs. 2C19 corresponds to S-mephenytoin hydroxylase and metabolizes many psychiatric medications in use today (e.g., proton pump inhibitors, antiepileptic agents). It is also responsible for metabolism of the chemotherapeutic agent, cyclophosphamide. Genotyping and classification of patients based on 2C19 works similarly to that of 2d6. However, amplifications and deletions of this gene have not been characterized in the scientific literature. Thus, classification of patients is limited to that of poor (at least one reduced functional allele) and extensive metabolizers (at least one wild-type allele).

Oncotype Dx

The Oncotype Dx assay, marketed by Genomic Health Inc. Redwood City, CA,[94] determines the expression of 21 genes in breast tissue.[201] It is intended for use in women with early-stage, node-negative, ER-positive breast cancer who will be treated with hormonal therapy.[199,200] The assay provides an assessment of the likelihood of response to chemotherapy and of recurrence within 10 years. The result of this assay is a recurrence score that ranges from 0 to 100. A score above 31 indicates high risk of recurrence, whereas a score of 18 or less indicates low risk of recurrence. Scores greater than 18 but lower than 31 indicate an indeterminate recurrence risk. This test can thus be used for clinical decision making following triaging of patients to the most appropriate therapy—those at high risk can be treated more aggressively, whereas for those at lower risk, standard therapy is recommended. This assay was included in the 2007 American Society of Clinical Oncology (ASCO) clinical guidelines on the use of tumor markers in breast cancer and in the 2008 National Comprehensive Cancer Network (NCCN) breast cancer treatment guidelines.[113,184] Evidence suggests that the test may also be useful in the treatment of postmenopausal women with node-positive, ER-positive, invasive breast cancer.[5]

Agendia MammaPrint

The Agendia MammaPrint assay is the first genomic FDA-cleared IVDMIA (in vitro diagnostic multivariate index assay) used to assess the risk of breast cancer recurrence.[4] It is intended for use in women younger than 60 years of age who are diagnosed with early-stage breast cancer (stage 1 or 2) that is node negative with <5 cm tumors. Assessment is performed on fresh frozen tumor tissue obtained during surgery with samples being sent directly to Agendia Laboratories in The Netherlands. The assay can be used to identify which tumors are most likely to recur after surgery, independent of estrogen receptor status and any prior therapies.

From a technical perspective, the assay measures the expression of 70 genes involved in important signal transduction pathways responsible for breast cancer metastasis. The genes function in various aspects of the metastatic process, including (1) cell cycle progression, (2) angiogenesis, (3) invasion, and (4) cell migration. The assay is based on initial microarray studies performed on samples (both ER positive and negative) with 10-year follow-up data. The analysis identified a 231-gene biomarker signature and after validation was later enriched to capture the 70 most prognostic genes capable of stratifying patients for likelihood of recurrence.[291] This 70-gene biomarker signature has been independently validated in other cohorts.[42] It provides a picture of alterations in gene activity and likelihood of disease spread. Patients are stratified into one of two groups—low risk or high risk—for distant metastasis (there is no intermediate risk group). Because disease can be characterized based on aggressiveness, this knowledge allows a clinician to tailor therapy specifically to the patient. Specifically, for women at low risk based on their MammaPrint score and traditional risk factors, hormonal therapy (such as tamoxifen) may be sufficient. In contrast, for women at high risk based on MammaPrint score and additional risk factors, more aggressive treatment may be recommended, possibly including chemotherapy.

Pathwork Diagnostics Tissue of Origin Test

The tissue of origin test uses gene expression information from tumor samples to reliably determine a cancer's tissue of origin.[209] It is performed on individuals with poorly differentiated or undifferentiated tumors. Such a diagnosis poses a problem because cancer treatment guidelines are dependent on knowing the origin of the primary tumor.[33] In approximately 5% of cancers, the primary tumor site cannot be determined, and therefore the appropriate therapy cannot be selected.

Historically, such assessments have been performed based on immunohistochemical analyses that are subjective, as they are based on pathologist review and interpretation. In contrast, the tissue of origin test measures gene expression using microarrays to interrogate a panel of 1550 genes in addition

to 110 control genes. These data are then compared with gene expression patterns from a panel of 15 known tumor tissue types representing 90% of all solid tumors. This comparison results in a similarity score that can aid in determining the most likely tissue of origin. The tissue of origin test uses formalin-fixed paraffin-embedded (FFPE) or frozen specimens. A Clinical Laboratory Improvement Amendments (CLIA)-certified laboratory service is available for this analysis, requiring specimens to be sent directly to Pathwork Diagnostics Laboratory, Redwood City, CA. The in vitro diagnostic kit is FDA cleared for use on frozen samples.

CHAPTER 25

Kidney Function Tests

Edmund J. Lamb, Ph.D., F.R.C.Path., and Christopher P. Price, Ph.D., F.R.S.C., F.R.C.Path.

The functional unit of the kidney is the nephron, with each kidney containing between 0.4 and 1.2 million nephrons. In nearly all types of renal disease, impaired function of the kidneys is attributed to a diminished number of functioning nephrons rather than to compromised function of individual nephrons. Because glomerular filtration is the initiating phase of all nephron functions, quantitative or qualitative assessment of the glomerular filtration rate (GFR)—or some variable that bears a constant relationship to it—and assessment of the integrity of the filtration barrier generally provide the most useful indices for physicians to assess the severity and progress of kidney damage.

Specific defects in particular functions of the nephrons can also be identified and evaluated. For example, assessment of the maximum concentrating capacity of the kidneys gives an estimate of antidiuretic hormone (ADH)-controlled reabsorption of solute-free water in the distal portion of the tubule. Pinpoint defects, caused by genetically determined deficiencies of specific tubular transport systems or ion channels and giving rise to characteristic biochemical disorders, are considered in Chapter 48.

This chapter describes tests that have proved practical and useful for screening for and diagnosing impaired kidney function in clinical laboratories, and for monitoring the course and management of progressive chronic kidney disease (CKD). In general, where blood markers are discussed, either plasma or serum can be used for most of these tests (the term *serum* is mainly used throughout this chapter). This chapter provides an overview of contemporary methodology with reference intervals and discussion of the clinical utility of the tests.

URINE ANALYSIS

Examination of the urine is often the first step in the assessment of a patient suspected of having, or confirmed as having, deterioration in kidney function. The appearance (color and odor) of urine itself can be helpful; darkening from the pale normal straw color indicates more concentrated urine or the presence of another pigment. Hemoglobin and myoglobin give a pink-red-brown coloration, depending on the concentration. Turbidity in a fresh sample may indicate infection but also may be due to fat particles in a patient with nephrotic syndrome. Excessive foaming of urine when shaken suggests proteinuria. Urine is often chemically evaluated at the point of care with the help of reagent strip tests, which are available for a variety of analytes, or it is microscopically examined.

Reagent Strip (Dipstick) Testing

Over the years, many tests of renal significance have been adapted for use on strips of cellulose or pads of cellulose or strips of plastic that have been coated or impregnated with reagents for the analyte in question. This type of analytical test is commonly known as a *dipstick test.* A reagent strip may contain reagents for just one test per stick or reagents for multiple tests on a single stick. With this type of test, different methods detect substances that overflow into the urine, such as glucose, ketones, bilirubin diglucuronate, and urobilinogen, changes in the concentration of which reflect a change in another organ system in the body. These tests also detect changes in constituents that are more directly linked to alterations brought about by some pathologic condition affecting the kidney or urinary tract. Urine samples for reagent strip testing should be collected in sterile containers, and testing should be performed on fresh urine. Reagent strips should be used only if they have been stored properly desiccated because they can deteriorate in a matter of hours. Strict attention must be paid after sample addition to the timing of reading the absorbance change, which differs between analytes (e.g., from 30 seconds to 2 minutes). Examples of method principles and comments on the performance of tests pertinent to the assessment of kidney function are given in the following sections.

Total Protein

The reagent strip test for total protein includes a cellulose test pad impregnated with tetrabromphenol blue and a citrate pH 3 buffer. The reaction is based on the *protein error of indicators phenomenon,* by which certain chemical indicators demonstrate one color in the presence of protein and another in its absence. Thus tetrabromphenol blue is green in the presence of protein at pH 3 but yellow in its absence. The test has a lower detection limit of 150 to 300 mg/L, depending on the type and proportions of protein present. The reagent is most sensitive to albumin and less sensitive to globulins, Bence Jones protein, mucoproteins, and hemoglobin.[29,109,138] Indeed, it is confusing to note that one commercial application of this principle has been manufactured as Albustix, although the

chemical principle underlying this test is identical to those of devices that claim to measure protein.[109]

Although not all patients with CKD will have proteinuria, proteinuria is a common finding in patients with kidney disease, and its presence suggests a poorer prognosis.[129-131,273] Use of a reagent strip assay has been considered an important screening test in any patient suspected of having renal disease. Among patients with suspected or proven CKD, including reflux nephropathy, and early glomerulonephritis, and those with hypertension or previously detected asymptomatic hematuria, annual urinalysis for proteinuria has been accepted as a useful way of identifying patients at risk of progressive kidney disease. Currently, no proven role has been identified for reagent strip protein analysis in the screening of unselected populations.[218,345] For many years, reagent strip testing for proteinuria was deemed inadequate for the detection of CKD among patients with diabetes, in whom urinary albumin loss should be measured specifically (see later); growing consensus suggests that reagent strip testing is also inadequate in other clinical scenarios.

Protein excretion displays considerable biological variability, which may be increased by (1) upright posture, (2) exercise, (3) fever, (4) symptomatic urinary tract infection (UTI),[41] (5) heart failure, and (6) kidney disease. Because standard urine reagent strips rely on estimation of protein concentration, this in turn depends on hydration or how concentrated the urine sample is; these tests therefore give only a rough indication of the presence or absence of pathologic proteinuria. Ralston and associates observed poor specificity for reagent strip analysis in detecting protein loss of 300 mg/d in a rheumatology outpatient population.[258] A pooled analysis of six studies undertaken in obstetric patients reported positive and negative likelihood ratios for "+" protein or greater on reagent strip analysis, for predicting 300 mg/d proteinuria as 0.6 (95%-CI: 0.45 to 0.8) and 3.48 (1.66 to 7.27), respectively,[336] suggesting that reagent strips are not good at ruling in or ruling out significant proteinuria. The Scottish Intercollegiate Guidelines Network (SIGN)[285] and the National Institute for Health and Clinical Excellence (NICE)[216] guard against the use of reagent strips to detect proteinuria. An evidence-based systematic review undertaken by the U.S. National Academy of Clinical Biochemistry (NACB) recommended against routine screening for proteinuria with reagent strip analysis.[214] Academy reviewers found no evidence that the use of urine reagent strip testing for proteinuria at the point of care improved patient outcomes; they described significant evidence of a high false-negative rate and poor negative predictive value compared with laboratory testing. The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF-KDOQI), NACB, SIGN, and NICE concur that these devices may give false-negative results when the urine is dilute.[214,216,218,285] Most authors agree that positive tests require confirmation by laboratory measurement of the protein-to-creatinine ratio (PCR) or the albumin-to-creatinine ratio (ACR) on an early morning or random urine sample.[218] A suitable protocol for the further investigation of patients found to have proteinuria at screening is given in Figure 25-1.

Automated devices capable of reading color changes in reagent strips using reflectance spectrometry have become available. These reduce interoperator variability and improve diagnostic accuracy.[2,275,279,335] A creatinine test pad (using the peroxidase-like activity of transition metal creatinine complexes) has been added to some reagent strip systems to enable a PCR to be reported, thereby reducing the intraindividual variation seen with random urine collections. An evaluation of one such device (Multistix PRO 10LS, Siemens plc, Camberley, Surrey, United Kingdom) read semiquantitatively on the Clinitek Status automated strip reader (Siemens plc) in a renal outpatient setting concluded that the test was suitable for ruling out significant proteinuria (>0.3 g/d).[108]

Albumin

Reagent strip methods are available for the more specific detection of albumin at low concentrations (i.e., in the microalbuminuric range—approximately 20 to 200 mg/L). Both photometric and immunologic methods for detecting albumin have been described for use with urine samples, the former based on binding of bis(3′,3″-diiodo-4′,4″-hydroxy-5′,5″-dinitrophenyl)-3,4,5,6-tetrabromosulfonephthalein (DIDNTB) at pH 1.5.[257] For example, the Clinitek microalbumin reagent strip read on a Clinitek Status analyzer (both products of Siemens) produces semiquantitative ACR results, whereas the DCA 2000+ device (Siemens) is capable of reporting a fully quantitative ACR result. Medicines and Healthcare Products Regulatory Agency reports[200,201] and other published evaluations[238,239] have demonstrated reasonable analytical performance. Good diagnostic performance has been reported in the detection of significant proteinuria in hypertensive pregnancy,[335] in ruling out significant albuminuria (>30 mg/d) in a CKD outpatient population,[107] and in ruling out albuminuria (>3.4 mg/mmol) in a general population.[102]

Hemoglobin

The presence of hemoglobin in the urine may be due to glomerular, tubulointerstitial, or postrenal disease, although the latter two causes are the more common. The presence of blood in the urine is detected by using a phase contrast microscope to determine the presence of red cells in the urine sediment, or by using a reagent strip test. Chemical detection of hemoglobin in urine depends on the peroxidase activity of the protein employing a peroxide substrate and an oxygen acceptor.

For this test, the reagent pad is impregnated with buffered tetramethyl benzidine (TMB) and an organic peroxide. The method depends on detection of the peroxidase activity of hemoglobin, which catalyzes the reaction of cumene hydroperoxide and TMB. The color change ranges from orange through pale to dark green, and red cells, free hemoglobin, and myoglobin are all detected. Two reagent pads are used for the low hemoglobin concentration; if intact red cells are

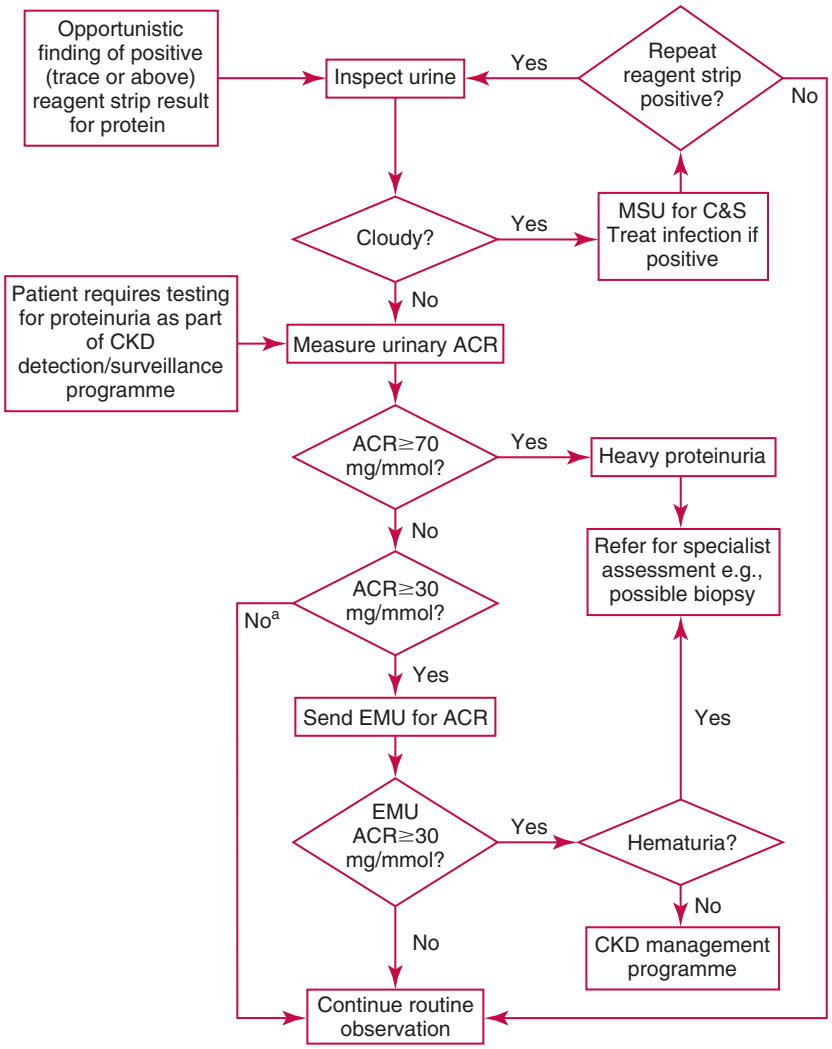

Figure 25-1 Suggested protocol for the further investigation of a nondiabetic individual demonstrating a positive (trace or above) reagent strip test for proteinuria or a quantitative proteinuria test. Reagent strip device results should be confirmed using laboratory testing of the albumin-to-creatinine ratio (ACR) on at least two additional occasions. Patients with two or more positive (≥30 mg albumin/mmol creatinine) tests on early morning samples 1 to 2 weeks apart should be diagnosed as having persistent proteinuria. (The possibility of postural proteinuria should be excluded by examination of an early morning urine.) Protein-to-creatinine ratio (PCR) measurement can be substituted for the ACR: approximate PCR equivalents to ACRs of 30 and 70 mg/mmol are 50 and 100 mg/mmol, respectively. This protocol is adapted from U.K. National Institute for Health and Clinical Excellence (NICE) guidance: other countries and professional organizations have alternate versions (see www.nice.org.uk/CG73 for further information). *C&S,* Culture and sensitivity; *CKD,* chronic kidney disease; *EMU,* early morning urine; *MSU,* midstream urine. [a]In the absence of a systemic disease such as diabetes or hypertension with a borderline increase in albumin (3 to 30 mg/mmol), total protein (15 to 50 mg/mmol) loss without hematuria, or a rise in serum creatinine, a serious primary renal pathology is unlikely. In a diabetic patient, lesser degrees of proteinuria may be significant and should elicit appropriate investigation and management (see "Proteinuria and Albuminuria: Clinical Significance"). *Note:* U.S. guidelines express albuminuria or proteinuria as mg/g creatinine, whereas other guidelines use mg/mmol creatinine. An approximate conversion factor of 0.1136 can be used to convert results in mg/g to mg/mmol (e.g., 30 mg/mmol = 264 mg/g, 70 mg/mmol = 616 mg/g).

present, the low-concentration pad will have a speckled appearance, with a solid color indicating hemolyzed red cells. The detection limit for free hemoglobin is 150 to 600 µg/L, or 5 to 20 intact red cells/µL. The test is equally sensitive to hemoglobin and to myoglobin. Water must not be used as a negative control with this test because of the matrix requirements of the assay; a false-positive result will be obtained.

The presence of free hemoglobin or red cells in the urine indicates the presence of renal or bladder disease. Hematuria can be present in a range of kidney diseases, including glomerular nephritis, polycystic kidney disease, sickle cell disease, vasculitis, and a range of infections. A spectrum of urological diseases may also give rise to hematuria, including (1) bladder, (2) prostate, and (3) pelvic and/or (4) ureteral malignancy, (5) kidney stones, (6) trauma, (7) bladder damage, and (8) ureteral stricture.

Glucose

For glucose measurements, the reagent pad is impregnated with glucose oxidase, peroxidase, potassium iodide, and a blue dye. The reaction employs glucose oxidase and peroxidase to produce hydrogen peroxide, which is subsequently reduced with concurrent oxidation of potassium iodide to release iodine. The free iodine blends with the background color to produce a range of colors from green to dark brown. The detection limit of this method is in the range of 72 to 127 mg/dL (4 to 7 mmol/L), with an upper limit of 2018 mg/dL (111 mmol/L).

Leukocytes

The reagent strip test for leukocytes uses an absorbent cellulose pad impregnated with a buffered mixture of derivatized pyrrole amino acid ester and diazonium salt. Granulocytic leukocytes contain esterases, which catalyze the hydrolysis of the derivatized pyrrole amino acid ester to liberate 3-hydroxy-5-phenylpyrrole. This pyrrole then reacts with a diazonium salt to produce a purple product. The test is claimed to have a detection limit of 5 to 15 cells/µL in urine, and the darkest color block is equivalent to 500 cells/µL or greater. A decrease in the true test result may occur in samples with elevated glucose concentration, high specific gravity, or the presence of cephaloxin, cephalothin, tetracycline, or high concentrations of oxalic acid.

Nitrite

To measure nitrite, the reagent pad is impregnated with *p*-arsanilic acid and tetrahydro-benzo(h)quinolin-3-ol. The reaction is based on arsanilic acid in the presence of nitrite converting to a diazonium salt, which couples with the quinolol to produce a pink color. The detection limit of the test is 61 to 103 µg/dL (13 to 22 µmol/L) nitrite in urine with a normal specific gravity. The test is less sensitive with urine that has a high specific gravity. At urine ascorbic acid concentrations above approximately 25 mg/dL (1.4 mmol/L), a false-negative result may occur at low nitrite concentrations [81 µg/dL (13 µmol/L) or less]. The test measures only nitrite and is claimed to detect populations of bacteria at a value of 10^5/mL or more.

The presence of leukocyte esterase is indicative of pyuria (i.e., the presence of white blood cells in the urine; significant pyuria is normally defined as a urinary white cell count ≥10 leukocytes/mL). The detection of nitrite is indicative of the presence of bacteria that degrade nitrate excreted in the urine. The combination of the two tests is valuable in patients with UTI. The absence of both constituents is a valuable test to "rule out" UTI, thereby reducing the number of samples sent to the laboratory for additional tests. The nitrite test may be less helpful in young children, in whom the urine remains in the bladder for less time, thereby limiting the time for nitrite production.

Specific Gravity

The test device for specific gravity consists of an absorbent cellulose pad impregnated with bromthymol blue, polymethylvinyl ether, and/or maleic anhydride and sodium hydroxide. The test depends on the apparent pK_a change of the pretreated polyelectrolyte in relation to ionic strength; the hydrogen ions released are detected by the pH indicator. The color changes from dark blue at low specific gravity (1.000) to yellow-green at a specific gravity of 1.030. The specific gravity can provide an indication of the concentration of urine; care must be taken with interpretation depending on the method principle, because those devices that detect ionic species will underestimate the specific gravity in the presence of glucose, and so forth. Urine collected after intravenous administration of iodine-containing radiopaque compounds for radiologic studies may give extraordinarily high values. Glucose and protein may also contribute substantial increments to the density of urine, and semiquantitative determination of these substances is necessary for valid interpretation or correction of urine specific gravity measurements. Diabetic patients with uncontrolled hyperglycemia and glucosuria may have high urine specific gravity, even when the normal renal concentrating function is seriously impaired.

pH

To measure the pH of a sample, the test pad is impregnated with indicators, one example being a mixture of methyl red and bromthymol blue. Methyl red in diluted form is red at pH values below 4.2 and yellow at values above 6.2. Bromthymol blue is yellow at pH values below 6.0 and blue at values above 7.6. At a pH within these values, the indicators give shades of orange and green, respectively. Thus the reagent blocks are compared with a color chart, where the lowest pH block at 5.0 is orange and the highest at 8.5 is blue. It is important to recognize that the pH of urine is altered by standing, as is the color of the reagent blocks; therefore careful adherence to the recommended procedure is important. Measurement of urine pH is helpful in the assessment of patients with renal tubular acidosis and in stone formers, although evaluation using a pH electrode may be more informative.

Microscopic Examination of Urine

Microscopic examination of the sediment obtained from centrifugation of a fresh urine sample shows the presence of (1) a few cells (erythrocytes, leukocytes, and cells derived from the kidney and urinary tract), (2) casts [composed predominantly of Tamm-Horsfall glycoprotein (THG)], and (3) possibly fat or pigmented particles. An increase in red cells or casts implies hematuria possibly caused by glomerular disease; white cells or casts imply the presence of white cells in the tubules. Inflammation of the upper urinary tract may result in polymorphonuclear leukocytes and various types of casts; in lower urinary tract inflammation, the casts are not present. In acute glomerulonephritis, hematuria may lead to coloration of the urine and the presence of large numbers of red cells and white cells; as the duration of the disease increases, the amount of sediment diminishes. Nephrologists will often describe urine as having an *active urinary sediment,* or as *bland.* Having an active urinary sediment means that signs (red blood cells, white blood cells, casts) of active kidney inflammation can be detected when urine is examined under the microscope.

New Instrumental Techniques

Flow cytometry and flow imaging systems have been developed for the characterization of erythrocytes in the differential diagnosis of hematuria and as means of improving the recognition of other particulate material in urine. This form of analysis has been used to discriminate between and quantify the particulate matter in a defined volume of urine, bringing the added benefit of better standardization of the technique.[234] Thus the flow imaging method can identify (1) red blood cells, (2) white blood cells, (3) white blood cell clumps, (4) hyaline casts, (5) pathologic casts, (6) squamous epithelial cells, (7) nonsquamous epithelial cells, (8) yeast, (9) crystals, and (10) sperm. These fully automated systems have the potential to replace urinary microscopy because they offer better discriminatory power and quantitation while providing closer agreement between laboratories.[348] The principles of flow cytometry are described in Chapter 10. A flow imaging analyzer, such as the Iris iQ200 (Iris Diagnostics, Chatsworth, Calif), analyzes unspun urine by aspirating sample through a flowcell positioned in a microscope. A digital camera captures the images, and neural network–based particle image recognition software is used to identify and count the particles present from five hundred 884 × 680 µm fields with 0.68 µm resolution. The number of particles for the volume scanned is then calculated. Flow image analysis has been shown to be more accurate than the flow cytometric approach while helping to improve workflow and save valuable technologist time by reducing the number of manual microscopic examinations required.[182,325] However, it has been suggested that manual microscopy may still be required for the assessment of crystals.[197]

Proton nuclear magnetic resonance (NMR) has been investigated as a means of characterizing low molecular weight molecules.[219] Metabolic profiles have been generated, and with the use of sophisticated computer analysis, distinctive patterns of molecules have been associated with damage to specific parts of the nephron. It is expected that this technique will be used to identify individual molecules for which selective assays can then be developed.[219]

QUANTITATIVE ASSESSMENT OF PROTEINURIA: TOTAL PROTEIN AND ALBUMIN

Higher molecular weight proteins are retained within the circulation by the glomerular filter, and lower molecular weight proteins are freely filtered and reabsorbed and catabolized within the tubular cells. Consequently, the appearance of notable amounts of protein in the urine suggests renal disease. Commonly, proteinuria is classified as tubular or glomerular, depending on the pattern of proteinuria observed. A third category, overflow proteinuria, is also recognized in which filtration of excessive amounts of low molecular weight protein exceeds the tubular capacity for reabsorption (Table 25-1). Examples of the latter include Bence Jones proteinuria and myoglobinuria. Proteinuria is a potent risk marker for progressive kidney disease, and reduction of protein excretion is a therapeutic target. This section considers the analytical approach and the rationale used in the quantitation of urinary proteins, with emphasis on total protein and albumin measurement.

Clinical Significance

The clinical significance of proteinuria was discussed earlier (see section on urine analysis) and will be discussed in Chapter 48, along with the physiology and pathophysiology of renal protein handling. Most commonly, proteinuria reflects albuminuria. Several groups have suggested that urinary total protein measurement can be replaced by urine albumin measurement.[12,161,224] This may provide a more specific and sensitive measure of changes in glomerular permeability and is consistent with most,[178,216,218] but not all,[38,285] current national and international guidelines. Strong evidence has linked urinary albumin loss to cardiovascular mortality and kidney disease progression in diabetes.[103] Other evidence suggests that urinary albumin is a more sensitive test to enable detection of glomerular pathology associated with some other systemic diseases, including hypertension and systemic sclerosis.[60,292] In health, relatively small amounts of albumin (less than 30 mg/d) are lost in the urine. Because of this, and because total protein assays are imprecise at low concentrations, relatively large increases in urine albumin loss can occur without a significant measurable increase in urinary total protein. In a methodologic study of urine from patients attending renal transplant, general nephrology, and medicine and obstetric clinics, Newman and colleagues observed increased albumin losses (defined here as >25 mg/d) in 63% of samples that were classified as not having increased total protein loss (defined here as >250 mg/d).[224] Changes in albumin excretion may also reflect overall changes in vascular permeability and therefore may not indicate explicit deterioration in renal function.[99]

TABLE 25-1 Characterization of Proteinuria

Type of Proteinuria	Causes	Examples of Proteins Seen
Glomerular	Increased glomerular permeability	Progressively increasing excretion of higher molecular weight proteins as permeability increases (e.g., albumin, IgG)
Overflow	Increased plasma concentration of relatively freely filtered protein	Bence Jones protein Lysozyme Myoglobin
Tubular	Proximal tubular damage: decreased tubular reabsorptive capacity and/or release of intracellular components (e.g., due to nephrotoxic drugs)	α_1-Microglobulin β_2-Microglobulin Retinol binding protein Enzymuria (e.g., *N*-acetyl-β-D-glucosaminidase, alkaline phosphatase, α-glutathione-S-transferase)
	Decreased nephron number: increased filtered load per nephron	As above
	Distal tubular damage	Tamm-Horsfall glycoprotein π-Glutathione-S-transferase

Concern has been expressed that replacing urinary total protein measurement with albumin measurement may cause tubular proteinuria to be missed.[218]

Microalbuminuria is the term used to describe an increase in urinary excretion of albumin above the reference interval for healthy nondiabetic subjects, but at an excretion that is not generally detectable by less sensitive clinical tests such as reagent strips designed to measure total protein. Approximately, this equates to urinary albumin concentrations between 20 and 200 mg/L. The term *microalbuminuria* is somewhat misleading, in that the albumin being measured is identical in form to that circulating in plasma, and the so-called microalbuminuric range actually refers to increased albumin losses.[206] Nevertheless, the phrase is widely used in clinical practice. Increased urinary albumin loss (microalbuminuria) is considered a clinically important indicator of deteriorating renal function in diabetic subjects. For example, it is now accepted by both European and U.S. diabetes societies that regular screening of urinary albumin loss is valuable in monitoring type 1 and type 2 diabetes.* This recommendation came as a consequence of the widespread availability of sensitive assays for urinary albumin measurement and effective treatments, validated in large multinational trials, along with detailed cost-benefit analyses in the vanguard of evidence-based medicine.

Because large numbers of clinical studies have been performed, guidelines for microalbuminuria screening are now established (Figure 25-2).[19,26,215,217,300] The diagnosis of microalbuminuria requires demonstration of increased albumin loss (increased ACR or increased albumin loss in a timed collection) in at least two of three urine samples collected in the absence of infection or an acute metabolic crisis. Establishing the diagnosis has both prognostic and management implications in the care of patients with diabetes mellitus. The best possible metabolic control of diabetes should be achieved before patients are examined for microalbuminuria, and patients should not be screened during other transitory illnesses. Screening should commence 5 years after diagnosis in patients with type 1 diabetes mellitus and at diagnosis in patients with type 2 diabetes without proteinuria, and should continue on an annual basis up to the age of 75 years. An early morning (preferred) midstream urine sample should be sent to the laboratory for albumin measurement. Exact definitions of microalbuminria differ among national societies.[206] In the United Kingdom, an ACR less than or equal to 23 mg/g (≤2.5 mg/mmol) in a male, or 32 mg/g (≤3.5 mg/mmol) in a female, requires no further investigation until the time of the patient's next annual review.[215] Patients demonstrating ACRs above this cutoff should have urine samples sent to the laboratory on two other occasions (ideally within 1 month) for albumin estimation. Patients demonstrating increased ACRs in one or both of these additional samples have microalbuminuria. It is important to consider other causes of increased albumin excretion, especially in the case of type 1 diabetes present for less than 5 years. These may include nondiabetic renal disease, menstrual contamination, vaginal discharge, uncontrolled hypertension, UTI, heart failure, and strenuous exercise.

Once microalbuminuria has been established, an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker (ARB) is typically prescribed, because these classes of antihypertensive agent have distinct antiproteinuric effects above and beyond their effects on blood pressure. Several major trials have shown such drugs to be effective in reducing not just proteinuria but also the rate of fall in GFR when used in both microalbuminuric and proteinuric diabetes. It has also been suggested that ACE inhibitors should be prescribed for normotensive microalbuminuric patients with diabetes, because the definition of *normotension* as currently used may not reflect the actual intraglomerular pressure, and a lower blood pressure cutoff should be used in such a high-risk group.

Some workers consider that once microalbuminuria is established in a patient with diabetes, it may already be too

*References 19, 141, 209, 215, 217, and 300.

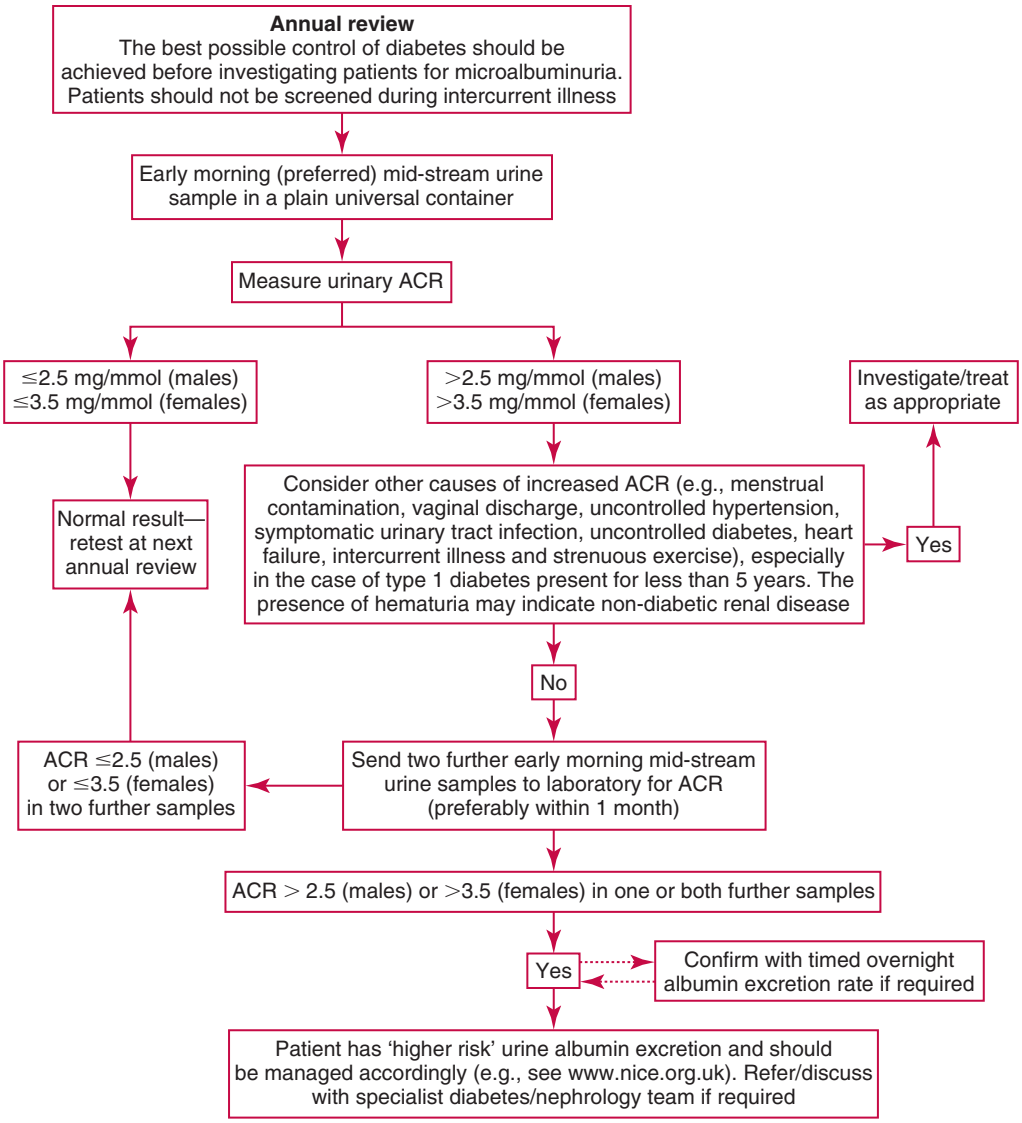

Figure 25-2 Screening for microalbuminuria in diabetes mellitus. Patients demonstrating "higher risk" urine albumin excretion should be managed accordingly. This protocol is adapted from the U.K. National Institute for Health and Clinical Excellence (NICE) guidance: other countries and professional organizations have alternate versions (see www.nice.org.uk and Reference 206 for further information). *ACR*, Albumin-to-creatinine ratio. *Note:* U.S. guidelines express albuminuria as mg/g creatinine, whereas other guidelines use mg/mmol creatinine. An approximate conversion factor of 0.1136 can be used to convert results in mg/g to mg/mmol (e.g., 2.5 mg/mmol = 22 mg/g, 3.5 mg/mmol = 31 mg/g).

late to prevent the development of nephropathy,[221] and the use of other, earlier markers may be beneficial. As will be discussed later in the chapter, markers of tubular damage have not, to date, been convincingly shown to demonstrate advantages over urinary albumin in the detection of diabetic nephropathy. Considerable work has been undertaken to look for genetic linkages to the development of nephropathy in persons with diabetes. This work has included studies of polymorphisms of ACE and insulin genes, but as yet no clear relationship has been demonstrated.[280]

Increased urinary albumin loss is common among the general population and probably is not solely attributable to the presence of diabetes. Epidemiologic data from the Third National Health and Nutrition Examination Survey (NHANES III) in the United States suggest that the population prevalence of microalbuminuria is 7.8%.[142] Similar estimates have been reported from population surveys in Australia (6.8%)[9] and The Netherlands (7.2%).[119] In The Netherlands study, even after individuals with diabetes and hypertension were excluded, the population prevalence was still 6.6%. Among patients with risk factors for CKD, prevalences were notably higher. For example, in the NHANES III study, 28.8% of people with diabetes and 16.0% of those with hypertension had microalbuminuria.[142]

Strong evidence has linked albuminuria to cardiovascular and noncardiovascular morbidity and mortality in nondiabetic individuals.* Moreover, the relationship between albuminuria and cardiovascular morbidity and mortality extends down to concentrations of albuminuria below those currently used as thresholds in establishing diabetic nephropathy, suggesting that currently used thresholds may not be optimal.[118] Albuminuria also predicts future decline in GFR[155,230] and the requirement for renal replacement therapy.[326] In contrast to the situation among the diabetic population, however, little information is currently available concerning the risks and benefits of intervention (e.g., with ACE inhibitors or ARBs) in microalbuminuric nondiabetic individuals.

Sample Collection for Total Protein and Albumin Measurement

Extensive discussion is provided in the literature about the appropriate urine sample to use for investigation of protein excretion. It is generally recognized that a 24-hour sample is the definitive means of demonstrating the presence of proteinuria. However, overnight, first void in the morning [early morning urine (EMU)], second void in the morning, or random sample collections have also been used. Because creatinine excretion in the urine is fairly constant throughout the 24-hour period, measurement of ACR (or PCR) ratios allows correction for variations in urinary concentration.[16,148] A body of literature supports the use of ACR as a suitable alternative to timed measurement of urine albumin loss.† Similarly, several authors have recommended use of the PCR based on its excellent diagnostic performance and the good correlation that has been demonstrated with the 24-hour collection.‡ Ginsberg and coworkers studied this in detail and found little variation in the ratio during the daytime, indicating that the first void and either of the two subsequent collections can give a reliable indication of 24-hour urine protein loss.[96] Newman and associates demonstrated a significant reduction in intraindividual variation in the PCR compared with protein excretion in random urines collected throughout the day (a mean reduction to 38.6% from 96.5%).[222] They described a similar experience with albumin loss (a decrease to 52.1% from 80.0%).[222] The ratio to osmolality or to specific gravity to correct for dilution effects associated with changes in water excreted during the day has also been reported.[222] In a systematic review, random urine PCR was shown to perform better as a test for ruling out significant proteinuria than as a rule-in test; the authors suggested that positive PCR results may still require confirmation with a 24-hour collection.[253]

Although the reference point remains the accurately timed 24-hour specimen, it is widely accepted that this is a difficult procedure to control effectively, and that inaccuracies in urinary collection may contribute to errors in estimation of protein losses. In practice, for screening purposes, spot urine ACRs (or PCRs) can be used to rule out the necessity for 24-hour collections.[218] An EMU sample is preferred because it correlates well with 24-hour protein loss and is required to exclude the diagnosis of orthostatic (postural) proteinuria.[218] However, a random urine sample is acceptable if no EMU sample is available. If required, daily albumin or protein loss (in mg) can be roughly estimated by multiplying the ACR or PCR (measured in mg/mmol) by a factor of 10 because, although daily excretion of creatinine depends on muscle mass, an average daily loss of 10 mmol creatinine per day can be assumed.[148,194]

Analytical Methodology – s—Total Protein

Numerous methods are used for measurement of protein in urine, including (1) the original Lowry method,[185] (2) turbidimetry after mixing with trichloroacetic or sulfosalicylic acid,[227] (3) turbidimetry with benzethonium chloride [benzyl dimethyl (2-{2-*p*-1,1,3,3-tetramethyl butylphenoxy}ethoxy) ethyl] ammonium chloride,[198] and dye binding with (4) Coomassie Brilliant Blue,[343] (5) pyrogallol red molybdate,[334] and (6) pyrocatecholviolet-molybdate, which is used in dry-slide applications.

Total protein measurement is more difficult in urine than in serum. The concentration of urinary protein is normally low (100 to 200 mg/L); large sample-to-sample variation in the amount and composition of proteins is common; the concentration of nonprotein potentially interfering substances is high relative to the protein concentration and is highly variable; and the inorganic ion content is high. All these factors affect the precision and accuracy of the various methods.

Concerns about different responses to different proteins have led to many variants of the methods being published. Because of the need for automation, the benzethonium chloride and dye-binding methods have become the most popular in current clinical use.[45] The analytical range of the turbidimetric assays has been of concern, with the equivalent to an "antigen excess" equivalence point being apparent when high protein concentrations give a lower signal because an inadequate amount of denaturant is present relative to protein. This limitation can be overcome by monitoring the rate of turbidity formation.

As with urine reagent strip analysis, turbidimetric and dye binding methods do not provide equal analytical specificity and sensitivity for all proteins. Most approaches tend to react more strongly with albumin than with globulin and other nonalbumin proteins,[199,227,286] although incorporating sodium dodecyl sulfate (SDS) in pyrogallol red reagent is claimed to reduce this issue.[231] Significant interferences include aminoglycosides,[191] nonvisible hematuria,[349] and infused modified gelatin solutions used as plasma expanders,[61] all of which may falsely increase measured urinary total protein concentration.

No reference measurement procedure is listed by the Joint Committee for Traceability in Laboratory Medicine (JCTLM), and no standardized reference material for urinary total protein is available. Because a variable mixture of proteins is measured, it is difficult to define the latter. The variety of

†Typical concentrations observed in health.

methods in use means that significant between-laboratory variation is inevitable.[44] This variation tends to diminish at higher concentrations of urinary total protein, presumably in part as albumin becomes the predominant protein. In addition to methodologic differences between various protein assays, calibration differences have been found to be one of the major determinants of intermethod variability.[45,114,190]

Analytical Methodology—Albumin

Urinary albumin is measured by most diagnostic laboratories predominantly by using quantitative immunoturbidimetric or nephelometric approaches capable of detecting albumin at low concentrations. Commercial assays typically have lower limits of quantitation of between 2 and 5 mg/L. As for total protein, no JCTLM reference measurement procedure or standardized reference material is currently available for urinary albumin, although the National Kidney Disease Education Program and the International Federation of Clinical Chemistry and Laboratory Medicine have established a joint committee to address these issues.[203,206] Most commonly, urinary albumin assays are standardized against a serum-based calibrant (CRM 470) distributed by the Institute for Reference Materials and Measurements of the European Commission, as has been recommended by Kidney Disease Improving Global Outcomes (KDIGO).[178] Although intuitively, standardization issues should be more easily addressed than those for total protein measurement, albumin is known to undergo polymerization and fragmentation on storage, when freeze-thawed and when lyophilized.[20,203] Some data have suggested that a significant proportion of albumin present in urine may be nonimmunoreactive,[52,53,187,232] although studies would appear to have refuted this hypothesis as being caused by coeluting proteins in size exclusion high-performance liquid chromatography (HPLC).[288,310,311]

Dry chemistry systems have been developed for the quantitation of albumin in urine.[153,157] For example, in one such device, the urine albumin laterally flows along a porous matrix through an area containing gold particle–labeled antibodies to albumin. In the presence of albumin, these antibody molecules are neutralized and pass through a portion of the matrix containing immobilized albumin to a detection zone, where they appear pink.[157] Point-of-care testing devices for urinary albumin have been discussed previously.

Reference Intervals and Definitions of Proteinuria and Albuminuria

The typical urinary total protein loss is less than 150 mg/d. The proteins lost are made up of albumin (typically <30 mg/d) and some smaller proteins, together with proteins secreted by the tubules, of which THG predominates.[123] Typical concentrations of proteins found in urine are listed in Table 25-2.

No consistent definition of *proteinuria* is available. Proteinuria is commonly detected at the point of care using urine reagent strip devices, and "clinical" proteinuria has sometimes been defined as equivalent to a color change of "+" or greater on the relevant pad on the strip. This equates to approximately 300 mg/L of total protein, or a PCR of 50 mg/mmol, or protein loss of approximately 500 mg/d (assuming an average urine volume of 1.5 L/d). North American guidelines define *proteinuria* as a PCR greater than 23 mg/mmol.[148,218] Australasian guidelines state that the cutoff for abnormal varies between 150 and 300 mg/d, depending on the laboratory.[38] An upper limit of normal loss of 150 mg/d is equivalent to a urinary PCR of 15 mg/mmol (given average daily creatinine excretion of 10 mmol), whereas Scottish guidelines have defined *proteinuria* as a PCR ≥ 100 mg/mmol, approximately equivalent to a loss of 1000 mg/d.[285] In England and Wales, the NICE CKD guideline defines *proteinuria* as a PCR ≥ 50 mg/mmol, or an ACR ≥ 30 mg/mmol (approximately equivalent to a total protein loss of 500 mg/d, or an albumin loss of 300 mg/d).[216] Both Scottish and NICE Guidelines recommend that the classification of CKD should be extended to include a suffix "p" to identify patients with proteinuria at any stage of kidney disease, acknowledging the importance of proteinuria as a risk factor. In the setting of preeclampsia, significant proteinuria is defined as 300 mg or more per day.[59]

Among patients with diabetes, the classification of diabetic nephropathy has been based on urinary albumin loss (commonly expressed as an ACR). In contrast to urinary total protein loss, definitions of *normoalbuminuria, microalbuminuria,* and *macroalbuminuria* are reasonably consistent across

international guidelines, allowing for slight differences in units of expression.* In the United Kingdom, patients are categorized as normoalbuminuric (≤2.5 mg/mmol in males, ≤3.5 mg/mmol in females), microalbuminuric (>2.5/3.5 to 29 mg/mmol), and macroalbuminuric or proteinuric (≥30 mg/mmol).[216,217]

The KDIGO classification of CKD is clear in that it requires urinary albumin measurement as a marker of kidney damage to facilitate diagnosis of stage 1 and 2 CKD,[178] with a diagnostic threshold value of 3.4 mg/mmol. In other words, the presence of low-concentration albuminuria (microalbuminuria) in an individual with a GFR of 60 mL/min/1.73 m^2 or less is indicative of CKD irrespective of whether or not diabetes mellitus is present.

QUANTITATIVE ASSESSMENT OF PROTEINURIA: OTHER URINARY PROTEINS

Bence Jones Proteinuria

The presence of immunoglobulin light chains (Bence Jones proteins, 22 kDa) in the urine is an important indication of the presence of myeloma and, in approximately 20% of cases, may occur in the absence of a paraprotein band in the serum.[15] The pathologic significance of these proteins is considered in greater detail in Chapter 44. A variety of tests have been used for the detection of Bence Jones protein, including the classic heat test and the Bradshaw test. To date, electrophoresis supplemented by immunofixation has been the most reliable approach.[15,340] Quantitation of Bence Jones protein excretion may be required when patients with light chain only myeloma are monitored. This has generally been achieved by using a combination of electrophoresis and densitometry,[15] but recently described immunoassays for free light chains in serum and urine may play a role in this setting (see Chapter 44).

Myoglobinuria

Myoglobin is a small (17.8 kDa), heme-containing protein catabolized by endocytosis and proteolysis in the proximal tubule following glomerular filtration. Typically, only 0.01 to 5.0% of filtered protein appears in the urine. However, following rhabdomyolysis, large amounts of myoglobin are released into the plasma, saturating the tubular reabsorptive mechanism. This results in the appearance of notable quantities of myoglobin in the urine (which may color the urine red-brown). Further, myoglobin is directly toxic to the renal tubules and can cause acute tubular necrosis with acute renal failure.[352] Myoglobin will give a positive reaction with hemoglobin reagent strip tests, and basic methods of detection have relied on this principle following removal of hemoglobin (e.g., by ammonium sulfate precipitation), although false-negative and false-positive results were common.[14] Urinary myoglobin is better measured by immunochemical means, although preconcentration of urine may be required.[184] However, for most purposes, evidence that rhabdomyolysis has occurred is better provided by an increase in serum creatine kinase activity not attributable to a cardiac source. Urinary myoglobin measurement provides no additional prognostic or diagnostic information in this setting.[14]

Tubular Proteinuria

In practice, the integrity of the renal tubule is assessed indirectly through measurement of functional change and detection of tissue damage. The most common approach, however, has been the measurement of urinary concentrations of low molecular weight proteins using immunoassay technology. These are freely filtered at the glomerulus and then are reabsorbed and catabolized within the proximal tubule. Consequently, the appearance of notable quantities of these proteins in the urine reflects failure of the tubular reabsorptive mechanisms (see Table 25-1). The most commonly measured proteins are α_1-microglobulin and retinol binding protein (RBP). In the past, there has been considerable study of the excretion of β_2-microglobulin; however, it is an impractical marker because of its instability in urine at a pH less than 6. α_1-Microglobulin (Mr 31 kDa) is also referred to as protein HC because of its human complex–forming capacity with IgA. It is synthesized by the liver, and the free form is readily filtered at the glomerulus.[338] RBP (Mr 22 kDa) is also synthesized by the liver and is found in the plasma as a complex with prealbumin; the protein is the carrier protein for vitamin A.[17,318] For identification of tubular damage, urinary RBP may be more sensitive than α_1-microglobulin, but the higher concentration and excellent stability of the latter in human urine ex vivo facilitate its use as a marker of tubular damage in clinical studies.[143,241] Cystatin C, generally measured in serum as a marker of GFR (discussed later), is also measured in urine as a marker of proximal tubular damage.[116] THG, located in the thick ascending limb of the loop of Henle,[124] has been used as a marker of more distal tubular damage.[243]

Lysozyme is an enzyme that occurs in neutrophilic granulocytes, monocytes, and macrophages, and in several organs of the body, including the spleen, kidney, and gastrointestinal tract. It is freely filtered by the kidney and absorbed by the proximal tubules. Thus lysozymuria is seen in conditions associated with both tubular damage and increased endogenous synthesis. Urinary lysozyme can be measured by a range of methods, including catalytic activity and immunoassay; its primary clinical application has been in the monitoring of patients with monocytic leukemia.[233] The reference interval for the excretion of lysozyme in healthy adults is reported to be 1.3 to 3.6 mg/d.[321]

Tubular damage results in the release of intracellular components into the urinary tract, and measurement of these components reflects the functional integrity of the tubule. A large number of enzymes have been measured in urine. The enzyme *N*-acetyl-β-D-glucosaminidase (NAG) is stable in urine and has been widely used as a marker of tubular

*U.S. guidelines express albuminuria or proteinuria as mg/g creatinine, whereas other guidelines use mg/mmol creatinine. An approximate conversion factor of 0.1136 can be used to convert results in mg/g to mg/mmol (e.g., 200 mg/g = 23 mg/mmol, 30 mg/g = 3.4 mg/mmol).

integrity. Measurement of NAG has been undertaken in a variety of diseases associated with renal injury, including hypertension, drug nephrotoxicity, transplantation, and diabetic nephropathy.[254] It has been used to predict progression to renal failure in patients with idiopathic membranous nephropathy.[13] However, although it is a sensitive marker of kidney damage, it has not generally been shown to provide any unique benefit over other markers of tubular proteinuria. Measurement of α- and π-*glutathione-S-transferase* (EC 2.5.1.18) isoenzymes has been proposed to discriminate between proximal and distal tubular damage, respectively,[151] but the role of these markers in clinical practice has yet to be established. An evaluation of several of these biomarkers in patients presenting to hospital with nonoliguric acute tubular necrosis suggested that urinary cystatin C and α_1-microglobulin were the best predictors of an unfavorable outcome as reflected by the requirement for renal replacement therapy.[116]

Several new markers, including kidney injury molecule-1 (KIM-1)[111] and neutrophil gelatinase-associated lipocalin (NGAL),[64] have emerged as indicators of tubular injury that may be useful early predictors of acute kidney injury (AKI). Whereas increases in serum creatinine concentration may not be seen for several days following AKI, changes in concentrations of these newer biomarkers appear to occur more rapidly (within hours). KIM-1 is a type 1 transmembrane protein that usually is not present in urine but is expressed on the proximal tubule apical membrane in response to injury.[111] Renal expression of NGAL is increased following kidney injury, and in an emergency care setting, has been found to be a better predictor of the presence of AKI than urinary NAG, α_1-microglobulin, α_1-acid glycoprotein, or serum creatinine concentration.[225] Measurement of plasma NGAL concentrations has been found to be useful in predicting AKI.[63] A urinary NGAL assay suitable for use on an automated analyzer has been described.[18]

Several additional markers are available for monitoring the breakdown of basement membrane components, including *collagen* breakdown products[133,347] and *laminin* fragments.[255] However, at present, few of these markers have found a place in the clinical laboratory.

Characterization of Proteinuria

As glomerular damage increases, the permeability of the membrane decreases, with an increasing proportion of higher molecular weight proteins appearing in the urine. The relative clearance of a variety of proteins can be measured to assess the selectivity of the membrane and to provide an assessment of glomerular damage. The *protein selectivity index* is discussed in the third edition of this textbook, but it is generally considered to be of limited value. A commercial semiautomated sodium dodecyl sulfate–agarose gel electrophoresis system (Hydragel, Sebia Electrophoresis, Norcross, Ga) has been introduced for qualitative analysis of urinary proteins. This separates proteins on the basis of their molecular size, enabling visualization of glomerular, tubular, and mixed patterns of proteinuria. This approach has also been used for the detection and quantitation of Bence Jones proteinuria.[169] Panels of protein measurements, including albumin, α_1-microglobulin, IgG, and α_2-macroglobulin, have been employed in the differential diagnosis of prerenal and postrenal disease.[121] This general strategy was extended with the inclusion of reagent strip tests for hematuria, leukocyturia, and proteinuria in the development of an expert system achieving concordance of 98% with clinical diagnosis.[132]

Analytical Methodology—Individual Urinary Proteins

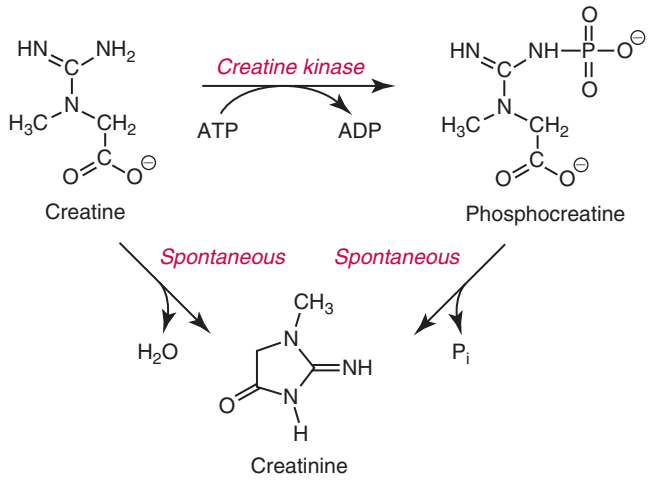
Immunoassay is the preferred method for the accurate and sensitive quantitation of individual proteins (see Chapter 16). A variety of approaches have been used, including (1) immunodiffusion immunoassay, (2) electroimmunoassay, (3) light-scattering assay with particle enhancement, and (4) labeled immunometric assay (e.g., KIM-1, NGAL), but (5) light-scattering immunoassay, with turbidimetric or nephelometric detection of immunoaggregate formation, is the most popular approach. Enzymuria can be measured using a variety of enzyme assay approaches. For example, one method used for the assay of NAG employs the substrate 4-methylumbelliferyl-*N*-acetyl-β-D-glucosaminide with fluorometric measurement of the methylumbelliferone released by the enzyme.[245] Alternative substrates generating products capable of being detected in the visible spectrum have also been described.[351]

CREATININE

Creatinine is a metabolite of creatine.

Biochemistry and Physiology

Creatine is synthesized in the kidneys, liver, and pancreas by two enzymatically mediated reactions. In the first, transamidation of arginine and glycine forms guanidinoacetic acid; in the second, methylation of guanidinoacetic acid occurs with *S*-adenosylmethionine as the methyl donor. Creatine is then transported in blood to other organs such as muscle and brain, where it is phosphorylated to phosphocreatine, a high-energy compound.



Interconversion of phosphocreatine and creatine is a particular feature of the metabolic processes of muscle contraction. A proportion of free creatine in muscle (thought to be between 1% and 2%/d) spontaneously and irreversibly converts to its anhydride waste product, creatinine. Thus the amount of creatinine produced each day is fairly constant and is related to the muscle mass. In health, the blood concentration of creatinine is also fairly constant, although it may be influenced by diet (see later). Creatinine (Mr 113 Da) is present in all body fluids and secretions and is freely filtered by the glomerulus. Although it is not reabsorbed to any great extent by the renal tubules, a small but notable tubular secretion is present. Creatinine production decreases as the circulating concentration of creatinine increases; several mechanisms for this have been proposed, including feedback inhibition of the production of creatine, reconversion of creatinine to creatine, and conversion to other metabolites.[98,117]

Clinical Significance

The clinical utility of creatinine measurement is considered later in this chapter, together with other GFR markers.

Analytical Methodology

Serum creatinine is measured in virtually all clinical laboratories as a test of kidney function. Most laboratories use adaptations of the same assay for measurements in both serum and urine. Both chemical and enzymatic methods are used to measure creatinine in body fluids.

Chemical Methods: The Jaffe Reaction

Most chemical methods for measuring creatinine are based primarily on the reaction with alkaline picrate. In this reaction, first described by Jaffe in 1886, creatinine reacts with picrate ion in an alkaline medium to yield an orange-red complex. Despite considerable literature on the subject, the reaction mechanism and the structure of the product remain unclear.[329]

The Jaffe reaction is not specific for creatinine. Many compounds have been reported to produce a Jaffe-like chromogen, including (1) protein,[39,49] (2) glucose, (3) ascorbic acid, (4) ketone bodies,[337](5) pyruvate, (6) guanidine, (7) hemoglobin F,[49] (8) blood-substitute products,[3] and (9) cephalosporins[312]; the reader is referred to comprehensive reviews.[28,298] The degree of interference from these compounds is dependent on the exact reaction conditions chosen. The effects of ketones and ketoacids are probably of greatest significance clinically, although the effect is very method dependent. Thus reports on acetoacetate interference vary from a negligible increase to an increase of 3.5 mg/dL (310 µmol/L) in the apparent creatinine concentration at an acetoacetate concentration of 8 mmol/L. Bilirubin is a negative interferent with the Jaffe reaction. The addition of buffering ions, such as borate and phosphate, together with surfactant, has been used to minimize the effects of this interference. A popular maneuver in this context has been the addition of ferricyanide (O'Leary method), which oxidizes bilirubin to biliverdin, hence reducing its interference.[152,228] Noncreatinine chromogens do not generally contribute to measured urinary creatinine concentration.

Several approaches have been used in an attempt to improve the general specificity of the Jaffe reaction. These have included (1) absorption of creatinine into hydrated aluminum silicate (Fuller's earth, Lloyd's reagent) with subsequent elution, (2) acid blanking, (3) use of ion-exchange resins[337] or solvent extraction, and (4) oxidation of interferants with compounds such as cerium sulfate; generally these modifications have not proved practical or sucessful.

The greatest success in terms of common usage and specificity has come from the use of a kinetic measurement approach in combination with careful choice of reactant concentrations. Although manual methods have traditionally been equilibrium methods, with 10 to 15 minutes allowed for color development at room temperature, kinetic assays were developed in a quest both for specificity and for faster and automated analyses. Early studies of interferences in kinetic methods identified two types of noncreatinine chromogens: those whose rates of adduct formation were very rapid in the first 20 seconds after mixing of reagent and sample (e.g., acetoacetate), and those whose rates did not become rapid until 80 to 100 seconds after mixing (e.g., protein). The "window" between 20 and 80 seconds, therefore, was a period in which the rate signal being observed could be attributed predominantly to the creatinine-picrate reaction; (some investigators found 60 seconds as the upper limit of this window). Thus, improved specificity in kinetic assays was achieved by selecting times for rate measurements 20 to 80 seconds after initiation of the reaction (mixing). This approach has been implemented on various automated instruments, and kinetic assays are now the most widely used approach to creatinine measurement. An extensive literature exists on the choice of reactant concentrations and reading interval, and on the choice of wavelength and reaction temperature. Brief comments follow.

Picrate Concentration

The Jaffe reaction is pseudo-first order with respect to picrate up to 30 mmol/L picrate, with most methods employing a concentration between 3 and 16 mmol/L. At concentrations greater than 6 mmol/L, the rate of color development becomes nonlinear, so a two-point fixed interval rather than a multiple data point approach is required.

Hydroxide Concentration

The initial rate of reaction is pseudo-first order with respect to hydroxide concentrations above 0.5 mmol/L; however, at 500 mmol/L, degradation of the Jaffe complex is increased. Furthermore, at hydroxide concentrations greater than 200 mmol/L, the blank absorbance increases notably.

Wavelength

Although the absorbance maximum of the Jaffe reaction is between 490 and 500 nm, improved method linearity and reduced blank values have been reported at other wavelengths, the choice varying with hydroxide concentration.

Temperature

The rate of Jaffe complex formation and the absorptivity of the complex are temperature dependent, with measurable differences observed even between 25 °C and 37 °C. Consequently, temperature control is an important component of assay reproducibility.

"Compensation"

In an attempt to adjust for reaction with noncreatinine chromogens, some manufacturers have introduced so-called "compensated" Jaffe assays, in which a fixed concentration is automatically subtracted from each result. For example, Roche Diagnostics Ltd. (Lewes, Sussex, United Kingdom) has realigned its assays on the Cobas Integra and Hitachi systems by −0.20 mg/dL and −0.32 mg/dL (−18 and −28 μmol/L), respectively. Such assays produce lower results more closely aligned with isotope dilution mass spectrometry (IDMS) reference measurement procedures at concentrations within the reference interval.[159,331] However, they make an assumption that the noncreatinine chromogen interference is a constant between samples; this is clearly an oversimplification, especially when adult and pediatric samples are compared.[49]

Other chemical approaches to the measurement of creatinine have been tried. These include (1) reaction with 1,4-naphthoquinone-2-sulphonate, (2) use of *o*-nitrobenzaldehyde to convert creatinine to methylguanidine and its reaction with α-naphthol and sodium hypochlorite under alkaline conditions,[327] and (3) reaction with 3,5-dinitrobenzoic acid.[236] None of these reactions are widely used in clinical laboratories.

Enzymatic Methods

Enzymes from several metabolic pathways have been investigated for the enzymatic measurement of creatinine. All methods involve a multistep approach leading to a photometric equlibrium. Primarily three approaches are used; they are described in the following paragraphs (Figure 25-3).

Creatininase

The enzyme creatininase (EC 3.5.2.10; creatinine amidohydrolase) catalyzes the conversion of creatinine to creatine. The creatine is then detected with a series of enzyme-mediated reactions involving creatine kinase, pyruvate kinase, and lactate dehydrogenase, with monitoring of the decrease in absorbance at 340 nm (Figure 25-3, *A*). Initiating the reaction with creatininase allows for the removal of endogenous creatine and pyruvate in a preincubation reaction. The kinetics of the reaction is poor, and 30-minute incubation is required to allow the reaction to reach equilibrium. This shortcoming can be overcome by a kinetic approach but with a further reduction in sensitivity. The approach has not been popular, in part because of poor sensitivity, poor precision, and the relatively high cost of reagents.

Creatininase and Creatinase

An alternative, more popular approach has used the enzyme creatinase (EC 3.5.3.3; creatine amidinohydrolase), which yields sarcosine and urea, the former being measured with additional enzyme-mediated steps using sarcosine oxidase (EC 1.5.3.1; yielding glycine, formaldehyde, and hydrogen peroxide) and peroxidase (Figure 25-3, *B*).[89,106] Hydrogen peroxide can be detected through a variety of methods. Care must be taken to watch for interference (e.g., by bilirubin) in the final reaction sequence. This problem has been approached with the addition of potassium ferricyanide (with limited success) or bilirubin oxidase. The potential interference caused by ascorbic acid can be overcome by inclusion of ascorbate oxidase. The influence of endogenous intermediate creatine and urea can be overcome by a preincubation step, initiating the reaction with creatininase. This system has been incorporated in a point-of-care testing device using polarographic detection.[270] An alternative detection system involves measurement of the reduction of nicotanimide adenine dinucleotide (NAD) by formaldehyde in the presence of formaldehyde dehydrogenase (Figure 25-3, *C*).[307]

Creatinine Deaminase

Creatinine deaminase (EC 3.5.4.21; creatinine iminohydrolase) catalyzes the conversion of creatinine to *N*-methylhydantoin and ammonia (Figure 25-3, *D*).[315] Early methods concentrated on the detection of ammonia using glutamate dehydrogenase or the Berthelot reaction.[193] An alternative approach involves the enzyme *N*-methylhydantoin amidohydrolase.[87]

Dry Chemistry Systems

Several multilayer dry reagent methods have been described for the measurement of creatinine using enzyme-mediated reactions. An early "two-slide" approach employed creatinine deaminase, with ammonia diffusing through a semipermeable and optically opaque layer to react with bromphenol blue to obtain an increase in absorbance at 600 nm. A second multilayer film lacking the enzyme was used to quantitate endogenous ammonia, enabling blank correction.[309] A later, more precise, single-slide method used the creatininase-creatinase reaction sequence.[195] Lidocaine metabolites have been reported to interfere with this method.[287] The creatinine deaminase system described previously has been used and adapted for use as a point-of-care testing device (Figure 25-3, *D*).[101] In all cases, the color produced in the film is quantitated by reflectance.

A dry chemistry system has been described in which a nonenzymatic approach was used, based on the reaction with 3,5-dinitrobenzoic acid.[301]

Other Methods

A definitive method employing IDMS was described by Welch et al in 1986.[339] Gas chromatography–IDMS (GC-IDMS) is now accepted as the method of choice for establishing the true concentration of creatinine in serum because of its excellent specificity and low imprecision.[293,303] Three GC-IDMS methods have been approved by the JCTLM as reference measurement procedures for serum creatinine.[212] In these procedures, creatinine must be derivatized before GC

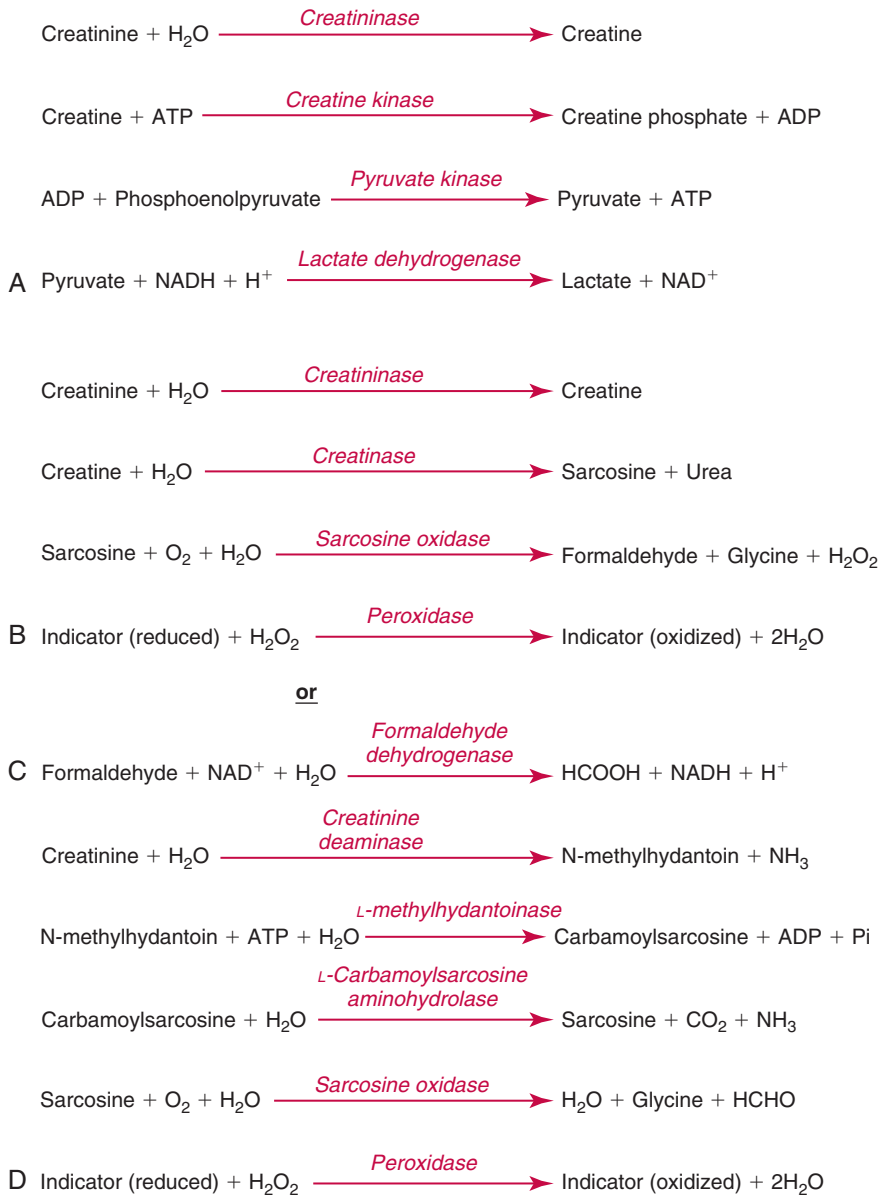


Figure 25-3 Determination of creatinine using a variety of enzymatic methods. For additional details, see text.

analysis because of its polarity. In addition, a cation-exchange cleanup step before GC analysis is necessary because creatine is derivatized into the same chemical species as creatinine. In 2003, a method coupling HPLC with IDMS for the direct quantification of creatinine was reported.[304] This method offered simplicity and improved speed of analysis because only a simple protein precipitation without derivatization is required.

Sensitive and specific approaches to creatinine measurement using HPLC have been described using both cation-exchange[35,112,267] and reversed-phase techniques.[296,299] Separation is followed by quantitation using an on-stream Jaffe reaction,[35] native absorbance of creatinine at ≈230 nm,* or enzymatic detection.[183] All HPLC approaches are reported to be rapid, specific, and precise, and several have been proposed as candidate reference methods.[183,267,320] Thienpont and colleagues reported between-day and within-run imprecision of less than 1% with deviation from GC-IDMS target values of +0.1%.[320] HPLC appears to provide an excellent designated comparison method for in-house use by manufacturers.[212]

A capillary electrophoresis approach to serum creatinine measurement using diode array detection has been described.[354] In addition, a high-performance capillary electrophoresis method[56] and a reagent-free midinfrared method[289] for urinary creatinine measurement have been described.

Quality Issues and Preanalytical Considerations With Creatinine Methods

The method used for measurement of creatinine is complex by virtue of the number of variants of the Jaffe reaction and

the innovations attempted using enzymatic procedures to overcome the limitations of the former. Although enzymatic methods are more expensive, they are used in dry chemistry systems (with their lower reagent requirement), including some point-of-care testing devices. Kinetic Jaffe approaches predominate in wet chemistry analytical systems. Any laboratorian assessing a new creatinine method (e.g., as part of an analyzer purchase) should review the data for that method on interference due to bilirubin, protein, glucose, and ketones/ketoacids; bilirubin will also be particularly important in enzymatic procedures that generate hydrogen peroxide. Despite criticism of the Jaffe methods, good correlation has been noted invariably between them and enzymatic procedures, with differences likely to be due as much to calibration as to interference.

Creatinine in serum, plasma, or diluted urine is stable for at least 7 days at 4 °C, and serum creatinine is stable during long-term frozen storage (at −20 °C and below) and after repeated thawing and refreezing.[67] However, it should be noted that delayed separation (beyond 14 hours) of serum from erythrocytes leads to a significant increase in apparent serum creatinine concentration using some kinetic Jaffe (but not enzymatic) assays, possibly as the result of release of noncreatinine chromogens from the red cells.[85,291] Bacterial contamination, which can occur in samples stored for long periods of time, has been reported to falsely lower creatinine values measured using the Jaffe reaction, purportedly as the result of bacterial production of a substance that retards the reaction.[66] Creatinine concentration increases in blood after meals containing cooked meat because of the conversion of creatine to creatinine; ideally, blood for serum creatinine measurement should be obtained in the fasting state.[134,135,196,240,248] Clearly, this latter problem will affect both enzymatic and Jaffe creatinine methods.

Different methods for assaying serum creatinine have varying degrees of accuracy and imprecision. As a result of reaction with noncreatinine chromogens, Jaffe methods often have overestimated true serum creatinine concentrations by up to 20% compared with HPLC or IDMS methods, at physiologic concentrations.[23,39,168] Data from College of American Pathologists (CAP) surveys using a fresh-frozen serum sample have shown that historically most creatinine methods had a positive bias [range, −0.06 to 0.31 mg/dL (−5.3 to 27 µmol/L) at a concentration of 0.90 mg/dL (80 µmol/L)] compared with GC-IDMS reference measurements.[207] The bias varied between different modifications of the Jaffe assay, contributing to interlaboratory variation. Variation in bias was related more to instrument manufacturer than to method principle, suggesting a strong influence of calibration differences on bias. This echoes earlier CAP data demonstrating that systematic differences in the calibration of serum creatinine assays accounted for 85% of observed differences between laboratories.[268] Proficiency studies have demonstrated that although between-laboratory coefficients of variation (CVs) less than 3% are achievable within method groups, overall between-laboratory agreement across methods is much poorer.[39,168] Systematic variation between laboratories of 0.2 to 0.4 mg/dL (18 to 36 µmol/L) has been common,[125,168] with one study reporting a median method group standard deviation of 0.058 mg/dL (5.1 µmol/L) and median CVs of 6.4% at a creatinine concentration of 0.90 mg/dL (80 µmol/L).[207] This is still outside desirable performance standards defined in terms of biological variation.[212,298] Further, interlaboratory and within-laboratory agreement deteriorates as serum creatinine concentration nears the reference interval; the exponential relationship between serum creatinine and GFR means that imprecision at lower creatinine concentrations contributes to greater error in GFR estimation than at higher creatinine concentrations. Additionally, certified reference material is lacking, further contributing to variation between laboratories.

Over the past decade, appreciation of CKD as a major public health issue[38,178,216,218,285] and of its identification using GFR-estimating equations has led to increased focus on the measurement of creatinine. Creatinine-based estimates of GFR (see later) will clearly vary, depending on how accurate the creatinine measurement is that is used in the calculation. The more a method overestimates "true" creatinine, the greater will be the underestimation of GFR, and vice versa. It is no surprise that there have been calls for an international standard to be used when serum creatinine assays are calibrated.[218] Standardized serum matrix reference materials (SRM 967) with known creatinine concentrations [0.80 mg/dL (71 µmol/L) and 4.00 mg/dL (354 µmol/L)] have been prepared by the National Institute of Standards of Technology (NIST) and submitted to the JCTLM for inclusion in a list of standardized reference materials.[212] It is anticipated that use of this material, in combination with IDMS reference methods, will assist reagent manufacturers in achieving better consensus between methods.[235] In practice, most clinical laboratory methods have adjusted their calibration to be traceable to an IDMS reference measurement procedure.[204,205]

Although undoubtedly desirable, it must be recognized that standardization is only one arm of the problem. Standardization will not solve the problem of different reactivity with noncreatinine chromogens across different patient samples, which can be resolved only by the use of highly specific creatinine methods. Wider adoption of enzymatic methods could further improve between-laboratory agreement in creatinine measurement, but these methods are used by a small minority of laboratories at present. For example, of 687 participants in the United Kingdom National External Quality Assessment Scheme for serum creatinine in April 2009, 39% used traditional kinetic Jaffe reactions, 35% used a "compensated" kinetic Jaffe assay, 2% used an equilibrium Jaffe method, 5% used an O'Leary modification of a kinetic Jaffe assay, 6% used an enzymatic assay, and 13% used a dry-slide enzymatic method. In the United States, 2405 laboratories in the CAP Survey in May 2009 used creatinine assays with "traditional" calibration, and 3355 used assays with IDMS-traceable calibration. Overall, 64% used kinetic Jaffe reactions, 8% used "rate-blanked" kinetic Jaffe assays, 4% used an equilibrium Jaffe method, and 23% used an enzymatic assay (including Vitros dry-slide users).

Reference Intervals

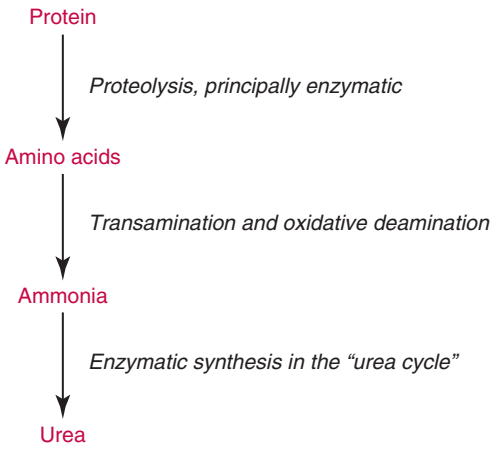
Given the previous discussion, reference intervals for serum creatinine have been method dependent; a selection of reported reference values for different methods may be found in the fourth edition of this textbook. A 2008 systematic review of creatinine reference intervals in which studies were included only when, in particular, their calibration was traceable to the reference IDMS procedure; proposed adult reference intervals of 0.72 to 1.18 mg/dL (64 to 104 µmol/L) in men and 0.55 to 1.02 mg/dL (49 to 90 µmol/L) in women.[43] These data were derived using an enzymatic (Roche Diagnostics Ltd.) assay. Reference interval data for children may be found in the same publication.

Urinary creatinine excretion is higher in men (14 to 26 mg/kg/d, 124 to 230 µmol/kg/d) than in women (11 to 20 mg/kg/d, 97 to 177 µmol/kg/d). Creatinine excretion decreases with age: typically, for a 70-kg man, creatinine excretion will decline from approximately 14.5 to 9.1 mmol/d with advancing age from 30 to 80 years.[244] Measurement of urinary creatinine excretion can be a useful indication of the completeness of a timed urine collection. Creatinine excretion is often used as a method of normalizing the urinary excretion of analytes, that is, the excretion of the test analyte (in mmol or grams) is divided by the total amount of creatinine (in mmol or grams) excreted in the same urine specimen. This method is a rough correction for volume differences between patient specimens. Similarly, expressing the concentration of a substance as a ratio to the creatinine concentration is a useful method of adjusting for urinary concentration differences in random ("spot") urine samples. The benefits of this approach in reporting urinary total protein and albumin measurements have been discussed.

UREA

Biochemistry and Physiology

Catabolism of proteins and nucleic acids results in the formation of urea and ammonia, the so-called nonprotein nitrogenous compounds. As ammonia has no role in assessing kidney function, it is discussed in Chapter 32.



Urea [$CO(NH_2)_2$, Mr 60 Da] is the major nitrogen-containing metabolic product of protein catabolism in humans, accounting for more than 75% of the nonprotein nitrogen eventually excreted. The biosynthesis of urea from amino nitrogen–derived ammonia is carried out exclusively by hepatic enzymes of the urea cycle. During the process of protein catabolism, amino acid nitrogen is converted to urea in the liver by the action of so-called urea cycle enzymes (Figure 25-4).

More than 90% of urea is excreted through the kidneys, with losses through the gastrointestinal tract and skin accounting for most of the remaining minor fraction. Consequently, kidney disease is associated with accumulation of urea in blood. An increase in serum urea concentration characterizes the uremic (azotemic) state. Urea is neither actively reabsorbed nor secreted by the tubules but is filtered freely by the glomeruli. In a normal kidney, 40 to 70% of the highly diffusible urea moves passively out of the renal tubule and into the interstitium, ultimately to re-enter plasma. The back-diffusion of urea is also dependent on urine flow rate, with less entering the interstitium in high-flow states (e.g., pregnancy) and vice versa. Consequently, urea clearance generally

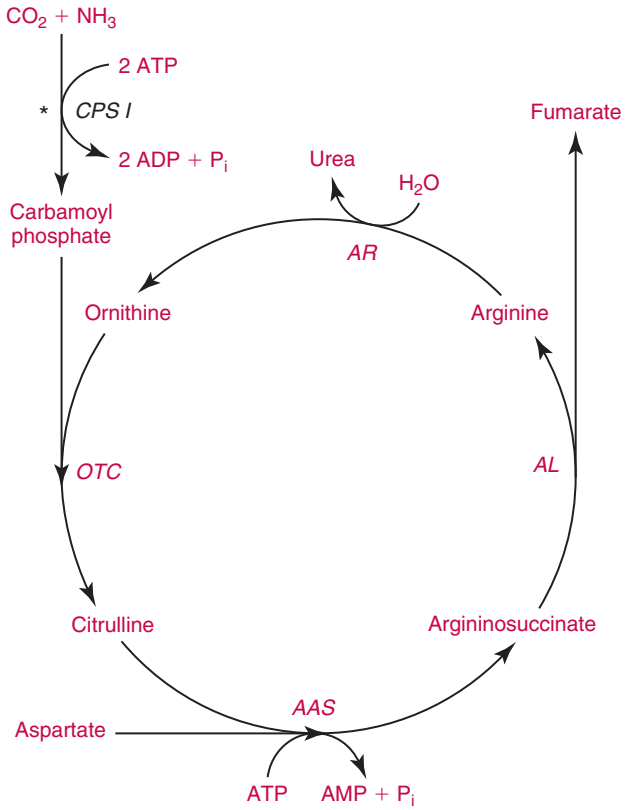


Figure 25-4 The urea cycle pathway. *AAS*, Argininosuccinate synthetase; *ADP*, adenosine diphosphate; *AL*, argininosuccinate lyase; *AR*, arginase; *ATP*, adenosine triphosphate; *CPS I*, carbamyl phosphate synthetase I (N*-acetylglutamate as positive allosteric effector); *OTC*, ornithine transcarbamylase; P_i, inorganic phosphate.**

underestimates GFR. In end-stage renal disease, osmotic diuresis in the remaining functional nephrons limits the back-diffusion of urea, so that urea clearance approaches inulin clearance. Measurement of blood and serum urea has been used for many years as an indicator of kidney function. However, it is generally accepted that creatinine measurement provides better information in this respect. Serum and urinary urea measurement may still provide useful clinical information in particular circumstances, and the measurement of urea in dialysis fluids is widely used in assessing the adequacy of renal replacement therapy (see Chapter 48).

Clinical Significance

Numerous extrarenal factors influence the circulating urea concentration, limiting its value as a test of kidney function. For example, plasma urea concentration is increased by a high-protein diet, increased protein catabolism, reabsorption of blood proteins after gastrointestinal hemorrhage, treatment with cortisol or its synthetic analogs, dehydration, and decreased perfusion of the kidneys (e.g., heart failure). In the prerenal situations already discussed, the plasma creatinine concentration may be normal. In obstructive postrenal conditions (e.g., malignancy, nephrolithiasis, prostatism), both serum creatinine and urea concentrations will be increased, although in these situations, the increase in serum urea is greater than in creatinine because of increased back-diffusion. These considerations give rise to the principal clinical utility of serum urea, which lies in its measurement in conjunction with that of serum creatinine and subsequent calculation of the urea nitrogen-to-creatinine ratio. This can be used as a crude discriminator between prerenal and postrenal azotemia. For a normal individual on a normal diet, the reference interval for the ratio is between 12 and 20 mg urea/mg creatinine (49 and 81 mol urea/mol creatinine). Significantly lower ratios usually denote acute tubular necrosis, low protein intake, starvation, or severe liver disease (decreased urea synthesis). Increased serum urea with *normal* creatinine concentrations giving rise to high ratios may be seen with any of the prerenal states described previously. High ratios associated with *elevated* creatinine concentrations may denote postrenal obstruction or prerenal azotemia superimposed on kidney disease.

Urea clearance is a poor indicator of GFR, as its production rate is dependent on several nonrenal factors, including diet and the activity of the urea cycle enzymes. A high-protein diet causes notable increases in urinary urea excretion. In addition, the variable amount of back-diffusion will influence both serum and urinary urea concentrations.[147] Measurement of urinary urea has little place in clinical diagnosis and management; however, it does provide a crude index of overall nitrogen balance and may be used as a guide to replacement in patients receiving parenteral nutrition. On an average protein diet, urinary excretion expressed as urea nitrogen is 12 to 20 g/d.

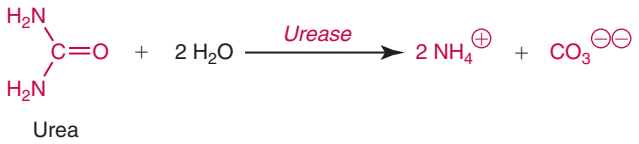
Although *blood urea nitrogen* (BUN) continues to be used for ordering the serum urea nitrogen test, this terminology is incorrect and obsolete, because blood is rarely analyzed for urea. The long-established habit of reporting and expressing results of a urea assay in units of urea nitrogen appears to be strongly entrenched in the United States, although the SI system recommends the use of urea, expressed in mmol/L. Thus, it behooves students of clinical chemistry to have in mind the conversion factors for urea to urea nitrogen. Because 60 g (1 g MW) of urea contains 28 g (2 g atomic weight) of nitrogen, the factor is 0.467 for converting urea mass units to those of urea nitrogen, and 2.14 for converting urea nitrogen mass units to those of urea. The factor for converting urea nitrogen in mg/dL to urea in mmol/L is 0.357.

Analytical Methodology

Direct chemical and indirect enzymatic methods are the two principal approaches that have been used to quantify urea in body fluids. Although once widely used, the chemical method has largely been superseded by enzymatic approaches. For a more detailed description of direct urea measurement, the reader is referred to Taylor and Vadgama.[316]

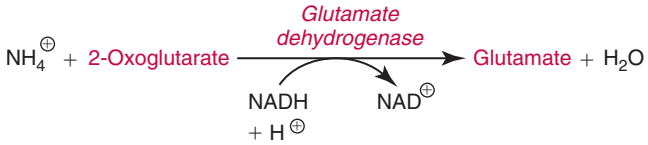
Enzymatic Methods

A vast majority of urea measurements in clinical laboratories are undertaken using enzymatic methods based on preliminary hydrolysis of urea with urease (urea amidohydrolase; EC 3.5.1.5; main source jack bean meal) to generate ammonium ion, which then is quantitated. This approach has been used in equilibrium, rate, conductimetric, and dry chemistry systems.[316]



Urea

Spectrophotometric approaches to ammonium quantitation include the Berthelot reaction and the enzymatic assay with glutamate dehydrogenase [L-glutamate:NAD(P) oxidoreductase (deaminating); EC 1.4.1.3].[276] This latter approach has been accepted as a reference method[277] and adapted to a variety of analytical platforms.



For serum assays, the reaction system is usually formulated with urease, so that the addition of sample containing urea starts the reaction. A decrease in absorbance resulting from the glutamate dehydrogenase reaction is monitored at 340 nm. In another example of a coupled-enzyme assay system for urea, ammonia produced from urea by urease

then reacts with glutamate and adenosine triphosphate in the presence of glutamine synthetase (EC 6.3.1.2). Adenosine diphosphate produced in this second enzymatic reaction is then quantitated in third and fourth steps using pyruvate kinase (EC 2.7.1.40) and pyruvate oxidase (EC 1.2.3.3), respectively, thus generating peroxide. In the final step, peroxide reacts with phenol and 4-aminophenazone, catalyzed by peroxidase (EC 1.11.1.7), to yield a quinone-monoamine dye that can be quantitated spectrophotometrically.[174]

Methods for the measurement of urea using dry chemistry systems using the urease approach and a variety of detection methods have been described.[252,297] It is also possible to measure urea using a conductimetric method in which sample and a urease-containing reagent are incubated in a conductivity cell with the rate of change of the conductivity being monitored as the urea is converted to an ionic species. In a potentiometric approach, an ammonium ion-selective electrode is employed and the urease is immobilized on a membrane.[265] This principle has been applied in the NOVA 12 (NOVA Biomedical, Waltham, Mass.),[100] i-STAT (Abbott Point of Core, Princeton, NJ),[208] and AVL OMNI (Roche Diagnostics Ltd., Lewes, East Sussex, United Kingdom) analytical systems. A similar approach has been used to enable real-time monitoring of dialysis efficiency.[92] Alternative enzymatic approaches to the measurement of urea have been described. For example, Morishita and colleagues[210] have described a system incorporating leucine dehydrogenase (EC 1.4.1.9), in addition to urease, which eliminates interference from endogenous ammonium.

The specificity of all of the methods is good, particularly for the urease-glutamate dehydrogenase procedure; however, endogenous ammonia interference must be expected when the protocol employs the sample to initiate the reaction. This may be relevant in aged samples, in some urines, and in particular metabolic disorders. Typically, within-run CVs of less than 3.0% with between-day values of less than 4.0% are achievable in the concentration interval of 14 to 20 mg/dL (5 to 7 mmol/L). Given the high intrinsic biological variation of serum urea, this is well within desired standards of analytical performance.[316]

Other Methods

An improved IDMS method for serum urea measurement has been listed by JCTLM as a reference method.[150] As discussed previously, laboratory urea measurements using standard enzymatic techniques are generally of an acceptable quality for most clinical purposes. New approaches to urea measurement generally are targeted at novel clinical applications, including point-of-care testing. For example, Eddy and Arnold[72] have developed a near-infrared spectroscopy technique for measuring urea in hemodialysis fluids. This would facilitate noninvasive monitoring of dialysis efficacy in real time. A novel enzymatic assay, using luminometric detection, demonstrates sensitivity that would make the method suitable for in vivo monitoring studies using microdialysis techniques.[213]

Reference Intervals

The reference interval for serum urea nitrogen in healthy adults is 6 to 20 mg/dL (2.1 to 7.1 mmol/L expressed as urea). In adults older than 60 years of age, the reference interval is 8 to 23 mg/dL (2.9 to 8.2 mmol/L). Serum concentrations tend to be slightly lower in children and in pregnancy and slightly higher in males than in females.

URIC ACID

In humans, uric acid (2,6,8-trihydroxypurine) is the major product of catabolism of the purine nucleosides, adenosine and guanosine (Figure 25-5).

Biochemistry and Physiology

Purines from the catabolism of dietary nucleic acid are converted to uric acid directly. The bulk of purines excreted as uric acid arise from degradation of endogenous nucleic acids. The daily synthesis rate of uric acid is approximately 400 mg; dietary sources contribute another 300 mg. In men consuming a purine-free diet, the total body pool of exchangeable urate is estimated at 1200 mg; in women it is estimated to be 600 mg. By contrast, patients with gouty arthritis and tissue deposition of urate may have urate pools as large as 18,000 to 30,000 mg.

Overproduction of uric acid may result from increased synthesis of purine precursors. Synthesis and metabolism of the major precursors are illustrated in the outline in Figure 25-5. The second enzymatic step in the synthetic pathway (Figure 25-5, *A*), formation of 5′-phosphoribosylamine, is the first irreversibly committed step in purine biosynthesis. The intracellular concentration of the substrate phosphoribosylpyrophosphate (PRPP) regulates de novo purine synthesis. The enzyme PRPP-amidotransferase is controlled through feedback inhibition by the purine nucleotides that are the final products of the biosynthetic pathway. The first purine nucleotide formed by ring closure is inosine monophosphate (IMP); adenosine and guanosine monophosphates are derived from IMP through enzymatically mediated interconversions. Adenine and guanine nucleotides may then be used as precursors for the corresponding nucleosides that are the building blocks of deoxyribonucleic acid and ribonucleic acid, or, when further phosphorylated, these nucleotides become carriers of high-energy bonds in the form of ATP and guanosine triphosphate.

Catabolism of the nucleotides (Figure 25-5, *B*) begins with removal of their ribose-linked phosphate, a process catalyzed by purine 5′-nucleotidase. Removal of the ribose moiety of inosine and guanosine by the action of purine-nucleoside phosphorylase forms hypoxanthine and guanine, both of which are converted to xanthine. Xanthine is converted to uric acid through the action of xanthine oxidase.

Reutilization of the major purine bases, adenine, hypoxanthine, and guanine, is achieved through "salvage" pathways (Figure 25-5, *C*), in which phosphoribosylation of the free bases leads to resynthesis of the respective nucleotide

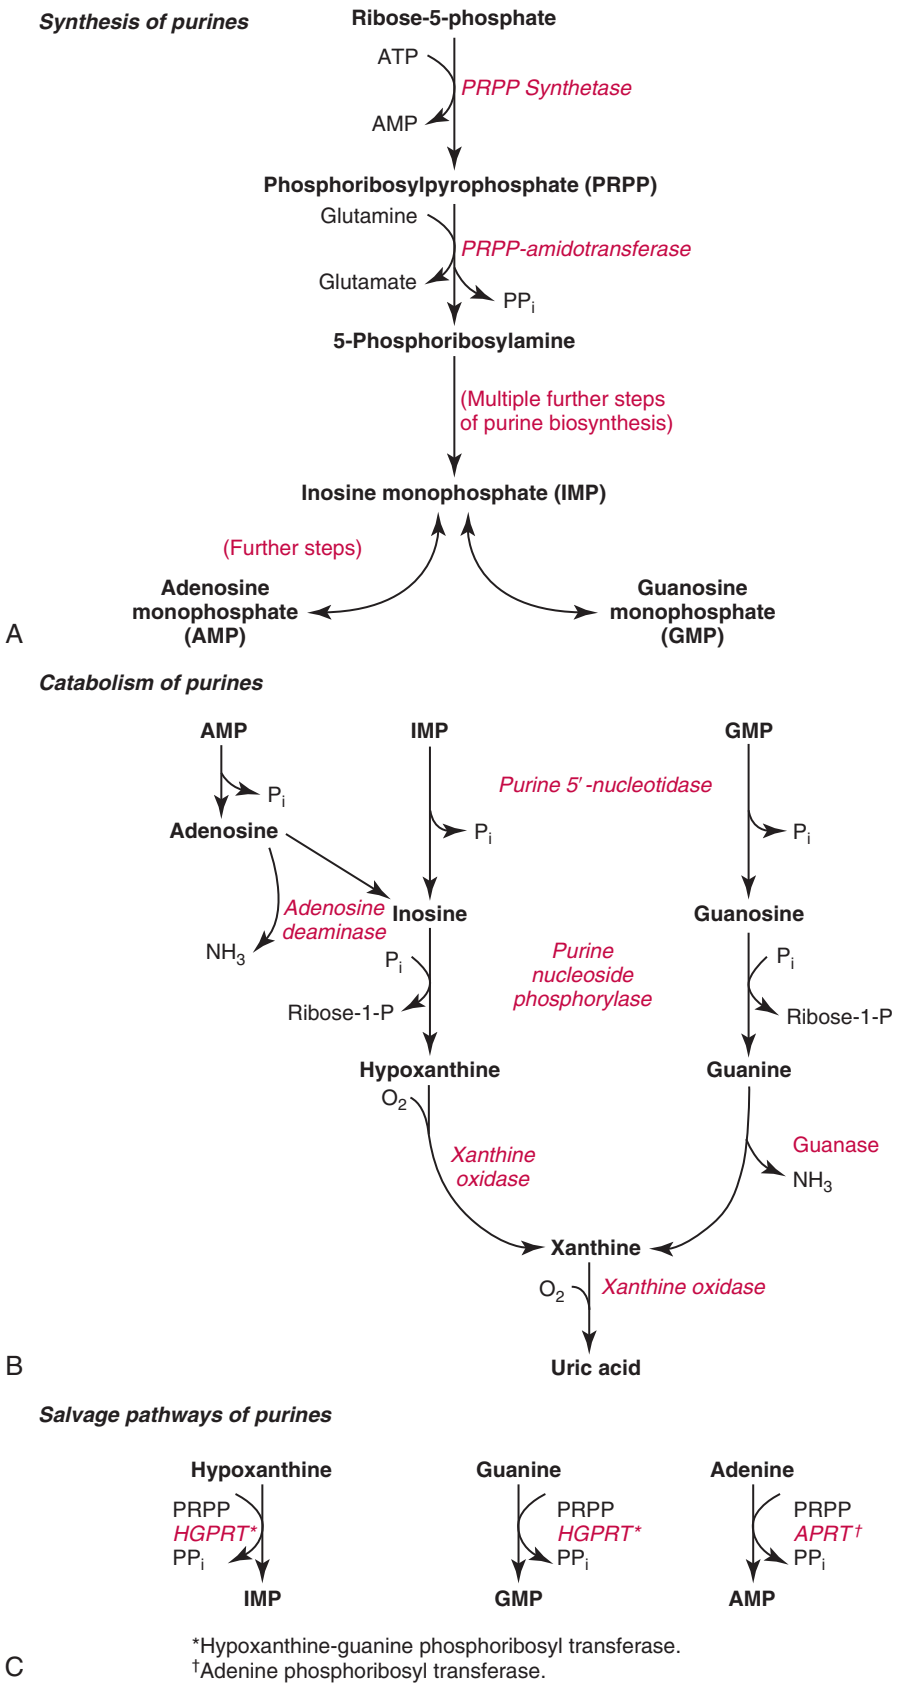


Figure 25-5 Metabolism of purines. A, Synthesis. B, Catabolism. C, Salvage pathways.

monophosphates. Adenine is converted to adenosine monophosphate through the action of adenine phosphoribosyl transferase (APRT), hypoxanthine, and guanine to their monophosphates through hypoxanthine-guanine phosphoribosyl transferase (HGPRT). The HGPRT pathway is quantitatively more important than the APRT pathway.

Lower primates and mammals other than humans carry purine metabolism one step further with the formation of allantoin from uric acid, a step mediated by uricase ([urate:oxygen] oxidoreductase; EC 1.7.3.3). In humans, approximately 75% of uric acid excreted is lost in the urine; most of the remainder is secreted into the gastrointestinal tract, where it is degraded to allantoin and other compounds by bacterial enzymes.

Renal handling of uric acid is complex and involves four sequential steps: (1) glomerular filtration of virtually all the uric acid in capillary plasma entering the glomerulus; (2) reabsorption in the proximal convoluted tubule of about 98 to 100% of filtered uric acid; (3) subsequent secretion of uric acid into the lumen in the distal portion of the proximal tubule; and (4) further reabsorption in the distal tubule. The net urinary excretion of uric acid is 6 to 12% of the amount filtered.

The physicochemical properties of uric acid are important in considering uric acid concentrations in the circulation, in tissue, and in the kidneys. The first pK_a of uric acid is 5.57; above this pH, uric acid exists chiefly as urate ion, which is more soluble than uric acid. At a urine pH below 5.75, uric acid is the preponderant form.

BOX 25-1 Causes of Hyperuricemia

Increased Formation
Primary
Idiopathic
Inherited metabolic disorders

Secondary
Excess dietary purine intake
Increased nucleic acid turnover (e.g., leukemia, myeloma, radiotherapy, chemotherapy, trauma)
Psoriasis
Altered ATP metabolism
Tissue hypoxia
Preeclampsia
Alcohol

Decreased Excretion
Primary (Idiopathic)
Secondary
Acute or chronic kidney disease
Increased renal reabsorption
Reduced secretion
Lead poisoning
Preeclampsia
Organic acids (e.g., lactate, acetoacetate)
Salicylate (low doses)
Thiazide diuretics
Trisomy 21 (Down syndrome)

Clinical Significance

More than 20 inherited disorders of purine metabolism giving rise to both hypouricemias and hyperuricemias have been recognized to date. Most are very rare, and the diagnosis requires support from a specialist purine laboratory. Symptoms that should raise suspicion include kidney failure or stones in a child or young adult, "gravel" in an infant's diaper, unexplained neurologic problems in an infant, child, or adolescent, and gout presenting in a man or woman younger than 30 years old.

Hyperuricemia

Hyperuricemia is most commonly defined by serum uric acid concentrations greater than 7.0 mg/dL (0.42 mmol/L) in men, or greater than 6.0 mg/dL (0.36 mmol/L) in women. The major causes of hyperuricemia are summarized in Box 25-1. Asymptomatic hyperuricemia is frequently detected through biochemical screening; long-term follow-up of asymptomatic hyperuricemic patients is undertaken because many are at risk for kidney disease that may develop as a result of hyperuricemia and hyperuricuria; few of these patients ever develop the clinical syndrome of gout.[284]

Measurement of serum uric acid is predominantly used in the investigation of gout, either as a result of a primary hyperuricemia or caused by other conditions or treatments that give rise to secondary hyperuricemias. It is also used in the diagnosis and monitoring of pregnancy-induced hypertension (preeclamptic toxemia).

Gout occurs when monosodium urate precipitates from supersaturated body fluids; the deposits of urate are responsible for the clinical signs and symptoms. Gouty arthritis may be associated with urate crystals in joint fluid and with deposits of crystals (tophi) in tissues surrounding the joint. The deposits may occur in other soft tissue as well, and wherever they occur, they elicit an intense inflammatory response consisting of polymorphonuclear leukocytes and macrophages. The big toe (first metatarsophalangeal) joint is the classic site for gout. Gout is a condition characterized by occasional attacks and long periods of remission: it is important to appreciate that the serum uric acid concentration is often normal during an acute attack. Kidney disease associated with hyperuricemia may take one or more of several forms: (1) gouty nephropathy with urate deposition in renal parenchyma, (2) acute intratubular deposition of urate crystals, and (3) urate nephrolithiasis.[37]

Gout may be classified as primary or secondary. *Primary gout* is associated with "essential" hyperuricemia, which has a polygenic basis. In more than 99% of cases, the cause is uncertain, but the condition is probably due to a combination of metabolic overproduction of purines (25% of patients have increased PRPP amidotransferase activity), decreased renal excretion (80% of patients show decreased renal tubular secretion of uric acid), and increased dietary intake. Very

rarely, primary gout is attributable to inherited defects of enzymes in the pathways of purine metabolism. The *Lesch-Nyhan syndrome* is characterized by a complete deficiency of HGPRT (EC 2.4.2.8), the major enzyme of the purine salvage pathways. This X-linked genetic disorder is manifested clinically by mental retardation, abnormal muscle movements, and behavioral problems (self-mutilation and pathologic aggressiveness). Patients may, in the first weeks of life, have symptoms of crystalluria, acute kidney failure, and gout. Hyperuricemia, hyperuricuria, and markedly decreased activities of HGPRT are present in erythrocytes, fibroblasts, and other cells. Intracellular activities of PRPP and rates of purine synthesis are increased. Neurologic symptoms of this syndrome may be related to decreased availability of purines to the developing brain, which has limited capacity for de novo purine synthesis and therefore relies on the purine salvage pathways to supply it with most of the purine nucleotides it requires. DNA technology has been applied to prenatal diagnosis in the first trimester using chorionic biopsy material. HGPRT assays on cultured fibroblasts obtained by amniocentesis may be used in the second trimester. Partial deficiency of HGPRT (severe X-linked gout) presents in adolescence or early adulthood as early gout, kidney failure, or nephrolithiasis. Increased activities of intracellular PRPP production with consequent increased uric acid concentrations can also occur owing to mutations in PRPP synthetase (EC 2.7.6.1) (phosphoribosyl pyrophosphate synthetase superactivity), which is also inherited as an X-linked recessive trait. An autosomal dominant familial juvenile hyperuricemic nephropathy has been recognized. Glucose-6-phosphatase deficiency leads to hyperuricemia as a result of both overproduction and underexcretion of uric acid.

Secondary gout is a result of hyperuricemia attributable to several identifiable causes. Renal retention of uric acid may occur in acute or chronic kidney disease of any type or as a consequence of administration of drugs; diuretics, in particular, are implicated in the latter instance. Organic acidemia caused by increased acetoacetic acid in diabetic ketoacidosis or to lactic acidosis may interfere with tubular secretion of urate. Increased nucleic acid turnover and a consequent increase in catabolism of purines may be encountered in rapid proliferation of tumor cells and in massive destruction of tumor cells on therapy with certain chemotherapeutic agents.

Management of an acute attack of gout generally involves the use of nonsteroidal anti-inflammatory drugs (NSAIDs). Patients should be advised to avoid foods that have high purine content (e.g., liver, kidney, red meat, sardines) and drugs that affect urate excretion (thiazide diuretics and salicylates). Specific pharmacologic interventions include the use of uricosuric drugs (e.g., probenecid, sulfinpyrazone), which enhance renal excretion of uric acid by blocking carriers in the tubular cells that mediate reabsorption, or the xanthine oxidase inhibitor allopurinol. Measurement of urinary uric acid excretion is an aid in selecting appropriate treatment in this context. Patients excreting less than 600 mg/d (3.6 mmol/d) uric acid are candidates for treatment with uricosuric drugs, which are contraindicated in patients with urate stones or kidney failure. Conversely, patients excreting more than 600 mg/d (3.6 mmol/d) are candidates for treatment with allopurinol. The NSAIDs azapropazone and tiaprofenic acid have a uricosuric effect and so have a place in both long-term and short-term management of gout.

Uric acid kidney stones occur in approximately one in five patients with clinical gout. Although serum and urinary uric acid should be measured in stone formers, many uric acid stone formers do not demonstrate hyperuricuria or hyperuricemia. However, this may reflect the use of reference intervals derived in a purine-rich, westernized society.[278] The cause of uric acid stone formation also involves the passage of a persistently acid urine with loss of the postprandial alkaline tide.[37] Undissociated uric acid (pK_a 5.57) is relatively insoluble, whereas urate at pH 7.0 is greater than 10 times more soluble. Thus, in patients with urinary pH persistently less than 6.0, normal urinary concentrations of uric acid will produce supersaturation. Measurement of urinary pH throughout the day can be useful.[278] Pure uric acid stones account for approximately 8% of all urinary tract stones and, unlike many of the calcium-containing stones, are radiolucent. Allopurinol is the mainstay of treatment of uric acid stones. Hyperuricuria is also a risk factor for calcium stone formation (see Chapter 48). Consequently, attempts to increase urinary pH with potassium alkali salts may be counterproductive as a result of increased calcium stone formation.

Preeclamptic toxemia is associated with increasing serum uric acid concentration, probably caused by uteroplacental tissue breakdown and decreased kidney perfusion.[77] Serum urate measurement can be used as an indicator of the severity of preeclampsia: Redman and coworkers[259] noted that concentrations in excess of 6.0 mg/dL (0.36 mmol/L) at 32 weeks' gestation are associated with a high perinatal mortality rate. More recently, uric acid has been proposed as one of a panel of eight small molecular weight metabolites that could be used for the detection of preeclampsia.[149]

Hypouricemia

Hypouricemia, often defined as serum urate concentrations less than 2.0 mg/dL (0.12 mmol/L), is much less common than hyperuricemia. It may be secondary to any one of a number of underlying conditions. Severe hepatocellular disease with reduced purine synthesis or xanthine oxidase activity is one possibility. Another is defective renal tubular reabsorption of uric acid. Defective reabsorption may be congenital, as in generalized Fanconi's syndrome, or acquired. The reabsorption defect may be acquired acutely because of injection of radiopaque contrast media or chronically because of exposure to toxic agents. Overtreatment of hyperuricemia with allopurinol or uricosuric drugs and cancer chemotherapy with 6-mercaptopurine or azathioprine (inhibitors of de novo purine synthesis) may also cause hypouricemia. Very rarely, hypouricemia may occur as the result of an inherited metabolic defect. Hypouricemia in combination with xanthinuria is rarely encountered and suggests a deficiency of

xanthine oxidase, either in isolation or as part of combined molybdenum cofactor deficiency (sulfite oxidase/xanthine oxidase deficiency). Purine nucleoside phosphorylase (EC 2.4.2.1) deficiency and other inherited defects have been described.

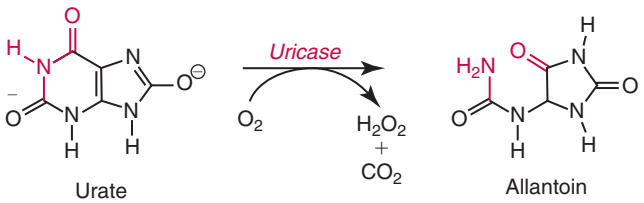
Analytical Methodology

Phosphotungstic acid (PTA), uricase, and HPLC-based methods have been described for measuring uric acid.[251] PTA methods are now rarely used; the reader is referred to a review for additional details.[251]

Uricase Methods

Uricase methods are more specific than and have replaced older PTA methods. Uricase [(urate : oxygen) oxidoreductase; EC 1.7.3.3; main sources *Aspergillus flavus, Candida utilis, Bacillus fastidiosus,* and hog liver] is used as a single step or as the initial step to oxidize uric acid. Uricase methods became feasible and popular as a result of the availability of high-quality, low-cost preparations of the bacterial enzyme. Preliminary precipitation of protein is not required. Generally, only guanine, xanthine, and a few other structural analogs of uric acid act as alternative substrates, and then only at concentrations improbable in biological fluids.

Uricase acts on uric acid to produce allantoin, hydrogen peroxide, and carbon dioxide.



The reaction can be observed in the rate or the equilibrium mode. The *Bacillus fastidiosus* enzyme has the highest Michaelis constant (10×10^{-5} mol/L), and the hog liver has the lowest (1.7×10^{-5} mol/L); the choice of enzyme influences the incubation period required to reach equilibrium and the conditions for a pseudo first-order kinetic approach. The decrease in absorbance as urate is converted may be monitored by a spectrophotometer at 293 nm.[70] However, at this wavelength, most of the absorbance is due to serum proteins. Therefore, there is a high signal-to-noise ratio, which can compromise the precision of the method. A high-quality spectrophotometer with narrow bandpass is necessary, and this is rarely satisfied with automated analyzers.

Most current enzymatic assays for uric acid in serum involve a peroxidase system coupled with one of a number of oxygen acceptors to produce a chromogen.[145,342] For example, one popular method measures hydrogen peroxide with the aid of horseradish peroxidase (donor : hydrogen-peroxide oxidoreductase; EC 1.11.1.7) and an oxygen acceptor to yield a chromogen in the visible spectrum.[88] Its popularity is probably due to the use of less expensive enzymes and greater analytical sensitivity. The most common oxygen acceptor used is 4-aminophenazone, together with phenol or a substituted phenol. The benefit of using substituted phenols is the enhanced molar absorptivity, as follows: phenol $\cong 5.5 \times 10^3$ L • mol/cm, tribromo-phenol $\cong 23.6 \times 10^3$ L • mol/cm, and tribromo-3-hydroxybenzoic acid $\cong 30.0 \times 10^3$ L • mol/cm. Alternative oxygen acceptors include 3-methyl-1-benzothiazoline hydrazone (MBTH), 2,2′-azino-di-(3-ethyl-benzothiazoline)-6-sulfonate (ABTS), and *o*-dianisidine.

Although many combinations of oxygen acceptor and phenol have been described, the choice should be guided by minimization of interference and sufficient absorbance to ensure good precision. The use of a substituted phenol yielding a highly absorbing product helps to reduce potential interference by reducing the sample volume requirement. The major interferants to minimize are ascorbic acid and bilirubin. In general, it is necessary to employ ascorbate oxidase (L-ascorbate : oxygen oxidoreductase; EC 1.10.3.3) in uric acid methods.[172] Aminophenazone with a substituted phenol or the addition of ferrocyanide[88,126] has been used to minimize bilirubin interference. Alternatively, use of the oxygen acceptor azure-D2 [3,7-diamino-5-phenothiazine (thionine) derivative], which can be monitored at 600 nm, reduces the spectral but not the chemical[344] interference caused by hyperbilirubinemia.[162] It has also been shown that unknown metabolites in the serum of patients with kidney failure, thought to be phenolic compounds, will interfere by competing with the reagent phenol, giving low recovery of urate.[137] This interference can be overcome by using a phenolic derivative, thereby generating a higher-absorbing product and reducing the sample volume.

Although many methods for the quantitation of uric acid are described in the literature, the most popular methods today employ the uricase-mediated reaction; however, the specificity of this reaction may be compromised by the choice of detector reaction, owing to an interfering enzyme or a molecule that competes in the final absorbance generation step. In practice, reactions that generate a visible end product are preferred because of the higher absorbance obtained; however, care should be taken that interference caused by ascorbate, bilirubin, and unspecified interferants in serum from patients with kidney failure is minimized.

Dry Chemistry Systems

Devices that use uricase in a dry reagent format to measure uric acid have been described. For example, a multilayer film system employs uricase and peroxidase separated by a semipermeable membrane from a leuco dye that is oxidized to form a colored product.[144] A cellulose matrix pad system employs uricase, peroxidase, and MBTH as oxygen acceptors; the system uses a diluted serum sample, which helps to reduce interferences, although ascorbic acid was shown to be a significant interferant.[146] A third system incorporates separation of serum from red cells and uricase, peroxidase, and a substituted phenol to measure uric acid.[42] All three systems use a reflectance meter system to facilitate accurate and precise quantitation of the color change.

Several electrochemical and biosensor systems have been described for the measurement of uric acid. In most cases, uricase is employed, being linked in examples to an oxygen electrode[353] or to a metal-organic probe whose fluorescence is quenched by oxygen.[281] Detection of uric acid has been demonstrated as part of a multianalyte array.[323] A nonenzymatic approach has also been described on a microchip, based on chemiluminescence microflow injection analysis.[113]

HPLC Methods

HPLC methods using ion-exchange or reversed-phase columns have been used to separate and quantify uric acid. The column effluent is monitored at 293 nm to detect the eluting uric acid. HPLC methods are specific and fast, mobile phases are simple, and the retention time for uric acid is less than 6 minutes—reasonable conditions that recommend these methods for reference use.[128] JCTLM-listed reference methods for the assay of uric acid in serum and urine use IDMS.[74,294,303,319]

Reference Intervals

Using an enzymatic method, the reference interval for uric acid has been reported to be 3.5 to 7.2 mg/dL (0.21 to 0.43 mmol/L) for males and 2.6 to 6.0 mg/dL (0.16 to 0.36 mmol/L) for females.[321] The concentration of serum uric acid increases gradually with age, rising about 10% between the ages of 20 and 60 years. A significant rise is seen in women after the menopause; concentrations similar to those in men are reached. During pregnancy, serum uric acid concentrations fall during the first trimester and until about 24 weeks' gestation, when concentrations begin to rise and eventually exceed nonpregnant concentrations.[40,181] Using an enzymatic assay, reference intervals at 32, 36, and 38 weeks' gestation have been reported as 1.9 to 5.5 mg/dL (0.11 to 0.32 mmol/L), 2.0 to 5.8 mg/dL (0.12 to 0.34 mmol/L), and 2.7 to 6.5 mg/dL (0.16 to 0.38 mmol/L), respectively.[181]

Urinary uric acid excretion in individuals on a diet containing purines is 250 to 750 mg/d (1.5 to 4.5 mmol/d). Excretion may decrease by 20 to 25% on a purine-free diet to less than 400 mg/d.

ASSESSMENT OF KIDNEY FUNCTION: ESTIMATION OF GLOMERULAR FILTRATION RATE

The GFR is widely accepted as the best overall measure of kidney function, enabling a statement of the complex functions of the kidney in a single numeric expression.[218] A decrease in GFR precedes kidney failure in all forms of progressive disease. Different kidney pathological conditions can progress to renal failure and dialysis dependency at rates varying from weeks to several decades.[36,262] Symptoms accompanying progressive kidney disease (see Chapter 48) and their correlation with falling GFR will be influenced by this rate of progression. Measuring GFR in established disease is useful in targeting treatment, monitoring progression, and predicting the point at which renal replacement therapy will be required. It is also used as a guide to dosage of renally excreted drugs to prevent potential drug toxicity. Several methods are used to measure the GFR; most involve the ability of the kidneys to clear an exogenous or endogenous marker. Improving methods and the discovery of new markers of GFR and glomerular or tubular damage will continue to provide important contributions to the early diagnosis of renal disease.

The Concept of Clearance

Most of the clinical laboratory information used to assess kidney function is derived from or related to measurement of the clearance of some substance by the kidneys. *Renal clearance of a substance* is defined as the volume of plasma from which the substance is completely cleared (removed) by the kidneys per unit of time.

Provided a substance *S* is in stable concentration in the plasma and is physiologically inert, freely filtered at the glomerulus, and neither secreted, reabsorbed, synthesized, nor metabolized by the kidney, the amount of that substance filtered at the glomerulus is equal to the amount excreted in the urine (i.e., the amount of *S* entering the kidney must exactly equal the amount leaving it). The amount of *S* filtered at the glomerulus equals GFR multiplied by plasma *S* concentration: GFR × *PS*. The amount of *S* excreted equals the urine *S* concentration (*US*) multiplied by the urinary flow rate (V, volume excreted per unit time).

Because filtered *S* = excreted *S*,

$$\mathrm{GFR} \times PS = US \times V \quad \textbf{(1)}$$

$$\mathrm{GFR} = (US \times V)/PS \quad \textbf{(2)}$$

where

GFR = the flow rate in milliliters per minute of plasma through the glomerular membranes, estimated as *clearance* in units of milliliters of plasma cleared of a substance per minute
US = urinary concentration of the substance
V = volumetric flow rate of urine in milliliters per minute
PS = plasma concentration of the substance

The term (*US* × V)/*PS* is defined as the clearance of substance *S* and is an accurate estimate of GFR, provided the aforementioned criteria are satisfied. Inulin satisfies these criteria and has long been regarded as the most accurate (gold standard) estimate of GFR (see later).

Kidney size and GFR are roughly proportional to body size. It is conventional therefore to adjust clearance estimates to a standard body surface area (BSA) of 1.73 m^2, according to the formula devised by Du Bois and Du Bois in 1916[68]:

$$\mathrm{BSA} = \mathrm{Weight\ (kg)}^{0.425} \times \mathrm{Height\ (cm)}^{0.725} \times 7.1 \times 10^{-3} \quad \textbf{(3)}$$

A variety of exogenous (radioisotopic and nonradioisotopic) and endogenous markers have been used to estimate clearance (Table 25-3). Measurement of clearance may require accurate measurements of serum and urinary concentrations of the marker used plus a reliable urine collection. For a

TABLE 25-3 Markers of Glomerular Filtration Rate: Hierarchical Arrangement

Hierarchy	Marker	Advantages	Disadvantages
Gold standard	Inulin (sinsitrin) continuous-infusion urinary clearance method	Gold standard	Exogenous Time-consuming[75] Requires timed urine collection Poor specificity of analysis Extrarenal clearance = 0.083 mL/min/kg
Silver standard	Inulin (sinistrin) single-bolus plasma clearance method		Exogenous Time-consuming[75] Poor specificity of analysis Extrarenal clearance = 0.083 mL/min/kg
	^{51}Cr-EDTA	Radioisotopic (simple measurement) Close correlation with inulin clearance[33]	Exogenous Radioisotopic (risks of ionizing radiation) Time-consuming[261] Extrarenal clearance = 0.079 mL/min/kg ^{51}Cr less readily available than ^{99m}Technetium (Tc)
	^{99m}Tc-DTPA	Radioisotopic (simple measurement) Can be used for gamma camera imaging	Exogenous Radioisotopic (risks of ionizing radiation) Time-consuming[73,261] Protein binding
	^{125}I-iothalamate	Radioisotopic (simple measurement)	Exogenous Radioisotopic (risks of ionizing radiation) Not available in all countries Reports of allergic reactions
	Iohexol	Nonradioisotopic	Exogenous Extrarenal clearance = 0.087 mL/min/kg[94,156] Reports of allergic reactions
Bronze standard	Creatinine	Endogenous Inexpensive Can be used to estimate GFR from equations (e.g., MDRD)	Poor sensitivity and specificity
	Cystatin C	Not secreted/reabsorbed Constitutively expressed More sensitive and specific than creatinine	Influence of thyroid function[62,90,139]
Of uncertain clinical use	Creatinine clearance	Endogenous Inexpensive	Requires timed urine collection Inaccurate
	Urea	Endogenous Inexpensive	Poor sensitivity and specificity
	Retinol binding protein (RBP)	Endogenous Not secreted/reabsorbed	Nonrenal influences on production rate
	α_1-Microglobulin	Endogenous Not secreted/reabsorbed	Nonrenal influences on production rate Less freely filtered than RBP

GFR, Glomerular filtration rate; *MDRD,* Modification of Diet in Renal Disease study.

reliable serum measurement, the substance must have reached a steady-state concentration and must not be rapidly changing. For a reliable urine collection, the urine flow must be adequate (several mL/min), the collection period long enough, and complete bladder emptying achieved; this is problematic. Table 25-4 provides some reference data for GFR using a variety of methods.

Exogenous Markers of Glomerular Filtration Rate

Ideally, GFR is measured using exogenous markers, although practical limitations restrict their widespread use. Exogenous markers are also used to determine a GFR that is used to set a benchmark against which deterioration in GFR can be monitored using an endogenous marker such as creatinine.

TABLE 25-4 Glomerular Filtration Rate: Reference Values

Study	Method	Age, y	GFR*, Mean ± SD (Range) mL/min/1.73 m^2)	n
Slack and Wilson[295]	Inulin (constant infusion)	20-29		47

*All values have been rounded up or down to the nearest whole number.
GFR, Glomerular filtration rate.

Measurement of GFR using an exogenous molecule does enable smaller deteriorations in renal function to be observed, even when the imprecision in measurement is taken into account.

Radioisotopic Markers

Radiopharmaceuticals that have been used include ^{51}Cr-ethylenediaminetetraacetic acid (EDTA),[7,8,21,33,46] ^{99m}Tc-diethylenetriaminepentaacetic acid (DTPA), and ^{125}I-iothalamate. ^{51}Cr-EDTA is preferred to ^{99m}Tc-DTPA and ^{125}I-iothalamate because its clearance is considered to be closest to that of inulin.[22,33] ^{99m}Tc-DTPA offers the advantage that it can also be used for gamma camera imaging. ^{125}I-iothalamate is no longer approved for intravascular use in some countries.[22] GFR measurements may be based on urinary or plasma clearance of the marker. To ensure accuracy when GFR is measured using urinary or plasma clearance methods, it is essential that (1) renal tubular secretion or reabsorption does not contribute to elimination of the compound, (2) plasma protein binding of the radiopharmaceutical is negligible, and (3) no extrarenal elimination of the marker occurs. Incomplete bladder emptying may also contribute to inaccuracy in urinary clearance approaches. ^{99m}Tc-DTPA has been associated with problems of plasma protein binding of the tracer, but more recent formulations have minimized this problem.[22] For research purposes, in patients with low (<30 mL/min) GFR and in patients with ascites or edema, measurement is best performed using a urinary clearance method.[22] From a clinical management perspective, in most patients, urinary or plasma clearance approaches are acceptable.

Constant-infusion or single-bolus injection methods may be used to administer an exogenous marker. In the constant-infusion technique, the fasting subject is required to drink 500 mL of water 1 hour before the study begins, after which he or she is required to take 200 mL every half hour until the

end of the study. The subject remains supine throughout the study. An intravenous loading dose of the marker selected is then followed by a constant infusion of a given quantity of marker per minute for 3 hours. After equilibration for 1 hour, blood is taken and urine samples are collected at hourly intervals for 3 hours. This technique can be used with any of the exogenous markers, the dosage being all that will vary between molecules. For example, for inulin, an intravenous loading dose of 2.3 g would be followed by a constant infusion of 18.1 mg/min for 3 hours.

Single-bolus plasma clearance methods have obvious practical advantages compared with the complex continuous-infusion methods. A single dose of the marker [e.g., inulin, 70 mg/kg; iohexol, 5 mL; Ominipaque, 300 mg iodine/mL (Nycomed AS, Oslo, Norway); or ^{51}Cr-EDTA, 50 to 100 μCi) is injected, and venous blood samples are collected at timed intervals (e.g., typically 120, 180, and 240 minutes after the start of the injection for ^{51}Cr-EDTA). The GFR is calculated using knowledge of the amount of marker injected and the decrease in marker concentration (activity) as a function of time. Elimination of the marker is described by a two-compartment model, which comprises an initial equilibration or distribution phase while the marker mixes between vascular and extravascular spaces and is being cleared from the plasma by the kidney. This gives rise to a biexponential clearance curve (Figure 25-6). The first sample should be taken no earlier than 2 hours after injection to avoid inclusion of the fast exponential in the GFR calculation.[81]

GFR is normally calculated using single-exponential analysis by plotting log marker concentration against time and using slope-intercept analysis. The half-life is calculated from the slope *(k)* and the volume of distribution *(C_0)* of the marker just after injection.

$$GFR = k \times C_0 \quad (4)$$

Because this model ignores the distribution phase, GFR is overestimated. Various corrections are used to adjust for this (e.g., those proposed by Chantler and Barratt[46] and Brochner-Mortensen[32]). For additional details, see Blake and colleagues.[21]

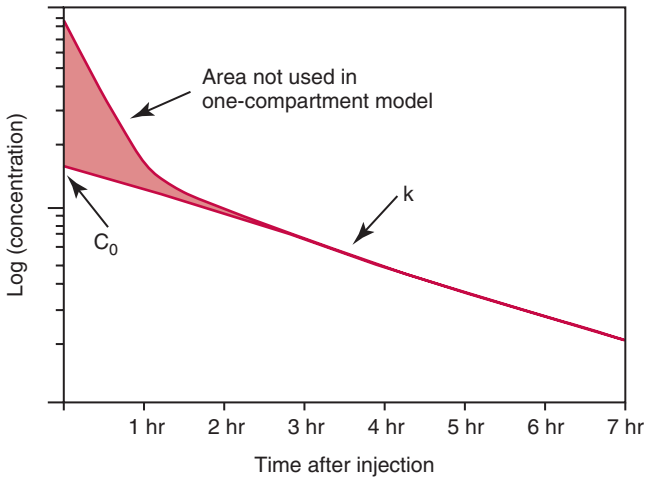

Figure 25-6 Semilog plot used in a single compartmental analysis of the plasma disappearance curve of a glomerular filtration rate (GFR) marker. In this simplified representation of contrast agent elimination, the distribution phase *(colored area)* is neglected, which leads to underestimation of the true area under the curve.

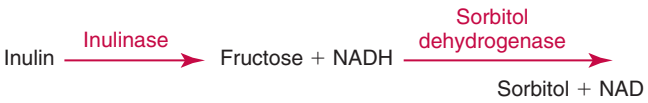
Nonradiosotopic Markers

Nonradioactive compounds used to measure GFR include inulin and iohexol.[73]

Inulin Clearance

The fructose polymer inulin (Mr ≈5000 Da) satisfies the criteria as an ideal marker of GFR. Inulin clearance using a constant-infusion urinary clearance approach has long been regarded as the gold standard measure of GFR. Acceptable single-bolus plasma clearance approaches have also been evaluated.[328] However, lack of availability of simple laboratory methods of measurement remains an impediment to universal usage. Early methods for the measurement of inulin were based on the hydrolysis of inulin with concentrated sulfuric acid and condensation with anthrone to give a green product that could be read at 620 nm. Newer methods have been based on the enzyme inulinase (EC 3.2.17), which converts inulin to fructose; the fructose is then determined with the aid of sorbitol dehydrogenase (EC 1.1.1.14) according to the following reaction sequence[308]:



The amount of inulin present can be determined from the reduction of nicotinamide-adenine dinucleotide, reduced form (NADH), measured as a decrease in absorbance at 340 nm. The method can be calibrated with inulin or fructose; endogenous fructose in each sample is measured by incubation with an inactivated inulinase reagent. Urine samples require predilution (typically 1 in 40) before analysis. Typical between-run imprecision of less than ±2% for serum and less than ±4% for urine can be obtained with an automated assay.

An alternative method for detecting the fructose produced involves the use of fructokinase (EC 2.7.1.4), phosphoglucose isomerase, and glucose-6-phosphate dehydrogenase (EC 1.1.1.49), measuring in this case the nicotinamide-adenine dinucleotide phosphate, reduced form (NADPH), produced.[249,306]

Iohexol Clearance

Clearance of the nonradioactive x-ray contrast agent iohexol has been proposed as a simpler alternative to inulin clearance

in the assessment of GFR.[6,93,94,122,156] Serum iohexol can be measured by HPLC with reversed-phase separation and UV detection, following prior deproteinization with perchloric acid.[156] Analytical imprecision is less than ±3% intraassay and ±5% interassay. Rapid, inexpensive capillary electrophoresis iohexol measurement techniques have been described.[140,266] Single-bolus plasma clearance of iohexol demonstrates excellent agreement with constant-infusion urinary inulin clearance.[94] Biological variability in patients with kidney disease using this technique is approximately 6%.[93] The nonradioisotopic and stable nature of iohexol enables analysis of samples to be delayed and common reference centers to be used for multinational studies. An outpatient procedure based on filter paper blood spots has been described.[226]

Endogenous Markers of Glomerular Filtration Rate

Although the clearance of infused markers is generally considered a more accurate assessment of GFR, to date these procedures have generally been considered too costly and cumbersome for routine use, particularly when GFR must be assessed on a regular basis (e.g., when patients are receiving nephrotoxic drugs). Recognition of CKD as a major public health issue has focused attention on the need for simple and readily available markers of GFR.[216,218] Creatinine and certain low molecular weight proteins (e.g., cystatin C) have been used as endogenous markers of GFR. The use of urea in this context is of limited value[313] and will not be discussed further. Endogenous markers obviate the necessity for injection and require only a single blood sample, simplifying the procedure for the patient, the clinician, and the laboratory. The most widely used endogenous marker of GFR is creatinine, expressed as its serum concentration or as renal clearance. Creatinine as a marker of GFR was first used in 1926 by Rehberg,[260] who exogenously administered creatinine. This led to the work of Popper and Mandel,[247] who in 1937 developed the use of endogenous creatinine clearance.

Creatinine

Most commonly, GFR is assessed by measuring serum creatinine. Creatinine is freely filtered at the glomerulus, and its concentration is inversely related to GFR. As a GFR marker, it is convenient and inexpensive to measure but is affected by (1) age, (2) gender, (3) exercise, (4) certain drugs (e.g., cimetidine,[324] trimethoprim), (5) muscle mass, and (6) nutritional status.[244,298] As previously discussed, significant preanalytical influences and analytical interferences are a problem.[154,298] Further, a small (but significant) and variable proportion of the creatinine appearing in the urine is derived from tubular secretion: typically, 7 to 10% is due to tubular secretion,[202] but this amount is increased in the presence of renal insufficiency. Perhaps most important, serum creatinine remains within the reference interval until notable renal function has been lost (Figure 25-7).[244,290]

Because plasma creatinine is derived from creatine and phosphocreatine breakdown in muscle, the reference interval encompasses the range of muscle mass observed in the reference population used. This limitation contributes to the insensitivity of creatinine as a marker of diminished GFR. Additionally, in patients with CKD, extrarenal clearance of creatinine becomes important when caused by degradation as a result of bacterial overgrowth in the small intestine, further blunting the anticipated increase in plasma creatinine in response to falling GFR.[218] Consequently, serum creatinine measurement will not detect patients with stage 2 CKD (GFR, 60 to 89 mL/min/1.73 m^2) and will fail to identify many patients with stage 3 CKD (GFR, 30 to 59 mL/min/1.73 m^2). Thus, although an elevated serum creatinine concentration generally equates with impaired kidney function, a normal serum creatinine does not necessarily equate with normal kidney function. Because of all these limitations, it is recommended that serum creatinine measurement alone is not used to assess kidney function.[218]

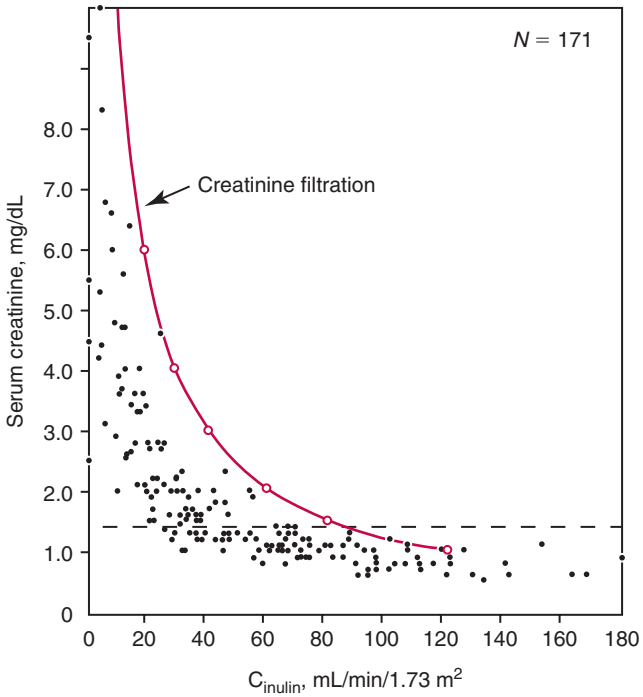


Figure 25-7 The relationship between serum creatinine concentration and glomerular filtration rate (GFR), measured as the clearance of inulin, in 171 patients with glomerular disease. The hypothetical relationship between GFR and serum creatinine is shown as a *continuous line*, assuming that only filtration of creatinine takes place. The *dashed horizontal line* represents the upper limit of a normal serum creatinine (1.4 mg/dL). Because of creatinine secretion and/or a creatinine deficit through gut excretion, the serum creatinine consistently overestimates the GFR. *(From Shemesh O, Golbetz H, Kriss JP, Myers BD. Limitations of creatinine as a filtration marker in glomerulopathic patients. Kidney Int 1985;28:830.)*[290]

Creatinine Clearance

Because creatinine is endogenously produced and released into body fluids at a reasonably constant rate, its clearance

can be measured as an indicator of GFR.[244] Creatinine clearance in the past has been seen as more sensitive for detection of renal dysfunction than serum creatinine measurement. However, it requires a timed urine collection, which introduces its own inaccuracies,[97,242,263] and is inconvenient and unpleasant. In adults, the intraindividual day-to-day CV for repeated measures of creatinine clearance exceeds 25%.[34] Although tubular secretion undermines the theoretical value of creatinine as a marker of GFR, in the context of creatinine clearance, this has previously to some extent been offset by the use of nonspecific methods to measure serum creatinine, which lead to an overestimation of serum concentration. The use of enzymatic assays or "compensated" Jaffe methods has removed this fortuitous offset. Consequently, creatinine clearance overestimates GFR, usually equaling or exceeding inulin GFR in adults by a factor of 10 to 40% at clearances above 80 mL/min. However, as GFR falls, tubular secretion rises disproportionately and creatinine clearance can reach nearly twice that of inulin.[332] Tubular reabsorption of creatinine has been reported at low GFRs but may represent diffusion of creatinine through gap junctions between tubular cells or directly through the tubular epithelial cells, down a concentration gradient.[244] Whatever the mechanism, this further devalues the use of creatinine clearance. Hence at best, creatinine clearance can provide only a crude index of GFR.

Estimating Glomerular Filtration Rate

The mathematical relationship between plasma creatinine and GFR can be improved by correcting for the confounding variables that make this relationship nonlinear. More than 25 different equations have been derived that estimate GFR using serum creatinine corrected for some or all of gender, body size, race, and age.[163,218] These generally produce a better estimate of GFR than serum creatinine alone or measured creatinine clearance,[55,163,165,218,332] and professional societies throughout the world have recommended that such estimates should be used in preference to, or in association with, serum creatinine.[38,178,216,218,285] In adults, two main equations have been used: the Cockcroft and Gault equation and the Modification of Diet in Renal Disease (MDRD) Study equation.

The Cockcroft and Gault equation is one of the earliest of these equations.[50] A full discussion of this equation may be found in the fourth edition of this textbook. It remains widely used, particularly in the context of assessing drug dosages for patients with kidney impairment. However, in addition to several theoretical objections to use of the equation (e.g., females were not included in the original derivation of the equation, and a reference GFR method was not used), the requirement for measurement of body weight has been a major practical impediment to the use of the equation in wider clinical practice.

The era of GFR estimation as a widely used simple clinical tool across both primary and secondary care really began with publication of the MDRD study equation in 1999.[175] The original MDRD equation was developed in a chronic renal insufficiency study in which 1628 predominantly middle-aged patients were enrolled. The equation was later validated against an iothalamate clearance estimate of GFR, and reported GFR is corrected for BSA. It is suitable for use in black African-Americans, and there is no requirement for patient weight. It originally used age, gender, race (black or white), serum creatinine, urea, and albumin as covariables.

$$\begin{aligned}\text{GFR (mL/min/1.73 m}^2) = {} & 170 \times [\text{serum creatinine (mg/dL)}]^{-0.999} \\ & \times (\text{age})^{-0.176} \times (0.762 \text{ if patient is female}) \\ & \times (1.180 \text{ if patient is black}) \\ & \times [\text{serum urea nitrogen (mg/dL)}]^{-0.170} \\ & \times [\text{serum albumin (g/dL)}]^{0.318}\end{aligned}$$

or

$$\begin{aligned}\text{GFR (mL/min/1.73 m}^2) = {} & 170 \times [\text{serum creatinine (}\mu\text{mol/L)} \\ & \times 0.011312]^{-0.999} \times (\text{age})^{-0.176} \\ & \times (0.762 \text{ if patient is female}) \\ & \times (1.180 \text{ if patient is black}) \\ & \times [\text{serum urea (mmol/L)} \times 2.801]^{-0.170} \\ & \times [\text{serum albumin (g/L)} \times 0.1]^{+0.318}\end{aligned}$$

These workers subsequently also published, in abstract form, an abbreviated version of this equation, which did not require albumin or urea.[179]

$$\begin{aligned}\text{GFR (mL/min/1.73 m}^2) = {} & 186 \times [\text{serum creatinine (mg/dL)}]^{-1.154} \\ & \times (\text{age})^{-0.203} \times (1.210 \text{ if patient is black}) \\ & \times (0.742 \text{ if patient is female})\end{aligned}$$

or

$$\begin{aligned}\text{GFR (mL/min/1.73 m}^2) = {} & 186 \times [\text{serum creatinine (}\mu\text{mol/L)} \\ & \times 0.011312]^{-1.154} \times (\text{age})^{-0.203} \\ & \times (1.210 \text{ if patient is black}) \\ & \times (0.742 \text{ if patient is female})\end{aligned}$$

Many publications subsequently highlighted the critical susceptibility of the MDRD equation to the bias of the creatinine assay used.[54,211,331,346] The creatinine assay used to derive the MDRD equation was a rate Jaffe method with a positive bias compared with reference creatinine assays. Increasing use of compensated and enzymatic creatinine assays and moves toward standardization of creatinine assays would have limited the accuracy and wider use of the MDRD equation. Subsequently, therefore, the equation has been indirectly restandardized against an IDMS assay, using a Roche enzymatic assay as the reference method.[176,177] In practice, this just required the substitution of a different constant factor.

$$\begin{aligned}\text{GFR (mL/min/1.73 m}^2) = {} & 175 \times [\text{serum creatinine (mg/dL)}]^{-1.154} \\ & \times (\text{age})^{-0.203} \times (1.210 \text{ if patient is black}) \\ & \times (0.742 \text{ if patient is female})\end{aligned}$$

or

$$\text{GFR (mL/min/1.73 m}^2) = 175 \times [\text{serum creatinine (µmol/L)} \times 0.011312]^{-1.154} \times (\text{age})^{-0.203} \times (1.210 \text{ if patient is black}) \times (0.742 \text{ if patient is female})$$

In the United States, the National Kidney Disease Education Program (NKDEP) has recommended that laboratories should use the form of the equation with the constant factor 175 or 186 depending on whether their creatinine assay is, or is not, calibrated to an IDMS reference method, respectively (see www.nkdep.nih.gov). In the United Kingdom, it has been recommended that all laboratories should use the IDMS-traceable version of the MDRD equation to estimate GFR, wherever possible using creatinine assays that are specific and zero biased compared with IDMS (e.g., enzymatic assays) and calibrated to a standardized reference material.[216] When such assays are not used, appropriate assay-specific adjustment factors should be employed to minimize between-laboratory variation (e.g., those provided by the U.K. National External Quality Assessment Scheme; www.birminghamquality.org.uk).[160] As discussed previously, during 2009 most clinical laboratory methods moved to calibration that was traceable to an IDMS reference measurement procedure.[204,205] Consequently, most laboratories should now be able to use the IDMS-traceable version of the MDRD equation.[176,177]

Generally, studies have confirmed that the MDRD equation provides a more accurate assessment of GFR than the Cockcroft and Gault equation,[91,246] including among diabetic patients with moderate to severe CKD,[264] although the differences are somewhat marginal and are not universally observed.[163] The most important advantage of the MDRD equation, however, remains its practical advantage of reliance only on readily available data.

However, the MDRD equation is not without its limitations. At higher values of GFR, it shows significant negative bias[246,274] and poor precision[91] compared with reference GFR techniques—a particular limitation in monitoring early diabetic nephropathy.[84,269] Evaluation in older people and South Asians has been limited,[164] and refinements of the equation may be required among Chinese populations.[186,355] Because of its poorer performance at higher values of GFR, several national societies and expert groups have recommended that numeric values of GFR should be reported only up to 60 mL/min/1.73 m^2 using the MDRD equation.[192,212,285] The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) has described an equation including log serum creatinine (modeled as a two-slope linear spline with gender-specific knots at creatinine concentrations of 0.9 and 0.7 mg/dL [80 and 62 µmol/L] in males and females, respectively), gender, race, and age on the natural scale.[180] This equation shows reduced bias compared with reference GFR measurements at higher values of GFR, and it has been suggested that the equation should replace the MDRD equation for clinical use.

Serum creatinine is an imperfect marker of GFR; therefore it is not altogether surprising that equations based predominantly upon it are imperfect. Their use cannot circumvent the very significant spectral interferences affecting serum creatinine measurement (i.e., hemolysis, icterus, and lipemia), and the equations are unsuitable for use in patients with AKI, in whom serum creatinine concentrations may change rapidly. In situations where the normal relationship between muscle mass and body size is disturbed, the equations will be inaccurate (e.g., among body builders, amputees, and people with muscle wasting disorders). Notwithstanding this, in general, equations improve the estimation of GFR compared with serum creatinine alone. Future developments could include the use of cystatin C (see later) and creatinine in combination in GFR estimating equations, possibly with the addition of other markers.

Cystatin C (and Other Low Molecular Weight Proteins)

Several proteins with molecular weights of less than 30 kDa are primarily cleared from the circulation by renal filtration and can be considered to be relatively freely filtered at the glomerulus. These include (1) α_2-microglobulin, (2) RBP, (3) α_1-microglobulin, (4) β-trace protein,[256] and (5) cystatin C. These proteins are filtered at the glomerulus, then are reabsorbed (and metabolized) in the proximal tubule or excreted into the urine; thus they are entirely eliminated from the circulation. Therefore they have the potential to meet the criteria for use as a marker of GFR. However, most of these have been shown to have serum concentrations that are influenced by other, nonrenal factors such as inflammation (α_2-microglobulin) and liver disease (RBP, α_1-microglobulin).[10] The relationship between circulating concentrations of these proteins shows the same curvilinear form as serum creatinine, but several groups have demonstrated that cystatin C measurement may offer a more sensitive and specific means of monitoring changes in GFR than serum creatinine.[79,104,158,223]

Cystatin C is a low molecular weight (12.8 kD) protein synthesized by all nucleated cells whose physiologic role is that of a cysteine protease inhibitor.[220] With regard to renal function, its most important attributes are its small size and high isoelectric point (pI 9.2), which enable it to be more freely filtered than previously mentioned proteins at the glomerulus.[104] The gene has been sequenced, and the promoter region has been identified as that of the housekeeping type, with no known regulatory elements. Consequently, the production rate of cystatin C has always been considered to be constant,[1] although several publications suggest an influence of thyroid hormone.[62,90,139] Serum concentrations of cystatin C appear to be relatively unaffected by muscle mass, diet, or gender.[158] No extrarenal routes of elimination are known; clearance from the circulation occurs only by glomerular filtration.[104,136,317]

Cystatin C can be measured by immunodiffusion or rocket electroimmunoassay, but the methods are too insensitive, and any form of labeled immunometric assay is too cumbersome and time-consuming for the response time required. The most practical approaches described are use of a latex particle–enhanced turbidimetric or nephelometric immunoassay; several commercial cystatin C methods are available,

including automated applications.[83] An intra-assay precision of less than ±3% can be expected at the upper limit of the reference interval (≈1.00 mg/L), with less than ±4% for the between-day value.[79,158,223,305] Further, cystatin C measurement appears resistant to spectral interferences affecting creatinine assays.[305]

Several reports have documented the correlation between serum cystatin C and creatinine (as a reciprocal), and GFR as assessed by ^{51}Cr-EDTA clearance or using a number of alternative exogenous markers. In almost all studies, the correlation of GFR with cystatin C is superior to that with creatinine.[250] Kyhse-Andersen and associates[158] first demonstrated, using receiver operator analysis, the superiority of cystatin C measurement compared with creatinine for the detection of kidney disease (Figure 25-8); this has been confirmed by meta-analysis.[65]

A further summary receiver operator curve meta-analysis showed an area under the curve of 0.95 for cystatin C and 0.91 for creatinine (P = 0.003).[167] Perhaps more critically, Newman and colleagues found that, in a group of patients with a range of GFRs, the cystatin C concentration increased sooner than creatinine as GFR declined; cystatin C concentration started to increase as GFR fell below about 80 mL/min/1.73 m^2 compared with about 40 mL/min/1.73 m^2 for serum creatinine.[223] Cystatin C therefore is especially useful when the clinician is trying to detect mild to moderate impairment of kidney function.[27,51]

With the emergence of GFR as the primary criterion in the classification of CKD, several authors have developed GFR estimating equations that use cystatin C.[120,166,170,302,341] The equation of Grubb and coworkers was developed in a large patient cohort using an iohexol reference procedure; overall, its performance was only marginally better than that of the MDRD equation[105]:

$$\text{GFR} = 84.69 \times \text{Cystatin C} - 1.680 \ (\times 0.948 \text{ if female})$$

Before now, there has been no international standardization of cystatin C measurement, although efforts are under way to address this.[24] This has limited the generalizability of cystatin C–based GFR estimating equations.

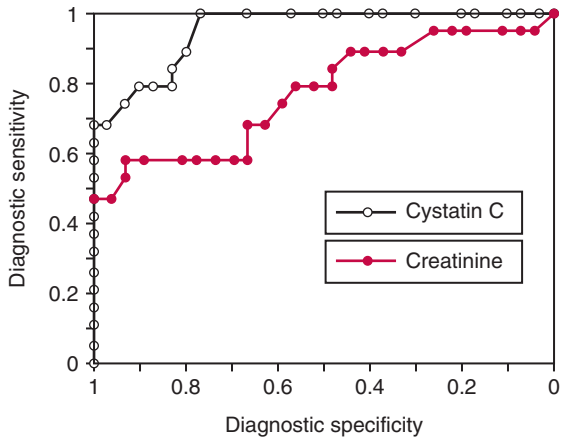

Figure 25-8 Receiver operating characteristic (ROC) curves comparing creatinine and cystatin C in the assessment of glomerular filtration rate (GFR). Nonparametric ROC plots were constructed to assess the diagnostic accuracy of serum concentrations of cystatin C and creatinine in distinguishing between normal and reduced GFR (<80 mL/min per 1.73 m^2) in 51 patients with various renal conditions. *(From Kyhse-Andersen J, Schmidt C, Nordin G, et al. Serum cystatin C, determined by a rapid, automated particle-enhanced turbidimetric method, is a better marker than serum creatinine for glomerular filtration rate. Clin Chem 1994;40:1921.)*

Assessment of Kidney Function at the Extremes of Age

As discussed previously in this chapter, current widely used markers of GFR are imperfect, and the limitations of these tests are accentuated in both pediatric and older populations. At birth, serum creatinine concentrations approximate those of the maternal circulation. Serum creatinine concentrations fall rapidly during the neonatal period, with slower falls observed in premature infants.[271] Serum creatinine concentrations are lower in infants than in adults, despite their lower GFR, reflecting the lower muscle mass (decreased creatinine production rate). The percentage of measured creatinine due to noncreatinine chromogen interference in Jaffe methods is proportionally increased in children, although compensatory adjustments applied to adult samples are probably inappropriate in children, for example, because of their lower total protein concentrations.[49] In the setting of pediatric intensive care medicine, the usefulness of serum creatinine may be further limited by analytical interferences caused by high concentrations of bilirubin and competition with creatinine for tubular secretion by commonly used antibiotics (e.g., trimethoprim, cimetidine). By contrast, serum cystatin C concentrations in infants appear to more closely reflect GFR, being increased in the first 3 months of life and then falling to approximate adult concentrations by age 1 year (Figure 25-9).[25,80]

Further, the diagnostic accuracy of cystatin C for reduced GFR is superior to that of creatinine in children.[115,350] As in adults, equations have been developed to enable GFR estimation in children based predominantly on height and serum creatinine measurement.[58,282] The Schwartz equation has been updated for use with an IDMS-traceable enzymatic creatinine assay. Further, a newly developed "CKiD" study equation has been developed that includes both serum cystatin C and creatinine, in addition to urea, height, and gender.[283] This new equation appears to be more accurate than either version of the original Schwartz equation.

Serum creatinine concentrations in healthy older people are not dissimilar to those in younger people, except among nonagenarians and centenarians, despite the decrease in GFR that occurs, on average, with aging.[322] Possible reasons for this include reduced muscle mass and poorer nutrition. Whatever the reason, the same concentration of serum creatinine may indicate very different degrees of kidney function in younger and older people, and a normal serum creatinine

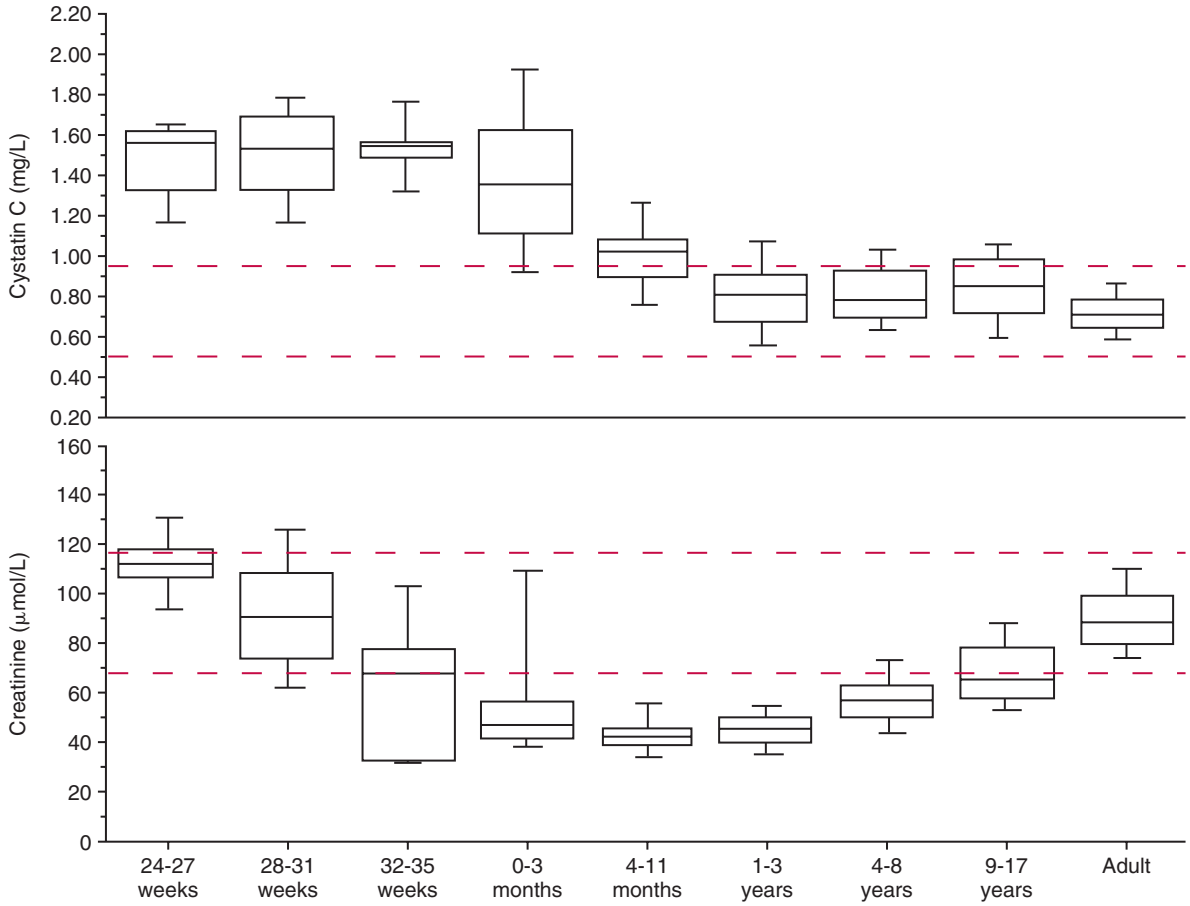

Figure 25-9 Age-related changes in cystatin C and creatinine superimposed upon the reference interval *(horizontal dashed lines)*. Box and Whiskers plot: the box represents the 25th to 75th percentiles with a horizontal line at the median; the whiskers extend to the highest and lowest values. *(From Newman DJ. Cystatin C. Ann Clin Biochem 2002;39:89-104.)*

concentration cannot exclude significant renal impairment. In two large primary care studies,[69,314] GFRs less than 50 mL/min estimated using the Cockcroft and Gault equation were common in patients with normal serum creatinine. This was most pronounced in older age groups (e.g., discordance between normal serum creatinine and reduced GFR was observed in 47% of patients aged 70 years or older, compared with 1.2% of patients aged 40 to 59 years[69]), and the sensitivity of serum creatinine for detecting severely reduced GFR (<30 mL/min/1.73 m^2) was only 46%.[314] As observed in children, serum cystatin C, however, does appear to reflect the age-related decline in kidney function[78,333] and appears to be more sensitive than serum creatinine for detection of reduced GFR.[82,229]

ACKNOWLEDGMENTS

Data on current creatinine method usage in the United Kingdom were provided by Finlay Mackenzie from the United Kingdom National External Quality Assessment Scheme, Birmingham, United Kingdom. Further information about the UKNEQAS estimated GFR scheme may be found at www.biminghamquality.org.uk/accessed May 5, 2011. We are grateful to the College of American Pathologists for data on current creatinine method usage in the United States (www.cap.org/accessed May 5, 2011).

CHAPTER 26

Carbohydrates

*David B. Sacks, M.B., Ch.B., F.R.C.Path.**

Carbohydrates, including sugars and starches, are widely distributed in plants and animals. They perform multiple functions, ranging from being structural components of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) (*ribose* and *deoxyribose* sugars) to serving as sources of energy *(glucose).* Glucose is derived from the breakdown of carbohydrates in the diet (grains, starchy vegetables, and legumes) and in body stores (glycogen), and by endogenous synthesis from protein or from the glycerol moiety of triglycerides. When energy intake exceeds expenditure, the excess is converted to fat and glycogen for storage in adipose tissue and liver or muscle, respectively. When energy expenditure exceeds calorie intake, endogenous glucose formation occurs from the breakdown of carbohydrate stores and from noncarbohydrate sources (e.g., amino acids, lactate, glycerol).

The glucose concentration in the blood is maintained within a fairly narrow interval under diverse conditions (feeding, fasting, or severe exercise) by hormones, such as insulin, glucagon, or epinephrine.

Measurement of glucose is one of the most commonly performed analytical procedures. The most frequently encountered disorder of carbohydrate metabolism is high blood glucose concentrations caused by diabetes mellitus, which affects approximately 9% of the U.S. adult population. The incidence of hypoglycemia (low blood glucose) is unknown, but, excluding patients who use exogenous insulin to control blood glucose, it is low.

CHEMISTRY OF CARBOHYDRATES

Carbohydrates are aldehyde or ketone derivatives of polyhydroxy (more than one —OH group), alcohols, or compounds that yield these derivatives on hydrolysis. The term *carbohydrate* refers to hydrates of carbon and is derived from the observation that empirical formulas for these compounds contain approximately one molecule of water per carbon atom. Thus glucose, $C_6H_{12}O_6$, and lactose, $C_{12}H_{22}O_{11}$, are written as $C_6(H_2O)_6$ and $C_{12}(H_2O)_{11}$, respectively. These compounds are not hydrates in the usual chemical sense, however, and noncarbohydrate compounds, such as lactic acid, $CH_3CH(OH)COOH$ or $C_3(H_2O)_3$, can have similar empirical formulas.

Monosaccharides

Monosaccharides, or simple sugars, consist of a single polyhydroxy aldehyde or ketone unit and cannot be hydrolyzed to a simpler form. The backbone is made up of a number of carbon atoms. Sugars containing three, four, five, six, and seven carbon atoms are known as *trioses, tetroses, pentoses, hexoses,* and *heptoses,* respectively. One of the carbon atoms is double bonded to an oxygen atom to form a carbonyl group. An *aldehyde* has the carbonyl group at the end of the carbon chain, whereas if the carbonyl group is at any other position, a *ketone* is formed (Figure 26-1). The simplest carbohydrate is glycol aldehyde, the aldehyde derivative of ethylene glycol. The aldehyde and ketone derivatives of glycerol are, respectively, glyceraldehyde and dihydroxyacetone (see Figure 26-1). Monosaccharides are termed *aldose* or *ketose,* according to the position of the carbonyl group (Figure 26-2).

Compounds that are identical in composition and differ only in spatial configuration are called *stereoisomers.* The carbon atoms in the unbranched chain are numbered, as shown by the numbers at the left of the formula for D-glucose (see Figure 26-2). The designation D or L refers to the position of the hydroxyl group on the carbon atom adjacent to the last (bottom) CH_2OH group. In general, the designation of D or L for a sugar molecule refers to the stereoisomeric forms of the highest-numbered asymmetric carbon atom.* By convention, the D-sugars are written with the hydroxyl group on the right, and the L-sugars are written with the hydroxyl group on the left (see Figure 26-2). Most sugars in the human body are of the D-configuration. Several different structures exist, depending on the relative positions of the hydroxyl groups on the carbon atoms.

*The author gratefully acknowledges the original contributions by Drs. Wendell T. Caraway and Nelson B. Watts on which portions of this chapter are based.

*Although the D and L designations are retained in this chapter, readers should be aware that in the Cahn-Ingold-Prelog system, a series of sequence rules determine configurations. In this system, the symbols R and S are used to designate configurations instead of D and L.

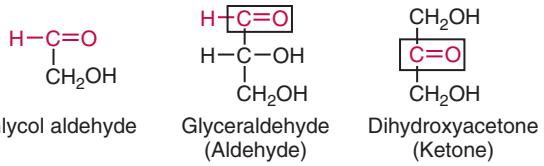

Figure 26-1 Two- and three-carbon carbohydrates.

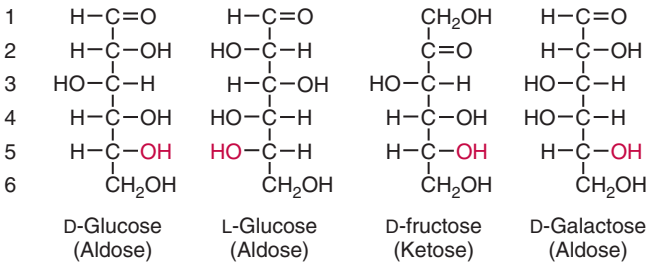

Figure 26-2 Typical six-carbon sugars.

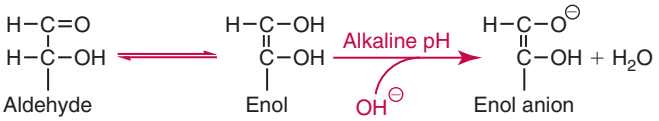
The formula for glucose can be written in the form of aldehyde or enol, a short-lived reactive species. Shift to the enol anion is favored in alkaline solution.



The presence of a double bond and a negative charge in the enol anion makes glucose an active reducing substance that is oxidized by relatively mild oxidizing agents, such as cupric (Cu^{2+}) and ferric (Fe^{3+}) ions. Glucose in hot alkaline solution readily reduces cupric ions to cuprous ions, and the carbonyl carbon is oxidized to carboxylic acid. The color change has been used as a presumptive indication for the presence of glucose, and for many years blood and urine glucose were measured this way. Other sugars reduce cupric ions in alkaline solution.

Aldehyde and alcohol groups react to form hemiacetals. In the case of glucose, the aldehyde group reacts with the hydroxyl group on carbon 5 (Figure 26-3). Note that this ring structure contains an additional asymmetric carbon atom and exists in two stereoisomeric forms. By convention, the form with the hydroxyl group on the right of the first carbon atom is called α-D-glucose, and the form with the hydroxyl group on the left is called β-D-glucose. The common anhydrous crystalline glucose is in the α-D-form. The β-D-form is obtained by crystallization from acetic acid. The two forms differ with respect to optical rotation of polarized light. The specific rotation—$[\alpha]_D^{25\,^\circ C}$—for the α-D-form is +113°, and for the β-D-form is +19.7°. As a result of mutarotation, either form in aqueous solution gives rise to an equilibrium mixture that has a specific rotation of +52.5°. The equilibrium established at room temperature is such that about 36% of glucose

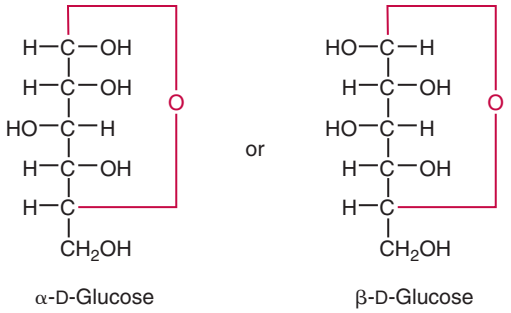


Figure 26-3 Structure of D-glucose (hemiacetal form).

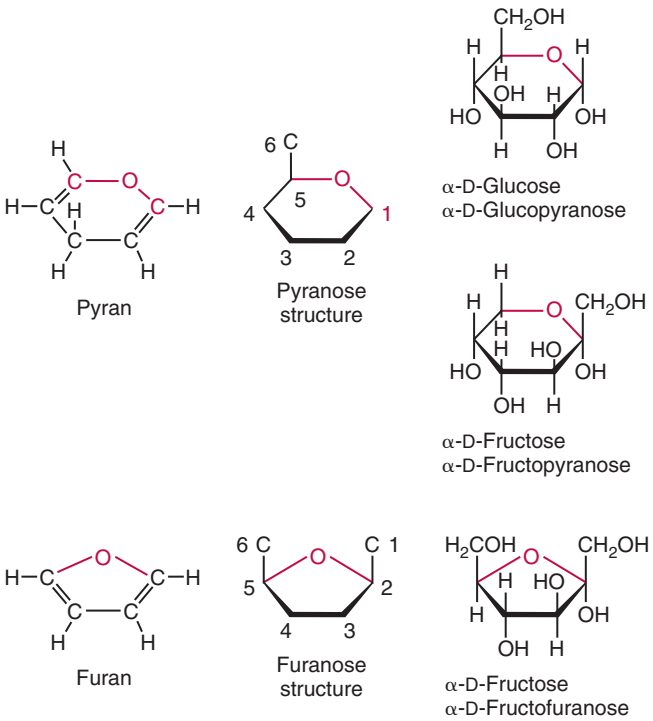

Figure 26-4 The Haworth formula for sugars.

exists in the α-form and 64% in the β-form; only a trace remains in the free aldehyde form. The enzyme glucose oxidase reacts only with β-D-glucose. For this reason, calibrating solutions to be used in glucose oxidase methods for glucose determinations should be permitted to stand at least 2 hours to obtain equilibrium comparable with that in the test samples to be analyzed.

From the ring structures shown in Figure 26-3, it is not apparent why the aldehyde group should react with the distant hydroxyl group on carbon 5. The spatial arrangement of the atoms is better represented by a symmetric ring structure, depicted by the Haworth formula, in which glucose is considered as having the same basic structure as pyran (Figure 26-4). In this formula, the plane of the ring is considered to be perpendicular to the plane of the paper, with heavy lines pointing toward the reader. Hydroxyl groups in position 1 are then below the plane (α-configuration) or above the plane (β-configuration). A six-member ring sugar, containing five carbons and one oxygen, is a derivative of pyran and is

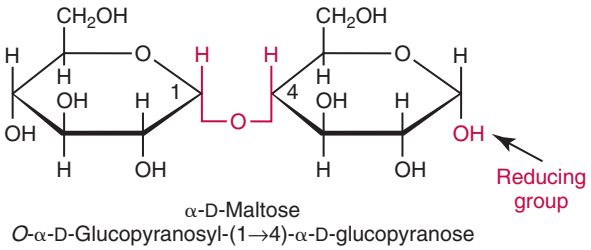
called a *pyranose.* When linkage occurs with formation of a five-member ring, containing four carbons and one oxygen, the sugar has the same basic structure as furan and is called a *furanose.* Representative formulas are shown in Figure 26-4. Fructose is shown in two cyclic forms. Fructopyranose is the configuration of free sugar, and fructofuranose occurs whenever fructose exists in combination in disaccharides and polysaccharides, as in sucrose and inulin.

Disaccharides

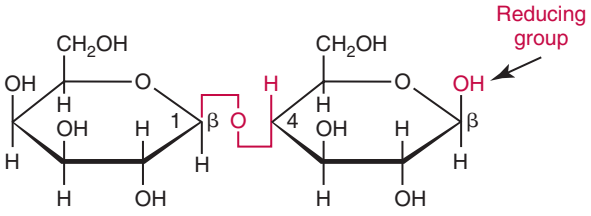
Two monosaccharides join covalently by an *O-glycosidic bond,* with the loss of a molecule of water, to form a disaccharide. The chemical bond between the sugars always involves the aldehyde or ketone group of one monosaccharide joined to an alcohol group (e.g., maltose) or to an aldehyde or ketone group (e.g., sucrose) of the other monosaccharide. The most common disaccharides are the following:

Maltose = Glucose + Glucose
Lactose = Glucose + Galactose
Sucrose = Glucose + Fructose

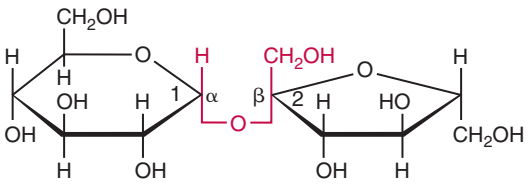
Several conventions are followed in the nomenclature of disaccharides (Figure 26-5). The compound is written with the nonreducing end to the left. An *O* precedes the name of the first (left) monosaccharide, emphasizing that the linkage occurs by an oxygen atom. The configuration of the anomeric (carbonyl) carbon is designated α or β. Five- (furanosyl) and six- (pyranosyl) membered rings are distinguished, and carbon atoms joined by the glycosidic bond are identified. Because sucrose has no reducing end, it is written as *O*-α-D-glucopyranosyl-(1 → 2)-β-D-fructofuranose or *O*-β-D-fructofuranosyl-(2 → 1)-α-D-glucopyranose. If the linkage between two monosaccharides is between the aldehyde or ketone group of one molecule and a hydroxyl group of another molecule (as in maltose and lactose), one potentially free ketone or aldehyde group remains on the second monosaccharide. Consequently, the second glucose residue can be oxidized (thus the disaccharide is a reducing sugar) and is capable of existing in α- or β-pyranose form. The reducing power, however, is only approximately 40% of the reducing power of the two single monosaccharides added together, primarily because one of the reducing groups is not available. On the other hand, if the linkage between two monosaccharides involves the aldehyde or ketone groups of both molecules (as in sucrose), a nonreducing sugar results because no free aldehyde or ketone group remains.



α-D-Maltose
O-α-D-Glucopyranosyl-(1→4)-α-D-glucopyranose



β-D-Lactose
O-β-D-Galactopyranosyl-(1→4)-β-D-glucopyranose



Sucrose
O-α-D-Glucopyranosyl-(1→2)-β-D-fructofuranose

Figure 26-5 Structural formulas of disaccharides.

Polysaccharides

The linkage of multiple monosaccharide units results in the formation of polysaccharides. The major storage carbohydrates are *starch* in plants and *glycogen* in animals, both of which form granules inside cells. The suffix *-an* attached to the name of a monosaccharide indicates the main type of sugar present in the polysaccharide. Starch and glycogen, for example, are *glucosans,* because they are composed of a series of glucose molecules. Inulin, a polysaccharide found in the tubers of certain plants, consists largely of fructose units and is known as a *fructosan.*

Nearly all starches consist of a mixture of two types of glucosans called *amyloses* and *amylopectins.* The relative proportions of these two glucosans in a starch vary from approximately 20% amylose and 80% amylopectin in wheat, potato, and ordinary corn starch to nearly 100% amylopectin in the starch of waxy corn. On the other hand, a few corn starches are known to contain as much as 75% amylose. Both amylose and amylopectin consist of glucose residues, but their structures exhibit one significant difference. Amylose consists of one long unbranched chain of glucose units linked together by α-1,4-linkages with only the terminal aldehyde group free (Figure 26-6). In amylopectin, most of the units are similarly connected with α-1,4-links, but α-1,6-glycosidic bonds are present every 24 to 30 residues, producing sidechains (see Figure 26-6). Amylopectin contains up to 1 million glucose residues. The structure of glycogen is similar to that of amylopectin, but branching is more extensive in glycogen and occurs every 8 to 12 glucose residues. These branches enhance the solubility of glycogen and allow the glucose residues to be mobilized more readily. Glycogen is most abundant in liver and is found in skeletal muscle as well. The most favorable conformation for α-1,4-linked polymers of D-glucose, such as starch or glycogen, is a tightly coiled helical structure.

The difference in structure between amylose and amylopectin is important when the appropriate starch substrate is selected for amylase determinations (see Chapter 22). The

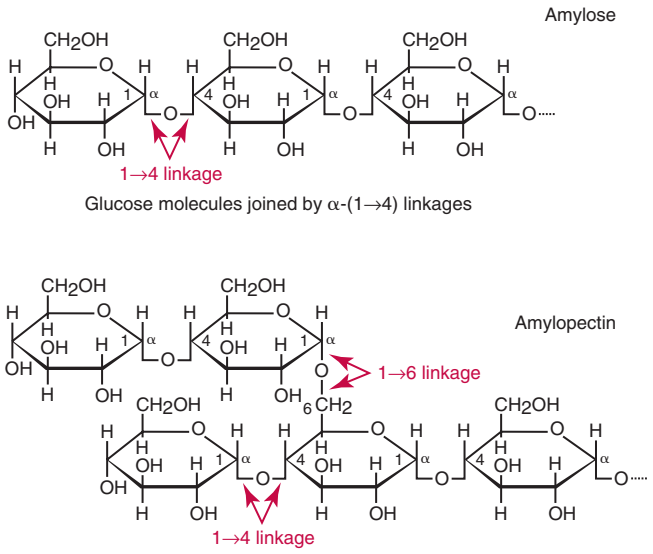


Figure 26-6 Structures of the polysaccharides amylose and amylopectin.

rate of hydrolysis is affected by structural differences in the starch. α-Amylase from the pancreas hydrolyzes internal α-1,4-glycosidic linkages. This hydrolysis results initially in the production of some maltose and a mixture of dextrins, which subsequently are hydrolyzed to maltose. The β-1,6-linkages are not attacked by α-amylase, and relatively large molecules of so-called residual (limit) dextrins are left after the action of the enzyme on amylopectin. *Dextrins* are the products of partial hydrolysis of starch. They are a complex mixture of molecules of different sizes. Those formed from amylose are unbranched chains, whereas amylopectins produce branched chains of glucose molecules. *Cellulose,* an important structural polysaccharide in plants, is an unbranched polymer of glucose residues joined by β-1,4-linkages. The β-configuration facilitates the formation of long straight chains, producing fibers of high tensile strength. The β-1,4-linkages are not hydrolyzed by α-amylases. Because humans do not have *cellulases,* they are unable to digest vegetable fiber.

Chitin, the principal component of the exoskeleton of arthropods (insects and crustacea), consists of *N*-acetyl-D-glucosamine residues in a β-1,4-linkage. The only chemical difference from cellulose is that the substituent at C-2 is an acetylated amino group instead of a hydroxyl group.

Glycoproteins

Glycosylation is one of the most frequent enzymatic modifications of proteins. Many integral membrane proteins have oligosaccharides covalently attached to the extracellular region, forming *glycoproteins.* In addition, most proteins that are secreted, such as antibodies, hormones, and coagulation factors, are glycoproteins. The number of attached carbohydrates varies among proteins and constitutes 1 to 70% of the weight of the glycoprotein. The oligosaccharides are attached by *O*-glycosidic linkages to the sidechain oxygen of serine

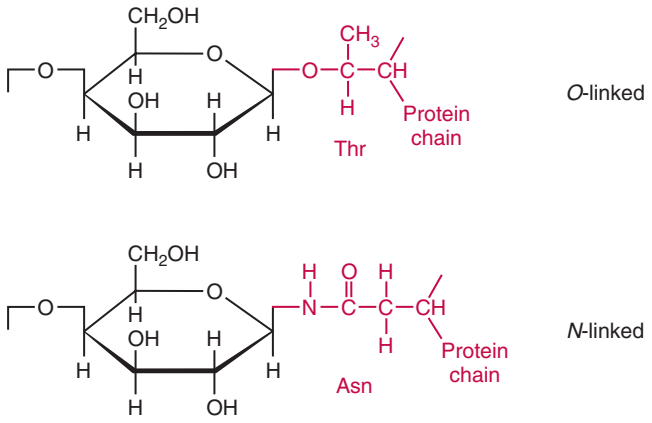

Figure 26-7 Glycosidic linkages between oligosaccharides and protein.

and/or threonine residues or by *N*-glycosidic linkages to the sidechain nitrogen of asparagine residues (Figure 26-7).

One of the biological functions of the carbohydrate chains is to regulate the life span of proteins. For example, removal of sialic acid residues from the end of oligosaccharide chains on erythrocytes results in the disappearance of red blood cells from the circulation. Carbohydrates have also been implicated in cell-cell recognition, and in secretion and targeting of proteins to specific subcellular domains. Defects in protein glycosylation have been linked to several forms of congenital muscular dystrophy that are associated with brain abnormalities.[53]

METABOLISM OF CARBOHYDRATES

Carbohydrate metabolism provides glucose, the primary energy source for the human body. After digestion of carbohydrates and absorption of glucose, blood glucose concentration is controlled by the action of several hormones. Glucose is synthesized de novo or stored in the tissue as glycogen.

Digestion and Absorption

Ingested starch and glycogen are partially digested by the action of salivary amylase in the mouth to form intermediate dextrins and maltose (see Chapter 51). The acid pH of the stomach inhibits amylase activity, but alkaline pancreatic secretions increase the pH in the small intestine, allowing pancreatic amylase to complete digestion to oligosaccharides, preponderantly maltose. Maltose, along with any ingested lactose and sucrose, is hydrolyzed by the appropriate disaccharidase (*maltase, lactase,* or *sucrase*) from the intestinal mucosa to glucose, galactose, and fructose.

These monosaccharides are absorbed across the wall of the duodenum and ileum by an active, energy-requiring, carrier-mediated transfer process. The rate of absorption for glucose and galactose is several times greater than for similar molecules absorbed by passive diffusion (e.g., xylose). Some conversion of fructose to glucose may occur during the process of absorption, and the interconversion can be visualized in terms of the enediol form common to both (Figure 26-8).

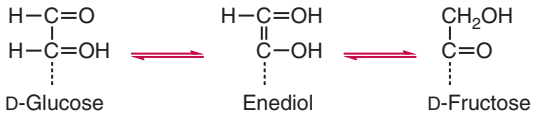

Figure 26-8 Interconversion of glucose and fructose.

Fructose is absorbed more slowly than glucose and galactose by a carrier-mediated process different from glucose and galactose transport mechanisms. The monosaccharides are then transported by the portal vein to the liver.

Intermediary Metabolism

The metabolism of hexoses proceeds according to the body's requirements. This results in (1) energy production by conversion to carbon dioxide and water, (2) storage as glycogen in the liver or as triglyceride in adipose tissue, or (3) conversion to keto acids, amino acids, or protein.

Some steps in the intermediary metabolism of glycogen and hexoses are shown in Figure 26-9. Each step is catalyzed by enzymes. In some cases, different enzymes are responsible for the forward and reverse reactions. For example, the initial phosphorylation of glucose is mediated by glucokinase, but the reverse reaction depends on glucose-6-phosphatase.

Various inborn errors of metabolism (Table 26-1) result from deficiencies or absence of some of the enzymes listed in Figure 26-9. Some of these are discussed later in the chapter. The relationship of carbohydrate metabolism to the production of lactate, ketone bodies, and triglycerides is also depicted in Figure 26-9. The pentose phosphate pathway, also known as the *hexose monophosphate shunt,* is an alternative pathway for glucose metabolism that generates the reduced form of nicotinamide-adenine dinucleotide phosphate (NADPH), which is used in maintaining the integrity of red blood cell membranes, in lipid and steroid biosynthesis, in hydroxylation reactions, and in other anabolic reactions. The complete picture of intermediary metabolism of carbohydrates is complex and is interwoven with the metabolism of lipids and amino acids. For details, readers should consult a biochemistry textbook.

Regulation of Blood Glucose Concentration

The concentration of glucose in the blood is regulated by the complex interplay of multiple pathways, modulated by a number of hormones. *Glycogenesis* is the conversion of glucose to glycogen. The reverse process, namely, the breakdown of glycogen to glucose and other intermediate products, is termed *glycogenolysis.* The formation of glucose from noncarbohydrate sources, such as amino acids, glycerol, or lactate, is termed *gluconeogenesis.* The conversion of glucose or other hexoses into lactate or pyruvate is called *glycolysis.* Further oxidation to carbon dioxide and water occurs through the Krebs (citric acid) cycle and the mitochondrial electron transport chain coupled to oxidative phosphorylation, generating energy in the form of adenosine triphosphate (ATP). Oxidation of glucose to carbon dioxide and water also occurs through the hexose monophosphate shunt pathway, which produces NADPH. Discussion of the hormones that regulate blood glucose is provided in Chapter 46.

TABLE 26-1 Inborn Errors of Carbohydrate Metabolism

Enzyme Deficiency	Disease State
Glucose-6-phosphatase (9)*	Type I GSD (von Gierke disease)
Muscle phosphorylase	Type V GSD (McArdle's disease)
Liver phosphorylase	Type VI GSD (Hers' disease)
Galactose-1-phosphate-uridyl transferase (2)	Galactosemia
Galactokinase (1)	Galactosemia
Uridine diphosphate-galactose-4-epimerase (3)	Galactosemia
Fructokinase (19)	Essential fructosuria
Fructose-1-phosphate aldolase (20)	Hereditary fructose intolerance
Pyruvate kinase (23)	Hemolytic anemia
Glucose-6-phosphate dehydrogenase (10)	Hemolytic disease

*Numbers in parentheses refer to enzymes in Figure 26-9.
GSD, Glycogen storage disease.

HYPOGLYCEMIA

Hypoglycemia is a blood glucose concentration below the fasting value, but it is difficult to define a specific limit.[73] The most widely suggested cutoff is 50 mg/dL, but some authors suggest 60 mg/dL.[8] A transient decline may occur 1.5 to 2 hours after a meal, and it is not uncommon for a plasma glucose concentration as low as 40 mg/dL to be observed 2 hours after ingestion of an oral glucose load. Similarly, extremely low fasting blood glucose values may occasionally be noted without symptoms or evidence of underlying disease. Hypoglycemia is rare in patients who do not have drug-treated diabetes mellitus.[19]

Symptoms of hypoglycemia vary among individuals, and none is specific. Epinephrine produces the classic signs and symptoms of hypoglycemia, namely, (1) trembling, (2) sweating, (3) nausea, (4) rapid pulse, (5) lightheadedness, (6) hunger, and (7) epigastric discomfort. These autonomic (neurogenic) symptoms are nonspecific and may be noted in other conditions, such as hyperthyroidism, pheochromocytoma, or even anxiety. Although controversial, it has been proposed that a rapid decrease in blood glucose may trigger the symptoms even though the blood glucose itself may not reach hypoglycemic values, whereas gradual onset of hypoglycemia may not produce symptoms.[25]

The brain cannot store or produce glucose, and in resting adults the central nervous system (CNS) consumes approximately 50% of the glucose used by the body.[31] Very low concentrations of plasma glucose (<20 or 30 mg/dL) cause severe

CNS dysfunction. During prolonged fasting or hypoglycemia, ketones may be used as an energy source. The broad spectrum of symptoms and signs of CNS dysfunction range from headache, confusion, blurred vision, and dizziness to seizures, loss of consciousness, and even death; these symptoms are known as *neuroglycopenia.* Restoration of plasma glucose usually produces a prompt recovery, but *irreversible damage may occur.*

The age of onset of hypoglycemia is a convenient way to classify the disorder (Box 26-1), but it should be borne in mind that some overlap occurs among the various groups. For example, some glycogen storage disorders may present in the third decade of life, and hormone deficiencies occur in childhood.

Hypoglycemia in Neonates and Infants

Neonatal blood glucose concentrations are much lower than adult concentrations (mean <35 mg/dL) and decline shortly after birth when liver glycogen stores are depleted. Glucose concentrations as low as 30 mg/dL in a term infant and 20 mg/dL in a premature infant may occur without clinical evidence of hypoglycemia. The more common causes of hypoglycemia in the neonatal period include prematurity, maternal diabetes, gestational diabetes mellitus (GDM), and maternal eclampsia (see Box 26-1; for review, see Haymond).[33] These are usually transient. Hypoglycemia with onset in early infancy is usually less transitory and may be due to inborn errors of metabolism or ketotic hypoglycemia; it usually occurs after fasting or a febrile illness.

Fasting Hypoglycemia in Adults

Hypoglycemia may result from a *decreased* rate of hepatic glucose production or an increased rate of glucose use. Symptoms suggestive of hypoglycemia are fairly common, but hypoglycemic disorders are rare. However, true hypoglycemia usually indicates serious underlying disease and may be life threatening. A precise threshold for establishing hypoglycemia is not always possible, and values as low as 30 mg/dL may be encountered in healthy premenopausal women after a 72-hour fast.[54] Symptoms usually begin at plasma glucose concentrations below 55 mg/dL, and impairment of cerebral function begins when glucose is less than 50 mg/dL.

More than 100 causes of hypoglycemia have been reported. Some of the more common conditions are listed in Box 26-1. Drugs are the most prevalent cause,[72] and a wide variety, including pentamidine, gatifloxacin, and quinine, can produce hypoglycemia. Oral hypoglycemic agents, which have a long half-life (35 hours for chlorpropamide), are the most frequent cause of drug-induced hypoglycemia. Sulfonylureas stimulate secretion of insulin, proinsulin, and C-peptide, and may mimic an insulinoma. Differentiation is made by demonstration of the drug in blood or urine. Surreptitious administration of insulin can be detected by finding low C-peptide concentrations with increased insulin concentrations.

Ethanol produces hypoglycemia by inhibiting gluconeogenesis, and this is aggravated by malnutrition (low glycogen stores) in patients with chronic alcoholism. Decreased glucose production in *hepatic failure* (e.g., viral hepatitis, toxins) caused by impaired gluconeogenesis or glycogen storage may result in hypoglycemia. Because dysfunction of more than 80% of the liver is necessary for hypoglycemia to develop, evidence of liver disease is invariably present. Deficiency of *growth hormone* (especially with coexistent ACTH deficiency), glucocorticoids, thyroid hormone, or glucagon may also produce hypoglycemia. Although a deficiency of glucocorticoids (e.g., Addison's disease) is most consistently associated with hypoglycemia, most glucocorticoid-deficient adults

BOX 26-1 Causes of Hypoglycemia

Neonates
- Small for gestational age/prematurity
- Respiratory distress syndrome
- Maternal diabetes mellitus
- Toxemia of pregnancy
- Other (e.g., cold stress, polycythemia)

Infants
- Ketotic hypoglycemia
- Congenital enzyme defects
- Glycogen storage disease
- Deficiency of gluconeogenic enzymes
- Galactosemia
- Hereditary fructose intolerance
- Leucine hypersensitivity
- Endogenous hyperinsulinism
- Reye's syndrome
- Idiopathic

Adults

Ill or Medicated Individual
- Drugs
  - Insulin or insulin secretagogue
  - Alcohol
  - Others (quinine, indomethacin)
- Critical illness
  - Hepatic, renal or cardiac failure
  - Sepsis (including malaria)
  - Inanation
- Hormone deficiency
  - Cortisol
  - Glucagon and epinephrine

Seemingly Healthy Individual
- Endogenous hyperinsulinism
- Insulinoma
- Functional β-cell disorders
  - Noninsulinoma pancreatogenous hypoglycemia
  - Post gastric bypass hypoglycemia
  - Insulin autoimmune hypoglycemia
  - Antibody to insulin
  - Antibody to insulin receptor
  - Insulin secretagogue
  - Other
- Accidental, surreptitious or malicious hypoglycemia

are not hypoglycemic. Hormonal deficiency causes hypoglycemia in children more frequently than in adults.

Demonstration of a low plasma glucose concentration in the presence of an abnormally high plasma insulin value is highly suggestive of an insulin-producing *pancreatic islet cell tumor.*[27] Because insulin concentrations exhibit a wide range in normal people, absolute hyperinsulinemia occurs in fewer than 50% of patients with insulinomas. Serum insulin concentrations inappropriately high for concurrent plasma glucose have been proposed to increase diagnostic accuracy. Critical diagnostic findings include a plasma insulin concentration of at least 18 pmol/L, plasma C-peptide concentrations greater than or equal to 0.2 nmol/L, and plasma proinsulin concentrations of at least 5.0 pmol/L when fasting plasma glucose is below 55 mg/dL. Ratios employing insulin and glucose have no diagnostic value. Provocative tests [glucagons,[42] tolbutamide,[74] calcium,[40] or suppression tests (infusion of insulin and measurement of C-peptide)], although strongly recommended in the past, generally are not necessary. Intra-arterial calcium stimulation with right hepatic vein sampling for insulin gradients appears to be a sensitive preoperative test for localizing insulinoma, although advances in imaging are making this approach far less common.[26]

Spontaneous production of *antibodies to insulin* may produce hypoglycemia (these antibodies are distinct from those elicited by insulin therapy and from the antibodies detected in certain patients with type 1 diabetes). Anti-insulin antibodies causing hypoglycemia have been reported in Graves' disease, multiple myeloma, systemic lupus erythematosus, and rheumatoid arthritis. This disorder is reported primarily among persons of Japanese or Korean ancestry and is less frequent among whites.[19] Patients exhibit postprandial hyperglycemia and fasting hypoglycemia.[61] Laboratory analysis demonstrates low plasma C-peptide and very high plasma insulin concentrations during hypoglycemia. The high insulin concentrations are believed to be an assay artifact caused by the antibody, and diagnosis is usually made by demonstrating high-titer serum insulin antibodies.

Nonpancreatic neoplasms that cause hypoglycemia are often extremely large mesenchymal neoplasms that appear to overuse glucose but may also have an inhibitory effect on glucose mobilization. Tumors of epithelial origin may cause hypoglycemia, frequently by producing insulin-like growth factor (IGF) II.[22,75]

Hypoglycemia caused by *septicemia* should be relatively easy to diagnose.[56] The mechanism is not well defined, but depleted glycogen stores, impaired gluconeogenesis, and increased peripheral use of glucose may be contributing factors. Glucose tolerance is commonly depressed in renal disease, and hypoglycemia may occur in end-stage *renal failure.*

Some of the conditions producing fasting hypoglycemia are readily apparent, but others require a lengthy diagnostic work-up. Once hypoglycemia is demonstrated, specific tests should be performed to establish the underlying cause. The *oral glucose tolerance test (OGTT) is not an appropriate study for evaluating a patient suspected of having hypoglycemia.*[19]

Postprandial Hypoglycemia

A group of disorders may produce hypoglycemia in the postprandial (fed) state.[34] These include drugs, antibodies to insulin or the insulin receptor, and inborn errors (e.g., fructose-1,6-diphosphatase deficiency). Also included is *reactive hypoglycemia* (referred to as *functional hypoglycemia*), which has been the subject of much debate.[8] Many commentaries and editorials have been published regarding the existence of reactive hypoglycemia (Hofeldt[34] and references listed therein). The general consensus is that no scientific evidence supports the existence of "functional hypoglycemia." It has been proposed that for individuals with vague symptoms after food ingestion, the preferred terminology should be *idiopathic reactive hypoglycemia*[34] or *idiopathic postprandial syndrome.*[73]

At the Third International Symposium on Hypoglycemia,[46] reactive hypoglycemia was defined as a clinical disorder in which the patient has postprandial symptoms suggesting hypoglycemia that occur in everyday life and are accompanied by a blood glucose concentration less than 45 to 50 mg/dL as determined by a specific glucose measurement on arterialized venous or capillary blood, respectively. Patients complain of autonomic symptoms occurring approximately 1 to 3 hours after eating and seem to obtain relief, lasting 30 to 45 minutes, by food intake. These symptoms are rarely due to low blood glucose concentrations (e.g., diabetes mellitus, gastrointestinal dysfunction, hormonal deficiency states). Most of these individuals have postprandial autonomic symptoms without neuroglycopenia in the postprandial state. Some experts in the field state that no true hypoglycemic disorder is characterized solely by autonomic symptoms.[73] A 5- or 6-hour glucose tolerance test was the standard procedure to establish the presence of postprandial hypoglycemia, but its use has been discredited.[8] The test is not reproducible in any particular individual, and low values for plasma glucose may be noted in the absence of symptoms, whereas symptoms may occur with normal glucose concentrations.[15] In addition, patients who have low blood glucose concentrations with autonomic symptoms 3 or 4 hours after an oral glucose load may have identical symptoms with normal blood glucose values after a mixed meal.[15] This may be due in part to anxiety provoked by the stressful environment during the glucose tolerance test. Demonstration of increased plasma epinephrine concentrations at the glucose nadir during an OGTT was reported to differentiate patients with reactive hypoglycemia,[12] but patients studied were identified on the basis of autonomic symptoms and signs, and only 25% demonstrated hypoglycemia. The OGTT should not be used in the diagnosis of reactive hypoglycemia.[76]

Postprandial hypoglycemia is infrequent, and demonstration of hypoglycemia during spontaneously occurring symptomatic episodes is necessary to establish the diagnosis.[61] If this is not possible, a 5-hour meal tolerance test[15] (which simulates the composition of a normal diet) or a *hyperglucidic* (high glucose) breakfast test[8] has been proposed. A protocol for a mixed-meal test can be found in Cryer and associates.[19]

A diagnosis of hypoglycemia has been used to explain a wide variety of disorders that appear unrelated to blood glucose abnormalities.[11] These nonspecific symptoms include fatigue, muscle spasms, palpitations, numbness, tingling, pain, sweating, mental dullness, sleepiness, weakness, and fainting. Behavior abnormalities, poor school performance, and delinquency have been incorrectly attributed to low blood glucose concentrations. Widespread use of the insensitive and nonspecific 5-hour glucose tolerance test caused overdiagnosis of hypoglycemia and led the American Diabetes Association (ADA) to publish a statement to discourage the inappropriate use of the OGTT for the diagnosis of hypoglycemia.[76] Lay publications[78] have supported this recommendation, but it is still important for the medical community to reassure such patients that low blood glucose is not the cause of their symptoms and to deal with specific abnormalities that might underlie patients' complaints or problems. A diagnosis of hypoglycemia should not be made unless a patient meets the criteria of *Whipple's triad of low blood glucose concentration with typical symptoms alleviated by glucose administration.* Demonstration of a plasma glucose concentration >70 mg/dL during a symptomatic episode indicates that the symptoms unequivocally are not the result of hypoglycemia.

Hypoglycemia in Diabetes Mellitus

Hypoglycemia occurs frequently in both type 1 diabetes and type 2 diabetes[20,30] and is the limiting factor in glycemic management of diabetes. Patients using insulin experience approximately one to two episodes of symptomatic hypoglycemia per week, and severe hypoglycemia (i.e., requiring assistance from others or associated with loss of consciousness) affects about 10% of this population per year. In patients practicing intensive insulin therapy (e.g., multiple injections, continuous subcutaneous insulin infusion), these figures are increased twofold to sixfold. The chief adverse event associated with intensive therapy in the Diabetes Control and Complications Trial (DCCT) was a threefold increase in the incidence of severe hypoglycemia.[23] An estimated 2 to 4% of people with type 1 diabetes die from hypoglycemia.[19] Similarly, hypoglycemia occurs in patients with type 2 diabetes (caused by oral hypoglycemic agents or insulin) but is less frequent than in type 1 diabetes. Recent evidence suggests that severe hypoglycemia may have long-term sequelae, including dementia and death from cardiovascular disease. Two pathophysiologic mechanisms contribute to hypoglycemia in patients with diabetes.

Defective Glucose Counter-Regulation

Counter-regulatory responses become impaired in patients with type 1 diabetes,[20] increasing the risk of hypoglycemia. The response of glucagon to hypoglycemia is impaired by an unknown mechanism early in the course of type 1 diabetes. Epinephrine secretory response to hypoglycemia becomes deficient later in the course of the disease. These defects are selective because other stimuli continue to elicit glucagon and epinephrine secretion. Glucose counter-regulation does not appear to be defective in patients with type 2 diabetes.

Hypoglycemia Unawareness

Up to 50% of patients with long-standing (more than 30 years) type 1 diabetes do not experience neurogenic warning symptoms and are prone to more severe hypoglycemia. The mechanism is thought to be associated with a decreased epinephrine response to hypoglycemia. Intensively treated patients with type 1 diabetes require lower plasma glucose concentrations to elicit symptoms of hypoglycemia. Some authors have claimed that human insulin results in an increased incidence of hypoglycemia unawareness, but analysis of 45 studies revealed no significant differences in hypoglycemic episodes between insulin from different species.[67]

Evaluation of Hypoglycemia

The Endocrine Society recently issued guidelines for the evaluation of adult hypoglycemic disorders.[19] These guidelines were cosponsored by the American Diabetes Association, the European Association for the Study of Diabetes, and the European Society of Endocrinology. Patients should be evaluated for hypoglycemia only if Whipple's triad—symptoms and/or signs of hypoglycemia, low plasma glucose concentration, and resolution of symptoms or signs after plasma glucose is raised—is documented.

The *classic diagnostic test is the prolonged fast,* which should be conducted in a hospital.[19] During the fast, the patient should be allowed to drink calorie-free fluids. All nonessential medications should be discontinued, and patients should be active when awake. Samples should be drawn every 6 hours for analysis of plasma glucose, insulin, C-peptide, proinsulin, and β-hydroxybutyrate. When plasma glucose concentration is less than 60 mg/dL, sampling should be performed every 1 to 2 hours. Samples for plasma insulin, C-peptide, and proinsulin should be analyzed only in those samples in which the glucose concentration is <60 mg/dL. The fast should be concluded when plasma glucose concentration falls to less than 45 mg/dL and the patient has symptoms and/or signs of hypoglycemia. If this does not occur, the fast should be terminated after 72 hours. At the conclusion of the fast, blood should be collected for analysis of glucose, insulin, C-peptide, proinsulin, β-hydroxybutyrate, and oral hypoglycemic agents. Then 1 mg of glucagon should be injected intravenously and plasma glucose concentration measured 10, 20, and 30 minutes later. This concludes the protocol, and the patient can be fed. Insulin antibodies should be measured, but not necessarily during hypoglycemia. When a deficiency is suspected, plasma cortisol, growth hormone, or glucagon should be measured at the beginning and end of the fast. A gender difference is observed in plasma glucose concentrations during prolonged fasting, with women exhibiting significantly lower concentrations than men. Low plasma glucose is necessary, but not sufficient, to establish the diagnosis. Absence of symptoms or signs of hypoglycemia during the fast excludes the diagnosis of a hypoglycemic disorder. Symptoms, signs, or both combined

TABLE 26-2 Methods of Glucose Analysis in 5819 Laboratories*

Method	Number†	Percent of Total	Mean, mg/dL	SD	CV, %

with concentrations of glucose less than 55 mg/dL, insulin of at least 18 pmol/L, C-peptide of at least 0.2 nmol/L, and proinsulin of at least 5.0 pmol/L document endogenous hyperinsulinism. If β-hydroxybutyrate is 2.7 mmol/L or less and glucose is increased by at least 25 mg/dL after intravenous glucagon (the latter indicating preserved hepatic glycogen stores), hypoglycemia is mediated by insulin or IGF.

Tolbutamide Tolerance Test

Tolbutamide [1-butyl-3-(*p*-tolylsulfonyl)urea] (Orinase) stimulates the normal pancreas to produce insulin. The response of the pancreas to intravenous tolbutamide has been used in the investigation of fasting hypoglycemia. Blood specimens are obtained for glucose and insulin before intravenous injection of 1 g of a water-soluble form of tolbutamide and at 2, 15, 30, 60, 90, and 120 minutes afterwards. Healthy people have a decrease in plasma glucose concentration to about 50% of the fasting value by 30 minutes, with a return to baseline at 120 minutes. Patients with fasting hypoglycemia exhibit a lower glucose nadir, with hypoglycemia persisting up to 2 hours. The insulin response provides further diagnostic information. The peak insulin concentration at 2 minutes is normally less than 150 μIU/mL. This value is increased in patients with islet cell tumors, and an increased insulin concentration at 60 minutes is reported to be the most reliable discriminator.[6] In various conditions such as liver disease, malnutrition, or renal insufficiency, plasma glucose responses to tolbutamide are indistinguishable from those seen with islet cell tumors, *but only patients with insulinoma exhibit exaggerated plasma insulin concentrations.*

DETERMINATION OF GLUCOSE IN BODY FLUIDS

Many analytical procedures are used to measure blood glucose concentrations. In the past, analyses were often performed with relatively nonspecific methods that could produce falsely increased values. Today, almost all common methods are enzymatic (e.g., hexokinase,[9,63] glucose oxidase), and older methods, such as photometric or oxidation reduction techniques, are rarely used. The glucose assays most widely used in the United States may be determined by inspecting proficiency testing surveys conducted by the College of American Pathologists (CAP). Results from 5819 laboratories reported in a survey conducted in 2009 are displayed in Table 26-2. These data show that automated hexokinase methods are used in 58% of participating laboratories. Glucose oxidase is the only other method that is widely used. The most significant change in the past 25 years is the disappearance of the *o*-toluidine method, which was used in the SMA 12/60 Autoanalyzer. It must be emphasized that these data apply only to this CAP survey and are weighted to laboratories participating on a voluntary basis or in compliance with state regulatory agencies. Furthermore, testing performed in physicians' offices is not included. Many kits are commercially available for measuring glucose and are widely used, especially in smaller laboratories. Reference to CAP surveys reveals that all methods exhibit coefficients of variation (CVs) less than or equal to 2.6% for glucose values on lyophilized serum. The method of glucose measurement does not influence the result. Comparison of pooled serum samples measured by ≈6000 clinical laboratories shows that mean glucose concentrations measured by the hexokinase and glucose oxidase methods are essentially the same.[57] However, when evaluated against a reference measurement procedure, significant biases of up to 13% are observed among different methods.

Specimen Collection and Storage

In individuals with a normal hematocrit, fasting whole blood glucose concentration is approximately 10 to 12% lower than plasma glucose. Although glucose concentrations in the water phase of red blood cells and plasma are similar (the erythrocyte plasma membrane is freely permeable to glucose), the water content of plasma (93%) is approximately 11% higher than that of whole blood. In most clinical laboratories,

plasma or serum is used for most glucose determinations; methods for self-monitoring of glucose use whole blood samples but may measure the glucose concentration in the plasma phase. Venous plasma is recommended for diagnosis of diabetes.[1,83]Although older methods of analysis reported that glucose concentrations in plasma were 5% lower than in serum,[44] a 2004 study indicated that glucose values measured in serum and plasma are essentially the same.[55] During fasting, capillary blood glucose concentration is only 2 to 5 mg/dL higher than that of venous blood. After a glucose load, however, capillary blood glucose concentrations are 20 to 70 mg/dL (mean ≈30 mg/dL; equivalent to 20 to 25%) higher than concurrently drawn venous blood samples.[43,45]

Glycolysis decreases serum glucose by approximately 5 to 7% in 1 hour (5 to 10 mg/dL) in normal uncentrifuged coagulated blood at room temperature.[13,81] The rate of in vitro glycolysis is higher in the presence of leukocytosis or bacterial contamination, but others have observed a slight decrease.[71] In separated, nonhemolyzed sterile serum, the glucose concentration is generally stable as long as 8 hours at 25 °C and up to 72 hours at 4 °C; variable stability is observed with longer storage periods.[7] Plasma, removed from the cells after moderate centrifugation, contains leukocytes that also metabolize glucose, although cell-free sterile plasma has no glycolytic activity.

Glycolysis has been found to be inhibited and glucose stabilized for as long as 3 days at room temperature by adding sodium fluoride (NaF) or, less commonly, sodium iodoacetate to the specimen.[25] Fluoride ions prevent glycolysis by inhibiting enolase, an enzyme that requires Mg^{2+}. This inhibition is due to the formation of an ionic complex consisting of Mg^{2+}, inorganic phosphate, and fluoride ions; this complex interferes with the interaction of enzyme and substrate. Fluoride is also a weak anticoagulant because it binds calcium; however, clotting may occur after several hours. It is therefore advisable to use a *combined fluoride-oxalate mixture,* such as 2 mg of potassium oxalate ($K_2C_2O_4$) and 2 mg NaF/mL of blood, to prevent late clotting. Other anticoagulants (e.g., EDTA, citrate, heparin) can also be used. Fluoride ions in high concentration inhibit the activity of urease and certain other enzymes; consequently, the specimens are unsuitable for determination of urea in procedures that require urease and for direct assay of some serum enzymes. $K_2C_2O_4$ causes loss of cell water, thereby diluting the plasma. Therefore, samples collected in these tubes should not be used for measurement of analytes other than glucose. Although fluoride maintains long-term blood glucose stability, the rate of decline in the first hour after sample collection is not altered, and glycolysis may continue for up to 4 hours.[13] A 2009 study showed that acidification of blood using citrate buffer inhibits in vitro glycolysis more effectively than fluoride.[29] To minimize glycolysis, the cells should be removed within minutes. Alternatively, the tube should be placed in ice-water slurry and the cells separated within 30 minutes.[83] Neither of these approaches is practical in routine analysis. It may not be necessary to use a fluoride-containing tube if plasma is separated from cells within 30 minutes of blood collection. However, inhibitors of glycolysis are required in patients with greatly increased leukocyte counts (e.g., blast crisis), because differences of up to 65 mg/dL have been observed between glucose values with and without glycolytic inhibitors after 1 to 2 hours of contact with the blood cells.

Cerebrospinal fluid (CSF) may be contaminated with bacteria or other cells and should be analyzed immediately for glucose. If a delay in measurement is unavoidable, the sample should be centrifuged and stored at 4 °C or at −20 °C.

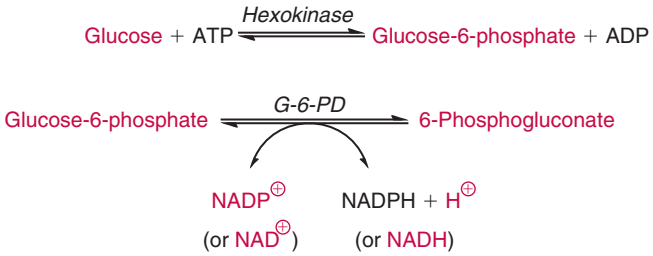
In 24-hour collections of urine, glucose may be preserved by adding 5 mL of glacial acetic acid to the container before starting the collection. The final pH of the urine is usually between 4 and 5, which inhibits bacterial activity. Other preservatives that have been proposed include 5 g of sodium benzoate per 24-hour specimen, or chlorhexidine and 0.1% sodium nitrate ($NaNO_2$) with 0.01% benzethonium chloride. These may be inadequate, and urine should be stored at 4 °C during collection. Urine samples may lose as much as 40% of their glucose after 24 hours at room temperature.[48]

Methods

Hexokinase and glucose oxidase are the two main types of methods used to measure glucose in body fluids.

Hexokinase Methods

Glucose is phosphorylated by ATP in the presence of hexokinase and Mg^{2+}. The glucose-6-phosphate formed is oxidized by glucose-6-phosphate dehydrogenase (G6PD) to 6-phosphogluconate in the presence of nicotinamide-adenine dinucleotide phosphate (NADPH). The amount of NADPH produced is directly proportional to the amount of glucose in the sample and is measured by absorbance at 340 nm. G6PD derived from yeast is used in the assay with $NADP^+$ as the cofactor. The oxidized form of nicotinamide-adenine dinucleotide (NAD^+) is the cofactor if bacterial *(Leuconostoc mesenteroides)* G6PD is used, and the NADH produced is measured at 340 nm.



A reference method based on this principle has been developed and validated.[59] Serum or plasma is deproteinated by adding solutions of barium hydroxide [$Ba(OH)_2$] and zinc sulfate ($ZnSO_4$). The clear supernatant is mixed with a reagent containing ATP, NAD^+, hexokinase, and G6PD, incubated at 25 °C until the reaction is complete, and NADH measured. Calibrators and blanks are carried through the entire procedure, including the deproteination step. Detailed specifications are given for the equipment, materials, and reagents, including tests of enzyme reagent adequacy.

Although highly accurate and precise, the reference method is too exacting and time-consuming for routine use in a clinical laboratory. An alternative approach is to apply the reaction directly to serum or plasma and use a specimen blank to correct for interfering substances that absorb at 340 nm.[58] Because almost all methods are automated and rely on commercially prepared reagents supplied in lyophilized form, only a general discussion of the procedure is presented here.

Serum or plasma may be used. NaF, with an anticoagulant such as EDTA, heparin, oxalate, or citrate, may be used. Hemolyzed specimens containing more than 0.5 g hemoglobin/dL are unsatisfactory because phosphate esters and enzymes released from red blood cells interfere with the assay. Other sources of interference include drugs, bilirubin, and lipemia (triglycerides ≥500 mg/dL cause positive interference). A sample blank is therefore recommended for lipemic and icteric samples. This blank is prepared by adding 10 µL of sample to isotonic saline or buffer instead of reagent. The absorbance of this mixture, read against water at 340 nm, is subtracted. Although fructose interferes in the assay, normal fasting serum has low fructose concentrations. After ingestion of sucrose 2 g/kg of body weight, serum fructose concentration increases up to 8 to 10 mg/dL within 1 hour, and this increase persists for 2 hours. Solutions administered during glucose tolerance testing therefore should not contain any fructose.

Absorbances of sample or calibrator reaction mixtures are measured after the reactions have continued to completion (equilibrium reaction). Although glucose concentrations may be calculated directly, based on the molar absorptivity of NADPH or NADH, inclusion of a set of calibrators is recommended to detect possible deterioration of enzymes, ATP, $NADP^+$, or NAD^+, all of which are unstable. Reagents may also contain substances that react with the coenzymes. The presence of these substances can be evaluated by measuring the increase in absorbance observed in a reagent blank. Reagents are unsuitable for use if the absorbance at 340 nm exceeds 0.35, using water as the blank. The highest calibrator provides a check on the linearity of response and the adequacy of the enzyme reagent. The procedure is linear from 0 to 500 mg/dL. Glucose concentrations that exceed 500 mg/dL should be diluted with isotonic saline and reassayed.

Hexokinase procedures in which indicator reactions produce colored products are available, enabling absorbance to be measured in the visible range.[84] An oxidation reduction system containing phenazine methosulfate (PMS) and a substituted tetrazolium compound, 2-(*p*-iodophenyl)-3-*p*-nitrophenyl-5-phenyltetrazolium chloride (INT), is reacted with NADPH formed in the reaction. The reduced INT is colored with maximum absorbance at 520 nm. The PMS-INT color developer must be refrigerated when not in use and must be protected from exposure to light to retard autoreduction.

Glucose Oxidase Methods

The enzyme glucose oxidase catalyzes the oxidation of glucose to gluconic acid and hydrogen peroxide (H_2O_2):

$$\text{Glucose} + 2H_2O + O_2 \xrightarrow{\text{Glucose Oxidase}} \text{Gluconic Acid} + 2\,H_2O_2$$

Addition of the enzyme peroxidase and a chromogenic oxygen acceptor, such as *o*-dianisidine, results in the formation of a colored compound that is measured:

$$\underset{\text{(Colorless)}}{\text{o} - \text{Dianisidine}} + H_2O_2 \xrightarrow{\text{Peroxidase}} \underset{\text{(Colored)}}{\text{Oxidized o} - \text{Dianisidine}} + 2H_2O$$

Glucose oxidase is highly specific for β-D-glucose. As noted earlier, 36% and 64% of glucose in solution are in α- and β-forms, respectively. Complete reaction of glucose therefore requires mutarotation of the α- to the β-form. Some commercial preparations of glucose oxidase contain an enzyme—mutarotase—that accelerates this reaction. Otherwise, extended incubation time allows spontaneous conversion.

The second step, involving peroxidase, *is much less specific than the glucose oxidase reaction.* Various substances, such as uric acid, ascorbic acid, bilirubin, hemoglobin, tetracycline, and glutathione, inhibit the reaction (presumably by competing with the chromogen for H_2O_2), producing lower values. Incorporation of potassium ferrocyanide significantly decreases interference by bilirubin. Most interfering substances can be eliminated by use of a Somogyi filtrate. Acid filtrates cannot be used because peroxides, which cause falsely increased results, may be released. Most modern methods omit the preparation of protein-free filtrates to make the procedure faster and simpler. Some glucose oxidase preparations contain catalase as a contaminant; catalase activity decomposes peroxide and decreases the final color obtained. Calibrators and unknowns should be analyzed simultaneously under conditions in which the rate of oxidation is proportional to the glucose concentration.

In some methods, the final mixture is acidified slightly to stop the reaction, and the intensity of the yellow chromophore is measured at 400 nm. In stronger acid solution, the color becomes pink, with maximum absorbance at 540 nm, and both sensitivity and stability are improved. Other approaches to measure the H_2O_2 produced include the peroxide-mediated oxidative coupling of 3-methyl-2-benzothiazolinone hydrazone (MBTH) with *N,N*-dimethylaniline (DMA) catalyzed by peroxidase,[32] or the oxidative coupling of *p*-aminophenazone (PAP) to phenol.[79] Both procedures have been automated. The MBTH-DMA and PAP procedures are not affected by high concentrations of creatinine, uric acid, or hemoglobin and are performed directly on serum. The chromogen 2-amino-4-hydroxybenzenesulfonic acid produces a yellow color in the presence of peroxidase and H_2O_2.[66] Additional components are not required to produce the color, and the assay can be performed on as little as 2 µL of serum.

Glucose oxidase methods are *suitable for measuring glucose in CSF but not in urine* as urine contains high concentrations of substances that interfere with the peroxidase reaction (such as uric acid), producing falsely low results. The glucose oxidase method therefore should *not be used for urine.* A

method in which the urine is first pretreated with an ion-exchange resin to remove interfering substances has been described.

Modified Glucose Oxidase Methods

Some instruments use a polarographic oxygen electrode that measures the rate of oxygen consumption after the sample is added to a solution containing glucose oxidase.[39] Because this measurement involves only the first reaction shown earlier, *interferences encountered in the peroxidase step are eliminated.* To prevent formation of oxygen from H_2O_2 by catalase present in some preparations of glucose oxidase, H_2O_2 is removed by two additional reactions:

$$H_2O_2 + C_2H_3OH \xrightarrow{Catalase} CH_3CHO + 2H_2O$$

$$H_2O_2 + 2\,H^+ + 2\,I^- \xrightarrow{Molybdate} I_2 + 2\,H_2O$$

The latter reaction is effective even when catalase activity has diminished on storage of reagents. The procedure can be applied directly to *urine, serum, plasma,* or *CSF.* However, this approach cannot be used for the *determination of glucose in whole blood* because blood cells consume oxygen.

In the YSI Model 23A (Yellow Springs Instrument Co., Yellow Springs, Ohio), glucose oxidase is immobilized in a thin layer of resinous material sandwiched between two membranes. When a buffered sample is introduced, glucose diffuses through the first polycarbonate membrane and reacts with the enzyme to produce H_2O_2. This diffuses through the second, smaller-pore cellulose acetate membrane and is oxidized at a platinum anode. The current generated is directly proportional to the glucose concentration in the diluted sample.

$$H_2O_2 \rightarrow 2H^+ + O_2 + 2e^-$$

The circuit is completed at a silver cathode, where oxygen is reduced to water.

$$4H^+ + O_2 + 4e^- \rightarrow 2H_2O$$

Any H_2O_2 diffusing back into the sample chamber is destroyed by catalase to prevent interference with the analysis. Determinations may be performed on 25 µL of *plasma, serum,* or *whole blood.* Good precision and correlation with an oxygen consumption rate analyzer have been reported.[17]

The Vitros System (Ortho-Clinical Diagnostics, Raritan, NJ) makes use of dry multilayer films for chemical analyses.[21] Glucose is measured by a glucose oxidase procedure. A 10-µL sample of *serum, plasma, urine, or CSF* is placed on a porous film on top of the layer containing the reagents. Glucose diffuses through the film and reacts with the reagents to produce a colored end product or dye. The intensity of this dye is measured through a lower transparent film by reflectance spectrophotometry. Advantages of this system include small sample size, absence of liquid reagents, and improved stability on storage.

Glucose Dehydrogenase Methods

The enzyme glucose dehydrogenase (β-D-glucose:NAD oxidoreductase; EC 1.1.1.47) catalyzes the oxidation of glucose to gluconolactone. Mutarotase is added to shorten the time necessary to reach equilibrium. The amount of NADH generated is proportional to the glucose concentration.

Glucose dehydrogenase for this assay is isolated from *Bacillus cereus.* The reaction appears to (1) be highly specific for glucose, (2) shows no interference from common anticoagulants and substances normally found in serum, and (3) provides results in close agreement with hexokinase procedures. However, products containing maltose, icodextrin (which is converted to maltose), or galactose spuriously increase results obtained with point-of-care glucose meters that use glucose dehydrogenase pyrrolo-quinoline quinine (GDH-PQQ). Maltose is found in some intravenous immune globulins, and icodextrin is a glucose polymer present in some peritoneal dialysis solutions. These substances do not interfere with glucose measuring systems that use glucose dehydrogenase with NAD as cofactor. Glucose dehydrogenase methods have been adapted to continuous-flow analyzers,[10] including the use of immobilized enzyme,[77] and to a centrifugal analyzer.[51]

Reference Intervals

Although glucose is assayed by several different analytical procedures, reference intervals do not vary significantly among methods. The following values should apply to virtually all currently used glucose assays.

	Sample Fasting Glucose, mg/dL
Plasma/Serum	
Adults	74-99 (4.1-5.5 mmol/L)
Children	60-100 (3.3-5.6 mmol/L)
Premature neonates	20-60 (1.1-3.3 mmol/L)
Term neonates	30-60 (1.7-3.3 mmol/L)
Whole blood	65-95 (3.6-5.3 mmol/L)
CSF	40-70 (2.2-3.9 mmol/L) (60% of plasma value)
Urine	
24 hour	1-15 mg/dL (0.1-0.8 mmol/L)

Note that the ADA criterion[1] of fasting glucose of 126 mg/dL or greater—not the reference interval—is used for the diagnosis of diabetes. Moreover, the threshold for diagnosis of hypoglycemia is variable and is considerably less than the lower limit of the reference interval. There is no sex difference. *Plasma glucose values increase with age from the third to the sixth decade:* fasting, approximately 2 mg/dL per decade; postprandial, 4 mg/dL per decade; and after a glucose challenge, 8 to 13 mg/dL per decade.[60] Fasting plasma glucose does not increase significantly after age 60, but glucose concentrations after a glucose challenge are substantially higher in older individuals.[24] Evidence of an association of increasing insulin resistance with age is inconsistent, and visceral obesity appears to be responsible for the reported decrease in glucose tolerance in middle age.[38,69]

BOX 26-2 Reducing Substances in Urine

Fructose	Ketone bodies
Lactose	Sulfanilamide
Galactose	Oxalic acid
Maltose	Hippuric acid
Arabinose	Homogentisic acid
Xylose	Glucuronic acid
Ribose	Formaldehyde
Uric acid	Isoniazid
Ascorbic acid	Salicylates
Creatinine	Cinchophen
Cysteine	Salicyluric acid
Glucose	

CSF glucose concentrations should be approximately 60% of plasma concentrations and *must always be compared with concurrently measured plasma glucose* for adequate clinical interpretation.

Measurement of Glucose in Urine

Examination of urine for glucose is rapid, inexpensive, and noninvasive and has been used to screen large numbers of samples. The older screening tests detect sugars that reduce copper, producing a color.[35] Unfortunately, these tests react with reducing substances other than glucose (Box 26-2). Qualitative, semiquantitative, and quantitative methods are available for measuring glucose in urine and have essentially replaced the nonspecific tests in adults. *Note:* A reducing sugar method, rather than an enzymatic method specific for glucose, must be used when screening neonates and infants for inborn errors of metabolism that result in the appearance of reducing sugars other than glucose (e.g., galactose, fructose) in the urine.

Qualitative Method

In one such method, using Benedict's reagent (cupric ion complexed to citrate in alkaline solution), reducing substances convert cupric to cuprous ions, forming yellow cuprous hydroxide or red cuprous oxide.

Semiquantitative Methods

Convenient paper test strips are commercially available from a number of manufacturers (Clinistix and Diastix, Siemens Healthcare Diagnostics, Deerfield, Ill; and Chemstrip 2GP, Roche Diagnostics, Branchburg, NJ). All strips use the *glucose-specific enzyme glucose oxidase in a chromogenic assay.* For example, Clinistix has filter paper impregnated with glucose oxidase, peroxidase, and the dye *o*-tolidine. Other dyes, such as tetramethylbenzidine (TMB) have been used. The test end of the strip is moistened with freshly voided urine and examined after 10 seconds. A blue color develops if glucose is present at a concentration of 100 mg/dL or greater. Results are read by comparing the test color with a standard color chart. Automated urinalysis systems capable of analyzing 300 strips per hour are commercially available. The test is more sensitive for glucose than the copper reduction test (Clinitest), which has a detection limit of 250 mg/dL. Despite these claims, evaluation of dipsticks reveals high imprecision at low urine glucose concentrations.[28] Clinitest was reported to detect glucose only when it was above 1 g/L, and only Chemstrip μG could differentiate urine glucose at 300 mg/L (upper limit of reference interval) from 600 mg/L.[4] The sensitivity of the strip has been adjusted to take into account the presence of enzyme inhibitors normally present in urine. Thus a positive test result is obtained with lower concentrations of glucose in water than in urine. For the same reason, misleading high results may be obtained with very dilute specimens.

False-positive results may be produced by contamination of urine with H_2O_2 or a strong oxidizing agent, such as hypochlorite (bleach). Exposure of dipsticks to air gives false-positive readings after 7 days.[18] False-negative results may occur with large quantities of reducing substances, such as ketones, ascorbic acid, and salicylates. In one study of 2000 urine specimens, 11 false-negative enzyme paper tests were encountered. Among the inhibitors identified were ascorbic acid, dipyrone, and meralluride sodium (Mercuhydrin). Several antibiotics contain ascorbic acid as a preservative, which is excreted essentially unchanged. For routine examinations, a negative result by the strip test is usually interpreted to mean that the urine specimen is negative for glucose.

Other strip tests (Keto-Diastix, Siemens Healthcare Diagnostics; and DiaScreen 2GK, Arkray USA, Medina, Minn) are designed for the semiquantitative estimation of both glucose and ketone bodies. The glucose portion of the strip uses the glucose oxidase-peroxidase method. The hydrogen peroxide produced oxidizes iodide to iodine, yielding various intensities of brown that correspond to the concentration of glucose in urine. The detection limit is 100 mg/dL. Diastix and Chemstrip glucose tests are reported to be less inhibited by ascorbic acid than Clinistix.

Quantitative Methods

Applications of various procedures for quantitative determination of glucose in urine were discussed earlier in this chapter under "Determination of Glucose in Body Fluids." Hexokinase or glucose dehydrogenase procedures are recommended for greatest accuracy and specificity. Glucose oxidase procedures that depend only on the consumption of oxygen or the production of H_2O_2 are also reliable. Glucose oxidase procedures that include the H_2O_2-peroxidase reaction are not acceptable.

LACTATE AND PYRUVATE

Lactic acid, an intermediate in carbohydrate metabolism (see Figure 26-9), is derived predominantly from white skeletal muscle, brain, skin, renal medulla, and erythrocytes.

The blood lactate concentration depends on the rate of production in these tissues and the rate of metabolism in the liver and kidneys. Approximately 65% of total basal lactate production is used by the liver, particularly in gluconeogenesis. The *Cori cycle* consists of the conversion of glucose to lactate in the periphery and the reconversion of lactate to glucose in the liver. Extrahepatic removal of lactate occurs by oxidation in red skeletal muscle and the renal cortex. A moderate increase in lactate production results in increased hepatic lactate clearance, but uptake by the liver is saturable when concentrations exceed 2 mmol/L. For example, during strenuous exercise, lactate concentrations may increase significantly, from an average concentration of about 0.9 mmol/L to more than 20 mmol/L within 10 seconds. There is no uniformly accepted concentration for the diagnosis of lactic acidosis, but lactate concentrations exceeding 5 mmol/L and pH less than 7.25 indicate significant lactic acidosis.

Under certain conditions, the ratio of lactate to pyruvate is an indicator of redox status. For example, by rearranging the equation for the equilibrium constant for the reaction catalyzed by lactate dehydrogenase (EC 1.1.1.27), the ratio of lactate to pyruvate is shown to be proportional to the ratio of NADH to NAD^+.

Clinical Significance

Pyruvate is one of the critical metabolites in the cells, most of which originate from glycolysis.[64] It is further metabolized by four enzyme systems, namely, (1) alanine aminotransferase (alanine production), (2) pyruvate carboxylase (the major regulatory enzyme in gluconeogenesis), (3) lactate dehydrogenase (lactate formation), and (4) pyruvate dehydrogenase (see Figure 26-9). The last is a complex of enzymes that decarboxylate pyruvate in the presence of oxygen to acetyl coenzyme A (CoA), allowing entry into the citric acid cycle. Measurement of pyruvate is useful in the evaluation of patients with inborn errors of metabolism who have increased serum lactate concentrations. A lactate-to-pyruvate ratio less than 25 suggests a defect in gluconeogenesis, whereas an increased ratio (≥35) indicates reduced intracellular conditions found in hypoxia. Inborn errors associated with an increased lactate-to-pyruvate ratio include pyruvate carboxylase deficiency and defects in oxidative phosphorylation.[68] A high lactate-to-pyruvate ratio appears to be a sensitive test for detecting mitochondrial muscle toxicity of zidovudine therapy.[14] Pyruvate is also measured in clinical studies evaluating reperfusion after myocardial ischemia. Patients with Alzheimer's disease were reported to have higher CSF pyruvate concentrations than control subjects, and concentrations correlate with the severity of dementia.[62]

Lactic acidosis occurs in two clinical settings: (1) type A (hypoxic), associated with *decreased tissue oxygenation,* such as shock, hypovolemia, and left ventricular failure; and (2) type B (metabolic), associated with *disease* (e.g., diabetes mellitus, neoplasia, liver disease), *drugs and/or toxins* (e.g., ethanol, methanol, salicylates), or *inborn errors of metabolism* (e.g., methylmalonic aciduria, propionic acidemia, fatty acid oxidation defects). Lactic acidosis is not uncommon and occurs in approximately 1% of hospital admissions. It has a mortality rate greater than 60%, and approaches 100% if hypotension is also present. Type A is much more common.

The mechanism of type B lactic acidosis is not known but is speculated to be a primary defect in mitochondrial function with impaired oxygen use. This leads to reduced stores of ATP and NAD^+, with accumulation of NADH and H^+. In the presence of decreased liver perfusion or liver disease, lactate removal from the blood is reduced, thereby aggravating the lactic acidosis.

Measurement of serum lactate in trauma patients on admission to the emergency department does not identify patients at risk of death, but may be useful to identify those patients at low risk of death.[36] Evidence obtained in 2008 from a multicenter trial supports measurement of lactate in fetal scalp blood during labor in the management of intrapartum fetal distress to prevent severe academia at birth.[82]

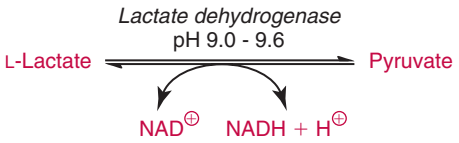
An uncommon and often undiagnosed cause of lactic acidosis is D-lactic acidosis.[80] It was thought that D-lactate was not produced in human metabolism, but normal individuals have a large capacity to metabolize D-lactate.[80] Moreover, absorption and accumulation of D-lactate from abnormal intestinal bacteria may cause systemic acidosis. This occurs after jejunoileal bypass surgery and manifests as altered mental status (from mild drowsiness to coma) with increased blood concentrations of D-lactate. Virtually all commonly used laboratory assays for lactate use L-lactate dehydrogenase, which does not detect D-lactate. D-Lactate can be measured by gas-liquid chromatography or, more easily, by using a specific D-lactate dehydrogenase (Sigma) from *Lactobacillus leishmanni.*[50] The enzyme assay can be readily automated. Lactate in CSF normally parallels concentrations in the blood, but not in children.[37] With biochemical alterations in the CNS, however, CSF lactate values change independently of blood values. Increased CSF concentrations are noted in cerebrovascular accidents, intracranial hemorrhage, bacterial meningitis, epilepsy, inborn errors of the electron transport chain, and other CNS disorders. In aseptic (viral) meningitis, lactate concentrations in CSF are not usually increased; hence, CSF lactate has been used to help discriminate between viral and bacterial meningitis,[3] but the clinical utility has been questioned. In a few children with inherited metabolic disease, CSF lactate concentrations may be increased despite plasma lactate in the reference interval.[37]

Methods for Measuring Lactate and Pyruvate in Body Fluids

Determination of Lactate in Whole Blood[2,47,49,52]

Principle

Lactate is oxidized to pyruvate by lactate dehydrogenase in the presence of NAD^+. The NADH formed in this reaction is measured by a spectrophotometer at 340 nm and serves as a measure of the lactate concentration.



The equilibrium of the reaction normally lies far to the left. However, by using a pH of 9.0 to 9.6 and an excess of NAD^+, and by trapping the reaction product pyruvate with hydrazine, the equilibrium can be shifted to the right. Pyruvate can also be removed by reacting it with L-glutamate in the presence of alanine aminotransferase. Use of tris(hydroxymethyl)-aminomethane (TRIS) buffer results in more rapid completion of a side reaction between NAD^+ and hydrazine and prevents the "creeping" of blank values observed when glycine buffer is used.[47]

Because of its high specificity and simplicity, the enzymatic method is the method of choice for measuring lactate, although other methods may also be used (e.g., gas chromatography,[70] photometry).

The Vitros Analyzer (Ortho-Clinical Diagnostics) uses an assay in which lactic acid is oxidized to pyruvate by lactate oxidase. The H_2O_2 generated oxidizes a chromogen system, and absorbance of the resulting dye complex, measured by a spectrophotometer at 540 nm, is directly proportional to the lactate concentration in the specimen. Each mole of lactate oxidized produces 0.5 mole of dye complex.

$$L-\text{Lactate} + O_2 \xrightarrow{\text{Lactate Oxidase}} \text{Pyruvate} + H_2O_2$$

$$2\,H_2O_2 + \text{4-aminoantipyrine} + \text{1,7-dihydronapthalene} \xrightarrow{\text{Peroxidase}} \text{red dye}$$

Reference Intervals

The reference intervals for lactate are as follows:

LACTATE

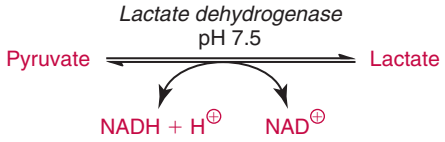
Specimen	mmol/L	mg/dL
Venous Blood		
At rest	0.5-1.3	5-12
In hospital	0.9-1.7	8-15
Arterial Blood		
At rest	0.36-0.75	3-7
In hospital	0.36-1.25	3-11

Patients in the hospital exhibit a wider range of lactate concentrations with lactic acidosis occurings when blood lactate concentrations exceed 5 mmol/L (45 mg/dL). Severe exercise dramatically increases lactate concentrations, and even movement of leg muscles by patients at bed rest may result in significant increases. Plasma values are about 7% higher than those in whole blood, although differences depend on the procedure used. CSF values are usually similar to blood concentrations, but may change independently in CNS disorders. Age-related reference intervals for CSF lactate (and lactate-to-pyruvate ratios) have been established in children.[5] The upper limit of the reference interval (90th percentile) for CSF lactate in children in hospital from birth to 15.5 years varies continuously from 1.78 to 1.88 mmol/L (16 to 17 mg/dL).[5] Normal 24-hour urine output of lactate is 5.5 to 22 mmol/d.

Determination of Pyruvate in Whole Blood

Principle

The reaction involved in the determination of pyruvate is essentially the reverse of the reaction used in the lactate procedure.



At about pH 7.5, the equilibrium constant strongly favors the reaction to the right. The method is very specific, and 2-oxoglutarate, oxaloacetate, acetoacetate, and β-hydroxybutyrate do not interfere, as with photometric methods.

Reference Intervals

Fasting venous blood, drawn with a patient at rest, has a pyruvate concentration of 0.03 to 0.10 mmol/L (0.3 to 0.9 mg/dL). Arterial blood contains 0.02 to 0.08 mmol/L (0.2 to 0.7 mg/dL). Values for CSF are 0.06 to 0.19 mmol/L (0.5 to 1.7 mg/dL).[65] Age-related reference intervals in CSF have been established in children.[5] Urine output of pyruvate is normally 1 mmol/d or less.

INBORN ERRORS OF CARBOHYDRATE METABOLISM

Deficiency or absence of an enzyme that participates in carbohydrate metabolism may result in accumulation of monosaccharides, which is measured in the urine (see Table 26-1 and Figure 26-9). Most of these conditions are inherited as autosomal recessive traits. Sugars frequently appear in the urine as a result of excessive consumption without underlying disease.

Disorders of Galactose Metabolism

Galactose is derived from milk in the diet. It resembles glucose in structure, but the hydroxyl group on the fourth carbon has a different spatial arrangement (see Figure 26-2). A deficiency of any of the enzymes that participate in the conversion of galactose to glucose results in *galactosemia.*

Galactose-1-Phosphate Uridyl Transferase Deficiency

Infants with this deficiency fail to thrive on milk because half of the milk sugar, lactose, is galactose. Within a few days of

milk ingestion, neonates manifest vomiting and diarrhea. Failure to thrive, liver disease, cataracts, and mental retardation develop later. Hypoglycemia may occasionally develop. The diagnosis should be considered when *the urine demonstrates the presence of a reducing substance that does not react in a glucose oxidase test.* Early detection and treatment (withholding galactose from the diet) are necessary to prevent irreversible changes. Because other reducing sugars may give similar results, galactose should be identified by paper chromatography (discussed later). Diagnosis is suggested by detecting galactose and galactose-1-phosphate in blood and is confirmed by direct assaying of red blood cell transferase activity. A spot test is also available.

Uridine Diphosphate Galactose-4-Epimerase Deficiency

This extremely rare disorder exhibits clinical findings similar to those of transferase deficiency.

Galactokinase Deficiency

This is a milder condition manifested predominantly by cataracts caused by galactitol deposits in the lens. The diagnosis is confirmed by demonstrating normal transferase activity and no galactokinase in red blood cells.

Disorders of Fructose Metabolism

Fructose may appear in the urine after fruit, honey, or syrup is eaten, but it has no significance in these circumstances. Three disorders of fructose metabolism, inherited as autosomal recessive traits, produce fructosuria.

Essential Fructosuria

This rare and harmless defect is due to lack of *fructokinase.*

Hereditary Fructose Intolerance

A *deficiency of fructose-1-phosphate aldolase* produces this rare disorder with hypoglycemia and liver failure. Fructose ingestion inhibits glycogenolysis and gluconeogenesis, producing hypoglycemia. Early detection is important because this condition responds to a diet devoid of sucrose and fructose.

Hereditary Fructose-1,6-Diphosphatase Deficiency

Patients with this deficiency have episodes of apnea and hyperventilation and hypoglycemia, ketosis, and lactic acidosis caused by severe impairment of gluconeogenesis. The condition is diagnosed by demonstrating the enzyme defect in liver biopsy specimens.

Disorders of Pentose Metabolism

Alimentary Pentosuria

Pentoses may be present in the urine after large quantities of fruits such as cherries, plums, or prunes are eaten.

Essential Pentosuria

This is a harmless inborn error caused by a *deficiency of L-xylulose reductase,* an enzyme involved in the glucuronic acid pathway.

Other Urinary Sugars

Lactose is sometimes detected in the urine of women during lactation and occasionally towards the end of pregnancy. Patients with *lactase deficiency,* a common disorder caused by a congenital or acquired deficiency of intestinal lactase, exhibit abdominal pain, diarrhea, and lactose in the urine.

Maltose has on rare occasions been detected in the urine of some patients.

Many *reducing substances* other than sugars may be found in urine (see Box 26-2). Ascorbic acid (vitamin C) may be ingested in large quantities or may be present in antibiotic preparations administered intravenously. In either case, excess concentrations usually appear in the urine and contribute significantly to the total reducing substances present.

Methods for Measuring Individual Sugars

Qualitative Tests for Glucose

Techniques for separating and identifying sugars have included (1) fermentation, (2) optical rotation, (3) osazone formation with phenylhydrazine, (4) specific chemical tests, and (5) paper or thin-layer chromatography. The availability of glucose oxidase test strips, specific for glucose, has greatly simplified the differentiation of glucose from other reducing substances. For practical purposes, the *urinary sugars of clinical interest are glucose and galactose.* Urine from infants and children should be tested routinely by both glucose oxidase and copper reduction tests to identify individuals with inborn errors of metabolism. Reducing substances other than glucose should be further identified by chromatographic procedures.

Qualitative Tests for Urinary Sugars Other Than Glucose

Fructose (Selivanoff's Test)

Hot HCl converts fructose to hydroxymethyl furfural (HMF), which links with *resorcinol* to produce a red compound. To make the reagent, dissolve 50 mg of resorcinol in 33 mL of concentrated HCl, and dilute to 100 mL with water. Add 0.5 mL of urine to 5 mL of reagent in a test tube, and bring to a boil. Fructose produces a red reaction within 30 seconds. The test is sensitive to 100 mg fructose/dL, provided there is no excess glucose. A 2-g/dL solution of glucose produces about the same color as 100 mg/dL of fructose after 30 seconds of boiling. A solution of fructose (0.5 g/dL) should be used as a control. With high concentrations of fructose, a red precipitate forms.

Pentoses (Bial's Test)

By heating with HCl, pentoses are converted to furfural, which reacts with orcinol to form green compounds. Dissolve 300 mg of orcinol in 100 mL of concentrated HCl, and add 0.25 mL of ferric chloride solution (10 g/dL). Glucose, if present in the urine, should be removed by fermentation with yeast. Add 0.5 mL of urine to 5 mL of reagent in a test tube, and bring to a boil. Pentoses produce a green reaction. The detection limit of the test is 100 mg pentose/dL. A solution of xylose (0.5 g/dL) should be used as a control.

Glucuronates produce a similar color if the boiling is prolonged. As with Selivanoff's reagent, fructose produces a red reaction.

Identification of Urinary Sugars by Paper Chromatography

Sugars can be separated by ascending or descending chromatography on paper and located after color development with dinitrosalicylic acid. Variable rates of migration depend on the solubility of the sugars in the particular solvent system. Presumptive identification is made by comparing the migration (R_f) value of the unknown to those of reference compounds. One procedure may be performed conveniently in a 6 × 18-inch Pyrex jar with a tightly fitting cover.

Identification of Urinary Sugars by Thin-Layer Chromatography

Urine sugars can be identified by thin-layer chromatographic techniques as described by Young and Jackson.[85] When frequent chromatographic separations are necessary, this method is preferred over paper chromatography because of the shorter time required. If such studies are performed infrequently, paper chromatography is simple, is adequate for most separations, and requires little actual working time.

GLYCOGEN STORAGE DISEASE

Glycogen, although present in most tissue, is stored principally in the liver and skeletal muscle. During fasting, liver glycogen is converted to glucose to provide energy for the whole body. In contrast, skeletal muscle lacks glucose-6-phosphatase, and muscle glycogen can be used only locally for energy. *Glycogen storage disease* is a generic name encompassing at least 10 rare inherited disorders of glycogen storage in tissue (see Table 26-1). The different forms of glycogen storage disease are categorized by numeric type in the chronological sequence in which these defects were identified. Each form is due to a deficiency of a specific enzyme in glycogen metabolism, producing a quantitative or qualitative defect of glycogen storage. Numerous mutations have been identified in patients with these conditions (http://www.ncbi.nim.nih.gov/omim/accessed April 26, 2011). The most common mutations are listed in Table 26-3. Because liver and skeletal muscle have the highest rates of glycogen metabolism, these are the structures most affected. The liver forms (types I, III, IV, and VI) are marked by *hepatomegaly* (caused by increased liver glycogen stores) and *hypoglycemia* (caused by inability to convert glycogen to glucose). Hypoglycemia is manifested by autonomic clinical symptoms (sweating, shakiness, and lightheaded feeling), growth retardation, and laboratory findings of decreased insulin and increased glucagon concentrations in the blood. The muscle forms (types II, IIIA, V, and VII), in contrast, have mild symptoms that *usually appear in young adulthood during strenuous exercise* owing to the inability to provide energy for muscle contraction. Other muscle disorders may exhibit similar symptoms but are readily differentiated by evaluation of glycogen stores. The specific diagnosis of each type is made directly by *demonstrating the enzyme defect in tissue.* A very brief overview is provided here; for a more detailed description, readers should consult Chen and Burchell.[16]

Type I (Glucose-6-Phosphatase Deficiency)

Type I is the most common and severe form, and patients have accumulation of glycogen of normal chemical structure in the liver. The disease is characterized by (1) massive hepatomegaly, (2) growth retardation, (3) fasting hypoglycemia, (4) increased lactic acid concentrations in the blood (caused by excessive glycolysis), (5) hyperuricemia (caused by competitive inhibition by lactate of renal tubular urate secretion and increased uric acid production), and (6) hypertriglyceridemia (increased lipolysis caused by decreased glucose). Glucagon and epinephrine do not produce hyperglycemia but result in increased lactate concentrations. The failure of blood glucose to increase in response to galactose administration (oral or intravenous) is diagnostic. Galactose is normally converted to glucose (see Figure 26-9), but in these patients glucose-6-phosphate cannot be hydrolyzed to glucose. Treatment includes partaking of frequent meals and nasogastric feeding at night to maintain blood glucose concentrations. Glucose-6-phosphatase activity can be assayed in a liver biopsy. Two main subtypes have been identified: type Ia and type Ib.[41] Type 1a (also called *von Gierke disease*) is caused by a deficiency of the glucose-6-phosphatase catalytic subunit, whereas type Ib is due to a defect in the glucose-6-phosphatase transport system. Another form, termed type 1c, was originally attributed to a defect in microsomal phosphate transport, but it is likely that types Ib and Ic represent a single disease.[41] Many mutations have been described in types Ia and Ib.[41]

Individuals with type I glycogen storage disease exhibit decreased availability of liver glycogen demonstrated by decreased or absent blood glucose response to epinephrine administration. An assay based on this phenomenon is known as the *epinephrine tolerance test.* With it, an intramuscular injection of 1 mL of a 1/1000 (1 g/L) solution of epinephrine hydrochloride is given, and blood samples are taken at 30, 45, 60, 90, and 120 minutes. Healthy people increase blood glucose by 35 to 45 mg/dL in 40 to 60 minutes, with a return to the fasting concentration within 2 hours. This test is rarely used because the diagnosis of von Gierke disease is based on failure to increase blood glucose in response to galactose administration, with confirmation by direct assay of glucose-6-phosphatase activity.

Type II (Acid α-Glucosidase Deficiency)

Type II is an autosomal recessive disorder that affects predominantly the heart and skeletal muscle, producing muscle weakness and cardiomegaly. Liver function is normal, and patients do not have hypoglycemia. Two forms are identified: (1) infantile *(Pompe disease),* which usually presents in the first few months of life (presenting symptoms include

weakness and respiratory difficulties, and patients usually die from cardiac failure within 1 year), and (2) a juvenile form that is milder and may present in the second or third decade of life with difficulty in walking. More than 200 mutations in the acid α-glucosidase gene are known (http://www.pompecenter.nl/en/). The diagnosis is made by measuring α-glucosidase (acid maltase) activity in skeletal muscle biopsy, peripheral blood cells or cultured skin fibroblasts. Enzyme replacement therapy with recombinant human acid α-glucosidase was approved in 2006.

Type III (Amylo-1,6-Glucosidase Deficiency)

Deficiency of glycogen debranching enzyme results in storage of an abnormal form of glycogen (limit dextrinosis). Both liver and muscle are usually affected (type IIIA), producing hepatomegaly and muscle weakness. Approximately 15% of patients have only liver involvement, without apparent muscle disease (type IIIB). Clinical and biochemical features resemble those of type I disease. Differentiation from type I is seen by a hyperglycemic response to galactose, lower concentrations of urate and lactate in the blood, and increased serum transaminase and creatine kinase activities. Enzyme deficiency can be demonstrated in muscle or liver and occasionally in erythrocytes.

Type IV (Branching Enzyme Deficiency)

Type IV is an extremely rare disorder manifested by production of an abnormal form of unbranched glycogen in all tissues. Patients exhibit hepatosplenomegaly with ascites and liver failure. Abnormal glycogen can be identified in the tissues and muscles; leukocytes or cultured fibroblasts can be used to demonstrate the enzyme deficiency.

Type V (Muscle Phosphorylase Deficiency)

Type V, also called *McArdle disease,* usually presents in the second or third decade with muscle cramps after exercise. Moderate exercise can be sustained, and patients get a "second wind" when symptoms disappear if exercise is continued. Increased plasma creatine kinase activities at rest, failure of ischemic exercise to increase serum lactate concentrations while producing an exaggerated increase in ammonia, myoglobinuria, and diminished activity of muscle phosphorylase establish the diagnosis. Patients respond to oral glucose administration or injections of glucagon.

Type VI (Liver Phosphorylase or Phosphorylase Kinase Deficiency)

Type VI, or *Hers' disease,* is a heterogeneous group of diseases arising from a deficiency of liver phosphorylase or one of the subunits of phosphorylase kinase. It is a rare and relatively benign disorder manifested as hepatomegaly caused by increased deposits of normal glycogen in the liver. Diagnosis is made by measuring enzyme activity in the liver or in red or white blood cells.

Type VII (Muscle Phosphofructokinase Deficiency)

Patients with this rare autosomal recessive disorder have deposits of abnormal glycogen in muscle. Exercise intolerance, unresponsiveness to glucose administration, and hemolysis (caused by decreased glycolysis in erythrocytes) are noted clinically, producing hyperbilirubinemia, pigmenturia, and reticulocytosis. The specific enzyme defect can be demonstrated.

CHAPTER 27

Lipids, Lipoproteins, Apolipoproteins, and Other Cardiovascular Risk Factors

*Alan T. Remaley, M.D., Ph.D., Nader Rifai, Ph.D., and G. Russell Warnick, M.S., M.B.A.**

Lipids are ubiquitous in the body tissue and play a vital role in virtually all aspects of life—(1) servinas hormones or hormone precursors, (2) aiding in digestion, (3) providing a source of metabolic fuel and energy storage, (4) acting as functional and structural components in cell membranes, and (5) forming insulation to allow nerve conduction or to prevent heat loss. In this chapter, we have categorized lipids into basic lipids, lipoproteins, and apolipoproteins. We discuss the basic biochemistry, clinical significance, and analytical considerations of each.

BASIC BIOCHEMISTRY

Much attention has been focused on certain lipids and the lipoproteins that transport them in the circulation, mainly because of their strong association with coronary heart disease (CHD). As a consequence, use of the term *lipids* in clinical chemistry and laboratory medicine has virtually become synonymous with lipoprotein metabolism and atherosclerosis—a key step in the pathogenesis of CHD. Much of this association has been recognized through the conduct of large-scale epidemiologic, and clinical studies. In the early 1980s, findings from the Coronary Primary Prevention Trial first demonstrated that a decrease in plasma cholesterol concentration results in a reduction in the incidence of CHD. Subsequently, several secondary prevention trials, using diet or drugs to lower blood cholesterol, have also shown a reduction in cardiovascular death and atherosclerotic clinical events. Based on these trials and other evidence, the National Heart, Lung, and Blood Institute established the National Cholesterol Education Program (NCEP) to increase public awareness about cholesterol; devise strategies for the diagnosis and treatment of hypercholesterolemia in adults, children, and adolescents; and improve the laboratory measurement of lipids. Other international and national organizations have established similar programs to address these issues.

Basic Lipid Biochemistry

The general term *lipid* applies to a class of hydrophobic compounds that are soluble in organic solvents and nearly insoluble in water. Chemically, lipids are usually enriched in carbon and hydrogen and after hydrolysis typically yield fatty acids or complex alcohols, which are usually esterified with fatty acids. Some lipids are more complex, containing other chemical groups, such as sialic, phosphoryl, amino, or sulfate groups. The presence of these charged or polar groups makes these lipids amphipathic, which gives them the property of having an affinity for both water and organic solvents; this is an important feature in their ability to form cell membranes. Lipids can been broadly subdivided into five groups based on their chemical structure (Box 27-1).

Cholesterol

Although every living organism has been found to contain sterols, cholesterol is found almost exclusively in animals, in which it is also the main sterol. Virtually all cells and body fluids contain some cholesterol. Similar to other sterols,

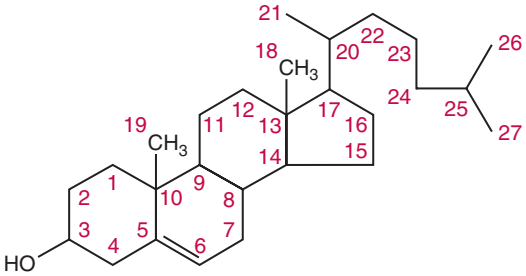
Perhydrocyclopentanophenanthrene (sterane) skeleton



Cholesterol

Figure 27-1 Structure of cholesterol.

BOX 27-1 Classification of Clinically Important Lipids

Sterol Derivatives
- Cholesterol and cholesteryl esters
- Steroid hormones
- Bile acids
- Vitamin D

Fatty Acids
- Short chain (2 to 4 carbon atoms)
- Medium chain (6 to 10 carbon atoms)
- Long chain (12 to 26 carbon atoms)
- Prostaglandins

Glycerol Esters
- Triglycerides, diglycerides, and monoglycerides (acylglycerols)
- Phosphoglycerides

Sphingosine Derivatives
- Sphingomyelin
- Glycosphingolipids

Terpenes (Isoprene Polymers)
- Vitamin A
- Vitamin E
- Vitamin K

cholesterol is a solid alcohol of high molecular weight that possesses a tetracyclic perhydrocyclopentanophenanthrene skeleton. It contains 27 carbon atoms, numbered as shown in Figure 27-1. Knowledge of the sterane skeleton structure and numbering system is important not only to clinical laboratorians but also to practicing clinicians, because cholesterol is the starting point in many different metabolic pathways. These include vitamin D synthesis (see Chapter 52), steroid hormone synthesis (see Chapter 53), and bile acid metabolism (see Chapter 50). Because the enzymes modifying the sterane cholesterol ring or its derivatives are known by their site and type of reaction (e.g., 21-hydroxylase in cortisol synthesis), the diagnosis of many disease states consequently depends on isolating the site of enzyme dysfunction (e.g., 21-hydroxylase deficiency in adrenogenital syndrome).

Cholesterol Absorption

Cholesterol enters the intestinal lumen from three sources: the diet, bile, and the intestine. Animal products—especially meat, egg yolk, seafood, and whole fat dairy products—provide the bulk of dietary cholesterol. Although cholesterol intake varies considerably based on the dietary intake of animal products, the average American diet is estimated to contain approximately 300 to 450 mg of cholesterol per day. A similar amount of cholesterol enters the gut from biliary secretion and from the turnover of intestinal mucosal cells, and possibly from direct intestinal secretions. Practically all cholesterol in the intestinal lumen is present in the unesterified or free form. Esterified cholesterol in the diet is rapidly hydrolyzed in the intestine to free cholesterol and free fatty acids by cholesterol esterases secreted from the pancreas and small intestine.

To be absorbed, unesterified cholesterol first must be solubilized. This occurs through the formation of mixed micelles that contain unesterified cholesterol, fatty acids, monoglycerides (derived from triglycerides), phospholipids, and conjugated bile acids. Formation of mixed micelles promotes cholesterol absorption by both solubilizing the cholesterol and facilitating its transport to the surface of the luminal cell, where it is absorbed by an active process involving the enterocyte protein NPC1L1, which is the drug target for the cholesterol absorption inhibitor ezetimibe. Because of their amphipathic properties, the bile acids act as detergents and are the most important factor affecting micelle formation. In the absence of bile acids, digestion and absorption of both cholesterol and triglyceride are severely impaired, leading to fat malabsorption. The quantity of dietary cholesterol that can be absorbed appears to depend on the amount that can be solubilized by micelles. On average, 30 to 60% of dietary and intestinal cholesterol is absorbed daily. With increments in dietary cholesterol, additional cholesterol is absorbed to a maximum of approximately 1 g/d when oral intake reaches 3 g/d. Absorption of cholesterol and other sterols, such as plant sterols, is limited by the presence of the ABCG5/G8 transporter on enterocytes, which pumps excess sterols back into the lumen for excretion. When this protein is defective, it results in a disease called *sitosterolemia,* which is characterized by a marked increase in plasma and tissue concentrations of plant sterols, such as sitosterol, and an increased risk for CHD. The ability of cholesterol to form micelles is also influenced by the quantity of dietary fat but not its degree of saturation. Increased amounts of fat in the diet results in expansion of mixed micelles, which in turn allows more

cholesterol to be solubilized and absorbed. Most cholesterol absorption occurs from the jejunum to the terminal ileum of the small intestine. As absorption of fat and cholesterol occurs in the small intestine, the micelles break up, thus reducing further cholesterol absorption.

After its absorption into the intestinal mucosal cell, cholesterol, together with triglycerides, phospholipids, and a number of specific apoproteins, is assembled into a large lipoprotein called a *chylomicron* (see later section on lipoprotein metabolism, exogenous pathway). One apoprotein component known as apolipoprotein (apo) B-48 is vital in the formation and secretion of chylomicrons. Patients with a rare deficiency in this process develop a disease called *chylomicron retention disorder,* which is characterized by excess lipid in enterocytes and fat malabsorption. Once secreted by enterocytes, chylomicrons enter the lymphatics, which eventually empty into the thoracic duct and enter the systemic venous circulation at the junction of the left subclavian vein and the left internal jugular vein.

Cholesterol Synthesis

Although cholesterol enters the body from the diet, it is also synthesized endogenously by all tissues from acetate. Knowledge of the endogenous cholesterol synthetic pathway has assumed great significance, because drug agents for the treatment of CHD have been sought to suppress or decrease endogenous cholesterol synthesis. The necessity for understanding the fundamental biochemistry of this pathway was originally underscored by the triparanol disaster of 1960. Triparanol is a drug that inhibits the final step in the endogenous cholesterol synthetic pathway—the conversion of desmosterol to cholesterol—but does not inhibit the rate-limiting enzyme of cholesterol synthesis, 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase (Figure 27-2). When triparanol was used to treat hypercholesterolemia, the drug caused tissue accumulation of desmosterol, resulting in the development of cataracts, alopecia, and accelerated atherosclerosis. Many drugs now used to treat CHD selectively suppress the rate-limiting enzyme HMG-CoA reductase, thereby lowering serum cholesterol concentrations significantly without accumulation of water-insoluble intermediates of cholesterol synthesis, such as desmosterol.

Although essentially all cells have the capacity to synthesize cholesterol from acetyl-CoA, almost 90% of synthesis occurs in the liver and gut; other organs and tissues depend, in part, on cholesterol delivery from the circulation. Cholesterol biosynthesis is best conceptualized as occurring in three stages (Figures 27-2 through 27-4). In the first stage, acetyl-CoA, a key metabolic intermediate that can be derived from carbohydrates, amino acids, and fatty acids, forms the six-carbon thioester HMG-CoA. In the second stage, HMG-CoA is reduced to mevalonate, then is decarboxylated to form five-carbon isoprene units. These isoprene units are condensed to form first a 10-carbon (geranyl pyrophosphate) and then a 15-carbon intermediate (farnesyl pyrophosphate). Two of these C_{15} molecules combine to produce the final product of the second stage—squalene, a 30-carbon acyclic hydrocarbon. The second stage is important, because it contains the step involving the microsomal enzyme HMG-CoA reductase, which is the rate-limiting enzyme in cholesterol biosynthesis. The enzyme that forms farnesyl pyrophosphate, geranyl transferase, is an important second site of regulation in cholesterol synthesis. This degree of inhibition still permits the formation of physiologically important intermediate isoprenoids in the absence of cholesterol synthesis. The third and final stage of synthesis occurs in the endoplasmic reticulum, with many of the intermediate products being bound to a specific carrier protein. Squalene, after initial oxidation, undergoes cyclization to form the four-ring, 30-carbon intermediate, lanosterol. In a series of oxidation-decarboxylation reactions, several sidechains are removed from the pentanophenanthrene structure to form the final 27-carbon molecule of cholesterol.

Cholesterol Esterification

Once synthesized, cholesterol is released into the circulation bound to lipoproteins, such as very low-density lipoprotein (VLDL; see later section on lipoprotein metabolism, endogenous pathway), which is one of the primary lipoproteins secreted by the liver. The major apoprotein found in VLDL is apo B-100. It is produced by the same gene as apo B-48, but represents the full-length product of the apo B gene. Apo B-48 is produced in the intestine by a post-transcriptional editing step, which introduces a stop codon in about the middle of the apo B-100 mRNA transcript, thus resulting in a protein about 48% the length of the full-length apo B-100 protein. The esterification of cholesterol is important, because it serves to enhance the lipid-carrying capacity of the lipoprotein in plasma and prevents intracellular toxicity by free

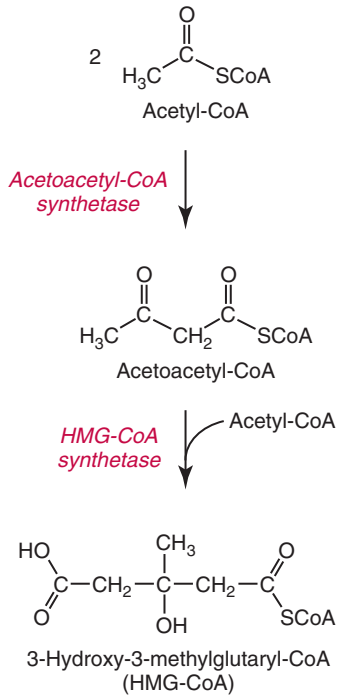


Figure 27-2 Cholesterol biosynthesis (stage 1).

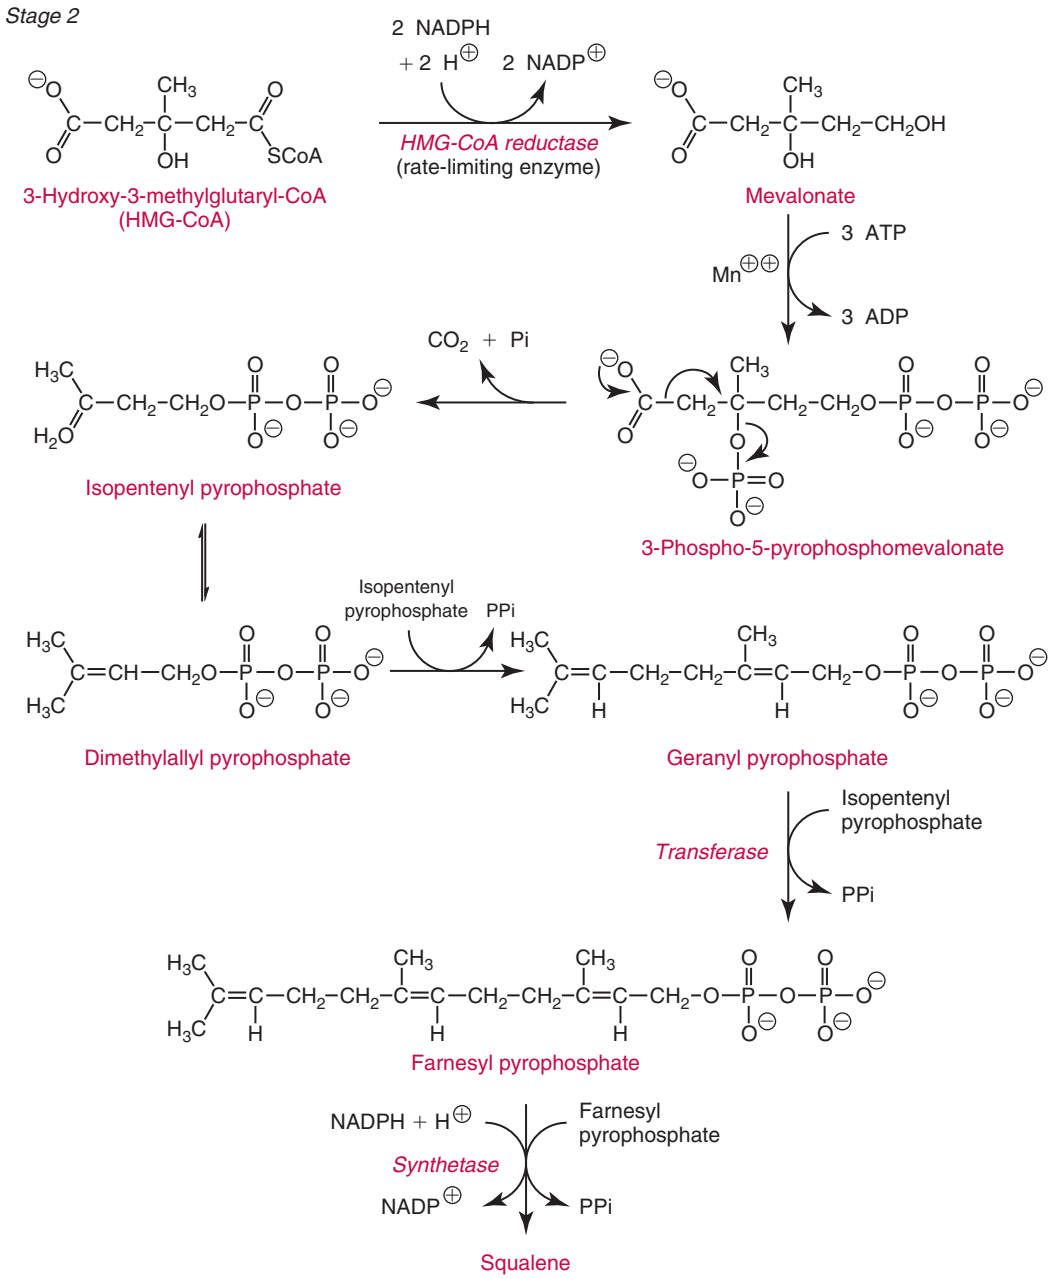

Figure 27-3 Cholesterol biosynthesis (stage 2).

cholesterol. The reaction is catalyzed by lecithin-cholesterol acyltransferase (LCAT) in the plasma and acylcholesterol acyltransferase (ACAT) within the cell. ACAT is an energy-requiring enzyme, and the initial reaction (Figure 27-5) involves activation of a fatty acid with thio coenzyme A (CoASH) to form an acyl-CoA, which in turn reacts with cholesterol to form an ester. The LCAT reaction does not require CoASH and results from fatty acid transfer from the second carbon position of phosphatidyl choline (lecithin) to the hydroxyl group on the A-ring of cholesterol (see Figure 27-5). Cholesteryl esters account for about 70% of the total cholesterol in plasma, and LCAT is responsible for the formation of virtually all plasma cholesteryl ester. LCAT is synthesized in the liver and released into the circulation; it primarily resides on lipoproteins and is activated by apo A-I and other apolipoproteins (see later section on apolipoproteins). The esterification of cholesterol by LCAT on the only polar group of cholesterol makes cholesteryl ester more hydrophobic than cholesterol. This causes the cholesterol on the surface of lipoproteins, once esterified, to partition into the more hydrophobic core of lipoproteins, where triglycerides are also located.

Cholesterol Catabolism

Once a lipoprotein enters the cell, its cholesteryl esters and triglycerides are hydrolyzed by lysosomal acid lipase. Lack or malfunction of this enzyme results in intracellular accumulation of cholesteryl esters and triglycerides, particularly in the

liver, and produces a clinical disorder known as *cholesteryl ester storage disease,* or *Wolman's disease.*

Cholesterol reaching the liver may be secreted unchanged into bile or metabolized to bile acids or resecreted on lipoproteins. Approximately one third of the daily production of cholesterol, or about 400 mg/d, is converted into bile acids (Figure 27-6). Conversion of cholesterol to cholic and chenodeoxycholic acids, the major bile acids in humans, involves shortening of the cholesterol sidechain and hydroxylation of the sterol nucleus. The first step, which is also the rate-limiting step, is hydroxylation of the 7-position of the sterol nucleus, catalyzed by the enzyme 7α-hydroxylase (see Figure 27-6).

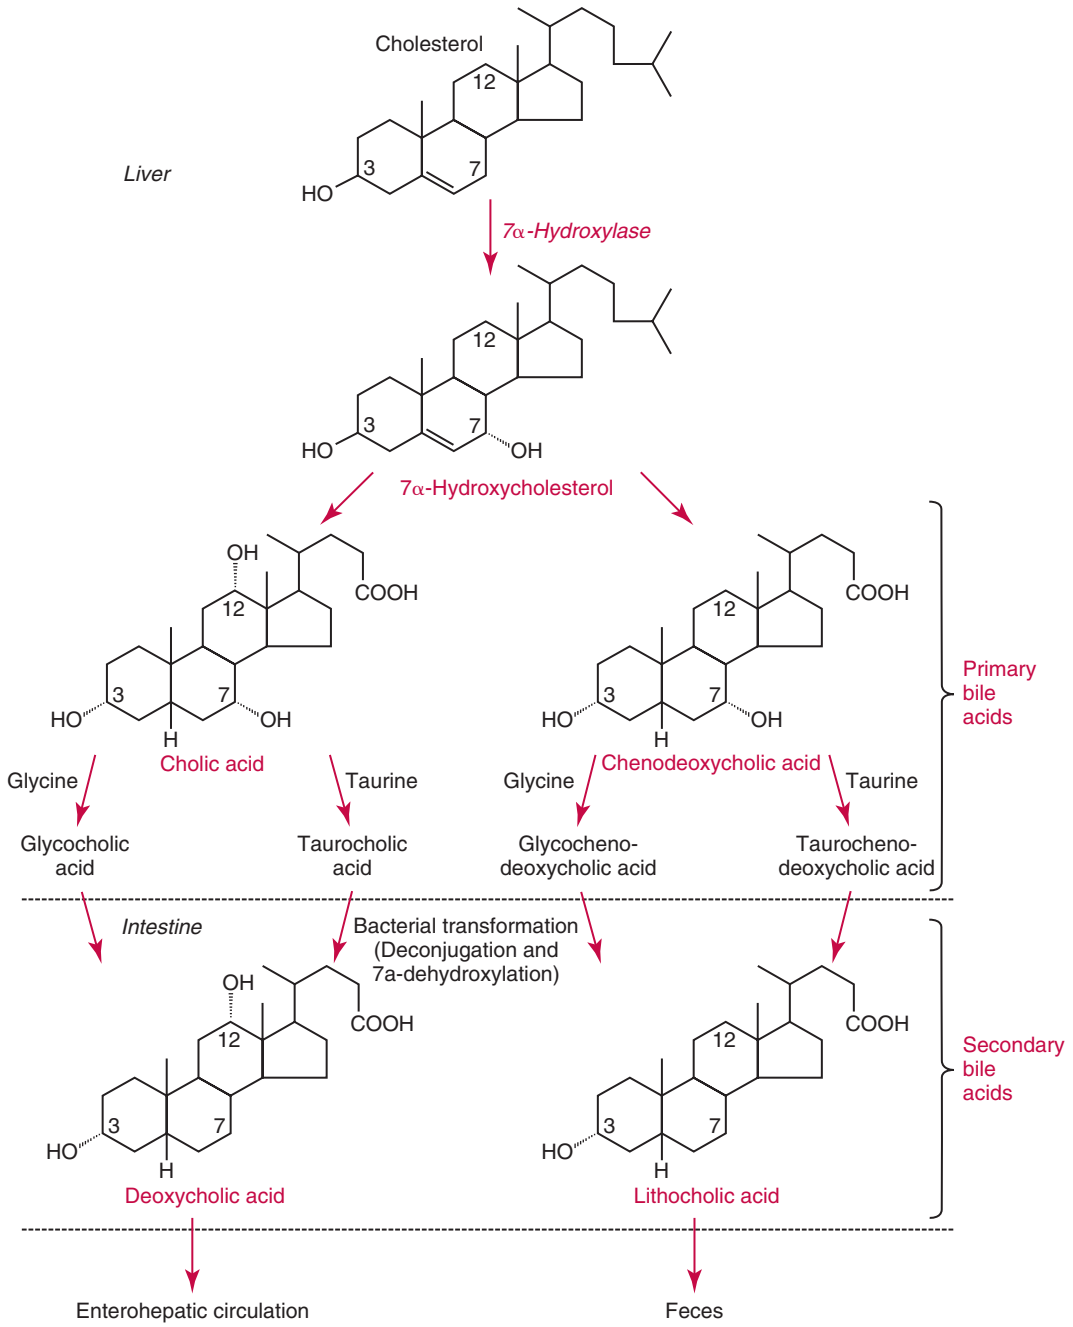

Figure 27-6 Bile acid synthesis.

The bile acids are made more polar after conjugation with glycine or taurine and then are excreted into the bile canaliculi. After reaching the small intestine, the conjugated bile acids play an active part in cholesterol and fat absorption, as discussed previously. Some of the bile acids are deconjugated and converted by bacteria in the intestine to secondary bile acids. Cholic acid is converted to deoxycholic acid, and chenodeoxycholic acid is metabolized to lithocholic acid. About 90% of the bile acids, except lithocholic, are reabsorbed in the lower third of the ileum and returned to the liver by the portal vein, which is called the enterohepatic circulation (see also Chapter 50).

A significant amount of cholesterol is also excreted directly into the biliary system, where it is solubilized to form mixed micelles with bile acids and phospholipids. If the amount of cholesterol in bile exceeds the capacity of these solubilizing agents, the excess cholesterol can precipitate, forming cholesterol gallstones, which account for about 80% of gallstones in Western societies.

It is important to note that except for the liver and a few endocrine tissues, such as the adrenal gland, most cells cannot further catabolize or modify cholesterol. Because of this and its limited aqueous solubility, cholesterol tends to accumulate in cells or extracellular spaces; this is another

feature of cholesterol that contributes to its ability to cause atherosclerosis.

Fatty Acids

The fatty acids are one of the simpler molecular forms of lipids. They are generically indicated by the chemical formula RCOOH, where "R" stands for an alkyl chain. Fatty acid chain lengths vary and are commonly classified according to the number of carbon atoms present. Three somewhat arbitrarily defined groups of fatty acids are those containing 2 to 4 carbon atoms (short chain), 6 to 10 carbon atoms (medium chain), and 12 to 26 carbon atoms (long chain). Those of importance in human nutrition and metabolism are of the long-chain class containing an even number of carbon atoms.

Fatty acids are further classified according to their degree of saturation. Saturated fatty acids have no double bonds between carbon atoms, monounsaturated fatty acids contain one double bond, and polyunsaturated fatty acids contain more than one double bond (Figure 27-7). The double bonds in polyunsaturated fatty acids of both animal and plant origin are usually 3 carbon atoms apart. Some fatty acids from marine fish living in deep, cold waters (e.g., salmon), which form oils at room temperature, possess numerous (up to 6) unsaturated bonds and usually are more than 20 carbon atoms long. These fatty acids are prone to oxidation, which occurs at the sites of unsaturation.

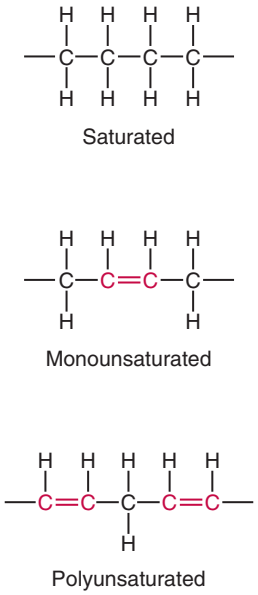

Figure 27-7 Saturated and unsaturated fatty acids.

Labeling of carbon atoms in fatty acids can take place from the carboxyl terminal (Δ-numbering system) or from the methyl terminal (η- or ω-numbering system; Table 27-1). In addition, carbon atoms may be labeled with Greek symbols, with α being adjacent to the carboxyl group and ω being farthest away. In the Δ-system, fatty acids are abbreviated according to the number of carbon atoms, the number of double bonds, and the position(s) of double bond(s). For example, linoleic acid, which contains 18 carbons and 2 unsaturated bonds between carbons 9 and 10 and between carbons 12 and 13, could be written as C_{18}:2.^{9,12} Using the η- or ω-system, linoleic acid would be abbreviated to C_{18}:2n-6, where only the first carbon forming the unsaturated pair is written. The *Geneva* or *systematic* classification is a third system of nomenclature (see Table 27-1).

In saturated fatty acids, the acyl chain is extended and flexible (i.e., the carbon atoms rotate freely around the longitudinal axis), and each internal carbon atom is fully saturated or, in other words, is covalently linked to two hydrogen molecules. *Cis*-unsaturated fatty acids have a fixed 30° bend in their acyl chains at each double bond, because two hydrogen molecules are missing from the same side of the carbon double bond, thus causing the bend. Lipids containing *cis*-unsaturated fatty acids, such as triglycerides or phospholipids, have lower melting points, because these lipids cannot interact and pack as tightly together by van der Waals interactions. As a consequence, lipids containing *cis*-unsaturated fatty acids, such as olive oil and other plant oils, are usually liquids at room temperature. In mammals, all naturally occurring unsaturated fatty acids are of the *cis* variety. *Trans* unsaturated fatty acids result from a chemical process called *catalytic hydrogenation,* a process used to "harden" unsaturated fats from plant sources in the manufacture of certain

TABLE 27-1 Fatty Acids Commonly Found in Human Tissue

Common Name	Systematic Name	Δ-Numbering	η-(ω) Numbering
Lauric	Dodecanoic	12:0	12:0

*Essential fatty acids.

foods, such as margarine. Although *trans* fatty acids are still unsaturated, one hydrogen is missing from each side of the carbon double bond, making these fatty acids resemble the more linear configuration of the acyl chain of saturated fatty acids, which also makes them solids at room temperature. Epidemiologic and experimental studies have shown that *trans* fatty acids may promote CHD; an effort is under way to reduce the use of catalytic hydrogenation in food processing and to reduce the consumption of *trans* fatty acids in the diet.[203]

Most fats in the human body are derived from the diet, which on the average in Western societies contains up to 40% fat, 90% of which is triglyceride. In addition, humans can synthesize most fatty acids, including saturated, monounsaturated, and some polyunsaturated fats; however, some fatty acids cannot be synthesized. One such fatty acid is linoleic acid (C_{18}:2[9,12]), which is found only in plants. Because it is vital for health and growth and development, it is termed an *essential fatty acid*. Linoleic acid is converted to arachidonic acid, which has an important role in prostaglandin synthesis and in myelinization of the central nervous system.

The fatty acid carboxyl group has a pK_a of approximately 4.8; thus free fatty acid molecules in both plasma and intracellular fluid (pH of 7.4 and 7.0, respectively) exist primarily in an ionized form. Much of the fatty acid in plasma exists as esters with cholesterol or glycerol, or is transported as a free fatty acid–albumin complex or a free fatty acid–prealbumin complex. One molecule of albumin can carry as many as 20 molecules of fatty acid. The normal concentration of free fatty acids in human blood is 0.30 to 1.10 mmol/L, or about 8 to 31 mg/dL of plasma. The flux of free fatty acids through the plasma is very large and is sensitive to physiologic energy demands (exercise and physical work), the concentration of blood glucose, and psychologic stresses that cause liberation of epinephrine.

Fatty Acid Catabolism

Long-chain fatty acids are oxidized in the mitochondria and produce energy by a series of reactions that operate in a repetitive manner to shorten the fatty acid chain by two carbon atoms at a time from the carboxy (—COOH) terminal of the molecule through a process known as β-oxidation. For example, 1 mole of C_{16} fatty acid is converted to 8 moles of acetyl-CoA. Acetyl-CoA does not normally accumulate in the cell but is enzymatically condensed with oxaloacetate, derived largely from carbohydrate metabolism (Figure 27-8), to yield citrate, which is a major component of the tricarboxylic acid cycle, also called *Krebs cycle*. The Krebs cycle serves as a common pathway for the final oxidation of nearly all food material, whether derived from carbohydrate, fat, or protein. It is important to note that the efficiency of the Krebs cycle depends on the availability of sufficient oxaloacetate to serve as an acceptor for acetyl-CoA.

Complete oxidation of a single fatty acid molecule produces a relatively large quantity of energy. For example, the complete oxidation of 1 mole of palmitic acid to carbon dioxide and water produces 16 moles of CO_2, 16 moles of H_2O, and 129 moles of adenosine triphosphate, or 2340 Cal.* Thus the standard free energy for oxidation of palmitic acid is 2340 Cal, whereas the free energy liberated by hydrolysis of 129 moles of ATP is 940 Cal, indicating that the efficiency of energy conservation in fatty acid oxidation is approximately 40% under standard conditions.

By means of suitable enzyme reactions, the chemical energy stored in fatty acids can be released for metabolic processes or stored in the form of high-energy compounds, such as ATP. Triglycerides that contain three fatty acid molecules, therefore, are an efficient storage form for metabolic energy. The amount of energy produced by metabolizing 1 mole of palmitic acid (16 carbon atoms) is approximately twice that produced by metabolizing an equivalent amount (2.5 mole) of glucose (6 carbon atoms per molecule). Carbohydrate storage also requires water for hydration; triglyceride storage does not. In addition to their high intrinsic energy content, triglycerides have a low density (<1 g/mL) and, because of their hydrophobic nature and peripheral distribution in the body, provide excellent insulation.

Ketone Formation

During prolonged starvation, or when carbohydrate metabolism is severely impaired, as in uncontrolled diabetes mellitus (see Chapter 26), the formation of acetyl-CoA exceeds the supply of oxaloacetate. The abundance of acetyl-CoA results from excessive mobilization of fatty acids from adipose tissue and excessive degradation of fatty acids by β-oxidation in the liver. The resulting acetyl-CoA excess is diverted to an alternative pathway in the mitochondria and forms acetoacetic acid, β-hydroxybutyric acid, and acetone—three compounds known collectively as *ketone bodies* (Figure 27-9). The presence of ketone bodies is a frequent finding in severe, uncontrolled diabetes mellitus.

As shown in Figure 27-9, the first product, acetoacetyl-CoA, condenses in the mitochondria with a third molecule of acetyl-CoA to yield HMG-CoA. This pool of HMG-CoA in the mitochondria is distinct from the pool in the cytosol, which is used for cholesterol biosynthesis. The HMG-CoA produced in the mitochondria is cleaved enzymatically to yield acetoacetate and acetyl-CoA. Some of the acetoacetate formed in liver cells is usually reduced to β-hydroxybutyrate. Because acetoacetate is unstable, a further portion decomposes to form carbon dioxide and acetone, the third ketone body found in severe, untreated diabetes mellitus. Ketosis, therefore, develops from excessive production of acetyl-CoA because the body attempts to derive necessary energy from stored fat in the absence of an adequate supply of carbohydrate metabolites (see Chapter 26).

Inadequate incorporation of acetyl-CoA into the Krebs cycle may be further aggravated by inhibition of the oxaloacetate-generating enzyme system through excess

*The unit used in discussing the energy value of food is the calorie (Cal), equal to 1000 calories or 1 kilocalorie (kcal). In the SI system, the unit of energy is the joule (J), and 1 calorie = 4.1868J.

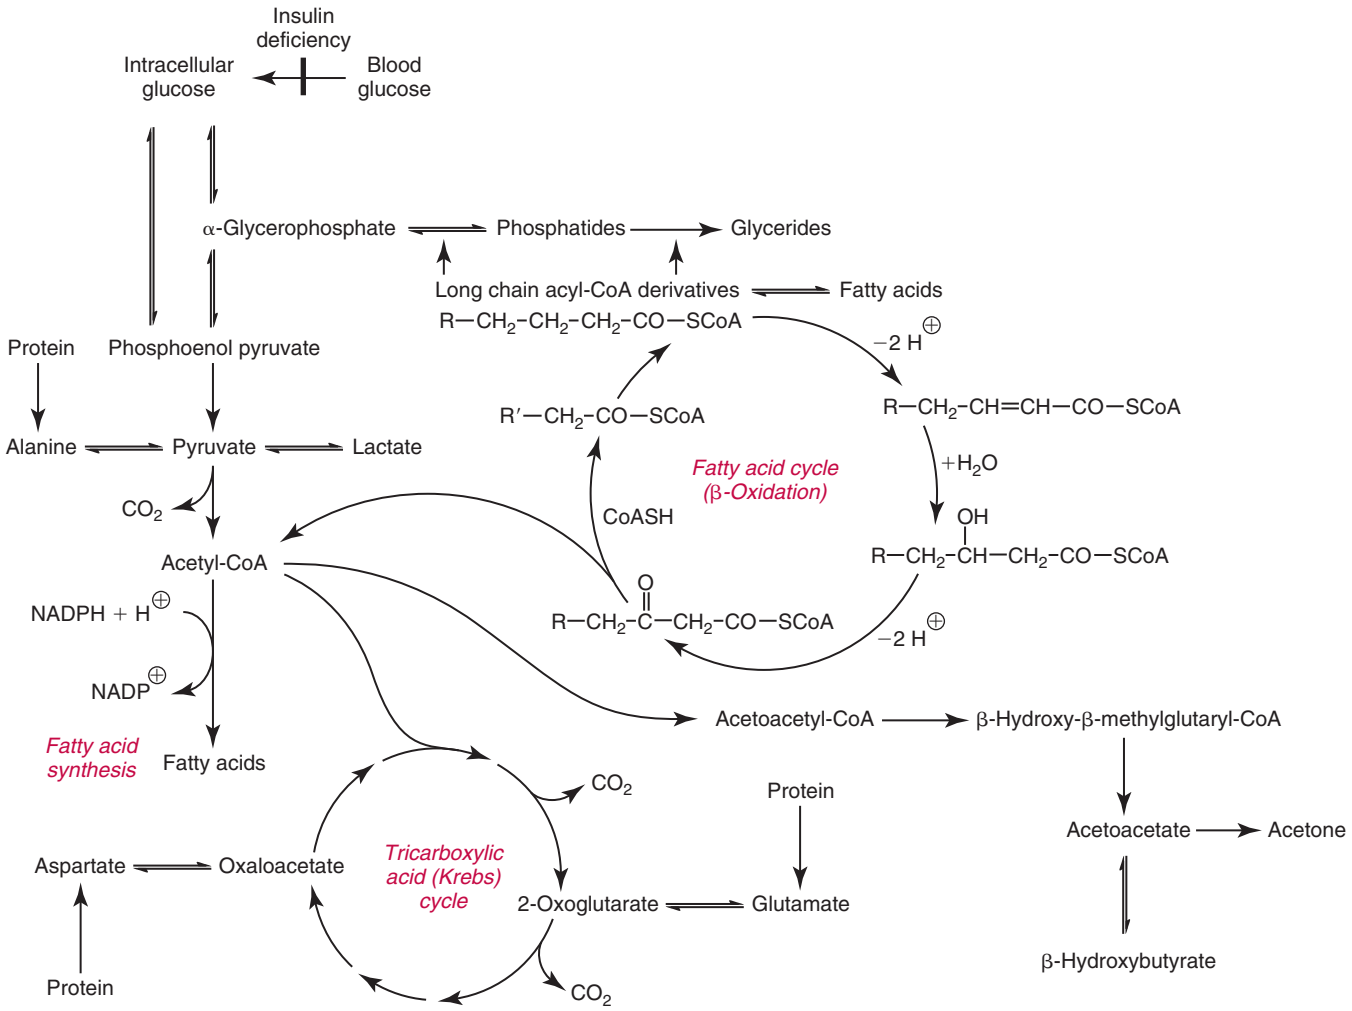

Figure 27-8 Metabolic relations among intermediates of carbohydrate, fat, and protein metabolism. Note that acetyl-CoA is produced from both carbohydrate and fat. The glucogenic amino acids, derived from protein metabolism, enter glycolytic paths as α-keto acids. Ketogenic amino acids enter as acetyl-CoA.

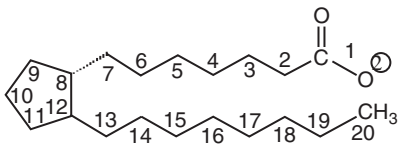
accumulation of palmitic-CoA and other long-chain fatty acid–CoA derivatives in the liver. Skeletal muscle and heart (and brain in prolonged fasting) use ketone bodies by resynthesizing their CoA derivatives and subsequently oxidizing them for the production of energy. Although liver cells are largely responsible for converting fatty acids, they cannot metabolize acetoacetate, because the liver lacks 3-ketoacid CoA transferase, the enzyme required for transferring CoA from succinyl-CoA.

The entire process of ketosis is reversed by restoring adequate metabolism of carbohydrate. In starvation, restoration consists of adequate carbohydrate ingestion; in diabetes mellitus, ketosis can be reversed by insulin administration, which permits circulating blood glucose to be taken up by the cells. With restored concentrations of oxaloacetate, acetyl-CoA can instead enter the Krebs cycle, thus restoring the normal pathway for energy metabolism. Eventually, the release of fatty acids from adipose tissue slows down and is finally reversed. A graphic view of these metabolic reactions is outlined in Figure 27-8, which shows the interrelationship between carbohydrate, fatty acid, and protein metabolism.

Prostaglandins

Prostaglandins and related compounds are derivatives of fatty acids, primarily arachidonate. This group consists of prostaglandins, thromboxanes, some hydroperoxy– and hydroxy–fatty acid derivatives, and leukotrienes. Although their full physiologic role is not completely known, these lipids are known to affect a wide variety of biological functions. In general, they are extremely potent, producing physiologic actions at concentrations as low as 1 μg/L.



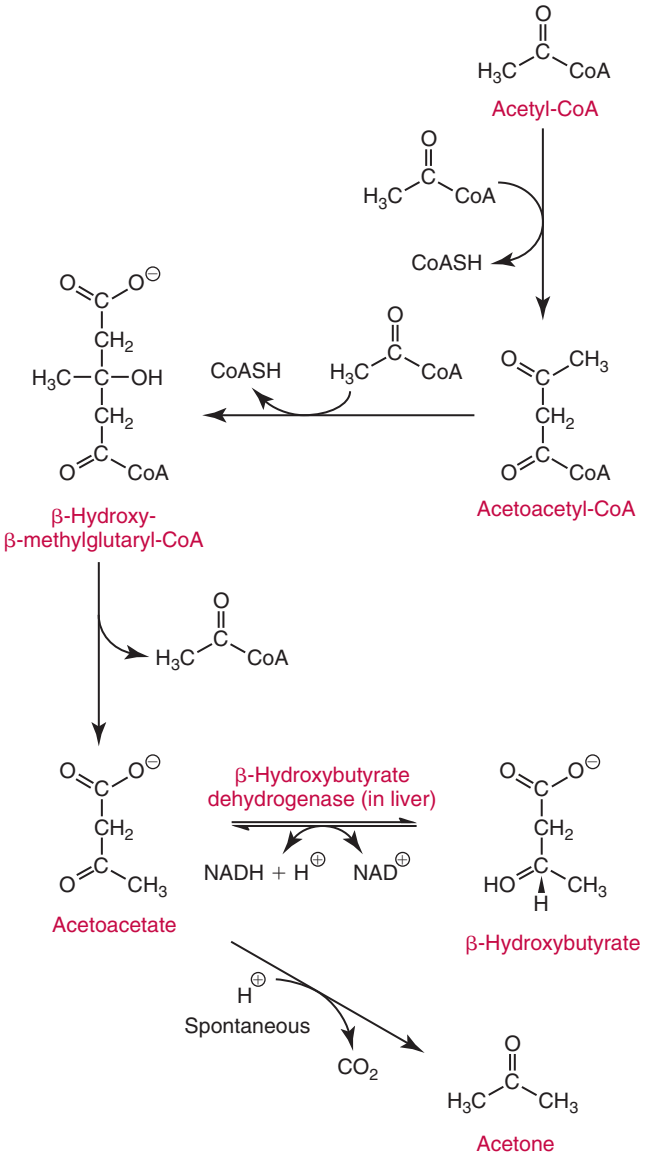


Figure 27-9 Formation of ketone bodies.

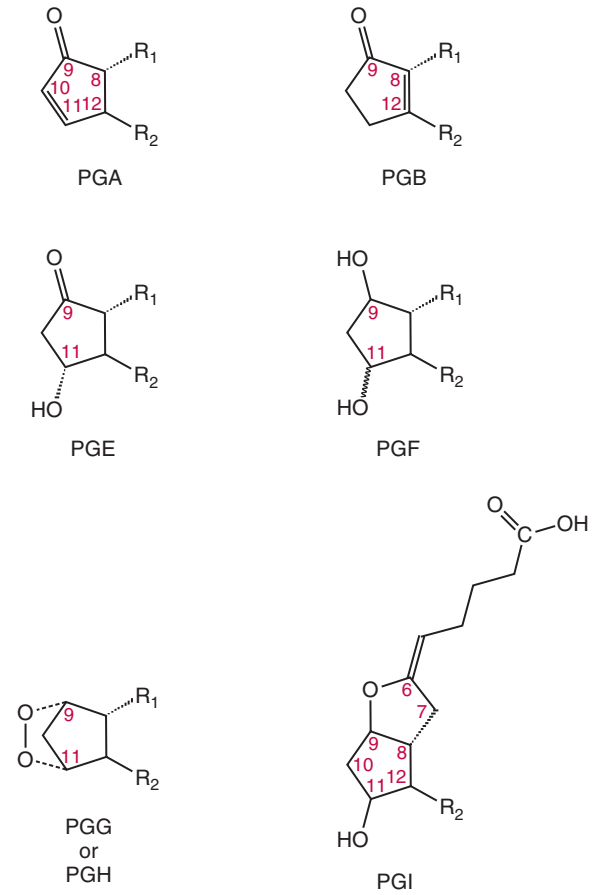

Figure 27-10 Major prostaglandin classes (series). R_1 and R_2 are prostaglandin side chains.

The prostaglandins are a series of C_{20} unsaturated fatty acids containing a cyclopentane ring; the parent fatty acid has been given the trivial name *prostanoic acid.* The seven-carbon chain linked to C-8 of prostanoic acid (R_1) projects below the plane of the ring, whereas the eight-carbon chain attached to C-12 (R_2) projects above the ring.

By convention, prostaglandins are abbreviated *PG,* with the class designated by a capital letter (A, B, E, F, G, H, and I), followed by a number and then in some cases a Greek letter (Figure 27-10). With the exception of PGG and PGH, which have the same ring structure (cyclopentane endoperoxide), the letters refer to different ring structures. PGA and PGB have keto groups at C-9, with the A series having a double bond between C-10 and C-11, and the B series having a double bond between C-8 and C-12. PGE also has a C-9 keto bond but a hydroxyl group at C-11. The F series has hydroxyl groups at both C-9 and C-11. The difference between PGG and PGH, which have identical ring structures, occurs in the sidechain at C-15 in R_2. The G series has a peroxide group, whereas the H series has a hydroxyl group. The I series has a double-ring formation, with the C-9 of the cyclopentane ring linked to C-6 of the sidechain by an oxygen molecule to form a second five-sided ring (see Figure 27-10). The endoperoxide PGs (G and H series) are intermediates in the formation of other PGs.

The number after the capital letter is usually written as a subscript and is used to designate the number of unsaturated bonds in the PG sidechains and not within the ring structure itself. In PGE_1, for example, a double bond exists between C-13 and C-14; in the 2 series (PGE_2), a double bond exists between C-13 and C-14 and between C-5 and C-6; and in the 3 series (PGE_3), an additional double bond occurs between C-17 and C-18. The 2 series is most common. The bond between C-13 and C-14 is always *trans,* whereas bonds between C-5 and C-6 and between C-17 and C-18 are always *cis.* At C-15, all naturally occurring prostaglandins have a hydroxyl group that projects below the plane of the ring. Use of the Greek letter (α or β) applies only to the F series and refers to the hydroxyl group found at C-9. In the α-series, the hydroxyl group projects below the ring plane in the same direction as the C-11 hydroxyl group, whereas the β-series

TABLE 27-2 Naturally Occurring Prostaglandins (PGs)

Primary PG	Other PG

Thromboxane B_2	$PGF_{3\alpha}$

denotes that the hydroxyl at C-9 is above the plane of the ring. Sixteen naturally occurring prostaglandins have been described (Table 27-2), but only seven, along with two thromboxanes, are commonly found throughout the body, and they are termed the *primary prostaglandins.*

Although prostaglandins have hormone-like actions, they are different from most other hormones in that (1) they are synthesized at the site of action, and (2) they are made in almost all tissues. Linoleic acid (C_{18}:$2^{9,12}$) is the precursor of two of the three 20-carbon fatty acids that form prostaglandins; linolenic acid (C_{18}:$2^{9,12,15}$) is the other precursor. Both of these fatty acids are considered essential because they cannot be synthesized in the body and, therefore, must be present in the diet. The three C_{20} fatty acids subsequently formed are C_{20}:$3^{5,8,11}$ (eicosatrienoic acid), C_{20}:$4^{5,8,11,14}$ (eicosatetraenoic or arachidonic acid), and C_{20}:$5^{8,11,14,17}$(eicosatrienoic acid). These three fatty acids form the PG_1, PG_2, and PG_3 series, respectively.

Once formed, prostaglandins exert very short-lived effects and are rapidly catabolized to inactive forms within a few seconds. Inactivation of prostaglandin appears to be mediated by two enzymes: 15 α-hydroxy-prostaglandin dehydrogenase and Δ^{13}-prostaglandin reductase. Prostaglandins are not stored; instead, precursor C_{20} fatty acids are present in tissue attached to the C-2 (see later section in this chapter on glycerol esters) of phosphoglycerides. When necessary, the C_{20} precursor is hydrolyzed by phospholipase A_2, which is specific for the C-2 position of phosphoglyceride. Release of the C_{20} fatty acid appears to be the rate-limiting step in prostaglandin synthesis and is stimulated by many different agents, such as bradykinin, thrombin, or angiotensin II.

Although it is probable that all prostaglandins follow a similar synthetic pathway, C_{20}:4 (arachidonic acid) has been the most intensively studied and is used to illustrate the pathway (Figure 27-11). Once released, arachidonic acid follows one of two pathways. The lipoxygenase route produces 12-L-hydroperoxy-5,8,10,14 eicosatetraenoic acid (HPETE); HPETE then spontaneously decomposes to 12-L-hydroxy-5,8,10,14 eicosatetraenoic acid (HETE). The alternative pathway is mediated by cyclooxygenase (COX) to produce the endoperoxides PGG_2 and PGH_2. The latter can be degraded to 12-L-hydroxy-5,8,10-heptadecatrienoic acid.

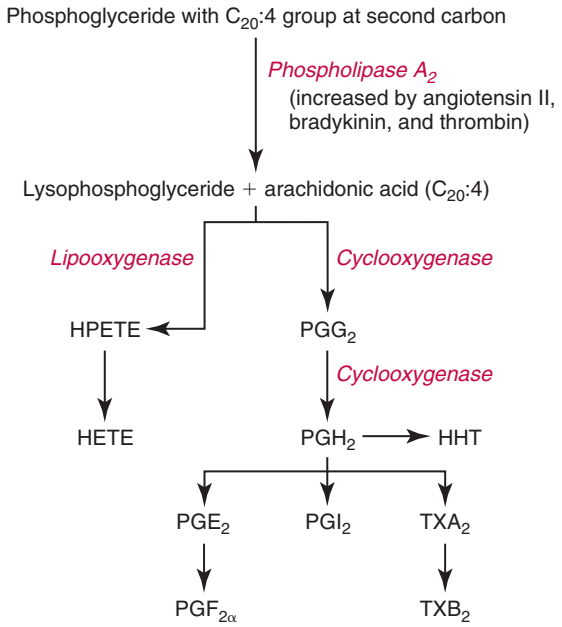

Figure 27-11 Synthesis of prostaglandins from arachidonic precursor. HPETE, HETE, HHT, 12-l-Hydroxy-5,8,10-heptadecatrienoic acid; *PG,* prostaglandin; *TX,* thromboxane.

What controls the entry into a specific pathway remains speculative; however, it is known that nonsteroidal anti-inflammatory drugs (NSAIDs; aspirin, ibuprofen, and indomethacin) inhibit the COXs, thereby decreasing prostaglandin synthesis. Two isoforms of COX are known: COX-1 and COX-2. COX-1 concentrations in general are constitutively expressed, whereas COX-2 is synthesized in response to inflammation. Certain drugs that inhibit both COXs have nephrotoxic and ulcerogenic side effects. Therefore, newer NSAIDs have been developed that preferentially inhibit COX-2 to reduce side effects, but they have been found to also be associated with an increased incidence of myocardial infarction.[94]

Prostaglandin I_2, or prostacyclin, is derived from arachidonic acid (see Figure 27-11) in the vascular endothelium. It has a powerful vasodilatory action, especially on the coronary arteries, and is responsible for inhibiting platelet aggregation. Thromboxane A_2 is synthesized from arachidonic acid but is also produced by platelets. It has the opposite effect of prostacyclin (i.e., it stimulates the contraction of arterial smooth muscle and enhances platelet aggregation). It has a very short half-life—about 30 seconds—and is rapidly converted to its inactive metabolite, thromboxane B_2. The thromboxanes are slightly different from other prostaglandins in that they contain six-sided rings of five carbon atoms and one oxygen atom (Figure 27-12). Table 27-3 lists some reported functions of the various prostaglandins.

Glycerol Esters (Acylglycerols)

Virtually all complex lipids contain fatty acids, and in most cases they are covalently linked to an alcohol. One of the most

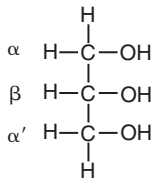
Adipose tissue	Inhibits triglyceride lipolysis

common alcohols found in lipids is glycerol, a three-carbon molecule containing three hydroxyl groups.



The two terminal carbon atoms in the molecule are chemically equivalent and are designated α and α′. The center carbon is labeled β. A common alternative labeling system uses the numeral 1 for the α-carbon, 2 for the β-carbon, and 3 for the α′-carbon.

The class of acylglycerol (glyceride) is determined by the number of fatty acyl groups present; one fatty acid, monoacylglycerols (monoglycerides); two fatty acids, diacylglycerols (diglycerides); three fatty acids, triacylglycerols (triglycerides). In a monoacylglycerol, the fatty acid may be linked to any of the three carbon atoms. By convention, the number system is used to indicate the carbon position (e.g.,

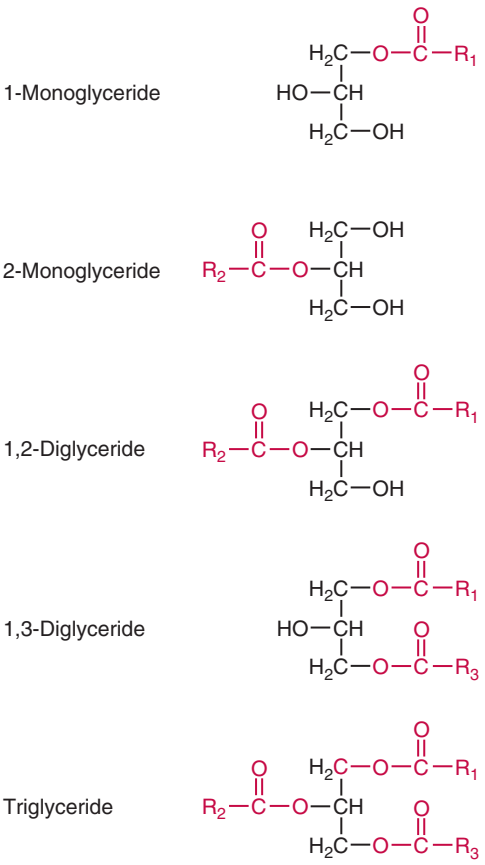


Figure 27-13 Structure and classification of glycerol esters (acylglycerols). R_1, R_2, and R_3 are fatty acids of varying chain length.

1-monoglyceride indicates a fatty acid attachment to the α-carbon). This numbering system applies to all acylglycerols, including the phosphoglycerides, as shown later. Diglycerides may be 1,2- or 1,3-diglycerides (Figure 27-13).

Triglycerides are the most prevalent glycerol esters encountered in the body and constitute 95% of tissue storage fat; they are the predominant form of glyceryl ester found in plasma. Fatty acid residues found in monoglycerides, diglycerides, or triglycerides vary considerably and usually include combinations of the long-chain fatty acids shown in Table 27-1. Triglycerides from plants (e.g., corn, sunflower seed, safflower oils) tend to have large quantities of *cis*-unsaturated fatty acids, such as C_{18}:2 or linoleic acid, and are liquid at room temperature. Triglycerides from animals, especially ruminants, tend to have C_{12}:0 through C_{18}:0 fatty acid residues (saturated fats) and are solids at room temperature. Rarely, some plant triglycerides, such as coconut oil, are highly saturated and may be solid at room temperature.

Triglycerides are digested in the duodenum and the proximal ileum. Through the action of pancreatic and intestinal lipases and in the presence of bile acids, which activate lipases, they are hydrolyzed to glycerol, monoglycerides, and fatty acids. After absorption, triglycerides are resynthesized in the intestinal epithelial cells and are combined with cholesterol and apo B-48 to form chylomicrons. Another major class of

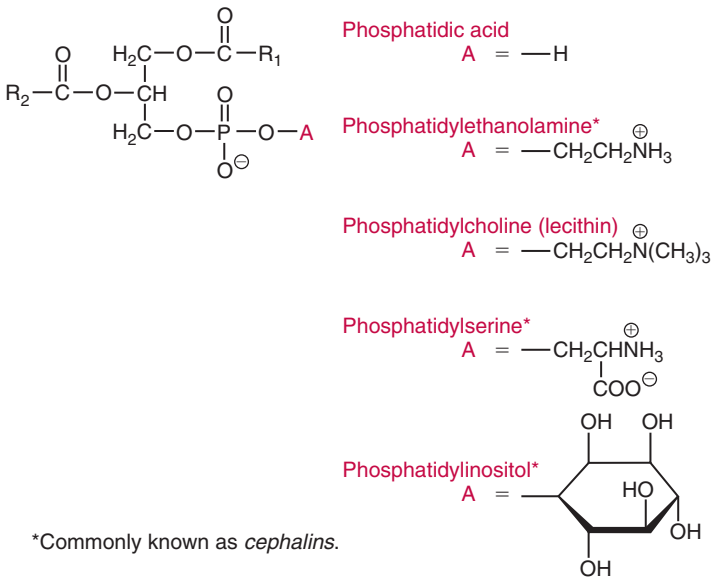

Figure 27-14 Structures of phosphoglycerides and common alcohol groups associated with them. R_1 and R_2 are fatty acid(s) of varying carbon atom lengths.

glycerol esters consists of those containing phosphoric acid at the third (α′) carbon atom; these esters are called *phosphoglycerides* (Figure 27-14). In their simplest form, the A group is an H atom; the molecule is therefore called a *diacylphosphoglyceride.* Usually, however, the A is an alcohol-derived group, such as choline, serine, inositol, or ethanolamine (see Figure 27-14). If A is choline, the molecule is referred to as *phosphatidylcholine;* if it is ethanolamine, it will be referred to as *phosphatidylethanolamine,* etc. The term *lecithin,* which is an older designation, is a commonly used term for phosphatidylcholines. Because of the wide variety of fatty acid residues at positions R_1 and R_2 (see Figure 27-14), many different types of phospholipids can be formed. These phospholipids are named according to the fatty acid acyl ester attached at C-1 and C-2 of the glycerol. Saturated fatty acids are typically attached to the C-1 position, whereas (poly)unsaturated fatty acids are often present at the C-2 position. In inner mitochondrial membranes, more complex phosphoglycerides known as *cardiolipins* can be found. They are derived from two phosphoglyceride molecules joined by a glycerol bridge.

Sphingolipids

Sphingolipids, a fourth class of lipids found in humans, are derived from the amino alcohol sphingosine (Figure 27-15). This dihydric 18-carbon alcohol contains an amino group at C-17. A fatty acid containing 18 or more carbon atoms can be bound to the amino group through an amide linkage to form *ceramide.* This is the intermediary step in the formation of three important sphingolipids: sphingomyelin, galactosylceramide, and glucosylceramide (see Figure 27-15). The sugar-containing ceramides can have a sulfate group attached (usually on the 2-position of the galactose residue) to form the sulfatides. The glycosyl ceramides can have additional monosaccharide moieties, such as galactose, *N*-acetylgalactosamine, and *N*-acetylneuraminic acid to form complex globosides and gangliosides. These complex sphingolipids form the major lipids of cell membranes, particularly in the central nervous system. Gangliosides, for example, are particularly prevalent in the gray matter of the brain, whereas membrane glycosphingolipids have major roles in cellular interactions, growth, and development. Some glycolipids on red cells form blood group antigens, whereas other glycolipids can be tumor antigens.

Terpenes

Terpenes are polymers of the five-carbon isoprene unit; they form the backbone of vitamins A, E, and K (see Chapter 31) and the dolichols, which play an important role in protein glycosylation.

Lipoproteins

Lipids synthesized in the liver and the intestine must be transported to various tissues to accomplish their metabolic functions. Because of their relative insolubility in aqueous solutions, they are transported in the plasma in macromolecular complexes called *lipoproteins.* Lipoproteins are typically spherical particles with more hydrophobic nonpolar lipids (triglycerides and cholesterol esters) in their core, and more polar or amphipathic lipids (phospholipids and free cholesterol) oriented near the surface as a single monolayer. They also contain one or more specific proteins, called *apolipoproteins,* which usually are located on their surface (Figure 27-16).[266] The association of core lipids with the overlying phospholipid, cholesterol, and protein coat is noncovalent, occurring primarily through hydrogen bonding and van der Waals forces. This binding is loose enough to allow spontaneous exchange of cholesterol, which is more water soluble than the other lipids, among plasma lipoproteins and between cell membranes. The other more hydrophobic lipids require specific transfer proteins to exchange between lipoproteins, such

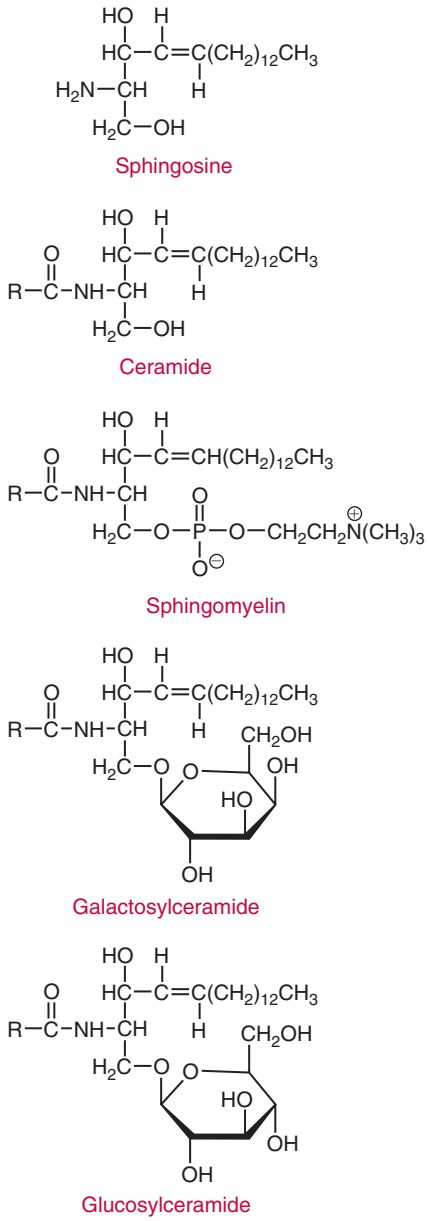

Figure 27-15 Structures of sphingolipids.

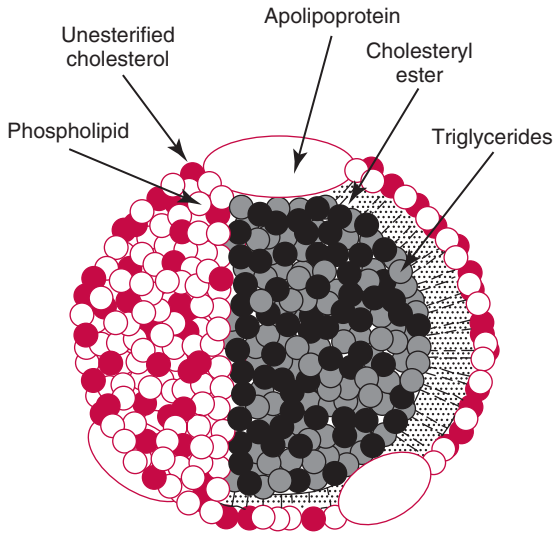

Figure 27-16 Structure of a typical lipoprotein particle.

as cholesteryl ester transfer protein (CETP), which exchanges triglycerides and cholesteryl esters between lipoproteins. Phospholipid transfer protein (PLTP) promotes the transfer of phospholipids between lipoproteins.

Lipoproteins have different physical and chemical properties (Table 27-4) because they contain different proportions of lipids and proteins (Table 27-5). Historically, lipoproteins have been categorized on the basis of differences in their hydrated densities, as determined by ultracentrifugation. Categories include (1) chylomicron, (2) VLDL, (3) intermediate-density lipoprotein (IDL), (4) low-density lipoprotein (LDL), (5) high-density lipoprotein (HDL), and (6) lipoprotein(a) [Lp(a)]. HDL can be further divided by density into two subpopulations: HDL_2 and HDL_3. Lp(a) consists of a distinct class of lipoproteins (see Table 27-4) that are structurally related to LDL, because similar to LDL, it contains one apo B-100 per particle and has a similar lipid composition.[79,177] In contrast to LDL, Lp(a) contains a carbohydrate-rich protein called apo(a), which is covalently bound to apo B-100 through a disulfide linkage. Apo(a) exhibits a significant sequence homology with plasminogen, but unlike plasminogen, Lp(a) is not an active protease. Lp(a) contains a high degree of variation in polypeptide chain length because of a variable number of kringle domains (Figure 27-17). Apo(a) contains 10 distinct classes of kringle 4–like domains that differ from each other in amino acid sequence. Kringle 4 type 1 and kringle 4 types 3 to 10 are present as a single copy, but kringle 4 type 2 is present in variable numbers of repeats (3 to >40) (see Figure 27-17).[157,323]

In the fasting state, most plasma triglycerides are present in VLDL. In the postprandial state, chylomicrons appear transiently and contribute significantly to the total plasma triglyceride concentration. LDL normally carries about 70% of total plasma cholesterol but very little triglyceride (see Table 27-5). HDL contains about 20 to 30% of plasma cholesterol.

Lipoproteins can be separated electrophoretically on agarose or on other solid support material, such as cellulose acetate, paper, or polyacrylamide gels.[224] At a pH of 8.6, HDL migrates with the α-globulins, LDL with the β-globulins, and VLDL and Lp(a) between the α- and β-globulins, in the pre–β-globulin region. IDL forms a broad band between β- and pre–β-globulins. Chylomicrons remain at the point of application. This forms the basis for the following common classification of lipoproteins: pre–β-lipoprotein, VLDL; β-lipoprotein, LDL; and α-lipoprotein, HDL.

Apolipoproteins

Apolipoproteins are the protein components of a lipoprotein. Characteristics and main known functions of the major apolipoproteins are summarized in Table 27-6. Each class of lipoprotein has a variety of apolipoproteins in differing proportions, with the exception of LDL, which contains only apo

B-100. Apo A-I is the major protein in HDL. Apo C-I, C-II, C-III, and E are present in various proportions in all lipoproteins except LDL. Apolipoproteins collectively have three major physiologic functions. They are involved in (1) activating important enzymes in the lipoprotein metabolic pathways, (2) maintaining the structural integrity of the lipoprotein complex, and (3) facilitating uptake of lipoprotein into cells through their recognition by specific cell surface receptors.[173] Besides these main apolipoproteins, lipoproteins have been found to weakly bind a large number of plasma proteins, but their relevance is not fully understood.[119]

Apolipoprotein A

Together, apolipoprotein A-I and apo A-II constitute about 90% of total HDL protein. The ratio of apo A-I to A-II in HDL is about 3:1.[41] In addition to being an important structural

component of HDL, apo A-I is a cofactor for LCAT, the enzyme responsible for forming cholesteryl esters in plasma. Some evidence suggests that apo A-II may inhibit LCAT and activate hepatic triglyceride lipase. Apo A-IV is a component of newly secreted chylomicrons, but it is not a major constituent of chylomicron remnants, VLDL, LDL, and HDL. The primary function of apo A-IV is currently unknown, but it has been shown to activate LCAT in vitro,[54] and available data suggest that it plays a role in the intestinal absorption of lipid. Apo A-V is a recently described apolipoprotein.[88] It is relatively low in abundance compared with other apolipoproteins and appears to modulate triglyceride concentrations by a mechanism that currently is not well understood. All these proteins, including most of the other apolipoproteins, contain a structural motif called an *amphipathic helix.* It is an α-helix with approximately half the amino acid residues comprising hydrophobic amino acids, which face toward the neutral lipid core when bound to a lipoprotein particle. The other side of the helix faces outward from the surface of a lipoprotein particle and contains polar or charged amino acids. In general, the binding of amphipathic helices to lipoproteins is relatively weak, thus allowing apolipoproteins to exchange between different lipoproteins during lipoprotein metabolism.

Apolipoprotein B

As already discussed, apolipoprotein B exists in two forms: apo B-100 and apo B-48.[173] Apo B-100, a single polypeptide of more than 4500 amino acids, is the full-length translation product of the apo B gene. In humans, apo B-100 is made in the liver and is secreted into plasma as part of VLDL. Apo B-100 is also the major apolipoprotein of LDL, the end product of VLDL catabolism. Each VLDL particle contains one molecule of apo B-100. In the fasting state, most of the apo B in plasma is apo B-100. Unlike other apolipoproteins, however, apo B-100 cannot move from one lipoprotein particle to another, because in addition to amphipathic helices, it has β-sheets[287]—a structural motif with much higher affinity for lipids. It is for this reason that apo B-100 remains with VLDL as it is transformed by lipolysis of its triglycerides and is eventually converted into LDL. Apo B-48 contains 2152 amino acids and is identical to the amino-terminal portion of apo B-100. Apo B-48 results from post-transcriptional modification of internal apo B-100 messenger ribonucleic acid, in which a single base substitution produces a stop codon corresponding to residue 2153 of apo B-100. Apo B-48 is made in the intestine and is the major apo B component of chylomicrons. Both apo B-100 and apo B-48 play important roles in the secretion of VLDL and chylomicrons, respectively. Apo B-100 is recognized by the LDL receptor in hepatic and peripheral tissues; it allows the LDL receptor-mediated internalization of LDL[44] (see later sections on lipoprotein metabolism, endogenous and exogenous pathways).

Apolipoprotein C

Apolipoproteins C-I, C-II, and C-III are associated with all lipoproteins except LDL. Apo C-I, the smallest of the C apolipoproteins, has been reported to activate LCAT in vitro, but its in vivo function is not clear. Apo C-II plays an important role in the metabolism of triglyceride-rich lipoprotein (VLDL and chylomicrons) by serving as an activator of lipoprotein lipase (LPL), an enzyme that hydrolyzes lipoprotein triglycerides. Because of differences in sialic acid content, apo C-III exists in at least three polymorphic forms.[46] In contrast to apo C-II, apo C-III decreases lipolysis by the inhibition of LPL.

Apolipoprotein E

Apolipoprotein E is a 34-kDa plasma glycoprotein that is found primarily in chylomicrons, VLDL, HDL, and chylomicron and in VLDL remnants. Removal of apo E–bearing lipoproteins is mediated by several different cellular receptors that recognize a cluster of positively charged amino acids in a specific region of apo E. Apo E plays a central role in the metabolism of chylomicrons and VLDL remnants. It regulates and facilitates lipoprotein uptake in the liver through the interaction of chylomicron remnants with chylomicron remnant receptors, and the binding of VLDL remnants to the LDL receptor, as well as probably proteoglycans.[173]

Three common apo E isoforms, designated E_2, E_3, and E_4, were initially distinguished by isoelectric-focusing electrophoresis.[340] These isoforms have amino acid substitutions at residues 112 and 158.[243,340] Apo E_2 has cysteine residues in both positions, and apo E_4 has arginine residues in both positions, whereas apo E_3 has cysteine and arginine at positions 112 and 158, respectively. Apo E_2 exhibits reduced binding affinity for the B and/or E remnant receptor compared with apo E_3, which tends to lead to an accumulation of apo E–containing lipoprotein in the circulation, whereas apo E_4–containing lipoproteins are cleared more rapidly than those containing apo E_3. These isoforms are coded for by three alleles of the apo E gene: ε2, ε3, and ε4. The ε3 allele is most frequent, although relative proportions of the three alleles vary among populations.[67,70,72] These apo E alleles have been shown to contribute significantly to the variability of LDL cholesterol and apo B-100 concentrations within populations.[281] Individuals with at least one ε2 allele tend to have lower concentrations of apo B-100 and LDL cholesterol than do those who are homozygous for the ε3 allele, whereas individuals with at least one ε4 allele tend to have higher concentrations of these analytes. This most likely occurs because increased hepatic uptake of lipoproteins in the presence of the ε4 allele leads to an increase in hepatic cholesterol and downregulation of the LDL receptor. Apo E_4 is also associated with increased cholesterol absorption; in the distant past, this may have offered a selective advantage, but it is a disadvantage with regard to CHD in populations that consume a high-fat diet. Variations at the apo E locus may explain some of the differences observed in plasma lipid and lipoprotein between individual responses to dietary and drug therapy.[230] Finally, the apo E_4 allele has been strongly associated with Alzheimer's disease and other neurologic diseases.[291] This association is likely related to the role of apo E in modulating lipid metabolism in the brain, but the exact connection between apo E_4 and neurologic disease is not known.

Lipoprotein Metabolism

The pathways of lipoprotein metabolism are complex and intersect at several points.[44,110,266] They include exogenous and endogenous pathways based on whether they carry lipids from dietary or hepatic origin (Figures 27-18 and 27-19).

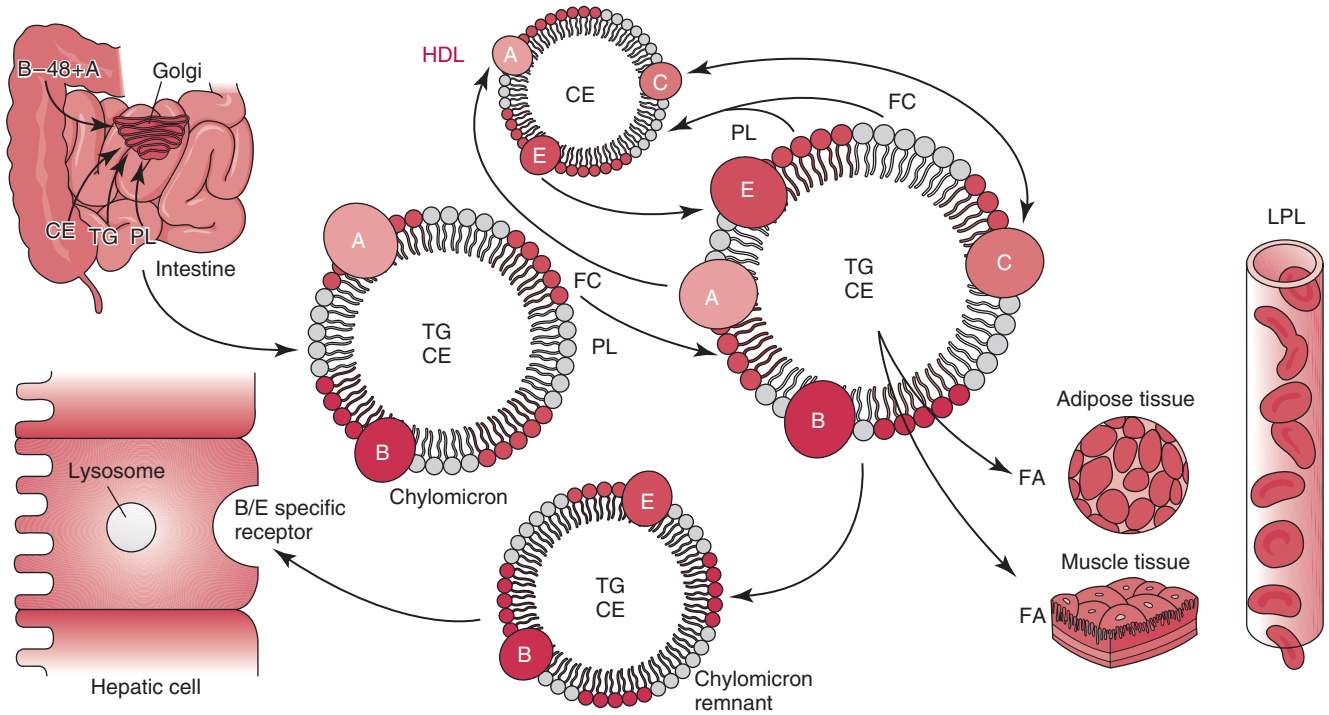

Figure 27-18 **Exogenous lipoprotein metabolism pathway. *A,* Apolipoprotein A-I; *B,* apolipoprotein B-48; *C,* apolipoprotein C-II; *CE,* cholesterol ester; *E,* apolipoprotein E; *FA,* fatty acid; *FC,* free cholesterol; *HDL,* high-density lipoprotein; *LPL,* lipoprotein lipase; *PL,* phospholipid; *TG,* triglyceride.**

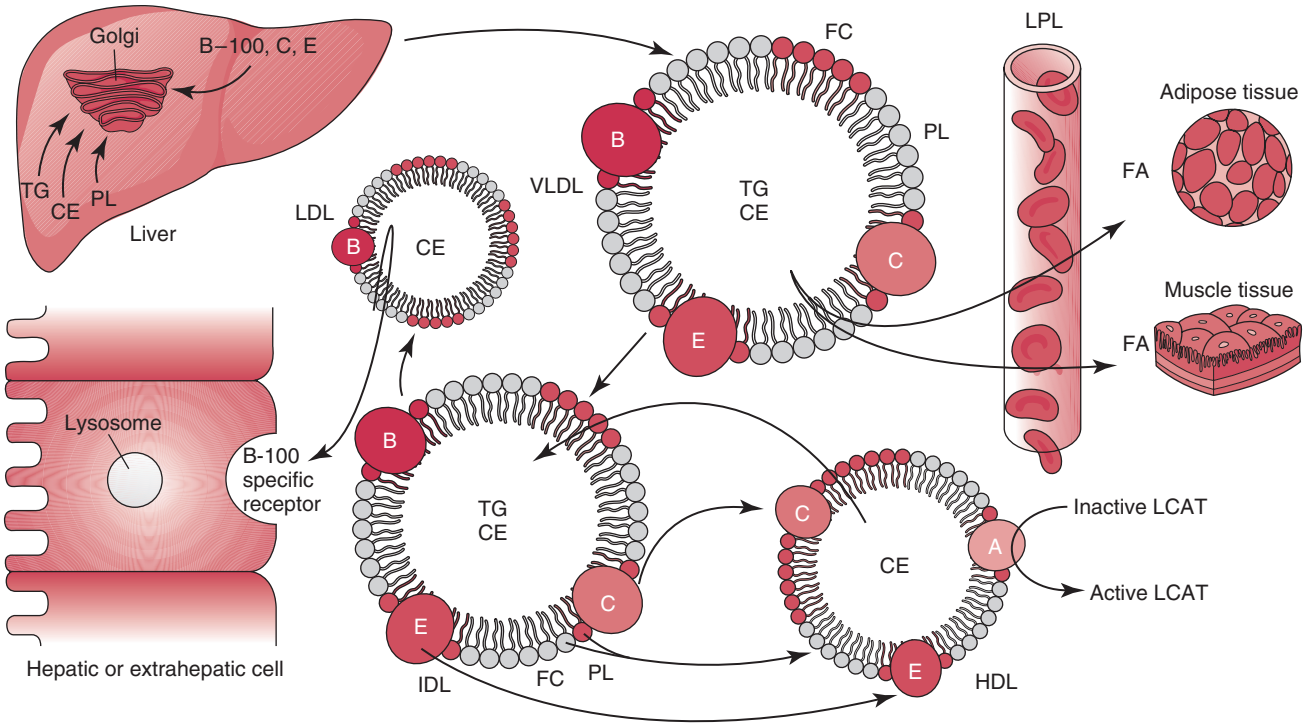

Figure 27-19 **Endogenous lipoprotein metabolism pathway. *A,* Apolipoprotein A-I; *B,* apolipoprotein B-100; *C,* apolipoprotein C-II; *CE,* cholesterol ester; *E,* apolipoprotein E; *FA,* fatty acid; *FC,* free cholesterol; *HDL,* high-density lipoprotein; *IDL,* intermediate-density lipoprotein; *LCAT,* lecithin cholesterol acyltransferase; *LDL,* low-density lipoprotein; *LPL,* lipoprotein lipase; *PL,* phospholipid; *TG,* triglyceride; *VLDL,* very low-density lipoproteins.**

Also included are the intracellular LDL receptor pathway (Figure 27-20) and the HDL reverse cholesterol transport pathway (Figure 27-21).

Exogenous Pathway

The primary function of the exogenous pathway is the absorption of dietary lipid and its delivery, particularly triglyceride, to peripheral tissues and the liver. The exogenous pathway begins when nascent chylomicrons are assembled from dietary triglycerides and cholesterol in the enterocytes and packaged in secretory vesicles in the Golgi apparatus. These particles are transported by exocytosis into the extracellular space and are introduced into the circulation through the lymphatic duct. The lipid content of nascent chylomicrons consists mainly of triglycerides (90% by mass), whereas protein components include apo B-48 and the A apolipoproteins (2% by mass).[105] Shortly after entering the circulation, these particles acquire the C apolipoproteins and apo E from circulating HDL (see Figure 27-18). Apo C-II, now present on the surface of chylomicrons, activates the LPL attached to the luminal surface of endothelial cells; this rapidly hydrolyzes the triglycerides to free fatty acids. The fatty acids are associated with albumin and can be taken up by muscle cells as an energy source or into adipose cells for storage. Simultaneously, some of the phospholipids and the apo A apolipoproteins are transferred back to HDL during lipolysis. The newly formed particle, the chylomicron remnant, contains 80 to 90% of the triglyceride content of the original chylomicron. Because of the presence of apo B-48 and apo E on its surface, the chylomicron remnant can be recognized by specific hepatic remnant receptors and is quickly internalized within hours by endocytosis. Components of the particle are then hydrolyzed within the lysosomes. The cholesterol released can be used for the synthesis of bile acids, can be incorporated into newly synthesized lipoprotein, or can be stored as cholesteryl ester. Furthermore, cholesterol from these remnants downregulates HMG-CoA reductase, the rate-limiting enzyme of cholesterol biosynthesis (see earlier section on cholesterol synthesis).

Endogenous Pathway

The endogenous pathway involves the delivery of lipids that are packaged in the liver to peripheral cells (see Figure 27-19). Hepatocytes have the ability to synthesize triglycerides from carbohydrates or fatty acids. In addition, when dietary cholesterol acquired from the receptor-mediated uptake of chylomicron remnants is insufficient, hepatocytes can synthesize their own cholesterol by increasing the activity of HMG-CoA reductase. Endogenously made triglycerides and cholesterol are packaged along with apo B-100 into VLDL particles in the endoplasmic reticulum; this involves the microsomal transfer protein. A defective microsomal transfer protein

Because of the presence of apolipoprotein B-100 on its surface, the LDL particle is recognized by a specific receptor in a coated pit and is taken into the cell in a coated vesicle** ***(top right).*** **Coated vesicles fuse together to form an endosome. The acidic environment of the endosome causes the LDL particle to dissociate from the receptors, which return to the cell surface. LDL particles are taken to a lysosome, where apolipoprotein B-100 is broken down into amino acids and cholesterol ester is converted to free cholesterol for cellular requirements. The cellular cholesterol level is self-regulated. Oversupply of cholesterol will lead to (1) decreased rates of cholesterol synthesis by inhibiting HMG-CoA reductase, (2) increased storage of cholesteryl esters by activating ACAT, and (3) inhibition of manufacture of new LDL receptors by suppressing transcription of the receptor gene into mRNA.** *(From Brown MS, Goldstein JL. How LDL receptors influence cholesterol and atherosclerosis. Sci Am 1984;251:58-66. Copyright 1984 by Scientific American, Inc. All rights reserved.)*

results in the inability to secrete apo B-containing lipoproteins and is referred to as *abetalipoproteimemia.* VLDL is a triglyceride-rich particle (55% by mass) that contains apo B-100, apo E, and small quantities of C apolipoproteins on its surface. Additional C apolipoproteins are transferred from HDL to VLDL after it enters the circulation. As in the case of chylomicron metabolism, apo C-II present on the surface of VLDL activates LPL on endothelial cells, which leads to the hydrolysis of VLDL triglycerides and the release of free fatty acids. It is important to note, however, that the rate of hydrolysis of VLDL triglyceride is significantly lower than that of chylomicron triglyceride. The average residence time of VLDL triglyceride is 15 to 60 minutes, compared with 5 to 10 minutes for chylomicron triglyceride.[118] This difference may be attributed to the fact that VLDL particles are smaller and bind to fewer LPL molecules than do chylomicrons.

During hydrolysis of VLDL triglycerides, C apolipoproteins are transferred back to HDL. VLDL particles are thus converted to VLDL remnants, some of which are taken up by the liver. The rest are converted to smaller, denser particles called *IDL.* Large IDL particles, which also have several molecules of apo E, bind the hepatic remnant receptors and are removed from the circulation. In humans, about 50% of IDL is removed by hepatocytes.

Surface materials from IDL, including some phospholipids, free cholesterol, and apolipoproteins, are transferred to

After formation in the liver and intestine, nascent discoidal HDL removes cholesterol from peripheral cells by the ABCA1 transporter. Additional cholesterol can also be removed from HDL by the ABCG1 transporter and by a passive diffusion mechanism. LCAT esterifies the cholesterol content of HDL to prevent it from re-entering the cells. Cholesterol esters are delivered to the liver by the SR-B1 receptor or by the LDL-R after transfer to LDL by CETP.** *(Reprinted from Gwynne JT: High density lipoprotein cholesterol levels as a marker of reverse cholesterol transport. Am J Cardiol 64:10G–17G, 1989. Copyright 1989, with permission from Excerpta Medica Inc.)*

HDL, or form HDL de novo in the circulation. Cholesteryl esters are transferred from HDL to LDL by CETP in exchange for triglyceride. The net result of the coupled lipolysis and cholesteryl ester exchange reaction is the replacement of much of the triglyceride core of the original VLDL with cholesteryl esters. IDL undergoes further hydrolysis, in which most of the remaining triglycerides are removed and all apolipoproteins except B-100 are transferred to other lipoproteins; this ultimately leads to the formation of LDL. Most LDL is eventually returned to the liver by the LDL receptor, but when present in excess, it infiltrates into the vessel wall, where it accumulates. This is a key initiation step in the process of atherosclerosis.

Low-Density Lipoprotein Receptor Pathway

The mechanism by which LDL is removed from the circulation is reasonably well understood and primarily occurs via the LDL receptor pathway. Compared with VLDL and chylomicrons, LDL has a relatively long residence time in the circulation of about 3 days.[118] Specific receptors present on plasma membranes recognize and bind apo B-100 associated with LDL (see Figures 27-19 and 27-20). LDL particles then are internalized and fuse with endosomes. Because of the acidic milieu of the endosome, LDL dissociates from the receptor, which returns to the cell surface for reuse, whereas LDL migrates to the lysosome. Once LDL is delivered to the lysosome, apo B-100 is degraded into small peptides and amino acids. Cholesteryl esters are also hydrolyzed, with the cholesterol then available for the synthesis of cell membranes, steroid hormone synthesis in endocrine tissues, or bile acid synthesis in hepatocytes. Cells have the ability to regulate their cholesterol content, most likely because of the cytotoxicity of excess cholesterol. Oversupply of free cholesterol (1) decreases the rate of endogenous cholesterol synthesis by inhibiting the rate-limiting enzyme HMG-CoA reductase; (2) increases the formation of cholesteryl esters, which are catalyzed by ACAT; and (3) inhibits the synthesis of new LDL receptors by suppressing transcription of the receptor gene. Many different intracellular pathways are available for coordinated gene regulation of cholesterol metabolism, but the sterol regulatory element-binding protein (SREBP) transcription factors, which sense intracellular cholesterol concentrations, appear to play the most central role.[289]

Approximately one third of LDL is taken up by extrahepatic tissue through scavenger receptors or non–receptor-mediated pinocytosis. Non–receptor-mediated uptake becomes important as plasma LDL concentrations increase, as in familial hypercholesterolemia (FH). Non–receptor-mediated uptake is not saturable and is not regulated. Scavenger receptors are unregulated and recognize LDL that has been modified in various ways, such as by oxidation. Scavenger receptors are largely found in macrophages; this probably accounts for the accumulation of lipid that occurs in these cells in atherosclerotic plaque. Macrophages that become engorged with cholesteryl esters are called *foam cells,* and are considered the earliest components of the atherosclerotic lesion.

Reverse Cholesterol Transfer Pathway

The reverse cholesterol transport pathway helps the body maintain cholesterol homeostasis by removing excess cholesterol from peripheral cells and delivering it to the liver for excretion. It is mediated mostly by HDL; this in part accounts for the antiatherogenic property of HDL. The pathway begins when HDL is secreted from the liver and intestine as disk-shaped nascent particles that contain phospholipids and apo A-I. Through the extracellular addition of surface components of triglyceride-rich particles, such as phospholipids, cholesterol, and certain apolipoproteins, nascent HDL is converted to spherical particles. Free cholesterol from cell membranes is also transferred to the nascent HDL (see Figure 27-21). This can occur by a passive process called *aqueous diffusion,* but it can also occur by specific energy, requiring transporters.[346] The ABCA1 transporter, which is the defective gene in Tangier disease, promotes the efflux of excess cellular cholesterol and phospholipids to nascent HDL. In contrast, the ABCG1 transporter and the SR-BI receptor promote the efflux of cholesterol to more lipid-rich forms of HDL. Once cholesterol is delivered to HDL by whatever mechanism, it is quickly esterified by the action of LCAT in the presence of its cofactor apo A-I. The size of the HDL particle depends

strongly on the quantity of accumulated cholesteryl esters and the activity of LCAT. Lysolecithin, a byproduct of this reaction (see previous discussion), is removed from circulation after binding with albumin. HDL cholesteryl esters are delivered to the liver by one of the following mechanisms: (1) cholesteryl esters are selectively taken up from HDL by the SR-BI receptor, and lipid-depleted forms of HDL are returned to the circulation for further transport; (2) cholesteryl esters are transferred from HDL to apo B-100–containing lipoprotein by a process mediated by cholesterol ester transfer protein; they then are taken up by the liver through receptors for these lipoproteins; or (3) HDL can be taken up in toto by holoparticle receptors, which possibly recognize apo E.[110] These processes constitute the reverse cholesterol transport mechanism by which cellular and lipoprotein cholesterol is delivered back to the liver for reuse or disposal.

Although LDL is the major product resulting from the catabolism of VLDL, some conversion of HDL subfractions also occurs during this process. Surface materials from triglyceride-rich particles that have been transferred to the small circulating HDL_3 are subsequently esterified by LCAT, as described earlier, to create the larger cholesteryl ester–rich HDL_2. It has been shown that in vitro HDL_2 is converted back to HDL_3 in the presence of hepatic LPL.[235] HDL_2 contains twice as many cholesterol molecules per unit of apolipoproteins as does HDL_3.

Reference Lipid, Lipoprotein Cholesterol, and Apolipoprotein Concentrations

At birth, the typical plasma cholesterol concentration is about 66 mg/dL; it is equally distributed among LDL and HDL, with a very small amount in VLDL. Triglyceride concentration is only about 36 mg/dL.[269] Cord blood apo A-I, apo B-100, and Lp(a) have mean concentrations of about 80, 33, and 4 mg/dL, respectively.[267,268] Lipid, lipoprotein cholesterol, and apolipoprotein concentrations rise sharply during the first few months of life, with LDL becoming the predominant carrier of plasma cholesterol, and then remain relatively unchanged until puberty. A profile consisting of total cholesterol of about 155 mg/dL, LDL cholesterol of 90 mg/dL, HDL cholesterol of 53 mg/dL, triglycerides of 55 mg/dL, apo B-100 of 86 mg/dL, and apo A-I of about 130 mg/dL is typical for a normal prepubertal subject. After puberty, triglycerides, LDL cholesterol, and apo B-100 are increased in both sexes, and HDL cholesterol and apo A-I are decreased in men. Lipid concentrations continue to increase throughout adult life, with total and LDL cholesterol and apo B-100 being higher in men than in women up to age 55.[45] Thereafter, women who are not receiving estrogen supplementation have higher total and LDL cholesterol and apo B-100 than their age-matched male counterparts.[111] In contrast to the other lipids, lipoproteins, and apolipoproteins, Lp(a) concentration increases slowly and gradually to reach Lp(a) adult values after the third year of life.[268]

Plasma lipid and lipoprotein concentrations in male and female subjects are presented in Tables 27-7 through 27-10. These reference intervals have been developed using the Lipid Research Clinics (LRC) population. Although reference intervals for apo A-I and B-100 from the Framingham Heart Study, using approved World Health Organization (WHO)/International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) calibrators, were published,[61,63]

distributions of these two proteins that better reflect the North American population have become available from the National Health and Nutrition Examination Survey III (NHANES III) (Tables 27-11 and 27-12).[29] Because NHANES was designed to reflect the U.S. population, data for the distribution of these proteins in the main American ethnic groups are available (Table 27-13). Using this information, apo B-100 cut points similar to those recommended for LDL-C can be developed; apo B-100 values that correspond to desirable, borderline high risk, high risk, and very high risk are 88, 115, 132, and 152 mg/dL; apo A-I values that correspond to low and high are 114 and 154 mg/dL.[29] Until Lp(a) measurement is better standardized, the development of appropriate reference intervals is not possible.[17]

CLINICAL SIGNIFICANCE

The clinical significance of lipids is primarily associated with CHD but is also associated with other vascular disorders, such as thrombotic stroke and peripheral vascular disease.

Association With Coronary Heart Disease

Increased cholesterol is a critical factor in the pathogenesis of atherosclerotic disease (see also Chapter 47). As early as 1910, Windaus described cholesterol in the lesions of diseased arteries. Subsequently, many studies confirmed that free and esterified cholesterol accumulates in the aorta, coronary arteries, and cerebral vessels, and that the rate of accumulation varies among individuals. The association between serum cholesterol and atherosclerosis in humans was first suggested in 1938, when Muller and Thanhauser each demonstrated familial aggregation of hypercholesterolemia and CHD.[205,313] Additional studies showed that when the total cholesterol concentration is high, the incidence and prevalence of CHD are also high.[101]

However, the relationship between cholesterol and atherosclerotic coronary disease is curvilinear.[109] According to the Multiple Risk Factor Intervention Trial (MRFIT), if a risk ratio of 1.0 is arbitrarily assigned at a cholesterol value of 200 mg/dL, the risk ratio increases to 2.0 at 250 mg/dL and to 4.0 at 300 mg/dL (Figure 27-22). Pathologic studies have helped to explain this curvilinear relationship. When 60% of the surface of coronary arteries is covered with plaque, one enters a critical phase in which any increase in serum cholesterol will markedly increase coronary disease risk. Results of the LRC-Coronary Primary Prevention Trial (CPPT) show that use of the concentration at the 95th percentile of a population distribution is inappropriate to define hypercholesterolemia. Data from this and other studies suggest that risk disproportionately increases as cholesterol concentrations increase; at concentrations of 200 to 240 mg/dL, the risk begins to accelerate at a greater rate. On average, each 1% reduction in cholesterol (2 to 3 mg/dL) results in an ≈2% reduction in CHD incidence—a relationship of considerable clinical and public health significance.[80] In addition, the Cholesterol-Lowering Atherosclerosis Study (CLAS) demonstrated the benefit of cholesterol lowering in people with established disease and even in those with normal or moderately increased cholesterol concentrations (185 to 240 mg/dL).[38] More recent studies have shown that individuals with preexisting disease may actually show reversal of atherosclerosis if they are aggressively treated so that they achieve LDL-C concentrations below 70 mg/dL.[42,222]

Many epidemiologic and clinical studies have shown that other lipids and lipoproteins besides LDL, such as HDL and lipoprotein subfractions, may be useful for predicting CHD risk.[50] For example, several studies have shown that small, dense LDL subfractions may be better correlated with CHD risk than large, less dense LDL subfractions.[26,49] Triglyceride itself may be a risk factor. Initially, a National Institutes of Health consensus conference on triglyceride and CHD failed to establish increased fasting triglyceride concentration as an independent risk factor.[7] However, NCEP and the Adult Treatment Panel III (ATP III) reports[8,11] have given triglycerides greater prominence in CHD risk prediction (see section on diagnosis of lipoprotein disorders, later in this chapter). Furthermore, fat tolerance and the ability to rapidly catabolize ingested triglycerides are reported to correlate well with atherogenic risk.[234] The degree of hypertriglyceridemia appearing after a meal controls the extent to which basal HDL_2 is converted by hepatic lipase to HDL_3. It has also been postulated that chylomicron remnants and IDL, the products of the breakdown of triglyceride-rich lipoprotein,

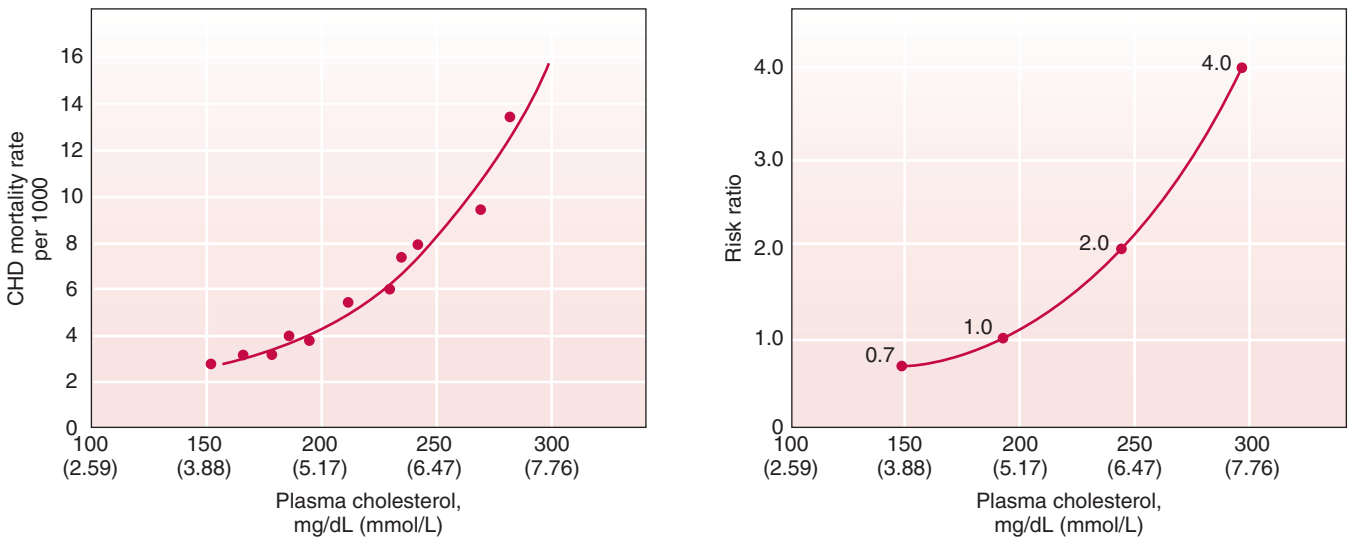

Figure 27-22 Relationship between cholesterol concentration and coronary heart disease mortality, expressed by yearly rate per 1000 and risk ratios [Multiple Risk Factor Intervention Trial (MRFIT) participants].

are important in atherogenesis.[350] They may promote atherosclerosis when their concentrations in plasma are high or their presence in circulation is prolonged by adversely affecting endothelial cell function.

In the early 1970s, Alaupovic suggested that apolipoproteins should be considered when the contribution of lipids and lipoproteins to the development of atherosclerotic disease is evaluated.[15] Several studies showed that in people with CHD, changes in serum concentrations of apo A-I and apo B-100 are similar to those for HDL and LDL, respectively. Apo B-100 values were increased and apo A-I values were decreased in people with CHD compared with those without disease. In many studies, apo A-I and apo B-100 were somewhat better discriminators of people with CHD than the cholesterol concentration of the corresponding lipoprotein,[62,152,172] at least in univariate analyses. Furthermore, these two apolipoproteins were shown to correlate better with the degree of coronary stenosis than LDL and HDL cholesterol.[210] It has been shown that only 14.5% of patients with myocardial infarction younger than the age of 60 years have LDL cholesterol above the 95th percentile. In contrast, 35% of these patients have apo B-100 above the 95th percentile.[295] The measurement of apo B-100 provides information regarding the number of apo B-100–containing particles, because only one apo B molecule is present per lipoprotein particle. If the concentration of LDL cholesterol is normal or slightly increased but apo B-100 is greatly increased, it is likely that the number of small, more atherogenic and dense LDL particles will also be high. Increased serum apo B-100 and decreased apo A-I concentrations were also found in children of parents with premature atherosclerotic disease.[91] Overall, these and other findings[42,106,158] suggest that apolipoproteins may be superior predictors of future CHD, and that tests for apo B and apo A-I are underutilized, most likely because they are still viewed as ancillary tests under most current guidelines for CHD risk prediction.

Although CHD often is not manifested clinically until the fourth decade of life, evidence clearly indicates that atherosclerosis is a process that begins early in life and progresses silently for decades. Autopsies performed on young American soldiers killed in action in Korea[83] and Vietnam[189] revealed atherosclerotic lesions. Coronary artery lesions were also found in aortas beginning at the age of 3 years[300] and starting at the age of 10 years in the International Atherosclerosis Project.[305] In the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study, intimal lesions appeared in all examined aortas and in more than half of the right coronary arteries of the youngest age group (15 to 19 years); they increased in prevalence and extent with age through the oldest age group (30 to 34 years).[304] This study also showed that some regions of the arteries were lesion prone and others were lesion resistant, and the propensity to develop raised or advanced lesions differed among right coronary artery, abdominal aorta, and thoracic aorta. Findings from the Bogalusa Heart Study[339] showed a correlation between systolic blood pressure, higher total and LDL cholesterol, and lower HDL cholesterol concentrations and the degree of coronary and aortic atherosclerosis in children and adolescents.[36] In the PDAY study, postmortem cholesterol and thiocyanate, a marker for cigarette smoking, predicted the extent of coronary and aortic atherosclerosis, respectively, in autopsies of those aged 14 to 34.[343] Therefore, a direct relation between determinant risk factors and the extent of atherosclerotic lesions in youth seems to exist and suggests that the identification and treatment of children and young adults who may be at high risk for developing CHD offer the possibility of preventing or delaying development of this disease.

Disorders of Lipoprotein Metabolism

Dyslipoproteinemia is diagnosed in most patients using plasma lipid and lipoprotein cholesterol concentrations. Dyslipoproteinemias were previously defined in terms of arbitrary cut points for lipids and lipoprotein; their definition is now based on the relationship between lipoprotein concentrations and risk for CHD (see discussion later in this chapter).

Primary versus Secondary Hyperlipoproteinemia

When hyperlipidemia is evaluated, it first should be determined whether it is from a primary lipoprotein disorder or is secondary to a wide variety of metabolic diseases. The diagnosis of primary hyperlipidemia is made after secondary causes have been ruled out. Causes of secondary hyperlipoproteinemia are listed in Table 27-14. The most commonly seen secondary causes in the first year of life are glycogen storage disease and congenital biliary atresia. Hypothyroidism, nephrotic syndrome, and diabetes mellitus are more prevalent later in childhood. Exogenous factors, such as dietary and alcohol intake, oral contraceptives, diabetes mellitus, and pharmacologic agents [e.g., steroids, isotretinoin (Accutane), and β-blockers], are the main secondary causes of hyperlipidemia in adults.[4,155]

Familial Dyslipoproteinemias

Historically, lipoprotein phenotypes reflecting lipoprotein metabolic disorders were classified into one of five patterns according to Fredrickson and coworkers based on an electrophoretic separation scheme. However, lipoprotein disorders are now more commonly classified according to the four metabolic pathways discussed previously (see Figures 27-18 through 27-21). Defects in these pathways leading to hyperlipidemia may be related to (1) increased production of lipoproteins, (2) abnormal intravascular processing (e.g., enzymatic hydrolysis of triglyceride), and (3) defective cellular uptake of lipoproteins. Finally, a significant decrease in production or an increase in removal of lipoproteins can lead to a marked reduction in lipid and lipoprotein concentrations. Multiple diseases described here alter the various steps of the four main metabolic pathways for lipoprotein metabolism.

Deficiency in Lipoprotein Lipase Activity

This disorder is characterized by marked hyperchylomicronemia and a corresponding hypertriglyceridemia, which can

TABLE 27-14 Causes of Secondary Hyperlipidemia and Dyslipoproteinemia

Disorder	Cause
Exogenous	Drugs: corticosteroids, isotretinoin (Accutane), thiazides, anticonvulsants, beta-blockers, anabolic steroids, certain oral contraceptives
	Alcohol
	Obesity
Endocrine and metabolic	Acute intermittent porphyria
	Diabetes mellitus

	Progeria (Hutchinson-Gilford syndrome)
	Systemic lupus erythematosus
	Werner's syndrome

reach as high as 10,000 mg/dL.[46] As discussed previously, LPL is essential for the hydrolysis of triglyceride and the conversion of chylomicrons to chylomicron remnants. The massive accumulation of chylomicrons in patients is usually related to a defect in lipolysis and an inability to catabolize dietary fat. The concentration of VLDL cholesterol is usually normal, and the concentrations of HDL cholesterol and LDL cholesterol are low (type I pattern). Furthermore, the concentration of apo C-II, the activator of LPL, is normal.

This disorder is usually expressed in childhood. In a review of 43 cases, 35 were manifested before the age of 10.[166,167] It appears that those patients with low to absent LPL activity in all tissues present with symptoms of the disease at an early age, whereas those with a partial deficiency in LPL activity become symptomatic later in life. This disease is usually detected after recurrent episodes of severe abdominal pain and repeated attacks of pancreatitis, which is the greatest source of morbidity in these patients. Eruptive xanthomas and lipemia retinalis are usually present when plasma triglyceride concentrations exceed 2000 and 4000 mg/dL, respectively.[46] The acuteness of the symptoms is directly proportional to the degree of hyperchylomicronemia. It is important to note that patients with this disorder *do not* appear to be predisposed to atherosclerotic disease.

The diagnosis is made by determination of LPL activity in postheparin plasma, because most LPL is firmly bound to proteoglycans on endothelial cells. Intravenously administered heparin binds LPL, causing its dissociation from heparan sulfate, present on the surface of endothelial cells, and its subsequent release to plasma.[125] This autosomal recessive disorder is extremely rare (one per million individuals), but more than 40 insertions and deletions in the LPL gene that lead to absent or truncated LPL protein with defective catalytic activity have been described.[46]

Deficiency in Apolipoprotein C-II

Deficient or defective apo C-II, the required activator for LPL, reduces the activity of this enzyme, impairs chylomicron catabolism, and increases plasma triglycerides (from 500 to 10,000 mg/dL). Those affected by this disorder have less than 10% of the normal concentration of apo C-II, which is the minimum amount necessary for normal LPL activity.[131] Total cholesterol tends to vary considerably (150 to 890 mg/dL) in these patients, but HDL and LDL cholesterol concentrations are often below the 5th percentile. Furthermore, plasma apo A-I, A-II, and B-100 concentrations are also decreased, whereas apo C-III and E concentrations are increased.

Although the clinical symptoms are similar to those seen in patients with LPL deficiency, they are usually milder and are expressed at a later age. The predominant symptom is usually recurrent abdominal pain caused by attacks of pancreatitis. Eruptive xanthomas and lipemia retinalis are not usually seen in these patients. As with LPL deficiency, patients with apo C-II deficiency are not predisposed to atherosclerosis.

The diagnosis is made upon documentation of low LPL activity in postheparin plasma in the absence of added apo C-II. Normal enzymatic activity is restored by the addition of normal apo C-II to the assay mixture. In another approach, the absence of apo C-II can be recognized by using an immunoassay for apo C-II. However, the latter approach may not distinguish between normal subjects and those with normal concentrations of a nonfunctional form of apo C-II. The defective apo C-II disorder is inherited in an autosomal recessive mode, but at an even lower frequency than LPL deficiency. More than 10 structural defects in the apo C-II gene that lead to the absence of apo C-II or the production of a defective apo C-II molecule have been described.[46] Subjects heterozygous for a defective apo C-II gene have normal lipid and lipoprotein profiles, because a sufficient amount of normal apo C-II is usually present to activate LPL.

tahir99-VRG & vip.persianss.ir

Familial Combined Hyperlipidemia

About 10 to 15% of patients with premature CHD have familial combined hyperlipidemia (FCHL), thus making it one of the more common forms of dyslipidemia.[99] This disorder is recognized as a distinct phenotype by studying family members of survivors of myocardial infarction. Patients with FCHL can have increased plasma concentrations of total and LDL cholesterol (type IIa) or triglyceride (type IV), or both (type IIb). In all cases, apo B-100 concentrations are increased. The presentation of lipoprotein patterns can vary in an individual over time.[109]

FCHL appears to be caused by overproduction of VLDL and apo B-100, but the underlying molecular defect is not known. Kinetic studies have shown that the rate of flux of apo B-100 from VLDL in FCHL is approximately twice that of normal subjects.[53,66] This causes apo B-100 to be increased (by more than 125 mg/dL) even in subjects with normal LDL cholesterol. Because of the decreased lipid-to-protein ratio in these patients, both VLDL and LDL particles tend to be small and dense. When increased, LDL cholesterol is about 190 mg/dL, but it is lower than that typically seen in heterozygous familial hypercholesterolemia. Triglyceride concentrations are usually between 200 and 400 mg/dL but can be significantly higher. The concentration of HDL cholesterol is usually mildly depressed, particularly in the presence of hypertriglyceridemia. Xanthomas and other clinical symptoms of hyperlipidemia, other than atherosclerosis, are not very common in these patients. The association of FCHL with CHD incidence is high. In addition to increased IDL, the presence of high concentrations of small, dense LDL and low concentrations of HDL cholesterol might explain the increased risk for CHD in this disorder.

Although the mutation(s) responsible for FCHL remain unknown, this disorder is associated with a major gene, apparently interacting with other genes, and it has a prevalence of 1 in 100 persons. Although expression of FCHL is delayed until adolescence, young children from families with premature CHD can present with increased cholesterol or triglyceride, or both.[155]

Hyperapobetalipoproteinemia

This disorder is characterized by increased LDL–apo B-100 concentrations with normal or moderately increased concentrations of LDL cholesterol.[154,293] The ratio of LDL cholesterol to apo B-100 is therefore reduced in these patients (≤1.2).[154] Total cholesterol and triglyceride may be normal but are usually increased, and HDL cholesterol and apo A-I are usually decreased. This disorder appears to be caused by overproduction of VLDL and apo B-100 in the liver, which leads to the formation of atherogenic small and dense LDL.[154] The exact mode of inheritance and the prevalence of this disorder remain unclear; however, about one third of children of a parent with premature CHD or hyperapobetalipoproteinemia will have this disorder.[294] Features common to hyperapobetalipoproteinemia have been reported to occur in patients with FCHL, suggesting metabolic and genetic associations between these two disorders.

Familial Hypertriglyceridemia

The production of large VLDL with abnormally high triglyceride content appears to be responsible for familial hypertriglyceridemia (FHTG).[137] The actual number of VLDL particles produced by the liver, however, is not increased. The cholesterol content of VLDL is also increased, but plasma LDL cholesterol and apo B-100 concentrations are normal. This finding suggests that the conversion of VLDL to LDL is not increased in these patients. Furthermore, plasma HDL cholesterol in FHTG is often dramatically decreased, probably secondary to the hypertriglyceridemia.

The cause of the overproduction of VLDL triglyceride is unknown. Administration of estrogen and corticosteroids aggravates hypertriglyceridemia in these patients and sometimes can lead to acute pancreatitis. The diagnosis of FHTG requires study of other family members to differentiate this disorder from FCHL. This disorder appears to be inherited in an autosomal dominant pattern with delayed expression and an estimated frequency in the population of about 1 : 500 persons, making this a relatively common disorder. About one in five children born to affected parents manifest the phenotype early in life.[96]

Type V Hyperlipoproteinemia

This disorder is characterized by an increase in both chylomicrons and VLDL and has an incidence of about 1 in 500. Although the exact molecular cause of this disorder is not known, the metabolic defect appears to be increased production or decreased removal of VLDL, or a combination of both. The activity of LPL in these patients may be normal or low, and the plasma concentration of apo C-II is normal.[155]

Although this disorder is not usually expressed in childhood, several affected preadolescents have been described.[155] Clinical presentations in adult patients include eruptive xanthomas, lipemia retinalis, pancreatitis, and abnormal glucose tolerance with hyperinsulinism.[46] Premature atherosclerotic complications are not as commonly seen as with FH. This heterogeneous syndrome appears to be inherited in an autosomal dominant mode, but its genetic basis has not yet been fully elucidated.

Dysbetalipoproteinemia (Type III)

This disorder is caused by a primary genetic defect in the removal of remnants of both intestinal chylomicrons and hepatic VLDL.[173] As indicated earlier, apo E present on the surface of lipoprotein remnants interacts with specific hepatic receptors and facilitates the removal of these lipoprotein particles from the circulation. Patients with dysbetalipoproteinemia may be homozygous for a rare mutation in apo E or may be homozygous for the apo E_2 allele.[340] These altered forms of apo E cannot as efficiently bind specific hepatic receptors, leading to the accumulation of lipoprotein remnants. These particles are cholesterol enriched with a density <1.006 g/mL, and are commonly referred to as β-VLDL or floating β-lipoprotein, in plasma.

The disease is characterized by increased plasma cholesterol and triglycerides, and the concentrations of the two

tahir99-VRG & vip.persianss.ir

lipids are about the same when expressed in milligrams per deciliter. β-VLDL present in type III has been shown to contain both apo B-100 and B-48, and therefore is related to triglyceride-rich lipoprotein remnants of both hepatic and intestinal origin. Both LDL and HDL cholesterol are lower than normal in these patients.[173]

This disorder has a late onset, rarely manifesting itself in childhood.[269] The most distinctive clinical presentation of dyslipoproteinemia is the presence of palmar xanthomas, yellow deposits that occur in the creases of the palms.[140] Tuberous and tuberoeruptive xanthomas also occur but are not unique to this syndrome. Premature atherosclerosis develops in 30% to more than 50% of these patients, particularly in the lower extremities.[306,326]

The apo E_2 alelle occurs in the homozygous state in about 1% of the population in North America; such subjects can exhibit an abnormal form of VLDL called *β-VLDL* or *broad beta,* based on its electrophoretic migration pattern. Overt type III hyperlipoproteinemia, however, occurs in only a small minority—less than 5% of patients homozygous for apo E_2—indicating that occurrence of the defective alleles is necessary but not sufficient to produce type III hyperlipoproteinemia.[321] The penetrance of hyperlipoproteinemia in these patients is modulated by genetic, hormonal, or environmental factors—such as hypothyroidism, glucose intolerance, decreased estrogen concentration after menopause, obesity, and diet—that may lead to decreased LDL receptor activity, increased VLDL production, or increased plasma cholesterol ester transfer protein. Because of the familial nature of this disorder and the predisposition of these patients to hyperlipoproteinemia and premature atherosclerotic disease, family members should be evaluated.

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is most often caused by a defect in the LDL receptor gene. As discussed earlier, this cell surface receptor is responsible for the recognition and removal of LDL from the circulation. The defects seen in patients with FH include reduced LDL binding because of defective or absent LDL receptors. In another variant of this disorder, the person may make defective LDL receptors that bind LDL normally but cannot efficiently internalize the LDL particles.[44] FH is characterized clinically by increased plasma LDL cholesterol concentration and cholesterol deposition in skin, tendons, and arteries; it usually is transmitted in an autosomal dominant manner, so that the disease is expressed in the heterozygous and homozygous states. Heterozygous FH is one of the most commonly seen genetic metabolic disorders, with an incidence of 1 in 500 persons in the United States. The prevalence of homozygous FH is about one in a million persons. Mean plasma LDL cholesterol in children and adult heterozygotes is usually two to three times that of normal people of similar age, whereas mean plasma LDL cholesterol of homozygotes is four to six times that of normal subjects.[98] Although the number of LDL particles is increased in these patients, their lipid composition and lipid-to-protein ratio are usually normal.[104] Apo B-100 is increased in proportion to LDL cholesterol. Triglyceride concentration may be normal or slightly increased, and HDL cholesterol concentration is slightly decreased in both heterozygotes and homozygotes.

Hypercholesterolemia is present at birth in most FH patients and persists throughout life. In heterozygotes, xanthomas appear toward the end of the second decade of life, and clinical manifestations of atherosclerotic disease appear during the fourth decade.[285] In homozygotes, the unique yellow-orange cutaneous xanthomas develop by the age of 4, if they are not already present at birth.[140] Tendon xanthomas and atherosclerotic complications begin during childhood. Death from myocardial infarction can occur in homozygotes before the end of the third decade and even earlier, but the prospect for these patients is much better with aggressive lipid-lowering therapy.[4,155]

Although increased plasma LDL cholesterol is indicative of the heterozygous form of FH, it is not sufficient to make the diagnosis; it is now common practice to confirm the diagnosis by sequencing the gene for the LDL receptor. More than 150 different mutations in the LDL receptor gene have been shown to significantly disrupt the normal process of LDL removal from the circulation.[98,123] Heterozygotes possess one normal and one mutant allele at the LDL receptor locus and therefore can remove LDL at about half the normal rate.

Recently, two other rare genetic mutations have been shown to lead to FH. Mutations in PCSK9, which is a hepatic secretory protein, can lead to an autosomal dominant form of FH.[159] PCSK9 normally downregulates expression of the LDL receptor; mutations that cause a gain of function, therefore, can lead to increased concentrations of circulating LDL by decreasing expression of the LDL receptor. Mutations in ARH lead to an autosomal recessive form of FH.[13] ARH is an adapter-like protein that appears to be necessary for proper recycling of the LDL receptor on the plasma membrane.

Familial Defective Apolipoprotein B-100

This disorder results from a mutation in the apo B-100 gene rather than the LDL receptor, resulting in a single substitution of glutamine for arginine at residue 3500 of apo B-100. This substitution reduces the positive charge of apo B-100 and decreases its affinity for the LDL receptor.[297] Other more rare mutations in apo B affecting its binding to the LDL receptor have also been described. Plasma LDL cholesterol in heterozygotes of this disorder can be normal to greatly increased because of inadequate removal of LDL particles by LDL receptors.[324] Those with increased LDL cholesterol have an increased incidence of CHD, but often the disease appears to be less aggressive than FH. Triglyceride and HDL cholesterol concentrations are not usually affected. It is often difficult to differentiate these patients from heterozygous FH patients; however, because the management these two disorders is similar, the distinction is not that clinically important.[137] The frequency of this mutation is 1 : 500 to 1 : 600 hypercholesterolemic persons in populations of European descent,[316] but the mutation is much rarer in non-European populations.

tahir99-VRG & vip.persianss.ir

Hypoalphalipoproteinemia

This disorder is characterized by normal plasma lipids and LDL cholesterol, and HDL cholesterol reduced to below the 5th percentile.[269,279] It is associated with an increased incidence of CHD.[314] Several known molecular defects can lead to hypoalphalipoproteinemia. Rarely, patients can have mutations in apo A-I, the main protein component of HDL, which can lead to profoundly low concentrations of HDL.[41,155] These patients typically have corneal clouding and xanthomas, and are at increased risk for development of premature CHD. Heterozygotes exhibit no clinical signs but have about half the normal concentrations of HDL cholesterol and apo A-I. Mutations, such as a rearrangement at the apolipoprotein gene locus that inactivates both apo A-I and C-III, deletion of the entire locus, and an insertion in the apo A-I gene have all been described.[138,155,226]

Tangier disease, so named because it was first observed in patients from Tangier Island in Chesapeake Bay (Eastern United States), is characterized by (1) severely reduced plasma HDL concentration, (2) abnormal HDL composition, and (3) accumulation of cholesteryl esters in many tissues throughout the body.[23,280,284] Kinetic studies have demonstrated that increased catabolism of HDL, rather than a defect in biosynthesis, is the cause of Tangier disease.[280] Tangier disease is caused by mutations in the *ABCA1* (ATP-binding cassette A1) gene on chromosome 9q31 and appears to be inherited in an autosomal dominant fashion. As already mentioned, the ABCA1 transporter is a key protein for the efflux of cholesterol from peripheral cells, particularly from macrophages. ABCA1 is also present in the liver and intestine and is important in the biogenesis of HDL. After lipid-free or lipid-poor apo A-I enters the plasma compartment via secretion from hepatocytes or enterocytes, or by dissociation from a lipoprotein particle, it must acquire additional lipid by the ABCA1 transporter, or it will be quickly catabolized by filtration in the kidney. Plasma cholesterol is usually decreased to about 70 mg/dL in homozygotes and to about 160 mg/dL in heterozygotes. Triglyceride concentrations vary depending on the diet.[23] In homozygotes, plasma HDL cholesterol and apo A-I concentrations are often undetectable; apo A-II is present at less than 10% of its normal concentration and is often found in apo B-100–containing lipoprotein.[24] Heterozygotes are characterized by half-normal concentrations of HDL cholesterol, apo A-I, and apo A-II.

Clinical symptoms of Tangier disease result from the deposition of cholesteryl esters in various tissues in the body. The three major clinical signs are hyperplastic orange tonsils, splenomegaly, and peripheral neuropathy. Other clinical signs that may be seen include hepatomegaly and corneal opacities. Severely reduced HDL cholesterol and enlarged orange tonsils are pathognomonic.[23,155] Current evidence suggests that these patients have an increased incidence of CHD, but they are seemingly less affected than would be expected from their low HDL; this has been attributed to the fact that patients also often have reduced concentrations of LDL.

Mutations in the gene for LCAT, which esterifies cholesterol, can also result in hypoalphalipoproteinemia.[275]

As already discussed, LCAT is important in the proper maturation of HDL. In the absence of LCAT, the primary form of HDL that is found is pre–β-HDL, which is the nascent discoidal form of HDL that is phospholipid rich but cholesterol poor. Because of its small size, this form of HDL is rapidly catabolized, leading to the low concentration of HDL found in these patients. This is an autosomal recessive disorder, but patients with mutations with partial activity develop only cloudy corneas and have a disorder called fish eye disease. Familial LCAT deficiency subjects have near complete absence of LCAT activity and develop not only cloudy corneas but also a mild hemolytic anemia, splenomegaly, and glomerulosclerosis, which is the main cause of morbidity in these patients. It is believed that patients develop renal disease because of the presence of Lp-X. This is an abnormal lipoprotein particle that also sometimes accumulates in liver disease and appears to be trapped by mesangial cells in the glomerulus, leading to fat deposition and eventually to glomerulosclerosis. Unlike other lipoprotein particles, which have a single layer of phospholipids on their surface, Lp-X has a phospholipid bilayer–like structure and can even form multilamellar vesicles with an aqueous core. It is believed that such structures are formed when neutral lipid, such as cholesteryl esters, is insufficient to form the neutral lipid core in lipoproteins. Patients with LCAT deficiency appear to have a modestly increased risk for CHD. Similar to Tangier disease subjects, they may be protected because they often have low LDL cholesterol concentrations, because much of the cholesterol on LDL is ultimately derived from HDL as a consequence of the reverse cholesterol transport pathway.

Diagnosis of Lipoprotein Disorders

On the basis of findings from many different studies, such as the MRFIT and the LRC-CPPT,[1,2,109] hypercholesterolemia in adults is now defined in terms of CHD risk. The National Institutes of Health ATP III of the NCEP[8] has issued its third report for the detection, evaluation, and treatment of hypercholesterolemia.[11] The ATP III built on earlier reports and expanded the indications for intensive cholesterol lowering. In ATP-I, strategies for primary prevention of CHD in subjects with LDL-C ≥160 mg/dL or 130 to 159 mg/dL and multiple risk factors (2+) were addressed. ATP II added new features; for subjects with existing CHD, a lower LDL-C goal of ≤100 mg/dL was established, and the HDL cholesterol value was given greater prominence. ATP III called for intensive LDL-C lowering in several other groups of patients. In this section, only a brief description of ATP III will be presented. Those interested in more detailed information should refer to the executive summary[67] or the complete report (http://www.nhlbi.nih.gov/guidelines/cholesterol/index.htm). An ATP IV report with additional updates is expected in 2012.

For the primary prevention of CHD, adults 20 years of age or older should have their fasting lipoprotein profile (total cholesterol, triglycerides, HDL-C, and LDL-C) measured once every 5 years. If a fasting sample is not available, then only total cholesterol and HDL-C should be considered. In

this instance, if total cholesterol is ≥200 mg/dL or HDL-C is ≤40 mg/dL, then a fasting lipoprotein profile is required. The cut points recommended for classification by ATP III are presented in Table 27-15. In addition to LDL-C, other risk determinants, presented in Box 27-2, are used to assess risk and determine goals and modalities of LDL-C–lowering therapy. The highest category of risk consists of those with CHD or CHD risk equivalents (other forms of atherosclerotic disease, such as peripheral arterial disease, abdominal aortic aneurysm, and symptomatic carotid artery disease, diabetes, or multiple risk factors that confer a 10-year risk for CHD >20%, as estimated by the Framingham risk score) (Table 27-16). The Framingham risk score is calculated for intermediate-risk individuals with two or more risk factors but with no history of CHD or risk equivalent. This is done to better estimate the CHD risk of these patients; an algorithm that includes age, gender, total cholesterol, HDL-C,

history of hypertension and treatment of hypertension, and cigarette smoking is used. The lowest risk category consists of those subjects having zero to one risk factor, in whom 10-year risk is ≤10%.

Although the primary target of risk reduction therapy is LDL-C, the ATP III recognized the metabolic syndrome, a constellation of several risk factors (increased triglycerides, decreased HDL-C, obesity, hypertension, and insulin resistance) as a secondary target of therapy. By definition, those with three or more of these risk factors are considered to have the metabolic syndrome.[11] Specific criteria for clinical identification of the metabolic syndrome are listed in Table 27-17.

The NCEP/Expert Panel on Blood Cholesterol Concentrations in Children and Adolescents[6] and the American Academy of Pediatrics[3,71] defined "high cholesterol" in children and adolescents from families with hypercholesterolemia or premature vascular disease as concentrations greater than the 95th percentile for total and LDL cholesterol in unaffected children (Table 27-18). "Borderline" total and LDL cholesterol concentrations are defined as values between the 75th and 95th percentiles. The NCEP panel referred to total

tahir99-VRG & vip.persianss.ir

and LDL cholesterol values below the 75th percentile as "desirable." Low HDL cholesterol was also defined as a concentration below 35 mg/dL. Children tend to have higher HDL cholesterol concentrations than adults; therefore, it is important to determine both LDL and HDL cholesterol concentrations before classifying the child as hypercholesterolemic. Unlike the criteria for the risk-based cholesterol classification system used in adults, guidelines for children and adolescents were based on consensus rather than directly on the association with coronary disease, because children as a group have very little disease. When lifetime risk data become available, different cutoffs may be suggested for the pediatric population.

As discussed earlier, universal cholesterol screening is currently recommended for all adults in the United States; however, for children, such a screening program remains highly controversial. According to the NCEP[6] and the American Academy of Pediatrics,[3,71] only children over the age of 2 should be screened for hypercholesterolemia when they have a parent with hypercholesterolemia (>240 mg/dL) or a positive family history (mother, father, uncle, aunt, or grandparent) with early documented CHD (at 55 years or less) such as myocardial infarction, angina pectoris, peripheral vascular disease, cerebrovascular disease, or sudden cardiac death. Children for whom the family history is not known and children with other CHD risk factors, such as obesity, diabetes, and hypertension, should also be screened for cholesterol.[71] Several studies have demonstrated the weakness of this selective approach to screening and have advocated general screening for children. The Bogalusa Heart Study found that by using the selective screening approach, only 50% of white children and 20% of black children with high LDL cholesterol concentrations (>95th percentile) were detected. Furthermore, it has been shown that self-reported cholesterol values among parents are an ineffective means of identifying children with high cholesterol.[249] More than 90% of children with total cholesterol greater than the 75th or 95th percentile were missed when physicians relied on cholesterol values reported by the parents. General screening, however, is expensive and time-consuming, and its effectiveness is limited by the fact that a significant number of children with high cholesterol concentrations will *not* remain hypercholesterolemic as adults.[162,246]

Universal screening for those older than 16 has been suggested on the basis of a finding that up to 66% of adolescents with increased LDL cholesterol are missed in a selective screening protocol.[270] When past adolescence, men usually do not start receiving routine healthcare examinations until about the age of 40. Although women typically visit their physicians earlier, this is the result of gynecological needs, and women may not be evaluated for a lipid disorder. Adolescents with increased LDL cholesterol who are missed in the selective screening process may not be identified until two decades later. At that time, the atherosclerotic process may be advanced, and a dietary management approach may not be sufficiently effective. Another possible yet unpopular approach is to do no screening at all. A prudent low-fat diet, such as the one outlined by the American Heart Association (AHA), can be recommended for all children (Table 27-19).[3,71] Such an approach will help prevent unnecessary anxiety, labeling, and overzealous treatment; however, it will miss completely those children with significant hypercholesterolemia, who are most at risk for adult CHD.

TABLE 27-18 NCEP Classification of Total and LDL Cholesterol in Children and Adolescents*

Category	Total Cholesterol	LDL Cholesterol
Desirable	<170	<110
Borderline	170-199	110-120
High	≥200	≥130

Management of Lipoprotein Disorders

Management of Hypercholesterolemia in Adults

According to ATP III, a central element in the clinical prevention of CHD is founded on a public health approach that entails a reduction in saturated fat and cholesterol intake (Table 27-20), increased physical activity, and weight control. Although this therapeutic life-style approach offers the

tahir99-VRG & vip.persianss.ir

opportunity for reducing the morbidity and mortality of CHD in the entire population, more intensified preventive measures for higher-risk individuals are indicated.[11] The primary goal is to reduce one's long-term (>10 years) and short-term risk (<10 years); the target LDL-C value depends on the person's absolute risk (Table 27-21). A more aggressive approach is recommended for those individuals who have already suffered a coronary event and for those with established CHD or those at very high risk of CHD, such as persons with diabetes. Specific models for therapeutic life-style changes and drug therapy in the primary prevention of CHD have been recommended (Figures 27-23 and 27-24). A combination approach of weight reduction, increased physical activity, and appropriate control of lipid concentrations is recommended for the management of patients with metabolic syndrome.

A wide variety of pharmacologic agents are available for cholesterol lowering in adults,[282] including (1) bile acid–binding resins (cholestyramine and colestipol), (2) niacin, (3) gemfibrozil, (4) ezetimibe, and (5) HMG-CoA reductase inhibitors (e.g., atorvastatin, fluvastatin, lovastatin, pravastatin, simvastatin); the latter group has been found to reduce LDL cholesterol by as much as 40%. Some of these drugs are better tolerated by individual patients than others, and all have demonstrated long-term safety. Niacin is the only FDA-approved drug that can significantly raise HDL cholesterol. Its use has been limited by side effects from flushing, although newer formulations have reduced this problem. These drugs can be used individually or in combination.[102,103]

TABLE 27-20 Nutrient Composition of the Therapeutic Life-Style Changes (TLC) Diet

Nutrient	Recommended Intake
Saturated fat	<7% of total calories
Polyunsaturated fat	Up to 10% of total calories
Monounsaturated fat	Up to 20% of total calories
Total fat	25-35% of total calories
Carbohydrate	50-60% of total calories

Management of Hypercholesterolemia in Children and Adolescents

To lower serum cholesterol concentration in children and adolescents, the NCEP adopted a strategy that combines two complementary approaches: a population approach and an individualized approach.[6,71]

Population Approach

Children and adolescents have relatively high cholesterol concentrations and a high intake of saturated fatty acids and cholesterol (see Table 27-19).[53,71] The population approach attempts to lower the mean cholesterol concentration by instituting population-wide modifications in nutrient intake and eating habits. The AHA Step-One diet is recommended (see Table 27-19). Even a modest decrease in mean cholesterol concentration in children and adolescents, if carried into adulthood, is likely to have a significant impact on lowering the incidence of CHD. The panel did not recommend any dietary changes for infants from birth to 2 years of age, because of concern about the effects of a low-fat diet during early development. Toddlers aged 2 and 3 should start making the transition to the recommended eating pattern. The NCEP

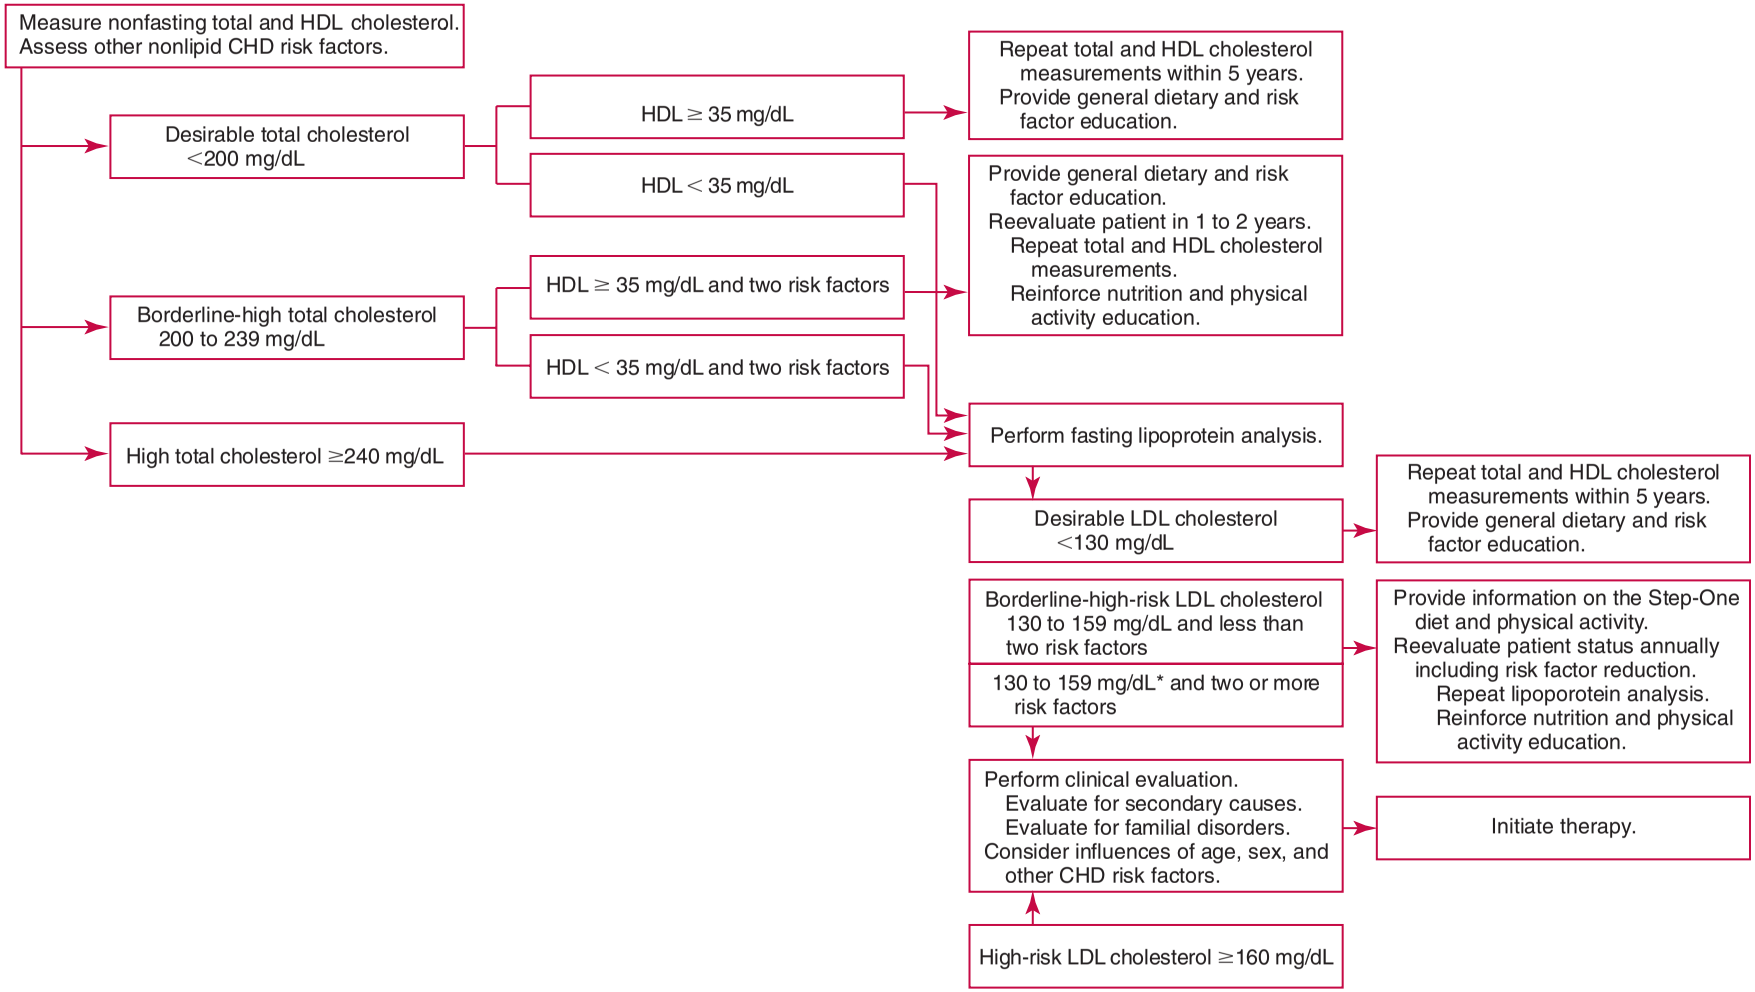
also directed recommendations to schools, health professionals, government agencies, the food industry, and mass media to help influence and modify the eating habits of children and adolescents. The most recent guidelines have stressed the importance of limiting *trans*-fatty acids to less than 1% of total calories consumed.[71] Because of mandatory food labeling requirements and because of local ordinances limiting the use of *trans*-fatty acids, it may now be easier to achieve this goal.

Individualized Approach

Instead of the universal approach used for LDL-C screening in adults, an individualized approach or selective screening is recommended for children older than 2 years of age who may be at risk for cardiovascular disease. Children at risk for cardiovascular disease are recognized because of a family history of hypercholesterolemia or premature cardiovascular disease. It is recommended that such patients be tested for fasting total cholesterol, HDL-C, triglycerides, and LDL-C (Figure 27-25).[6,71] If the family history is not known, or if the child has other risk factors, such as obesity, hypertension or diabetes, it is recommended that they be screened. In general, treatment guidelines for children are less aggressive than those for adults because of concern regarding potential negative consequences of treatment, particularly drug treatment. Under the NCEP guidelines,[12] children with an average LDL cholesterol concentration between 110 and 129 mg/dL are recommended to be placed on the AHA Step-One diet, counseled about other heart disease risk factors, and re-evaluated after 1 year. Those with an average LDL cholesterol concentration greater than 130 mg/dL should also be placed on the AHA Step-One diet and evaluated for secondary causes; their family members should be screened. If after 3 months of initiation of dietary therapy, the LDL cholesterol concentration remains greater than 130 mg/dL, the patient should be placed on the AHA Step-Two diet, which entails further reduction of saturated fatty acid and cholesterol intake (see

tahir99-VRG & vip.persianss.ir



*On the basis of the average of two determinations. If the first two LDL-cholesterol test results differ by more than 30 mg/dL, a third test result should be obtained within 1 to 8 weeks and the average value of the three tests used.

tahir99-VRG & vip.persianss.ir

Table 27-19). Drug therapy was recommended by the NCEP for children 10 years of age and older, if after careful adherence to dietary therapy (6 months to 1 year), the LDL cholesterol concentration remains greater than 190 mg/dL. The action concentration is lower (160 mg/dL) for patients who have a positive family history of premature CHD and for those with two or more other risk factors.

The American Academy of Pediatrics has developed alternative guidelines for lipid screening in children.[71] These guidelines are similar to the older NCEP guidelines, but emphasis is placed on identifying children who may be at risk because they are overweight [overweight is defined as body mass index (BMI) ≥85th percentile for age]. Children with hypertension or diabetes and those who smoke are recommended to be screened with a lipid panel. These additional groups were selected because it was estimated that only between 30% and 60% of children with hypercholesterolemia were being detected when the older NCEP screening criteria of a positive family history of hypercholesterolemia and premature cardiovascular disease were used. Another difference is the greater emphasis of the new guidelines on lowering the fat content of the diet for highest risk subjects. It is recommended to restrict saturated fat to 7% of total calories and to limit cholesterol to 200 mg/d. Finally, more information shows the safety and efficacy of lipid-lowering drug treatment in children, particularly statins, so the American Academy of Pediatrics recommends that subjects 8 years of age and older be considered candidates for drug treatment if their LDL-C is >190 mg/dL after other interventions have been tried. A lower threshold of LDL ≥160 mg/dL should be used in higher-risk subjects with a family history of premature cardiovascular disease, or with *two or more* risk factors, or with diabetes. Subjects younger than 8 years of age but with a marked increase in total cholesterol to greater than 500 mg/dL should be considered as candidates for drug therapy. Children, as well as adults, who have homozygous FH are relatively resistant to drug therapy, particularly statins, because they work in part by upregulating hepatic LDL receptors. Several alternative treatments that have been used include (1) long-term plasmapheresis every 2 weeks or a plasmapheresis-like procedure that selectively removes LDL, (2) partial ileal bypass or portacaval shunt to lower total and LDL cholesterol, and (3) liver transplantation, using livers from donors with functional LDL receptors. An early-stage clinical trial of an antisense oligonucleotide against apo B, which is delivered subcutaneously, has been shown to efficiently lower LDL concentrations in FH patients for several weeks.[129]

Management of Hypertriglyceridemia

Because evidence-based findings have shown triglycerides to be an independent risk factor for CHD in both men and women, greater emphasis is now placed on measurement of this marker and the management of those with increased triglycerides.[11] Furthermore, an *average to low-risk* triglyceride concentration has been redefined from <200 to <150 mg/dL; values of 150 to 199 mg/dL are considered borderline high, 200 to 499 mg/dL high, and ≥500 mg/dL very high. In the general population, several factors are associated with increased triglyceride concentrations, including obesity, cigarette smoking, physical inactivity, and excess alcohol intake, as well as several diseases (e.g., type 2 diabetes, chronic renal failure), drugs (e.g., corticosteroids, estrogens, retinoids), and genetic disorders (e.g., FCHL, FHTG). In clinical practice, hypertriglyceridemia is often associated with the metabolic syndrome. Triglyceride-rich lipoproteins or remnant lipoproteins are currently recognized to be atherogenic. In practice, VLDL cholesterol is often used as a measure of these atherogenic lipoproteins. Therefore, the ATP III suggested the addition of non-HDL cholesterol (total cholesterol–HDL cholesterol) as an indicator for all atherogenic lipoproteins (mainly LDL and VLDL).[11] Non–HDL-C is used as a secondary target of therapy in persons with triglycerides ≥200 mg/dL. The goal for non-HDL cholesterol in those with increased triglycerides is 30 mg/dL above that set for LDL cholesterol. The treatment of hypertriglyceridemia depends on the cause of the increase and the severity. Those with triglycerides <200 mg/dL are treated with weight reduction and increased physical activity; for those at 200 to 499 mg/dL, drug therapy is also considered (fibrate, nicotinic acid, and niacin). In the latter group, the non–HDL-C goal becomes a secondary target of therapy (Table 27-22). Those with triglycerides >500 mg/dL usually are at increased risk of pancreatitis and are treated with a low-fat diet (≤15% of calorie intake), weight reduction, increased physical activity, and triglyceride-lowering drugs. Although nicotinic acid and niacin are usually the drugs of choice, a combination therapy, such as gemfibrozil and resins, or gemfibrozil and an HMG-CoA reductase inhibitor, can also be used.[282]

TABLE 27-22 Comparison of LDL Cholesterol and Non-HDL Cholesterol Goals for Three Risk Categories

Risk Category	LDL Goal, mg/dL	Non-HDL Goal, mg/dL
CHD and CHD risk equivalent (10-year risk for CHD >20%)	<100	<130
Multiple (2+) risk factors and 10-year risk ≤20%	<130	<160
0-1 risk factor	<160	<190

MEASUREMENT OF LIPIDS, LIPOPROTEINS, AND APOLIPOPROTEINS

Lipoproteins and their lipid and apolipoprotein constituents have become increasingly important in characterizing the risk of cardiovascular disease, and in the diagnosis and

tahir99-VRG & vip.persianss.ir

management of disorders of lipoprotein metabolism. In recent decades, our knowledge of such disorders has evolved from an essentially descriptive association between elevated plasma lipids and increased risk for premature cardiovascular disease morbidity and mortality to a much broader understanding of the underlying biochemistry, physiology, and genetic interactions. Remarkable advances have been made in our understanding of the contribution of lipoproteins to the development and progression of arterial lesions. Advances have also been made in the analytical techniques and methods used for measuring lipids, lipoproteins, and apolipoproteins. In this section, we begin with a brief historical perspective on the development of measurement technology; this is followed by a more detailed discussion of pertinent methods.

Historical Perspective and Background

The causal relationship between increased plasma concentrations of LDL and risk of CHD and the efficacy of LDL lowering to reduce risk was widely acknowledged by the mid-1980s. Awareness of the importance of intervention emphasized the necessity for uniform means of defining hyperlipidemia and CHD risk. Previous practice had been to use arbitrarily defined cutoffs based on prevailing lipid and lipoprotein concentrations in the general population or in local populations of "normal patients." Because of the relative nonspecificity of early chemical methods for cholesterol measurement and the different types of methods then in use, significant biases existed between values obtained in different laboratories, and it was not uncommon for "normal" reference intervals to be laboratory specific. Quantitation of the relationship between total or LDL cholesterol concentration and risk for CHD, demonstration of the efficacy of treatment, and development of reference methods and Centers for Disease Control and Prevention (CDC) standardization programs for lipids and lipoproteins[208] made possible the use of risk-related cutoff points (see Tables 27-15 and 27-18). This led to the necessity for uniform definitions of hyperlipidemia based on commonly accepted risk-based lipid and lipoprotein cutoffs and the availability of accurate lipid and lipoprotein measurements.

Consensus Guidelines from Expert Panels

Beginning in the mid-1980s, the NCEP convened expert panels to develop guidelines for diagnosis and treatment of hypercholesterolemia[6,8,11] and for reliable lipid and lipoprotein measurements.[5,9] Two laboratory panels issued recommendations for blood lipids and lipoproteins. The first, the NCEP Laboratory Standardization Panel, focused on measurement of total cholesterol[5]; the second, the NCEP Working Group on Lipoprotein Measurement, addressed measurements of triglycerides, HDL cholesterol, and LDL cholesterol.[9] For more detail, refer to the original reports, both of which include extensive reviews of lipid and lipoprotein methods.[5,9] In 2009 expert recommendations for apo B were published.[62]

Here we summarize the principal considerations and recommendations for clinical lipid and lipoprotein measurements.

Basic Issues

In developing recommendations for lipid and lipoprotein measurement, the NCEP panel considered several basic issues. First, in most of the large-scale clinical and epidemiologic studies that established (1) relationships between lipids and lipoproteins, (2) risk for CHD, and (3) efficacy of cholesterol lowering, measurements were made in standardized laboratories in which the accuracy of measurements was traceable to CDC reference methods. This included studies such as the National Diet Heart Study in the 1960s, various LRC program studies (early 1970s to 1990), Specialized Centers of Research in Atherosclerosis studies (early 1970s to the present), and several NHANES studies conducted between 1960 and 1994.[208]

Second, various methods used in laboratory or nonlaboratory settings should be capable of similar accuracy (i.e., the reliability of the measurements should be independent of how, where, or by whom they were made). Ideally, it should be possible to consider all lipid measurements made in the United States (and eventually globally) as if they had been made in a single laboratory. This premise does *not* require that all laboratories use the same methods; it requires only that all methods be capable of providing values equivalent to those on which the relationships between lipids, lipoproteins, and the risk for CHD were established.

Third, as new methods are developed, particularly those that may be more accurate and precise for various lipoproteins or lipoprotein subfractions, the particular lipoprotein included in the measurement should be specified. This is done to ensure that new methods can be linked to those that were used to establish the known lipoprotein–CHD risk relationships.

To achieve these aims, development of reference methods that could be used as accuracy targets for lipid and lipoprotein measurements was required; also, guidelines for analytical performance were established.

Analytical Challenges

Plasma lipoproteins are heterogeneous and polydisperse macromolecular complexes that vary considerably in size, composition, and function, and consequently present exceptional analytical challenges (see Table 27-4). Traditionally, lipoprotein concentrations have been expressed in terms of their cholesterol content, because methods developed early on for measuring cholesterol and lipoproteins carry virtually all of the cholesterol that circulates in the plasma. This approach simplified the methods used to determine lipoproteins, because the lipoprotein fractions of interest have only to be separated from each other; the other plasma proteins do not have to be removed.

Analytically, cholesterol has a known molecular structure and can be accurately and precisely measured with appropriate chemical or biochemical methods. Triglycerides and the lipoproteins themselves, however, are not unique chemical entities (e.g., triglycerides consist of many possible fatty acyl groups covalently attached to three positions on a glycerol backbone through ester linkages) (see Figure 27-13).

tahir99-VRG & vip.persianss.ir

Fatty acyl groups vary in chain length and degree of saturation, leading to a mixture of triglycerides of somewhat different molecular weights. Consequently, triglyceride methods usually measure the glycerol backbone, and triglyceride concentration is then stated only in terms of molar concentration. In the United States, however, lipids have been traditionally expressed in terms of mass concentration (milligrams per deciliter), which is an approximation requiring an assumption about the average molecular weight of the triglyceride mixture. Because palmitate, stearate, and oleate are the major fatty acids in plasma triglycerides and have similar molecular weights, the conversion between molar and mass concentration usually assumes an average triglyceride molecular weight of 885 Da, the molecular weight of tri-oleyl glycerol (olein).

The situation is even more complicated for LDL and HDL. For example, LDL consists of a population of at least seven subparticles varying in size and lipid composition, each containing apo B-100 as the major apolipoprotein component. Thus, LDL has neither a unique molecular weight nor consistent composition of cholesterol or other lipids or proteins. HDL is even more heterogeneous, consisting of at least 12 subclasses, differing in composition, function, and even CHD risk relationships.[25] HDL has been commonly categorized into two major subclasses—HDL_2 and HDL_3—with the larger HDL_2 fraction showing a stronger inverse association with CHD.[266] Because of these characteristics, the exact concentration and composition of a fraction identified as LDL or HDL may vary, depending on how the fraction is isolated. Once isolated, however, the cholesterol content can be measured accurately. A major consideration, therefore, was to define the lipoproteins in a uniform way to afford a common basis for standardization and the assessment of accuracy without inhibiting the development of new methods or necessitating use of the same methods in all laboratories.

Analytical Approach

For more than 50 years, the CDC has maintained reference methods for cholesterol, triglycerides, and HDL cholesterol and has provided standardization programs[208] targeted for the research laboratories. In addition, these reference methods were used to establish the accuracy of lipid and lipoprotein measurements in several population studies, including the LRC prevalence and CPPT studies,[1,2] several NHANES studies conducted by the National Center for Health Statistics since the 1960s,[133] and others. From these studies, cut points for risk characterization in patients were derived. Consequently, and because the standardization programs were already accepted as authoritative by the general laboratory and research communities, the NCEP laboratory panels recommended the CDC reference methods as the basis for defining "accuracy" in the context of recommendations for reliable lipid and lipoprotein measurements.

Use of this approach had several advantages. First, it established the same basis for accuracy that had been used in developing the relationships between lipid and lipoprotein concentration and CHD; second, it provided a reference point by which the accuracy of existing or newly developed methods could be assessed.

Lipids and Lipoproteins

Various technologies have been used to separate and measure plasma lipids and lipoproteins and lipoprotein subfractions, including enzymatic, immunochemical, and chemical precipitation reagents, and physical methods, such as ultracentrifugation, electrophoresis, column chromatography, and others.[10,30] As mentioned earlier, the cholesterol content of any particular lipoprotein class can vary somewhat from individual to individual. Moreover, although different methods of lipoprotein separation may produce similar lipoprotein fractions, they usually do not produce identical fractions, giving rise to systematic biases between methods that purport to measure the same component. The present discussion focuses primarily on accepted reference methods and procedures commonly used in clinical practice for lipid and lipoprotein measurements.

Reference Methods

Reference methods are the "gold standards" or accuracy targets that have been developed for the more common analytes, such as cholesterol, triglycerides, and LDL and HDL cholesterol.[207] The reference method for cholesterol is fully validated and credentialed through the Joint Committee for Traceability in Laboratory Medicine. The other methods, although not formally credentialed, have been accepted by consensus.

Cholesterol

The CDC reference method for cholesterol[64,74,80] is based on a chemical method devised by Abell and associates. In the CDC version of this method,[80] a 0.5-mL aliquot of serum is treated with 5.0 mL of alcoholic KOH (0.36 mol/L) to hydrolyze the cholesteryl esters. Total cholesterol is then extracted from the mixture with 10 mL of hexane for 15 minutes. An aliquot of the extract is dried in vacuo, and the dry residue is treated with 3.2 mL of a mixture of acetic acid, acetic anhydride, and sulfuric acid (Liebermann-Burchard reagent) for color development. After 30 minutes, absorbance is read at 620 nm using pure cholesterol as the calibrator. This method is operated according to a strict protocol requiring replicate measurements in multiple analytical runs. The method exhibits an approximate 1.6% positive bias compared with isotope dilution mass spectrometry, which is considered to be the highest order method for cholesterol and was developed and applied by the National Institute of Standards and Technology.[80] Cholesterol may be expressed in terms of molar (millimoles per liter) or mass (milligrams per deciliter) concentration. Molar concentration is converted to mass concentration using the following equation:

$$\text{mg/dL} = \text{mmol/L} \times 38.7 \quad \textbf{(1)}$$

The CDC reference method, demonstrated to be readily transferable to other laboratories,[64] has been widely adopted by reference laboratories and diagnostic manufacturers as the

accuracy target and the basis for calibration in cholesterol measurements.

Triglycerides

In the CDC reference method for triglycerides,[9,207,208] the triglycerides first are extracted quantitatively with chloroform to remove water-soluble interfering substances, such as glucose and glycerol, from the serum. The extract is treated with silicic acid to remove phospholipids, and triglycerides in the extract are subjected to alkaline hydrolysis to produce unesterified fatty acids and glycerol. The glycerol produced is oxidized to produce formaldehyde, which is then reacted with chromotropic acid for color development. Absorbance of chromogen in the reaction mixture is measured at 570 nm:

$$\text{Triglycerides} + \text{KOH} \rightarrow \text{Fatty acids} + \text{Glycerol} \quad (2)$$

$$\text{Glycerol} + \text{Periodate} \rightarrow \text{Formic acid} + \text{Formaldehyde} \quad (3)$$

$$\text{Formaldehyde} + \text{Chromotropic acid} \rightarrow \text{Chromogen} \quad (4)$$

Results may be expressed in terms of molar concentration (millimoles per liter) or mass concentration (milligrams per deciliter). The following equation is used to convert mmol/dL to mg/dL:

$$\text{mg/dL} = \text{mmol/L} \times 88.5 \quad (5)$$

The equation assumes an average molecular weight of 885 g/mol (triolein) for plasma triglycerides. In addition, because of the preliminary extraction and adsorption steps, the CDC reference method measures only the glycerides and does *not* include free glycerol, the so-called triglyceride blank.

To facilitate standardization of triglyceride measurements, a designated comparison method (DCM) has been developed by the Cholesterol Reference Method Laboratory Network (CRMLN), involving similar extraction steps followed by more robust enzymatic quantitation of the triglyceride-derived glycerol.[90] This DCM, established in other reference laboratories, is expected to become the secondary accuracy target for triglycerides.

Because the original reference method of the CDC was complex and not robust, a new reference method for triglyceride based on gas chromatographic isotope dilution mass spectrometry (GC-IDMS) is being developed. In this method, all glycerides (triglycerides, diglycerides, and monoglycerides), as before, are chemically reduced to glycerol, which then is measured by GC-IDMS.

High-Density Lipoprotein Cholesterol

Both a reference method and a designated comparison method have been developed to measure HDL cholesterol.

Reference Method. Because HDL consists of several populations of particles that vary somewhat in their cholesterol content, HDL is commonly defined in terms of the method used to prepare the HDL-containing fraction. The CDC reference method[111,207] uses a combination of ultracentrifugation and polyanion precipitation to prepare the HDL-containing fraction. The cholesterol in this fraction is then quantitated using the CDC reference method for cholesterol. The method is as follows: VLDL and chylomicrons, if present, are first removed by ultracentrifugation of an accurately measured volume of serum for 16.2 hours at 33,700 rpm in a Beckman-type 50.4 rotor. Under these conditions, VLDL and any chylomicrons accumulate as a floating layer at the top of the ultracentrifuge tube (d = 1.006 g/mL). A tube-slicing technique is used to remove the VLDL fraction.[111,207] The infranatant, which contains IDL, LDL, Lp(a), HDL, and the other serum proteins, is recovered quantitatively. The apo B-100–containing lipoproteins in 2 mL of this fraction are precipitated by adding 80 µL of injectable heparin (5000 USP units/mL of 0.15 mol/L NaCl in water) and 100 µL of 1.0 mol/L manganese chloride to water. The precipitate is removed by centrifugation,[111,207] and cholesterol in the clear supernatant is measured. HDL cholesterol may be expressed in molar or mass concentration; molar concentration is converted to mass concentration using equation (1).

Heparin-$MnCl_2$ was selected as the precipitation reagent primarily for historical reasons, because it was the method most commonly used in early studies to establish the relationship between HDL cholesterol concentration and risk for CHD. The ultracentrifugation step was included to prevent interference with sedimentation of the apo B-100–containing lipoproteins by the lighter triglyceride-rich lipoproteins, VLDL, and chylomicrons.

Designated Comparison Method. Only a few laboratories have an ultracentrifuge and the experience required to reliably perform the CDC reference method for HDL cholesterol. Furthermore, ultracentrifugation is expensive and necessitates obtaining an impractically large specimen volume, typically 5.0 mL. As a practical alternative, the CRMLN laboratories developed and validated a modified dextran sulfate (50,000 Da) procedure as a DCM to provide results approximately equivalent to those of the CDC reference method (RM) while avoiding ultracentrifugation.[143] The $MgCl_2$ concentration in the precipitant reagent was decreased slightly from that used in the previously published primary method to increase HDL cholesterol values slightly, achieving closer agreement with the CDC reference method.

Low-Density Lipoprotein Cholesterol

The CDC has also defined a reference method for LDL cholesterol based on the same techniques already described for HDL cholesterol.[207] After ultracentrifugation to remove the VLDL and any chylomicrons present, the bottom fraction (d = 1.006) is subjected to precipitation by heparin and manganese, as described previously. After measurement of cholesterol in the d = 1.006 fraction and in the heparin-Mn^{2+} supernatant solution, LDL cholesterol is calculated by difference. It should be noted that the LDL fraction as measured by this reference method, which is commonly called β-quantification, is a so-called broad-cut fraction, which includes not only LDL but also IDL and Lp(a).

Application of Reference Methods to Standardization

Background

Early efforts in the mid 1980s to achieve general standardization of methods used by clinical laboratories began with a

fairly traditional approach with secondary reference materials provided to the laboratory community. The reference materials consisted of lyophilized serum pools with target values assigned on the basis of replicate measurements using the reference methods. However, problems were recognized with this approach, primarily from the confounding effects of matrix changes in the reference materials, making them noncommutable with native clinical samples.[195] Secondary reference materials prepared from pooled serum spiked with artificial analytes, and subjected to freezing and freeze drying, are not always commutable and did not behave like fresh patient specimens with some routine methods. In several notable cases, diagnostic manufacturers used the secondary reference materials to assign presumably reliable targets to their calibrators, but subsequently found that results on patient specimens became inaccurate. The problem was compounded by national proficiency testing programs, which, in an attempt to improve accuracy, began to report reference method target values with similarly prepared survey materials. Laboratories were adjusting calibration to achieve apparent accuracy on the survey materials; however, in some instances, results on actual patient specimens were made inaccurate.

Recognition of these problems focused attention on the issues of "analyte" and "matrix" effects in reference materials.[195] Procedures commonly used in preparing secondary reference materials were inducing changes in the analytes themselves and in the other constituents and fluids surrounding the analytes that made their analyses no longer comparable with measurements in authentic fresh patient specimens. After considerable study and deliberation, the conclusion was reached that the only universally reliable means of transferring accuracy from the reference methods to diagnostic manufacturers and individual laboratories was through direct comparison studies on fresh, representative patient specimens.[338] As a consequence, the CDC and other groups cooperated to organize a network of reference laboratories to provide the reference methods and fresh sample comparison studies.

The Cholesterol Reference Method Laboratory Network

Because the CDC standardization laboratory maintaining the reference methods did not have the capacity to perform all necessary comparison studies directly, it was obvious that the reference laboratory capability would have to be expanded to accommodate the needs of the industry and the laboratory community. To this end, the CDC and several other interested laboratories cooperated to establish the Cholesterol Reference Method Laboratory Network (CRMLN). Each participating network laboratory underwent stringent protocols to transfer the CDC reference methods and to maintain comparability with the CDC. In turn, the network laboratories performed comparison studies using fresh patient sera with the diagnostic manufacturers and with individual laboratories. Throughout the 1990s, the network was large and active to accommodate the demands of comparison studies. As standardization has steadily improved in subsequent years, the concentration of activity has declined, and the number of domestic U.S. network laboratories has decreased. However, at the same time, the network laboratory program has expanded to include additional international laboratories.

In 2009, the CRMLN included two experienced U.S. laboratories and five international partner laboratories in Canada, Europe, Asia, and South America (Boxes 27-3 and 27-4). The network offers protocols, based on Clinical and Laboratory Standards Institute guidelines, whereby diagnostic manufacturers ensure accuracy by completing comparison studies using the reference methods.[209] A measurement system qualifies for certification by demonstrating agreement within specified limits for total, HDL, and LDL cholesterol and for triglycerides. Based on comparison results, calibrator set points are adjusted if necessary to bring performance into agreement with the reference methods. Diagnostic manufacturers and distributors and instrument partners are encouraged to certify their systems at least every 2 years, and to ensure that every production lot is calibrated to maintain traceability to the accuracy targets; this can be accomplished through ongoing participation in the CDC and/or CRMLN program. The CDC Website (http://www.cdc.gov/labstandards/crmln.html/accessed May 9, 2011) provides details of the program, protocols for comparison studies, contact information for the CDC and/or CRMLN, and a listing of commercial methods that have qualified for certification.

Clinical laboratories can promote standardization by encouraging their reagent suppliers to participate in the CRMLN comparison process. In addition, individual laboratories can make arrangements with a CRMLN laboratory to participate in an abbreviated certification protocol for total cholesterol and to complete comparison studies for the other analytes, especially useful in the case of new or modified systems. The CRMLN program is supported by modest user fees.

Routine Methods

Reference methods are complex, typically time-consuming, and at least partially manual, and require a high degree of expertise for reliable operation. Consequently, simpler and more practical methods have evolved for routine clinical use.

Cholesterol

Enzymatic methods for cholesterol measurement are precise, accurate when calibrated appropriately, and easily adapted for use with modern analyzers. Commercially available cholesterol reagents commonly combine all of the enzymes and other required components into a single photometric reagent. The reagent usually is mixed with a few μL of serum or plasma and incubated under controlled conditions for color development, and absorbance is measured in the visible portion of the spectrum, generally at about 500 nm. The reagents typically use a bacterial cholesteryl ester hydrolase to cleave cholesteryl esters.

$$\text{Cholesteryl ester} + H_2O \xrightarrow{\textit{Cholesteryl ester hydrolase}} \text{Cholesterol} + \text{Fatty acid} \quad \textbf{(6)}$$

The 3-OH group of cholesterol is then oxidized to a ketone in an oxygen-requiring reaction catalyzed by cholesterol oxidase.

$$\text{Cholesterol} + O_2 \xrightarrow{\text{Cholesterol oxidase}} \text{Cholest-4-en-3-one} + H_2O_2 \quad \textbf{(7)}$$

H_2O_2, one of the reaction products, is measured in a peroxidase catalyzed reaction that forms a colored dye:

$$H_2O_2 + \text{Phenol} + \text{4-Aminoantipyrine} \xrightarrow{\text{Peroxidase}} \text{Quinoneimine dye} + 2\,H_2O \quad \textbf{(8)}$$

These methods may be subject to interference from other colored compounds or those that compete with the oxidation reaction or react with peroxide, such as bilirubin, ascorbic acid, and hemoglobin. Assays are usually linear up to about 600 or 700 mg/dL. Reagents have been refined by adding substances such as bilirubin oxidase and dual-wavelength readings to minimize the effects of hemolysis; interference from bilirubin generally is not an issue now in concentrations below 5 mg/dL.[30,74,211] Enzymatic reagents are not entirely specific for cholesterol, because β-hydroxy sterols and plant sterols (e.g., β-sitosterol) can also react. In human serum or plasma, however, this is not a major problem because these interfering sterols are generally present in very low concentrations.

In practice, reagent formulations vary from manufacturer to manufacturer. In most cases, the reagent from a particular

manufacturer will have been optimized for use with one or several specific instruments and calibration materials—usually those sold by that manufacturer. Over the past few years, most manufacturers have been supplying calibration materials with assigned values that are traceable to the CDC reference method; this has helped reduce interlaboratory variation. Thus, cholesterol methods are best thought of as "measurement systems" composed of reagent, calibrator (cholesterol standard), and instrument. When a reagent-calibrator-instrument system from a single manufacturer is used, cholesterol measurements within the laboratory usually are accurate within 1 to 3% of reference values, and such systems are routinely operated with coefficients of variation <2.5%. In some cases, however, a reagent from one manufacturer might be used with an instrument from another. In this instance, the responsibility is on the user rather than the manufacturer to ensure that reagent and sample volumes, time and temperature of incubation, and the calibration produce precise and accurate measurements. Although the cholesterol oxidase reagent described previously in this chapter is by far the most common, reagents have been developed using a cholesterol dehydrogenase sequence that may have advantages in some instances.[139] In addition, highly sensitive enzymatic methods have been described for specialized applications.[145] Free or unesterified cholesterol can be readily quantified by deleting the cholesterol esterase from the reagent.

Triglycerides

Triglycerides are commonly measured with enzyme reagents directly in plasma or serum. Reagents combining all required enzymes, cofactors, and buffers are available from various manufacturers; as for cholesterol, such reagents are optimized for use with particular instrument-calibrator systems. Several different enzyme sequences have been used. In all methods, the first step is the lipase-catalyzed hydrolysis of triglycerides to glycerol and fatty acids:

$$\text{Triglyceride} + 3\ H_2O \xrightarrow{\text{Lipase}} \text{Glycerol} + 3\ \text{fatty acids} \quad \textbf{(9)}$$

Glycerol then is phosphorylated in an ATP-requiring reaction catalyzed by glycerokinase:

$$\text{Glycerol} + \text{ATP} \xrightarrow{\text{Glycerokinase}} \text{Glycerophosphate} + \text{Adenosine diphosphate (ADP)} \quad \textbf{(10)}$$

In the most commonly used methods, glycerophosphate is oxidized to dihydroxyacetone and H_2O_2 in a glycerophosphate oxidase–catalyzed reaction,

$$\text{Glycerophosphate} + O_2 \xrightarrow{\text{Glycerophosphate oxidase}} \text{Dihydroxyacetone} + H_2O_2 \quad \textbf{(11)}$$

and the H_2O_2 formed in the reaction is measured as described in reaction (8).

Alternatively, glycerophosphate is measured in a reduced form of nicotinamide-adenine dinucleotide (NADH)-producing reaction, and NADH is measured by a spectrophotometer set at 340 nm or in a diaphorase-catalyzed reaction to form a reaction product whose absorbance is measured at 500 nm:

$$\text{Glycerophosphate} + \text{Nicotinamide-adenine dinucleotide (NAD)} \xrightarrow{\text{Glycerophosphate dehydrogenase}} \text{Dihydroxyacetone phosphate} + \text{NADH} + H^+ \quad \textbf{(12)}$$

$$\text{NADH} + \text{Tetrazolium dye} \xrightarrow{\text{Diaphorase}} \text{Formazan} + \text{NAD}^+ \quad \textbf{(13)}$$

Other methods measure the ADP produced in reaction (10), as shown in equations (14) and (15):

$$\text{ADP} + \text{Phosphoenol pyruvate} \xrightarrow{\text{Pyruvate kinase}} \text{ATP} + \text{Pyruvate} \quad \textbf{(14)}$$

$$\text{Pyruvate} + \text{NADH} + H^+ \xrightarrow{\text{Lactate dehydrogenase}} \text{Lactate} + \text{NAD}^+ \quad \textbf{(15)}$$

Loss of NADH is photometrically measured at 340 nm.

Enzymatic triglyceride methods are fairly specific in that they do not detect glucose or phospholipids. They are linear in the concentration range up to about 700 mg/dL, and when automated they are operated with coefficients of variation up to approximately 3%. The methods are usually calibrated with reference solutions of pure glycerol or with serum-based secondary calibrators. However, because all methods measure the glycerol component, any free glycerol in the sample contributes to the apparent amount of triglyceride. With routine methods, the decision must be made whether to correct for free glycerol by using a method that corrects for the free glycerol blank.

Triglyceride Blanks (Correction for Endogenous Glycerol). Glycerol concentrations in freshly collected serum or plasma in healthy subjects are usually less than 5 to 10 mg/dL. Because this small amount is medically insignificant, the triglyceride blank is usually ignored. Glycerol, however, can be higher in samples with increased triglyceride concentrations and from patients with conditions such as diabetes or those receiving total parenteral nutrition, but even in these conditions, the free glycerol concentration does not generally substantially affect the interpretation of a lipid result. Rarely, glycerol can be markedly increased by 50- to 100-fold in a rare disorder called *hyperglycerolemia,* which is the result of a deficiency in glycerokinase.[186]

Although triglyceride blanks in most cases can be ignored in clinical measurements, they can dramatically affect conclusions about method accuracy.[60] Triglyceride blanking usually requires a separate analysis of glycerol, expressed in terms of equivalent triglyceride concentration, and the measured blank value is subtracted from the total triglyceride measurement.[331] Free glycerol can be measured enzymatically using reactions such as those shown in equations (10) and (11), using a reagent that is identical to the triglyceride reagent but lacking lipase—an approach designated *two-cuvette blanking.* An alternative two-step approach carried out in a single cuvette consumes any free glycerol to produce a colorless product in a preliminary reaction before a lipase enzyme is added to cleave and measure the triglyceride-derived glycerol.

Triglyceride blanking by either of these approaches increases the time and cost of triglyceride analysis.[60] A more common practice, designated *calibration blanking* and used by some manufacturers, involves adjusting calibrator set points to compensate for the average amount of free glycerol in specimens. This is accomplished through a comparison study on actual patient specimens versus the reference method or an accurate equivalent. The calibration blanking approach will underestimate the blank in a few specimens but will give a better and reasonably reliable estimation for most specimens.

Traditionally, triglycerides have been determined on fasting samples obtained from patients after a 10- to 12-hour fast—a practice based on the historical practice in epidemiology studies to achieve a uniform metabolic state. However, patients do not routinely present to physicians' offices in the fasting state, and studies have suggested that triglyceride values measured on nonfasting samples may be more predictive of CHD risk.[225] Postprandial collections are more likely to include remnant lipoproteins that are more atherogenic and reflective of the patient's usual metabolic state. Some national guidelines have been modified to recommend nonfasting collections, and in the future, nonfasting may replace fasting collections. A disadvantage of this approach is that it will preclude the use of calculating LDL-C with the Friedewald equation, because of the presence of chylomicrons and elevated triglycerides.

Phospholipids

Quantitative measurement of phospholipids is rare in routine clinical practice but more common in research (e.g., in studies of dietary influences). The choline-containing phospholipids lecithin, lysolecithin, and sphingomyelin, which account for at least 95% of total phospholipids in serum, are readily measured by an enzymatic reaction sequence using phospholipase D, choline-oxidase, and horseradish peroxidase.[187,310] Kit methods with this enzymatic sequence are available commercially. Before enzymatic reagents became available, the common quantitative method involved extraction and acid digestion with analysis of the total lipid-bound phosphorus.[34]

High-Density Lipoprotein Cholesterol

Under current recommendations for characterizing the cardiovascular disease risk in patients, measurement of the two major cholesterol-carrying lipoproteins, HDL and LDL, is most important. Characterization of the β-VLDL characteristic of the uncommon type III or dysbetalipoproteinemia may be appropriate in a few patients. Measurement of lipoprotein subclasses including IDL or remnant lipoproteins is useful in research and can be helpful in some cases in managing patients.

HDL is classically defined in terms of its density range (1.063 to 1.21g/mL) obtained by ultracentrifugation, which has been used as the standard by which the accuracy of other HDL methods is judged. However, the density range of Lp(a) (1.04 to 1.08 g/mL) overlaps that of HDL (see Table 27-4), so in patients with high Lp(a) concentrations, ultracentrifugation at 1.063 g/mL would overestimate the true HDL concentration. As a consequence, the CDC reference method, described previously, uses precipitation to separate HDL, similar to the approach used for many research determinations.[337] Most routine laboratories now use the newer direct or homogeneous assays, which became available beginning in the early 1990s. The homogeneous assays have advantages in terms of efficiency and convenience, because they are capable of full automation. However, homogeneous assays have been shown to lack specificity, especially on specimens from patients with unusual lipoprotein distributions, and hence cannot be recommended for such patients or for research investigations. Because pretreatment precipitation methods were the standard for decades and preceded the currently more common homogeneous assays, these methods will be reviewed first.

Precipitation Methods. In earlier years, HDL cholesterol was most commonly measured (Box 27-5) in supernatant solutions after precipitation of the apo B-100–containing lipoproteins [VLDL, IDL, Lp(a), LDL, and, when present, chylomicrons] directly from plasma or serum using agents such as polyanions in the presence of divalent cations.[111] As indicated earlier, LDL and HDL are the largest contributors to total cholesterol in healthy people, with LDL accounting for about two thirds and HDL for about one third of the total cholesterol. On average, IDL and Lp(a) each account for only about 2 to 3 mg/dL of the total cholesterol, although their concentrations can be considerably higher in some individuals.

Polyanions bridge positively charged groups on lipoproteins; their action is facilitated in the presence of divalent cations, which interact with negatively charged groups, causing aggregation and a cloudy precipitate. Precipitation is usually complete within 10 to 15 minutes at room temperature; at 2 to 4 °C, a 30-minute incubation period is preferred.

BOX 27-5 Methods for HDL Separation/Quantification

Precipitation (First Generation)
- Heparin-Mn^{2+}
  - 0.46 mmol/L (LRC method)
  - 0.92 mmol/L (recommended for EDTA plasma)
- Dextran sulfate (50 kDa) Mg^{2+} (AACC Selected Method and DCM)
- Phosphotungstate-Mg^{2+}

Facilitated Separation (Second Generation)
- Magnetic with/dextran sulfate-Mg^{2+}

Homogeneous (Third Generation)
- Antibody four-reagent method (International Reagents Corp.)
- Polyethylene glycol modified enzymes w/cyclodextrin (Kyowa Medex)
- Synthetic polymer/detergent (Daiichi)
- Antibodies (Wako)
- Catalase (Denka Seiken)

The precipitate is then sedimented by centrifugation, typically for 45,000 g-min (i.e., the equivalent of 1500 × g for 30 minutes). Centrifugation at higher g-forces (e.g., 10,000 × g) accelerates sedimentation and can actually improve complete precipitation of apo B–containing particles. HDL cholesterol is then measured in the clear supernatant.

Of several polyanion-divalent cation combinations, heparan sulfate with $MnCl_2$ was adopted early on and became common in research laboratories and eventually used in the CDC reference method. With the transition to enzymatic cholesterol assays, residual Mn^{2+} was found to interfere, giving artifactually high results. Techniques were devised to reduce this interference, but additional manipulations were required, making them inconvenient for routine use [e.g., the chelator ethylenediaminetetraacetic acid (EDTA) added to the cholesterol reagent to complex residual manganite],[301] or carbonate was added in a second precipitation step to precipitate excess Mn^{2+}.[32] Most laboratories avoided these tedious approaches, rather adopting alternative precipitants such as dextran sulfate or phosphotungstate with Mg^{2+}.[333] A method that used dextran sulfate with molecular weight of 50 kDa was validated as a selected method; during the 1980s, dextran sulfate became the most common precipitation reagent.

The precipitability of lipoproteins with polyanions and divalent cations depends on the lipid and protein compositions of the particles.[47] Thus, various precipitants differ in precipitating apo B-100–containing lipoprotein completely while leaving most species of HDL in solution,[9,30] resulting in potential biases between reagents. With modern reagent-instrument-calibrator systems, conditions generally are optimized to produce values that closely approximate and are traceable to reference method values. Also, the precipitation methods can be inaccurate under certain conditions (e.g., precipitation of apo B-100–containing lipoprotein can be incomplete in samples with high concentrations of triglyceride-rich lipoproteins). Any residual turbidity in the supernate indicates inadequate sedimentation of the apo B-100–containing lipoprotein, resulting in overestimation of HDL cholesterol. Samples with high triglyceride concentrations (generally those above 400 mg/dL) frequently produce turbid supernatants because the triglycerides can reduce the density of the lipoprotein-precipitating reagent complex to the point that some of the complex remains unsedimented. In cases of extremely high triglyceride concentrations, some of the precipitate may even form a floating layer over a clear or turbid supernatant, in addition to the usual precipitate at the bottom of the centrifuge tube.

Such supernates require additional treatment by one of several techniques. Before precipitation, the sample can be ultracentrifuged and the triglyceride-rich lipoproteins removed as described previously for the reference method. Alternatively, a turbid supernatant sometimes can be cleared by centrifuging for a longer time or at higher g-forces.[332] Or more commonly, the sample can be diluted twofold with saline to reduce the concentration of triglyceride-rich lipoproteins before the precipitant is added. A fourth approach is to pass the turbid supernatant through a 0.45-μm filter to remove the unsedimented precipitate before cholesterol in the filtrate is measured.[332]

HDL cholesterol determination can also be affected by sample matrix effects, which arise from (1) the unusual nature of the sample itself, (2) processing effects, or (3) the addition of anticoagulants or preservatives.[195] For example, HDL cholesterol measurements can be inaccurate and usually are more variable when obtained from lyophilized samples than from fresh or frozen sera.

Additives including anticoagulants, such as citrate and fluoride, can have large osmotic effects that cause water to shift from the cells to the plasma. This dilutes the lipoprotein by 10% or more and produces erroneously low values. EDTA, earlier the preferred anticoagulant for lipoprotein measurements, causes a slight dilution, but has been used because it also inhibits certain oxidative and other changes that can affect some lipoprotein or apolipoprotein measurements. Lipid and lipoprotein concentrations in EDTA plasma tend to be about 3% lower than in serum—an effect that may not be readily noticeable in HDL cholesterol measurements. EDTA, however, complexes some of the Mn^{2+} in the heparin-Mn^{2+} method, and it has been found necessary to use a higher concentration of $MnCl_2$ (0.092 mol/L, final concentration in the reaction system) when the procedure is used with EDTA plasma than with serum (0.046 mol/L).[28,332] Heparin, by virtue of its high molecular weight, and when present in concentrations used for anticoagulation, has no measurable effect on lipid or lipoprotein concentration, and it does not affect HDL cholesterol measurements. A variation of the precipitation method, involving the use of magnetic beads complexed with dextran sulfate, helped reduced interference from high triglyceride samples,[114,216] but it is no longer commercially available.

Homogeneous Assays. A major breakthrough in HDL determination was reported in 1994,[136] with publication of the first of a series of so-called homogeneous methods for lipoproteins (see Box 27-5). Compared with earlier precipitation methods requiring manual pretreatment steps, homogeneous methods were much better suited for the automated systems used in the modern clinical laboratory. Elimination of manual pretreatment was timely, as laboratories were under pressure to reduce operating costs. The fully automated homogeneous methods also improved precision through more consistent pipetting of smaller specimen volumes and precise temperature control and reaction timing, which facilitated achieving the NCEP analytical performance goals.

The first homogeneous assay for HDL cholesterol required four successive reagent additions (International Reagents Corp., Kobe, Japan). The first reagent contained polyethylene glycol, resulting in aggregation of the apo B-100–containing chylomicrons, VLDL, and LDL. The second reagent protected or blocked the aggregated lipoproteins with antibodies to apo B-100 and apo C. The cholesterol reaction enzymes (cholesterol esterase, cholesterol oxidase, and peroxidase) were added in the third reagent, which acted only on the unprotected HDL cholesterol. The fourth reagent stopped the color reaction and solubilized the aggregates with guanidine salts,

clearing the reaction mixture for measurement of color. This breakthrough method, even though not suited for all analyzers because of the multiple reagent additions, was capable of full automation, paving the way for subsequent, two-reagent homogeneous methods.

In 1995, a second homogeneous method became available (Kyowa Medex Co., Tokyo, Japan[308]; Roche Diagnostics, Indianapolis, Ind) that used sulfated α-cyclodextrins together with Mg^{2+} to selectively block but not precipitate chylomicrons and VLDL, providing selectivity without the necessity for precipitation. Second, covalently linked polyethylene glycol molecules enhanced the specificities of the enzymes cholesterol esterase and cholesterol oxidase toward the cholesterol in HDL. Polyethylene glycol having an MW of 6000 Da was thought to optimize the specificities at concentrations lower than those used previously to precipitate lipoproteins, implying that modified enzymes were able to distinguish lipoprotein classes on the basis of their size and/or charge. The result was a fully automated homogeneous assay with only two reagent additions applicable for general use. The original kit included the second enzyme-containing reagent in lyophilized form, necessitating reconstitution, but a modification introduced in mid 1998 included both reagents in liquid form.[111] A third modification decreased the Mg^{2+} concentration, apparently to reduce carryover in pipetting.

A synthetic polymer together with a polyanion to block the non-HDL lipoproteins was used in a third homogeneous assay (Daiichi Pure Chemicals Co., Tokyo/Genzyme Corp., Cambridge, Mass).[115,169,216] A detergent was added that exposes only cholesterol in HDL to the enzymes, giving specificity for HDL-C. This method required two reagent additions: the first with the polyanion and polymer-blocking agents, and the second with detergent, enzymes, and substrates. A subsequent modification provided both reagents in liquid form with other changes to improve specificity and decrease potential interference.[112,151,345] A third modification without Mg^{2+} has been reported.[73,130]

A fourth early homogeneous assay was based on immunoinhibition and included two reagents (Wako Pure Chemicals Industry, Osaka, Japan).[163,188,229] The first reagent contained an antibody to human apo B-100 that reacted with apo B-100–containing lipoproteins, chylomicrons, VLDL, and LDL, blocking their reaction to enzymes added in the second reagent. The current formulation included both reagents in liquid form.

A fifth homogeneous method (Denka Seiken Co., Niigata, Japan/Polymedco Inc., Cortlandt Manor, NY/Randox Laboratories Limited, Crumlin, UK) allowed cholesterol esterase and oxidase to react with lipoproteins other than HDL, generating peroxidase, which in turn was scavenged by the enzyme catalase.[215,229] An inhibitor of catalase and a surfactant in a second reagent specifically reacted with HDL cholesterol, producing color through the usual peroxidase sequence.

In subsequent years, the various homogeneous reagents have undergone many additional modifications in attempts to improve their convenience and specificity. Currently, at least seven separate reagent formulations are available.

At least one instrument application for each of the homogeneous assays discussed previously in this chapter has qualified for certification by the CRMLN, implying at least the capability to achieve agreement with the reference method. However, conditions and especially calibration may be different on various instrument applications, and many have not been evaluated. Thus certification for the reagents cannot be considered universally applicable to all distributor versions, instrument applications, and lots. Similarly, published evaluation studies have confirmed that methods can be accurate but may not be so in every commercial application.[208] Laboratories choosing to adopt homogeneous assay applications that have not been certified by the CRMLN are encouraged to confirm that their particular systems are accurate. In addition, an evaluation of all current homogeneous HDL-C and LDL-C assays revealed that many of these assays lack ruggedness because of lack of lipoprotein specificity, especially on specimens with unusual lipoprotein composition.[196]

Specificity and Interference. The accuracy of measuring HDL cholesterol in each individual specimen is a function not only of mean bias or overall inaccuracy of a method related to calibration, but also its specificity for HDL cholesterol and absence of interference by other lipoproteins and constituents of the specimen matrix. CRMLN certification studies and many published evaluation studies undertaken to assess accuracy included only samples from relatively normal subjects. Most studies did not determine performance in samples from patients with extreme hyperlipidemias, such as type III or other conditions such as liver and kidney disease, which often result in unusual lipoproteins with atypical separation characteristics. Only a few studies have included such extreme specimens and have raised questions about the specificity of the homogeneous reagents.* Most studies of interference have used fairly traditional spiking designs; they have been relatively modest in scope and have not properly addressed abnormal lipoprotein composition.[22,114,127,151,215] Hemoglobin below 2 g/L and bilirubin less than 10 mg/dL do not interfere appreciably with any of the homogeneous methods.

Considerations in Choosing a High-Density Lipoprotein Method. Laboratories have had to consider the alternatives in deciding whether to replace a conventional pretreatment method with a homogeneous reagent: improved efficiency on the one hand versus occasional discrepant results on the other. Routine clinical laboratories tend to choose the fully automated methods, often because of unavoidable pressures to improve efficiency. Laboratories performing research and supporting lipid clinics, on the other hand, often choose to retain a conventional precipitation method. An important factor in the latter choice is that a laboratory supporting long-term studies cannot tolerate potential changes and shifts in results that may have occurred because of frequent modifications to the homogeneous reagents.

BOX 27-6 Methods for LDL Separation/ Quantification

β-Quantification
- Ultracentrifugation at density 1.006 kg/L to float and remove VLDL and any chylos
- Measurement of total cholesterol in bottom fraction (LDL-C + HDL-C)
- Precipitation of bottom fraction with heparin/Mn^{2+} to remove LDL
- Measurement of total cholesterol in supernatant, which equals HLD-C
- LDL is calculated by subtracting HDL-C from total cholesterol in bottom fraction; most commonly used by specialty lipid laboratories

Calculation Using Friedewald Formula
- (LDL chol) = (Total chol) − (HDL chol) − (Triglyceride)/5
- Originally proposed for epidemiology studies
- Became the most common method in routine clinical laboratories

Homogeneous Reagents
- LDL solubilization (Kyowa Medex)
- LDL protected/deprotected by surfactants (Daiichi)
- LDL protected/catalase (Wako)
- Non-HDL catalase/LDL azide (Denka Seiken)
- LDL protected by calixarene/cholesterol dehydrogenase (International Reagents Corp.)

Low-Density Lipoprotein Cholesterol

Methods for LDL cholesterol generally quantitate a so-called broad-cut fraction, including not only the primary LDL species in the 1.019 to 1.063 kg/L density range, but also IDL, density 1.006 to 1.019 kg/L, and Lp(a).[218] Therefore, the usual convention for total cholesterol on a fasting sample without cholesterol is based on the following formula:

$$\text{Total cholesterol (chol)} = \text{VLDL chol} + \text{LDL chol} + \text{HDL chol} \quad \textbf{(16)}$$

LDL cholesterol can be measured using both indirect and direct methods, and either approach has been used in major studies that established the relationship between LDL cholesterol concentration and risk for CHD.

Indirect Methods. Indirect methods for measuring LDL cholesterol are based on measuring a number of lipid-related analytes followed by their use in calculating the LDL cholesterol content of a specimen. This includes use of the Friedewald equation and the β-quantification method.

The Friedewald Equation. In the most widely used indirect method (Box 27-6), cholesterol, triglyceride, and HDL cholesterol are measured and LDL cholesterol is calculated from primary measurements using the empirical equation of Friedewald and colleagues[93]:

$$\text{(LDL chol)} = \text{(Total chol)} - \text{(HDL chol)} - \text{(Triglyceride)}/5 \quad \textbf{(17)}$$

where all concentrations are given in mg/dL (triglyceride/2.22 is used when units are expressed in mmol/L). The factor (triglyceride)/5 is an estimate of VLDL cholesterol concentration that is based on the average ratio of triglyceride to cholesterol in VLDL.

Several investigators have evaluated the accuracy of LDL cholesterol estimated by equation (17). For example, DeLong and colleagues recommended use of the expression 0.16 × (triglyceride) as a better estimate of VLDL cholesterol; consequently, the factor (triglyceride)/6 is used in few laboratories.[75] Other factors have been suggested for particular populations,[9] but no single factor has been accurate under all circumstances. However, when the original factor (triglyceride)/5 was compared with a combined ultracentrifugation-polyanion precipitation method in about 5000 samples, errors in LDL cholesterol estimated by equation (17) were found to be symmetrically distributed about zero.[334] On balance, the NCEP recommended use of the original factor (triglyceride/5) for estimating LDL cholesterol with equation (17).[9]

In practice, the Friedewald calculation is reasonably accurate, but under several well-known circumstances, the Friedewald equation cannot be used. First, calculation is precluded in samples that have triglyceride concentrations above 400 mg/dL or in those that contain increased quantities of chylomicrons (nonfasting specimens). At high triglyceride concentrations, the factor (triglyceride)/5 as an estimate of VLDL cholesterol concentration is not appropriate, because such samples can also contain chylomicrons, chylomicron remnants, or VLDL remnants, all of which have higher triglyceride/cholesterol ratios and can contribute to errors in estimation. Under these circumstances, use of the factor (triglyceride)/5 would overestimate VLDL cholesterol and therefore underestimate LDL cholesterol. The Friedewald equation has been found to be most accurate in samples with triglyceride concentrations below 200 mg/dL,[334] but the error becomes unacceptably large (i.e., >10%) at triglyceride concentrations greater than 400 mg/dL.

The opposite error can occur if the Friedewald equation is used in patients with type III hyperlipoproteinemia. Type III hyperlipoproteinemia is characterized in part by the presence of β-VLDL not normally present in the blood. Biochemically, as its name implies, β-VLDL occurs in the VLDL density range but has β mobility on electrophoresis and is much richer in cholesterol than the usual VLDL, with a ratio of triglyceride to cholesterol on the order of 3:1. Application of the factor (triglyceride)/5 in patients with type III hyperlipidemia would underestimate VLDL cholesterol and in turn would overestimate LDL cholesterol. Thus a patient with type III hyperlipoproteinemia may appear to have an artifactually high LDL cholesterol concentration.

Fortunately, both of these conditions are uncommon. The 95th percentile for fasting plasma triglycerides in the United States is below 300 mg/dL, indicating that only a small percentage of specimens will exceed the 400-mg/dL cutoff. Plasma from fasting subjects does not normally contain chylomicrons; even if present, chylomicrons can be observed visually as a floating "cream" layer in samples that have been

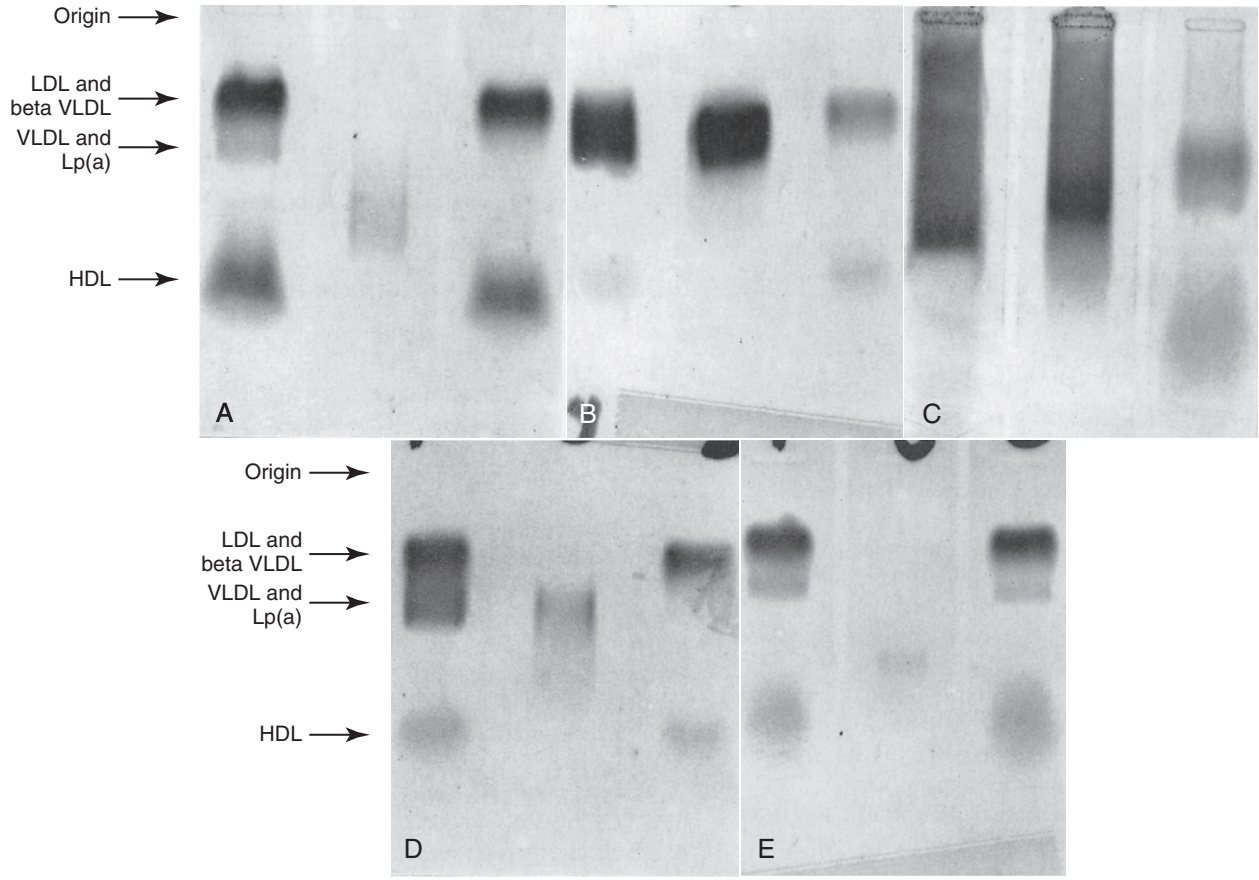

Figure 27-26 Agarose gel electrophoresis of plasma lipoprotein. In each photograph, the samples were applied in the following order, reading from left to right: unfractionated plasma, ultracentrifugal density 1.006 g/mL supernatant solution, ultracentrifugal infranatant solution. A, Pattern seen in normal samples and samples with high LDL cholesterol concentrations. B, Type III hyperlipoproteinemia pattern. C, Severe hypertriglyceridemia, triglyceride = 3840 mg/dL. Note chylomicrons at origin. D, Pattern observed in samples with moderately elevated triglyceride, triglyceride = 281 mg/dL, LDL cholesterol = 145 mg/dL. Note absence of chylomicrons. E, Pattern observed in patients with high concentrations of Lp(a). Note presence of Lp(a) in infranatant solution. This sample had an Lp(a) concentration of 77 mg/dL. *LDL,* Low-density lipoprotein; *Lp(a),* lipoprotein(a); *HDL,* high-density lipoprotein; *VLDL,* very low-density lipoprotein.

allowed to stand undisturbed at 4 °C overnight. Finally, the prevalence of type III hyperlipoproteinemia in the general population is only about 1 to 2 per 1000 persons.[161] On the other hand, as treatments for hyperlipidemia become more effective and more common, patients with very low triglyceride concentrations are encountered. In this instance, the calculation may be distorted and LDL cholesterol overestimated.[283] Nevertheless, because of the ease of the calculation and its reasonable accuracy, calculation of LDL-C has persisted as the most common approach to determining LDL cholesterol in patient management.

β-Quantification (Ultracentrifugation-Polyanion Precipitation). This method is the precursor to the reference methods developed for HDL and LDL and may be used in samples for which the Friedewald equation is unreliable. β-quantification follows the procedure adopted from the NIH Laboratory that was used in the LRC Program, combining preparative ultracentrifugation and polyanion precipitation.[111] An accurately measured aliquot of plasma at native density of 1.006 g/mL is first ultracentrifuged at 105,000 × g for 18 hours at 10 °C. VLDL and, if present, chylomicrons and/or β-VLDL float over the infranatant containing primarily LDL and HDL (Figure 27-26) plus any IDL and Lp(a) that may be present. The floating layer, removed with the aid of a tube slicer, is sometimes analyzed as a check on recovery and may be saved for electrophoretic analysis to determine the presence of β-VLDL. The infranatant solution is remixed and reconstituted to known volume, and its cholesterol content measured. HDL cholesterol is usually measured in a separate aliquot of plasma, but when necessary, an aliquot of the d 1.006 g/mL infranatant can be treated to remove the apo B-100–containing lipoproteins [IDL, LDL, and Lp(a)]; HDL cholesterol is then measured in the clear supernatant. VLDL and LDL cholesterol are calculated as follows:

$$(\text{VLDL chol}) = (\text{Total chol}) - (d > 1.006\ \text{g/mL chol}) \quad \textbf{(18)}$$

$$(\text{LDL chol}) = (d > 1.006\ \text{g/mL chol}) - (\text{HDL chol}) \quad \textbf{(19)}$$

LDL cholesterol measured in this way is unaffected by the presence of chylomicrons or other triglyceride-rich lipoproteins, or by β-VLDL. VLDL cholesterol is usually calculated from equation (18) rather than measured directly in the ultracentrifugal supernatant, because it can be difficult to recover this fraction quantitatively, particularly when triglyceride concentrations are high.

Lipoproteins Included in the "LDL Cholesterol" Measurement. In this context, the term *LDL cholesterol* includes cholesterol in IDL and Lp(a) fractions, as well as the core LDL. Although IDL and Lp(a) cholesterol usually contribute only a few mg/dL to the "total LDL cholesterol" measurement, their contributions can be significant in patients with increased high IDL or Lp(a) concentrations. For example, assuming that cholesterol (i.e., sterol nucleus) constitutes about 30% of the mass of Lp(a), it can be calculated that the Lp(a) cholesterol concentration would contribute about 12 mg/dL, or about 12%, to the LDL cholesterol measurement in a patient with an Lp(a) concentration of 40 mg/dL and an apparent LDL cholesterol concentration of 100 mg/dL. It has been suggested that a more specific measure of LDL cholesterol could be obtained by correcting the measured LDL cholesterol value for the contribution of Lp(a) cholesterol,[134,276] and a similar argument might be made for IDL. However, both IDL and Lp(a) contribute to increased risk for CHD [see later section on Lp(a)]; therefore, although such correction will increase the specificity of methods for LDL cholesterol, per se, it might also give LDL cholesterol values that underestimate cardiovascular risk. Moreover, this might occur more frequently with patients with CHD or those who are at risk for CHD based on their "LDL cholesterol" concentrations. Consequently, the NCEP Working Group on LDL Cholesterol Measurement suggested that LDL cholesterol values should *not* be corrected for the contribution of other atherogenic lipoproteins; this group also recommended that further research should be conducted to establish the individual contributions of IDL, Lp(a), and LDL cholesterol to CHD risk, as reflected in current LDL cholesterol measurements that include all three lipoprotein classes. NCEP guidelines published in 2001 expand on this concept by introducing the term *non-HDL cholesterol,* which includes all of the apo B–containing atherogenic lipoproteins, including not only Lp(a) and IDL, but also VLDL cholesterol, remnant lipoproteins, and chylomicrons for nonfasting samples.[11]

Diagnosis of the Type III Lipoprotein Pattern. The ratio of VLDL cholesterol to plasma triglyceride, expressed in terms of mass, is 0.2 or lower in normal samples and in those from patients with lipoprotein disorders other than type III hyperlipidemia or dysbetalipoproteinemia. In type III hyperlipoproteinemia, the ratio is 0.3 or higher because of the presence of β-VLDL; the elevated ratio can persist even after treatment. In addition, β-VLDL can be observed directly by subjecting the VLDL fraction to agarose gel electrophoresis, where it migrates electrophoretically with LDL rather than VLDL (see Figure 27-26). The combination of a VLDL cholesterol/plasma triglyceride ratio of 0.3 or higher and the observation of β-VLDL in the ultracentrifugal supernatant is considered diagnostic of the type III lipoprotein pattern.

Direct Methods. Selective precipitation and homogeneous immunoassay methods have been used to measure LDL cholesterol directly.

Selective Precipitation. Several direct methods reported for LDL cholesterol measurement are based on selective precipitation with polyvinyl sulfate or heparin at low pH.[132,171,204] LDL cholesterol is then calculated as the difference between total cholesterol and that in the supernatant, or in another variation, directly in the LDL precipitate. It is not clear whether atherogenic lipoproteins other than LDL itself are also detected; these methods might be expected to be subject to similar sources of error as those encountered with precipitation methods for HDL separation. A more specific method used a mixture of polyclonal antibodies to apo A-I and apo E linked to a resin to bind VLDL, IDL, and HDL, with LDL cholesterol measured in a filtrate by the usual methods. This method was reasonably precise and was in good agreement with ultracentrifugation-polyanion precipitation.[116,132,190,239] The reagent was in commercial distribution for several years, but because it required a separate pretreatment step, it was eventually superseded by a new class of direct homogeneous reagents patterned after the homogeneous reagents for HDL cholesterol.

Homogeneous Assays. Following approaches similar to those used with homogeneous methods for HDL cholesterol,[337] homogeneous assays have been developed to measure LDL cholesterol. For example, at least seven homogeneous LDL methods are commercially available (see Box 27-6), which differ by containing different detergents and other chemicals, allowing specific blocking or solubilization of lipoprotein classes to achieve specificity for LDL cholesterol. Most suppliers offer kits with two reagents; these are readily adaptable to most clinical chemistry analyzers.

Sugiuchi and colleagues developed the first homogeneous method for measuring LDL cholesterol[307]—a reagent distributed by Kyowa Medex, Tokyo and Roche Diagnostics, Indianapolis. With this method, LDL was directly measured by suppressing the other lipoproteins (other methods suppressed LDL first and reacted with other lipoproteins before determining LDL cholesterol). The method was formulated in two reagents. The first had $MgCl_2$, dye, buffer (pH 6.75), and α-cyclodextrin sulfate,[308] which has a highly concentrated negative charge to mask cholesterol in chylomicrons and VLDL in the presence of magnesium ions.[307] The second reagent included the enzymes cholesterol oxidase and cholesterol esterase, peroxidase, dye, buffer (pH 6.75), and a polyoxyethylene-polyoxypropylene polyether (POE-POP) to block cholesterol, especially in HDL.[307,308] The molecular mass of POP in the POE-POP molecule and the hydrophobicity index determine selectivity to LDL; 3850 Da was demonstrated to be optimum.[308]

TABLE 27-23 Analytical Performance of Homogeneous LDL-C Assays

			Recovery, %			Accuracy	
	Imprecision, CVs	Dynamic Range, mg/L	LDL	VLDL	IDL	Bias, %	Bias, mg/L
Kyowa	0.7-3.1	2-4100	97-105	16	52-64	0.8-11.2	−60 to −80
Daiichi	<3.1	4-10,000	87	19	31-47	3.9-5.1	−48 to −80
Wako	≤1.2	10-3000	—	—	—	0.4	−15
Denka	<1.8	70-5500	95	10	31	—	—
IRC	≤0.6	?-4000	—	—	—	—	—

A second method by Sekisuie Medical Co. (Tokyo, Japan; formerly Daiichi Pure Chemicals) was also a two-reagent system. The first reagent contained ascorbic acid oxidase, 4-aminoantipyrine, peroxidase, cholesterol oxidase, cholesterol esterase, buffer (pH 6.3), and a detergent, which solubilized all non-LDL lipoproteins, allowing reaction of their cholesterol with the esterase and oxidase enzymes, forming a colorless product. The second reagent contained N,N′-bis-(4-sulfobutyl)-m-toluidine Na_2 (DSBmT), buffer (pH 6.3), and a detergent to specifically release LDL cholesterol. The resulting hydrogen peroxide reacted with N,N′-bis-(4-sulfobutyl)-M-toluidine disodium salt to generate a colored product.

A third method (Wako Pure Chemicals) included a reagent with (1) Good's buffer (pH 6.8), [N-(2-hydroxy-3-sulfopropyl)-3,5-dimethoxyaniline, sodium salt], (2) cholesterol esterase, (3) cholesterol oxidase, (4) catalase, (5) polyanions, and (6) amphoteric surfactants, the latter selectively protecting LDL from enzymatic reaction. The non-LDL cholesterol reacted with esterase and oxidase, producing hydrogen peroxide, which was consumed by catalase. The second reagent included Good's buffer (pH 7.0), 4-aminoantipyrene, peroxidase, sodium azide, and a deprotecting reagent, which removed the protecting agent from LDL, enabling the specific reaction of cholesterol esterase and cholesterol oxidase with its cholesterol, producing hydrogen peroxide and a blue color complex.[85,193]

Non-LDL cholesterol was removed by a fourth method (Denka Seiken, Niigata, Japan/Polymedco Inc., Cortlandt Manor, NY) via a selective reaction with cholesterol oxidase and cholesterol esterase, with the resulting peroxide byproduct eliminated by reaction with catalase (CAT). In this two-reagent method, the first reagent contained $MgCl_2$, cholesterol esterase, cholesterol oxidase, catalase, N-(2-hydroxy-3-sulfopropyl)-3,5-dimethoxyaniline sodium salt, and Emulgen 66 (polyoxyethylene compound; Kao) and Emulgen 90 (both nonionic surfactants) in Good's buffer (PIPES; 100 mmol/L; pH 7.0). Its second reagent contained peroxidase, 4-aminoantipyrine, sodium azide (to inhibit the catalase), and Triton X-100 in Good's buffer. The hydrophilic/lipophilic balance of the detergents was chosen to obtain appropriate selectivity to the lipoproteins.[228]

In a fifth method (International Reagents Corp., Kokusai-Kobe, Japan), its first reagent contained the detergent calixarene, which converts LDL to a soluble complex. Cholesterol esters of HDL-C and VLDL-C were preferentially hydrolyzed by a cholesterol esterase (chromobacterium), cholesterol oxidase, and hydrazine, which divert the accessible cholesterol to cholestenone hydrazone. A second reagent with deoxycholate broke up the LDL-calixarene complex, allowing LDL-C to react with the esterase, a dehydrogenase, and β-NAD to yield cholestenone and β-NADH.

Analytical Performance of LDL Methods. Evaluations of LDL homogeneous assays indicate that CVs are generally <3% and consistently within the NCEP performance target of <4% CV (Table 27-23).[200] By contrast, CVs for the Friedewald calculation have been estimated to approximate 4% in expert laboratories but may be higher in routine clinical laboratories.[218]
